ON CERTAIN ERRORS RESPECTING THE STRUCTURE OF THE HEART ATTRIBUTED TO ARISTOTLE

IN all the commentaries upon the "Historia Animalium" which I have met with, Aristotle's express and repeated statement, that the heart of man and the largest animals contains only three cavities, is noted as a remarkable error. Even Cuvier, who had a great advantage over most of the commentators in his familiarity with the subject of Aristotle's description, and whose habitual caution and moderation seem to desert him when the opportunity of panegyrising the philosopher presents itself, is betrayed into something like a sneer on this topic.

"Du reste il n'attribue à cet organe que trois cavités, erreur qui prouve au moins qu'il en avait regardé la structure."[1]

To which remark, what follows will, I think, justify the reply, that it "prouve au moins" that Cuvier had not given ordinary attention, to say nothing of the careful study which they deserve, to sundry passages in the first and the third books of the "Historia" which I proceed to lay before the reader.

For convenience of reference these passages are marked *a*, *b*, *c*, &c.[2]

Book i. 17.—(*a*) "The heart has three cavities, it lies above the lung on the division of the windpipe, and has a fatty and thick membrane where it is united with the great vein and the aorta. It lies upon the aorta, with its point down the chest, in all animals that have a chest. In all, alike in those that have a chest and in those that have none, the foremost part of it is the apex. This is often overlooked through the turning upside down of the dissection. The rounded end of the heart is uppermost, the pointed end of it is largely fleshy and thick, and in its cavities there are tendons. In other animals which have a chest the heart lies in the middle of the chest; in men, more to the left side, between the nipples, a little inclined to the left nipple in the upper part of the chest. The heart is not large, and its general form is not elongated but rounded, except that the apex is produced into a point.

(*b*) "It has, as already stated, three cavities, the largest of them is on the right, the smallest on the left, the middle-sized one in the middle; they have all, also the two small ones, passages (τετρημένας) towards the lung, very evidently as respects one of the cavities. In the region of the union [with the great vein and the aorta] the largest cavity is connected with the largest vein (near which is the mesentery); the middle cavity, with the aorta.

(*c*) "Canals (πόροι) from the heart pass to the lung and divide in the same fashion as the windpipe does, closely accompanying those from the windpipe through the whole lung. The canals from the heart are uppermost.

(*d*) "No canal is common [to the branches of the windpipe and those of the vein] (οὐδεὶς δ' ἐστὶ κοινὸς πόρος) but through those parts of them which are in contact (τὴν σύναψιν) the air passes in and they [the πόροι] carry it to the heart.

(*e*) "One of the canals leads to the right cavity, the other to the left.

(*f*) "Of all the viscera, the heart alone contains blood [in itself]. The lung contains blood, not in itself but in the veins, the heart in itself; for in each of the cavities there is blood; the thinnest is in the middle cavity."

(Book iii. 3).—(*g*) "Two veins lie in the thorax alongside the spine, on its inner face; the larger more forwards, the smaller behind; the larger more to the right, the smaller, which some call *aorta* (on account of the tendinous part of it seen in dead bodies), to the left. These take their origin from the heart; they pass entire, preserving the nature of veins, through the other viscera that they reach; while the heart is rather a part of them, and more especially of the anterior and larger one, which is continued into veins above and below, while between these is the heart.

(*h*) "All hearts contain cavities, but in those of very small animals the largest (cavity) is hardly visible, those of middling size have another, and the biggest all three.

(*i*) "The point of the heart is directed forwards as was mentioned at first; the largest cavity to the right and upper side of it, the smallest to the left, and the middle sized one between these; both of these are much smaller than the largest.

(*k*) "They are all connected by passages (συντέτρηνται) with the lung, but on account of the smallness of the canals this is obscure except in one.

[1] "Histoire des Sciences Naturelles," i. p. 152.

[2] The text I have followed is that given by Aubert and Wimmer, "Aristoteles Thierkunde; kritsich berichtigter Text mit deutschen Uebersetzung;" but I have tried here and there to bring the English version rather closer to the original than the German translation, excellent as it is, seems to me to be.

(*l*) "The great vein proceeds from the largest cavity which lies upwards and to the right; next through the hollow middle (διὰ τοῦ κοῖλου τοῦ μέσου) it becomes vein again, this cavity being a part of the vein in which the blood stagnates.

(*m*) "The aorta [proceeds from] the middle [cavity], but not in the same way, for it is connected [with the middle cavity] by a much more narrow tube (σύριγγα).

(*n*) "The [great] vein extends through the heart, towards the aorta from the heart.

(*o*) "The great vein is membranous like skin, the aorta narrower than it and very tendinous, and as it extends towards the head and the lower parts it becomes narrow and altogether tendinous.

(*p*) "In the first place, a part of the great vein extends upwards from the heart towards the lung and the attachment of the aorta, the vein being large and undivided. It divides into two parts, the one to the lung, the other to the spine and the lowest vertebra of the neck.

(*q*) "The vein which extends to the lung first divides into two parts for the two halves of it and then extends alongside each tube (σύριγγα) and each passage (τρῆμα), the larger beside the larger and the smaller beside the smaller, so that no part [of the lung] can be found from which a passage (τρῆμα) and a vein are absent. The terminations are invisible on account of their minuteness, but the whole lung appears full of blood. The canals from the vein lie above the tubes given off from the windpipe."

The key to the whole of the foregoing description of the heart lies in the passages (*g*) and (*l*). They prove that Aristotle, like Galen, five hundred years afterwards, and like the great majority of the old Greek anatomists, did not reckon what we call the right auricle as a constituent of the heart at all, but as a hollow part or dilatation of the "great vein." Aristotle is careful to state that his observations were conducted on suffocated animals; and if any one will lay open the thorax of a dog or a rabbit, which has been killed with chloroform, in such a manner as to avoid wounding any important vessel, he will at once see why Aristotle adopted this view.

For, the vena cava inferior (*b*), the right auricle (*R.a*) and the vena cava superior and innominate vein (*V.I.*) distended with blood, seem to form one continuous column, to which the heart is attached as a sort of appendage (*g*). This column is, as Aristotle says, vein above (*a*) and vein below (*b*), the upper and the lower divisions being connected διὰ τοῦ κοῖλου τοῦ μέσου—or by means of the intervening cavity or chamber (*R.a.*)—which is the right auricle.

But when, from the four cavities of the heart recognised by us moderns, one is excluded, there remain three—which is just what Aristotle says. The solution of the difficulty is, in fact, as absurdly simple as that presented by the egg of Columbus; and any error there may be, is not to be put down to Aristotle, but to that inability to comprehend that the same facts may be accurately described in different ways, which is the special characteristic of the commentatorial mind. That the three cavities mentioned by Aristotle are just those which remain if the right auricle is omitted, is plain enough from what is said in (*b*), (*c*), (*e*), (*i*), and (*l*). For, in a suffocated animal, the "right cavity" which is directly connected with the great vein and is obviously the right ventricle, being distended with blood, will look much larger than the middle cavity, which, since it gives rise to the aorta, can only be the left ventricle. And this, again, will appear larger than the thin and collapsed left auricle, which must be Aristotle's left cavity, inasmuch as this cavity is said to be connected by πόροι with the lung. The reason why Aristotle considered the left auricle to be a part of the heart, while he merged the right auricle in the great vein, is, obviously, the small relative size of the venous trunks and their sharper demarcation from the auricle. Galen, however, perhaps more consistently, regarded the left auricle also as a mere part of the "arteria venosa." The canal which leads from the right cavity of the heart to the lung is, without doubt, the pulmonary artery. But it may be said that, in this case, Aristotle contradicts himself, inasmuch as in (*p*) and (*q*) a vessel which is obviously the pulmonary artery, is described as a branch of the great vein. How-

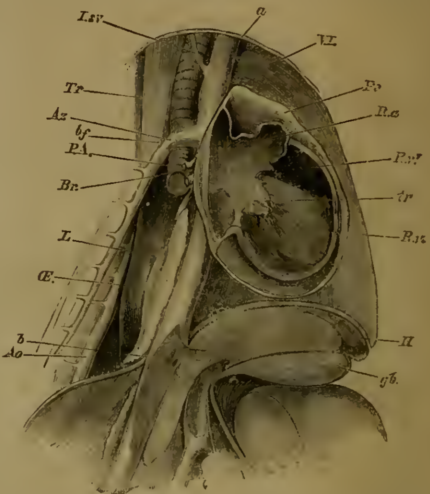

Fig. 1.—A dog having been killed by chloroform, enough of the right wall of the thorax was removed, without any notable bleeding, to expose the thoracic viscera. A carefully measured outline sketch of the parts *in situ* was then made, and on dissection, twenty-four hours afterwards, the necessary anatomical details were added. The woodcut is a faithfully reduced copy of the drawing thus constructed; and it represents the relations of the heart and great vessels as Aristotle saw them in a suffocated animal.

All but the inner lobe of the right lung has been removed; as well as the right half of the pericardium and the right walls of the right auricle and ventricle. It must be remembered that the thin transparent pericardial membrane appears nothing like so distinct in nature.

a.b., Aristotle's "great vein": *V.I.*, right vena innominata and vena cava superior; *b*, the inferior vena cava; *R.a*, the "hollow middle" part of the great vein or the right auricle; *R.v'*, the prolongation of the cavity of the right ventricle *R.v* towards the pulmonary artery; *tr*, one of the tricuspid valves; *Pc*, the pericardium; *I.sv*, superior intercortal vein; *Az*, vena azygos; *P.A.*, right pulmonary artery; *Br*, right bronchus; *L*, posterior lobe of the right lung; *Œ*, œsophagus; *Ao*, descending aorta; *H*, liver, in section, with hepatic vein, vena portæ, and gall-bladder, *gb*, separated by the diaphragm, also seen in section, from the thoracic cavity.

ever, this difficulty also disappears, if we reflect that, in Aristotle's way of looking at the matter, the line of demarcation between the great vein and the heart coincides with the right auriculo-ventricular aperture; and that, inasmuch as the conical prolongation of the right ventricle which leads to the pulmonary artery (Fig. 1, *R.v'*), lies close in front of the auricle, its base may very easily (as the figure shows) be regarded as part of the general opening of the great vein into the right ventricle. In fact it is clear that Aristotle, having failed to notice the valves of the heart, did not distinguish the part of the right ventricle from which the pulmonary artery arises (*R.v*) from the proper trunk of the artery on the one hand, and from the right auricle (*R.a*) on the other. Thus the root, as we may call it, of the pulmonary artery and the right auricle, taken together, are spoken of as the "part of the great vein which extends upwards;" and, as the vena azygos (*Az*) was one branch of this, so the "vein to the lung" was another branch of it. But the latter branch, being given off close to the connection of the great vein with the ventricle, was also counted as one of the two πόροι by which the "heart" (that is to say the right ventricle, the left ventricle, and the left auricle of our nomenclature) communicates with the lung.

The only other difficulty that I observe, is connected with (*k*). If Aristotle intended by this to affirm that the middle cavity (left ventricle), like the other two, is directly connected with the lung by a πόρος, he would be in error. But he has excluded this interpretation of his words by (*e*), in which the number and relations of the canals, the existence of which he admits, are distinctly defined. I can only imagine then, that so far as this passage applies to the left ventricle, it merely refers to the indirect communication of that cavity with the vessels of the lungs, through the left auricle.

On this evidence I submit that there is no escape from the conclusion that, instead of having committed a gross blunder, Aristotle has given a description of the heart which so far as it goes, is remarkably accurate. He is in error only in regard to the differences which he imagines to exist between large and small hearts (*h*).

Cuvier (who has been followed by other commentators) ascribes another error to Aristotle:—

"Aristote suppose que la trachée-artère se prolonge jusqu'au cœur, et semble croire, en conséquence, que l'air y pénètre (*l. c.* p. 152)."

Upon what foundation Cuvier rested the first of these two assertions, I am at a loss to divine. As a matter of fact, it will appear from the following excerpts that Aristotle gives an account of the structure of the lungs which is almost as good as that of the heart, and that it contains nothing about any prolongation of the windpipe to the heart.

"Within the neck lie what is called the œsophagus (so named on account of its length and its narrowness) and the windpipe (ἀρτηρία). The position of the windpipe in all animals that have one, is in front of the œsophagus. All animals which possess a lung have a windpipe. The windpipe is of a cartilaginous nature and is exsanguine, but is surrounded by many little veins . . . .

"It goes downwards towards the middle of the lung and then divides for each of the halves of the lung. In all animals that possess one, the lung is divided into two parts; but, in those which bring forth their young alive, the separation is not equally well marked, least of all in man.

"In oviparous animals, such as birds, and in quadrupeds which are oviparous, the one half of the lung is widely separated from the other; so that it appears as if they had two lungs. And from being single the windpipe becomes [divided into] two, which extend to each half of the lung. It is fastened to the great vein and to what is called the aorta. When the windpipe is blown up the air passes into the hollow parts of the lung. In these, are cartilaginous tubes (διαφύσεις) which unite at an angle; from the tubes passages (τρήματα) traverse the whole of the lung; they are continually given off, the smaller from the larger." (Book i., 16.)

That Aristotle speaks of the lung as a single organ divided into two halves and says that the division is least marked in man, is puzzling at first, but becomes intelligible if we reflect upon the close union of the bronchi, the pulmonary vessels and the mediastinal walls of the pleuræ in mammals;[1] and it is quite true that the lungs are much more obviously distinct from one another in birds.

Aubert and Wimmer translate the last paragraph of the passage just cited as follows:—

"Diese haben aber knorpelige Scheidewände, welche unter spitzen Winkeln zusammentreten, und aus ihnen führen Oeffnungen durch die ganze Lunge, indem sie sich in immer kleineren verzweigen."

But I cannot think that by διαφύσεις and τρήματα, in this passage, Aristotle meant either "partitions" or openings in the ordinary sense of the latter word. For, in Book iii., Cap. 3, in describing the distribution of the "vein which goes to the lung" (the pulmonary artery), he says that it

"Extends alongside each tube (σύριγγα) and each passage (τρῆμα), the larger beside the larger, and the smaller beside the smaller; so that no part [of the lung] can be found from which a passage (τρῆμα) and a vein are absent."

Moreover, in Book i., 17, he says—

"Canals (πόροι) from the heart pass to the lung and divide in the same fashion as the windpipe does, closely accompanying those from the windpipe through the whole lung."

And again in Book i., 17.—

"It (the lung) is entirely spongy, and alongside of each tube (σύριγγα) run canals (πόροι) from the great vein."

On comparing the last three statements with the facts of the case, it is plain that by σύριγγες, or tubes, Aristotle means the bronchi and so many of their larger divisions as obviously contain cartilages; and that by διαφύσεις χονδρώδεις he denotes the same things; and, if this be so, then the τρήματα must be the smaller bronchial canals, in which the cartilages disappear.

This view of the structure of the lung is perfectly correct so far as it extends; and, bearing it in mind, we shall be in a position to understand what Aristotle thought about the passage of air from the lungs into the heart. In every part of the lung, he says, in effect, there is an air tube which is derived from the trachea, and other tubes which are derived from the πόροι which lead from the lung to the heart, *suprà* (*c*). Their applied walls constitute the thin "synapses" (τὴν σύναψιν) through which the air passes out of the air tubes into the πόροι, or blood vessels, by transudation or diffusion; for there is no community between the cavities of the air tubes and cavities of the canals; that is to say, no opening from one into the other, *suprà* (*d*).

On the words "κοινὸς πόρος" Aubert and Wimmer remark (*l.c.* p. 239), "Da A. die Ansicht hat die Lungenluft würde dem Herzen zugeführt, so postulirt er statt vieler kleiner Verbindungen einen grossen Verbindungsgang zwischen Lunge und Herz."

But does Aristotle make this assumption? The only evidence so far as I know in favour of the affirmative answer to this question is the following passage:—

[1] In modern works on Veterinary Anatomy the lungs are sometimes described as two lobes of a single organ.

"*Συνήρτεται δὲ καὶ ἡ καρδία τῇ ἀρτηρίᾳ πιμελώδεσι καὶ χονδρώδεσι καὶ ἰνώδεσι δεσμοῖς· ᾗ δέ συνήρτεται, κοῖλόν ἐστιν. φυσωμένης δὲ τῆς ἀρτηρίας ἐν ἐνίοις μὲν οὐ κατάδηλον ποιεῖ, ἐν δὲ τοῖς μείζοσι τῶν ζῴων δῆλον ὅτι εἰσέρχεται τὸ πνεῦμα εἰς αὐτήν*" (i. cap. 16).

"The heart and the windpipe are connected by fatty and cartilaginous and fibrous bands; where they are connected it is hollow. Blowing into the windpipe does not show clearly in some animals, but in the larger animals it is clear that the air goes into it."

Aubert and Wimmer give a somewhat different rendering of this passage:—

"Auch das Herz hängt mit der Luftröhre durch fettreiche, knorpelige und faserige Bänder zusammen; und da, wo sie zusammenhängen, ist eine Höhlung. Beim Aufblasen der Lunge wird es bei manchen Thieren nicht wahrnehmbar, bei den grösseren aber ist es offenbar, dass die Luft in das Herz gelangt."

The sense here turns upon the signification which is to be ascribed to *εἰς αὐτήν*. But if these words refer to the heart, then Aristotle has distinctly pointed out the road which the air, in his opinion, takes, namely, through the "synapses"; and there is no reason that I can discover to believe that he "postulated" any other and more direct communication.

With respect to the meaning of *κοῖλόν ἐστιν*, Aubert and Wimmer observe:—

"Dies scheint wohl die kurze Lungenvene zu sein. Schneider bezieht dies auf die Vorkammern, allein diese werden unten als Höhlen des Herzens beschrieben."

I am disposed to think, on the contrary, that the words refer simply to the cavity of the pericardium. For a part of this cavity (*sinus transversus pericardii*) lies between the aorta, on the one hand, and the pulmonary vessels with the bifurcation of the trachea, on the other hand, and is much more conspicuous in some animals than in man. It is strictly correct, therefore, in Aristotle's words, to say that where the heart and the windpipe are connected "it is hollow." If he had meant to speak of one of the pulmonary veins, or of any of the cavities of the heart, he would have used the terms *πόροι* or *κοιλίας* which he always employs for these parts.

According to Aristotle, then, the air taken into the lungs passes from the final ramifications of the bronchial tubes into the corresponding branches of the pulmonary blood vessels, not through openings, but by transudation, or, as we should nowadays say, diffusion, through the thin partitions formed by the applied coats of the two sets of canals. But the "pneuma" which thus reached the interior of the blood vessels was not, in Aristotle's opinion, exactly the same thing as the air. It was "*ἀὴρ πολὺς ῥέων καὶ ἀθρόος*" ("De Mundo," iv., 9)—subtilized and condensed air; and it is hard to make out whether Aristotle considered it to possess the physical properties of a gas or those of a liquid. As he affirms that all the cavities of the heart contain blood (*f*), it is clear that he did not hold the erroneous view propounded in the next generation by Erasistratus. On the other hand, the fact that he supposes that the spermatic arteries do not contain blood but only an *αἱματῶδης ὑγρόν* ("Hist. Animalium," iii., 1), shows that his notions respecting the contents of the arteries were vague. Nor does he seem to have known that the pulse is characteristic only of the arteries; and as he thought that the arteries end in solid fibrous bands, he naturally could not have entertained the faintest conception of the true motion of the blood. But without attempting to read into Aristotle modern conceptions which never entered his mind, it is only just to observe that his view of what becomes of the air taken into the lungs is by no means worthy of contempt as a gross error. On the contrary, here, as in the case of his anatomy, what Aristotle asserts is true as far as it goes. Something does actually pass from the air contained in the lungs through the coats of the vessels into the blood, and thence to the heart; to wit, oxygen. And I think that it speaks very well for ancient Greek science that the investigator of so difficult a physiological problem as that of respiration, should have arrived at a conclusion, the statement of which, after the lapse of more than two thousand years, can be accepted as a thoroughly established scientific truth.

I trust that the case in favour of removing the statements about the heart, from the list of the "errors of Aristotle" is now clear; and that the evidence proves, on the contrary, that they justify us in forming a very favourable estimate of the oldest anatomical investigations among the Greeks of which any sufficient record remains.

But is Aristotle to be credited with the merit of having ascertained so much of the truth? This question will not appear superfluous to those who are acquainted with the extraordinary history of Aristotle's works, or who adopt the conclusion of Aubert and Wimmer, that, of the ten books of the "Historia Animalium" which have come down to us, three are largely or entirely spurious and that the others contain many interpolations by later writers.

It so happens, however, that, apart from other reasons, there are satisfactory internal grounds for ascribing the account of the heart to a writer of the time at which Aristotle lived. For, within thirty years of his death, the anatomists of the Alexandrian school had thoroughly investigated the structure and the functions of the valves of the heart. During this time, the manuscripts of Aristotle were in the possession of Theophrastus; and no interpolator of later date would have shown that he was ignorant of the nature and significance of these important structures, by the brief and obscure allusion—"in its cavities there are tendons (*a*)." On the other hand, Polybus, whose account of the vascular system is quoted in the "Historia Animalium" was an elder contemporary of Aristotle. Hence, if any part of the work faithfully represents that which Aristotle taught, we may safely conclude that the description of the heart does so. Having granted this much, however, it is another question, whether Aristotle is to be regarded as the first discoverer of the facts which he has so well stated, or whether he, like other men, was the intellectual child of his time and simply carried on a step or two the work which had been commenced by others.

On the subject of Aristotle's significance as an original worker in biology extraordinarily divergent views have been put forward. If we are to adopt Cuvier's estimate, Aristotle was simply a miracle:—

"Avant Aristote la philosophie, entièrement spéculative, se perdait dans les abstractions dépourvues de fondement; la science n'existait pas. Il semble qu'elle soit sortie toute faite du cerveau d'Aristote comme Minerve, toute armée, du cerveau de Jupiter. Seul, en effet, sans antécédents, sans rien emprunter aux siècles qui l'avaient précédé, puisqu'ils n'avaient rien produit de solide, le disciple de Platon découvrit et démontra plus de vérités, executa plus de travaux scientifiques en un vie de soixante-deux ans, qu'après lui vingt siècles n'en ont pu faire,"[1] &c., &c.

"Aristote est le premier qui ait introduit la méthode de l'induction, de la comparaison des observations pour en faire sortir des idées générales, et celle de l'expérience pour multiplier les faits dont ces idées générales peuvent être déduites."—ii. p. 515.

The late Mr. G. H. Lewes,[2] on the contrary, tells us "on a superficial examination, therefore, he [Aristotle] will seem to have given tolerable descriptions; especially if approached with that disposition to discover marvels which unconsciously determines us in our study of eminent writers. But a more unbiased and impartial criticism will disclose that he has given no single anatomical description of the least value. All that he knew may have been known and probably was known, without dissection. . . . . I do not assert that he never opened an animal; on the contrary, it seems highly probable that he had opened many . . . . . . He never followed the course of a vessel or a nerve; never laid bare the origin and insertion of a muscle; never discriminated the component parts of organs; never made clear to himself the connection of organs into systems."—(pp. 156-7.)

In the face of the description of the heart and lungs, just quoted, I think we may venture to say that no one who has acquired even an elementary practical acquaintance with anatomy, and knows of his own knowledge that which Aristotle describes, will agree with the opinion expressed by Mr. Lewes; and those who turn to the accounts of the structure of the rock lobster and that of the lobster, or to that of the Cephalopods and other Mollusks, in the fourth book of the "Historia Animalium" will probably feel inclined to object to it still more strongly.

On the other hand, Cuvier's exaggerated panegyric will as little bear the test of cool discussion. In Greece, the century before Aristotle's birth was a period of great intellectual activity, in the field of physical science no less than elsewhere. The method of induction has never been used to better effect than by Hippocrates; and the labours of such men as Alkmeon, Demokritus, and Polybus among Aristotle's predecessors, Diokles, and Praxagoras, among his contemporaries, laid a solid foundation for the scientific study of anatomy and development, independently of his labours. Aristotle himself informs us that the dissection of animals was commonly practised; that the aorta had been distinguished from the great vein; and that the connection of both with the heart had been observed by his predecessors. What they thought about the structure of the heart itself, or that of the lungs, he does not tell us, and we have no means of knowing. So far from arrogantly suggesting that he owed nothing to his predecessors, Aristotle is careful to refer to their observations and to explain why, in his judgment, they fell into the errors which he corrects.

Aristotle's knowledge, in fact, appears to have stood in the same relation to that of such men as Polybus and Diogenes of Apollonia, as that of Herophilus and Erasistratus did to his own, so far as the heart is concerned. He carried science a step beyond the point at which he found it; a meritorious, but not a miraculous, achievement. What he did required the possession of very good powers of observation; if they had been powers of the highest class he could hardly have left such conspicuous objects as the valves of the heart to be discovered by his successors.

And this leads me to make a final remark upon a singular feature of the "Historia Animalium." As a whole, it is a most notable production, full of accurate information and of extremely acute generalisations of the observations accumulated by naturalists up to that time. And yet, every here and there, one stumbles upon assertions respecting matters which lie within the scope of the commonest inspection, which are not so much to be called errors as stupidities. What is to be made of the statement that the sutures of women's skulls are different from those of men; that men and sundry male animals have more teeth than their respective females; that the back of the skull is empty, and so on? It is simply incredible to me that the Aristotle who wrote the account of the heart, also committed himself to absurdities which can be excused by no theoretical prepossession and which are contradicted by the plainest observation.

What, after all, were the original manuscripts of the "Historia Animalium"? If they were notes of Aristotle's lectures taken by some of his students, any lecturer who has chanced to look through such notes, would find the interspersion of a foundation of general and sometimes minute accuracy, with patches of transcendent blundering, perfectly intelligible. Some competent Greek scholar may perhaps think it worth while to tell us what may be said for or against the hypothesis thus hinted. One obvious difficulty in the way of adopting it is the fact that, in other works, Aristotle refers to the "Historia Animalium" as if it had already been made public by himself.

T. H. HUXLEY

ON THE NECESSITY FOR A NEW DEPARTURE IN SPECTRUM ANALYSIS

IT is now about a year since I gave an account of the results to which the final discussion of a complete set of photographs of the spectra of the metallic elements compared with the spectrum of the sun had led me.

The comparison was limited necessarily to the blue and violet portions of the spectrum, as photography was employed, and the methods since worked out by Capt. Abney for photographing the other regions were not then available. Of set purpose I limited it still more, as I wished to find the *dernier mot* in the present state of science regarding the coincidence of metallic with Fraunhofer's lines; and for this it was imperative to work on a large scale over a small region rather than on a small scale over a large one.

In point of fact, the work was limited to about the $\frac{1}{100}$th part of the spectrum, and this small part was mapped on a large scale. A complete map of the spectrum on the scale adopted would be about half a furlong long. The work took time: including interruptions of one kind and another, some four years were expended on it.

I have elsewhere discussed at some length the conclusion which stared us in the face when all the work was brought to focus, but it is important that I should here dwell upon it for a moment, especially as it is now possible, perhaps, to state it with more terseness and clearness than one could at first, when the new conception thus forced upon us and its consequences were less familiar to one's mind.

Simply, it amounted to this. The new work had made us acquainted with the fact that there were coincidences in the lines of metallic spectra of two perfectly distinct kinds.

The lines of one kind we could explain, on the hypothesis that the elements are truly elementary, by supposing that in the case, let us say, of coincident lines in the spectrum of iron and cobalt, the common line was due to an impurity either of iron in the cobalt or of cobalt in the iron. Most spectroscopic workers were of the true faith in this matter; they accepted the dicta of the chemist, and not only was the work which had shown how the phenomena observed *might be* thus explained received with favour, but no one, so far as I know, inquired whether there was any other "might be" in the matter. It is more than probable, however, that the future will have much to say on this very point; but with this set of coincidences I am not dealing in this paper.

So much for the one set of coincidences.

The other set was as different as possible. In this category there was, on the impurity hypothesis, no possible explanation forthcoming without changing ground. In fact, the separation of the coincidences into two classes was brought about by this very circumstance, since all the coincidences which, in accordance with a general law established for a constant temperature some years before, could be attributed to impurity had, as a matter of fact, been eliminated from the maps at a prior stage of the investigation. Further, be it noted that all the photographs represented the work of similar temperatures, for they were all taken with electric arcs, for the production of which the same number of Grove's cells was used in all cases.

Since therefore these lines which were common to two or more spectra, could not be traced to impurities, what was their probable origin? Their number was so great that to attribute them to physical coincidences, and to rest and be thankful accordingly, would have been to take the very pith and marrow out of the science of spectrum analysis, which we have heard so often is based absolutely upon different substances giving us spectra with special lines for each. The matter then was worthy of serious investigation.

Using the analogy presented by the spectroscopic behaviour of known compounds when simplified by heat, a simple explanation of these common lines lay on the surface. This explanation is as follows:—

The temperature of the sun and the electric arc is high enough to dissociate some of the so-called chemical elements, and give us a glimpse of the spectra of their bases, just as in the case of the various salts of calcium there is a temperature which just allows us to get a glimpse of a line indicating the metal calcium common to them all.

Hence it was allowable to term the coincident lines of the second order "basic lines," since they might point to the existence of a base common to the substances in the spectra of which they appeared. Davy, before he discovered potassium, used, as I have since found, the word "basic" to express the same idea.

I propose in the present paper to refer to some of the facts collected along one line of work to which my subsequent studies of these lines has led me, with a view to show that their true basic nature can now no longer be open to doubt.

Naturally the first thing to do was to see if these basic lines varied in their behaviour from other lines of spectra taken at random. Supposing them to represent mere chance coincidences—"physical coincidences," as they have been called, or again, lines so near together that our means cannot separate them—there is no reason why they should vary together when the temperature is changed; while, if they be truly basic, they *must* vary with temperature. Further, they must vary in such a way that other conditions being equal, they shall become stronger when the temperature is increased, and become fainter when the temperature is reduced.

Now what was the best mode of attacking this problem? I was unable to see a more expeditious one than that presented to us by the sun. The following consideration will show how we might hope for help in this quarter.

We are accustomed to say that the sun is surrounded by an enormous atmosphere, and that this atmosphere has in it the vapours of metals, such as iron, magnesium, &c., with which metals we are familiar on this planet. This statement has been based on the near agreement presented by the places of the lines in the spectrum of the substances as studied in our laboratories and the Fraunhofer lines themselves. The matching of these spectra is nothing like so perfect, and the conclusion drawn, therefore, is nothing like so firmly based, as is generally imagined; but this point need not occupy our attention at present; what it is important for us to bear in mind is this: whatever be the chemical nature of this atmosphere, it will certainly be hotter at bottom—that is, nearer the photosphere—than higher up. Hence, if temperature plays any part in moulding the conditions by which changes in the resulting spectrum are brought about, the spectrum of the atmosphere close to the photosphere will be different from that of any higher region, and therefore from the general spectrum of the sun, which practically gives us the summation of all the absorptions of all the regions from the top of the atmosphere to the bottom.

Now as a matter of fact we have the opportunity, when we observe the spectrum of a sun-spot or a prominence, of determining the spectrum of an isolated mass of vapours in the hottest region open to our inquiries, and seeing whether it is like or unlike the general spectrum of the sun. What then are the facts?

It is as unlike as possible: the intensities of the lines are inverted to a wonderful extent. More than this there is a constant difference between the spectra of sun-spots and the spectra of metallic prominences, though we see these phenomena generally at about the same *niveau* in the sun's atmosphere. This may arise from the fact that in the case of the spots we deal generally with a greater thickness of the vapours.

To get the best idea of this inversion I have prepared maps of the spectra of the chief chemical substances showing the behaviour of the various lines under the various conditions. The result is very striking; indeed it is striking to quite an unexpected degree. The whole character of the spectrum of iron, for instance, is changed when we pass from the iron lines seen among the Fraunhofer lines to those seen among the spot-and storm-lines; a complex spectrum is turned into a simple one, the feeble lines are exalted, the stronger ones suppressed almost altogether.

Since then the spectra of spots and prominences are confessedly the spectra of the hottest region of the sun available to our inquiries, we can test the nature of the basic lines by seeing how they behave when we pass from the general solar to these special solar spectra.

With special reference to this point I have brought together the various observations which have been recorded of the lines visible in solar disturbances at the sun's limb, and those observed to be widened, brightened, or otherwise modified in the spectra of solar spots.

The finest series of observations of this kind that we possess is that collected by Prof. Young near the time of the last maximum of sun-spots, during his stay at Sherman, at a height of 8,000 feet. The result which stares us in the face when we examine the work done by Young is most striking; but although his observations of the chromospheric lines extend over the whole visible spectrum, the list of lines in the solar spots is limited to the less refrangible region; we must therefore limit the discussion to this region.

As a basis for the discussion, I have used the lines given in Thalén's admirable tables, comparing them with those shown in Ångström's map, and indicating the intensities of the lines which are given in the tables, and which particular line occurs in the map only. A glance then shows which line is seen in spots and prominences, and how it is affected. In short we have in one view, for each metallic substance, exactly what happens to the lines of that substance—which lines are not touched; those which are visibly affected both in spots and storms, or those recorded in one table and not in the other.

Taking all the lines included in the discussion, the following statistics will show how they are distributed:—

Total number of lines in Thalén's list and map included in the discussion	345
Number of lines affected in spots	108
Number of lines bright in storms	122
Number of lines common to spots and storms	68
Number of lines seen in neither spots nor storms	183

So much for the list of lines as a whole. It is also necessary to show the number of lines assigned to each metal, and those among them which occur in both spots and storms, or only in one or the other.

Metal.	Number of Lines.	Number of lines common to spots and storms.	Number of lines due to		Unaffected.
			Spots.	Storms.	
Sodium ...	8	4	6	6	0
Magnesium	4	3	4	3	0
Barium ...	23	1	3	7	14
Calcium ...	25	7	15	10	7
Strontium ...	18	0	0	0	18
Nickel... ...	12	1	3	2	8
Cobalt... ...	19	3	3	3	16
Manganese ...	16	2	3	6	9
Cadmium ...	15	0	0	0	15
Chromium ...	14	3	3	5	9
Titanium ...	87	11	18	18	62
Iron... ...	104	33	50	62	25
	345	68	108	122	183

It will be seen that the ratio between the affected and unaffected lines is very variable. What strikes one, indeed, is the wonderful irregularity in the behaviour of the various lines; there is no relation, for instance, between the widening of the lines in the spots and their appearances in the prominences.

It may here be asked, "But what has this to do with basic lines?" I answer, it would have nothing to do with basic lines if Thalén had not observed them; but in his observations, which are the *ne plus ultra* of spectroscopic accuracy, he came across them abundantly. The basic lines therefore have the great advantage of not being new.

Among the 345 *lines given by Thalén are* 18 *with identical readings in two spectra.* They are, therefore, the exact equivalents of those lines which I have found to be basic in work on another part of the spectrum.

Now, for the reasons above given, if my explanation of their basic character be the correct one, then we should expect a considerable development of these lines in the spectrum of the hottest regions of the sun, which spots and storms enable us to study apart from the absorption going on at higher levels.

It is not too much to say that the result of this inquiry settles this question in the most conclusive way. What does come out in the strongest manner is the following very remarkable fact.

The only constant thing in the tables employed in the inquiry is, that *these basic lines are always widened in the spots.* However badly the brighter lines of a chemical substance, taken as a whole, may be represented amongst the spot lines, as the basic lines, among these which are often of the second or third order of intensity and sometimes even of the fourth, are never absent. The same fact holds almost equally true with regard to the storms.

The following comparison of Thalén's basic lines with those seen by Young in solar spots and storms shows this result:—

Thalén.					Young.		
Wave-length.	Common to		Intensity.		Spots.	Storms.	
					Widening.	Frequency.	Brightness.
5207·6	Fe	Cr	3	1	4	10	6
5203·7	Fe	Cr	3	1	4	10	6
5340·2	Fe	Mn	2	3	2	1	2
6064·5	Fe	Ti	2	2	3	5	2
5661·5	Fe	Ti	3	1	4	15	2
5403·1	Fe	Ti	2	3	4	5	3
5396·1	Fe	Ti	2	2	7	4	2
5352·4	Fe	Co	4	3	2	4	2
5265·8	Fe	Co	2	3	2	10	4
5168·3	Fe	Ni	3	5	4	40	30
5166·7	Fe	Mg	2	1	2	30	20
5681·4	Fe	Na	3	3	3	2	1
6121·2	Co	Ca	1	3	4	5	3
5601·7	Ca	Fe	4	1	2		
5597·2	Ca	Fe	3	1	2		
5856·5	Ca	Ni	3	4	2		
5425·0	Ba	Ti	3	3	4		
6449·0	Ca	Ba	2	3	2		

So far as my own knowledge of these matters goes, I can imagine no severer test to apply to the hypothesis that the basic lines in the above table are produced by the dissociation of the metals to which the lines are common,—in this case chiefly the metals of the iron group—in the hottest region of the sun, and to my mind the proof is conclusive that at that temperature we have a mixed mass of vapours in which the base is more predominant than the so-called chemical elements to which that base is common.

But although I hold that this is the most conclusive test to apply, it is not the only one which the sun affords us.

We have every reason to believe that there is a considerable difference in the temperature of the spot- and storm-stratum when it is absolutely quiescent and cut off from all visible action from below, and again when it is riddled with convection currents of the most tremendous character, in other words that its temperature at the sun-spot maxima and minima is not the same. Hence we may imagine that the difference of temperature will affect the basic lines especially, and that they will be stronger at one period of the sun-spot curve than at another.

I limit myself for the present to the statement that this comparison has also been made to a certain extent, and that the result of it is entirely in harmony with what has gone before, so far as the observations go, but more spots must be observed before a complete discussion is possible. This, however, is certain, that basic lines widened at Sherman in 1872 were not observed widened at Greenwich in 1877, or at Kensington in the spots which appeared last month.

I for my part, then, am perforce driven by the stern logic of facts to the conclusion that these "basic lines" are not accidental; are not "physical coincidences;" and do not owe their origin to impurities; but that their appearance in two or more spectra is dependent upon high temperature merely.

The original statement, then, that the spectrum of each element consists only of lines special to that element, is found to be insufficient when the highest temperatures and the greatest dispersions are employed, and a "higher law" has to be introduced to bring the statements of the text-books into harmony with the facts.

The dissociation of the elements of the iron group at the highest temperatures we can command and in the sun, is a cause by which this fact can be explained, if we accept the law of continuity, and reason on well based analogies.

This, of course, constitutes a new departure in spectrum analysis, whatever its bearing may be found to be upon Chemical Philosophy, when that subject is again studied as it once was.

To those who follow the line of reasoning on such a subject which the spectroscope provides us with, and even to those who admit the cogency of the conclusions, it will be astonishing that such a result has been arrived at in such an indirect way; there are, however, many minds so constituted that they will prefer to endow matter with any number of undreamt of qualities before they will accept such a solution.

But for all that, when the facts are well considered by competent authorities, it will, I think, be granted that an inorganic evolution is already glimpsed, in the study of which we shall not be baffled by any "breaks in strata."

J. NORMAN LOCKYER

MIND IN THE LOWER ANIMALS

Mind in the Lower Animals in Health and Disease. By W. Lauder Lindsay, M.D., F.R.S.E., F.L.S., &c. (London: C. Kegan Paul and Co., 1879.)

DR. LAUDER LINDSAY has long been known as a contributor to periodical literature in the province of comparative psychology. The work which he now publishes with the above title clearly represents a great amount of labour. It is in two large octavo volumes which together present somewhat over 1,000 pages, and contain references to the writings of about 200 authors. It is furnished with an excellent index and a bibliography. The latter, we are told, is "confined to works consulted by the author," and "almost exclusively to those published in Britain and in the English language." The work is also furnished with a long "enumeration of the animals whose character and habits form the basis of the author's generalisations." The list includes 908 species belonging to 516 genera, both the popular and the scientific names being in every case supplied.

In so extensive a work by so well-known a man there is, as we should expect, a great deal that is both of interest and value. Particularly in this connection may be pointed out his compilation and digestion of facts regarding the psychology of savages as contrasted with that of animals, and also many of his observations on the insanity of animals as compared with the insanity of man. His chapters on "General Adaptiveness and "The Use of Instruments" also deserve, on the whole, to be commended.

But while we welcome a book—and especially a popular book—the leading object of which is to prove the kinship of animal intelligence to human, it is impossible not to regret the occurrence of certain faults which the exercise of a little more judgment might have obviated. In the first place the work is painfully diffuse. Whole pages, and even chapters, might with advantage have been omitted, while there are but few chapters which might not, with equal advantage, have been considerably condensed. Those, for instance, on "Faults of Terminology," "Animal Reputation," "Responsibility of Animals," and others, appear utterly useless. Whether or not it is accurate to call the lower animals "dumb," "lower," &c., and whether or not the "reputation" of a dog suffers from the use of such terms as "dogging," "hounding," "cat and dog life," &c., and whether or not any one is so foolish as to suppose that a smuggler's dog is morally responsible for a smuggler's acts; whether or not these things are so, they are certainly not of sufficient importance to demand lengthy discussion. Again, such statements as the following are quite superfluous, at least out of a nursery-book:—

"While the dog barks, bites, growls, howls, whines, sniffs, and snarls; the horse neighs, kicks, stamps, paws, snorts, champs, lashes its tail; the cat purrs, scratches, hisses, mews; cattle low, butt, gore, bellow; the elephant trumpets, roars, screams; the sheep and goat bleat; the ass brays, the cock crows, and the hen clucks and cackles."

This is all quite true, but it is not new; and the same remark is applicable to pages and pages of both volumes. In short, unlimited diffusiveness is the worst fault of the book. The next worst fault is that of presenting alleged facts of animal intelligence on evidence that is obviously insufficient. Thus, for example, we are told that the hermit crab "has been noticed to feed the anemone (on his shell) with his pincer-like claws;" that ants "employ language of command;" that "snails are capable of concerted action;" that fish may die of "grief from bereavement;" that dogs exhibit "modesty or decency;" that monkeys "turn keys in doors, without noise, to secure themselves against interruption, discovery, or capture;" and so on, while in none of these cases are any facts or authorities given to support the assertions. Again, in many other cases where the facts and authorities are given, they are of a kind that ought not to have any place in a treatise which aims at a scientific discussion of its subject. For instance, we are told, without any expression of doubt on the part of the author, that "Daniell shows how a mere passing fancy for—a glimpse at—some dog, on the part of a pointer bitch, so impressed her memory and imagination that she transmitted this impress in a physical form to her progeny." Again, on no better authority than that of *The Animal World*—from which, indeed, Dr. Lindsay is very fond of quoting—we are expected to believe that "certain sparrows that failed, by seizing its wings with their bills, to lift a wounded companion, so as to convey it to a position of safety, got a twig, and while the maimed bird took hold of its centre by its bill, two of its companions seized, one each of its ends, so raised the helpless sparrow from the ground, and removed it to a safer place." And, to give only one other illustration, on the authority of an American paper called the *Christian Union*, we are told this painfully pathetic story:—"A young rat had fallen into a pail of pig-food; six older ones held a consultation so earnest in its character as to lead them to ignore the presence of human on-lookers. They decided on an ingenious scheme of rescue, and successfully carried it out. Entwining their legs together, they formed a chain, hanging downwards over the edge of the pail. The foremost or downmost rat grasped the drowning, and, as it subsequently proved, drowned, young one in its fore-paws, and both rescued and rescuer were then drawn up and out. When found to be dead, the rescuers gazed at their young comrade in 'mute despair,' wiped the tears from their eyes with their fore-paws, and departed without making any attempts to resuscitate it."

Evidently these rats were not acquainted with the Royal Humane Society's directions for the restoration of the apparently drowned, and considering that the calamity occurred in a civilised country, the most striking feature of the incident appears to be the ignorance which the animals displayed in yielding to grief "without making any attempts" to produce artificial respiration.

Another fault which pervades the work is that of undue eagerness to prove that no difference in kind exists between the mind of man and the mind of the lower animals—a fault which leads the author into the opposite error of disparaging such difference as does exist. Thus the book abounds with such statements as the following:—"There are countless thousands—many whole races—(of men) that are intellectually and morally the *inferiors* of many well-trained mammals, such as the chimpanzee, orang, dog, elephant, or horse; or birds, such as the parrot, starling, magpie, jackdaw, and various crows; as well as many animals much lower in the zoological scale, and not trained by man at all, such as the ant, bee, and wasp." And this belief in the mental equality, or even superiority, of animals as compared with the lower races of man, is doubtless the explanation of the writer's tendency to attribute to rational thought actions of animals which are much more probably due to other causes. For instance: "A cat was found drowned in a pond immediately after the death of a master to whom it had been much attached. It had left the house on his illness a fortnight previously, refusing to enter it again (*Animal World*). The inference was that grief had led to deliberate self-destruction; but the verdict of accidental drowning, is, of course, equally permissible." The word "equally" here serves to illustrate our meaning.

With regard to references there is also a serious complaint to be made. It is not enough to give the name of an author without any reference to the part of his writings where his facts or opinions are stated. Thus, although Dr. Lindsay's pages are thickly strewn with the names of his authorities in brackets, his readers will but rarely have the opportunity, without an impracticable amount of trouble, of seeing exactly what these authorities themselves have to say on the topics in connection with which they are quoted.

On minor faults or errors it is needless to dwell—such as the curious notion which Dr. Lindsay seems to entertain, that the word "glutton" is derived from the synonym of the wolverine, instead of *vice versâ* (p. 92). The chief faults are undoubtedly those which have been mentioned, and they have been mentioned in order to suggest that, should there be a second edition of the book, it would be greatly improved by presenting less diffusiveness and more discrimination than is presented by the first edition.

GEORGE J. ROMANES

OUR BOOK SHELF

An Atlas of Anatomy; or, Pictures of the Human Body, in Twenty-four Quarto Coloured Plates, comprising One Hundred Separate Figures. With descriptive Letterpress by Mrs. Fenwick Miller, Member of the London School Board, &c. (London: Edward Stanford, 1879.)

THIS work has been issued at a comparatively low price in the hope that it may be found useful both to science teachers and to all kinds of students. Children, we have it on the authority of Mrs. Miller, with their keen interest in the facts of Nature and with their fresh undistracted minds full of curiosity about what is around them, are always found to take a deep interest in the wonderful structure and functions of their own bodies. The subjects of anatomy and physiology have been introduced into many of the London Board Schools and have been found wonderfully popular among the children. An Inspector records that he has often been struck with the alacrity with which the children rush to their seats for an oral examination in physiology, even at the end of a long and tiring day of inspection. Truly such children must be very desirous to know all about themselves, and for such no doubt such a volume as this would prove quite an acceptable gift. Nearly all the drawings represented in the plates are new—never before published in any form in England. Some of them are from Dr. Heitzmann's Atlas, others are drawn from preparations in the Vienna Museum of Anatomy. In writing the letterpress the authoress had mainly in view the requirements of young students, and she has not assumed that any of her readers possess any knowledge of the subject. We are not disposed to be critical on a work published with such evidently good intentions. The physiological portions of the text are good, and if thoroughly taught to students and understood by them will place them far above the ordinary standpoint of the medical student of the day. The more purely anatomical descriptions would have been improved if written more for the plates than they have been. The plates themselves will be found extremely useful. We should have preferred that the amount of enlargement of the figures was always given; structures also like those figured at A on Plate xxiv. should be clearly defined as only diagrammatic representations, and a little greater attention to correctness of outline might fairly have been bestowed on the figures representing parts of the skeleton. The letterpress is accompanied by a pretty copious index to the plates, which might even still with advantage be greatly enlarged. This book in the hands of an intelligent teacher will be found most useful and instructive, and it may be made the text from which to preach many a most important practical lesson. Take the short paragraph headed Salivary Glands, how much human suffering might be avoided by a right comprehension of the facts therein stated.

Electric Transmission of Power. By Paget Higgs, LL.D., D.Sc. (London: E. and F. N. Spon, 1879.)

One of the important practical questions which an engineer continually has to face is the transmission of power from the place where the power is generated to the spot where the power is needed. Where the distance is great, belts and shafting are not only wasteful but impracticable, and hydraulic or pneumatic transmission is called into play. Here, again, great distances cannot be surmounted without great loss of power, and hence from time to time many wistful glances have been turned in the direction of electricity. It is only to-day, however, that, amid the manifold applications of electricity, its employment as an economical means of transmitting power has become a question of practical importance.

At the Loan Collection of Scientific Apparatus exhibited at South Kensington in 1876, two small magneto-electric machines made by Gramme were to be seen illustrating this electric transmission of power. The mechanical work expended in one machine was converted into electricity, conducted over a considerable space, and transformed again into mechanical work by the other machine. The amount of power practically reclaimable by such an arrangement, as shown by recent experiments quoted in the little work before us, "may amount to 48 per cent. of that expended in the first instance. This amount of reclaimed power is indubitably superior to that obtained with compressed air, and approaches the practical efficiency of hydraulic transmission" (p. 85). With great distances the relative efficiency of electric transmission must be still more marked, besides the advantage that the conductor, having nothing to burst or give way, can be led in any direction or freely moved whilst transmitting many horse-power. Already in France ploughing has been done by electricity with advantage, and where natural sources of power, as waterfalls or tidal action, exist in any neighbourhood, the extreme value to a community of this novel application of electricity is sufficiently obvious. Municipal authorities might find in the water supply of a town an unexpected source of income. For where there is a continuous supply of water under considerable pressure, as is the case in an increasing number of our large towns, baths and washhouses might be erected in the lower parts of the town, and the energy possessed by the water converted into electricity and distributed for sale as power, whilst the matter of the water would of course remain equally serviceable for the purposes intended.

To those interested in the general question of the electric transmission of power we do not know any better guide than Prof. Ayrton's admirable lecture on this subject before the British Association. To the student the work before us will be found useful for more extended reference, as it gives the salient features of the investigations by Mascart, Hopkinson, Siemens, Houston and Thomson, and others, on the efficiency of various dynamo-electric machines. But we regret that Dr. Higgs has issued this book with such precipitate haste, for, as it stands, it is a most slovenly piece of patchwork, and to be of real use to the public it must be in part rewritten and the facts presented in a more intelligible and orderly sequence.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Sun-Spots in Earnest

The communications in Nature, vol. xx. p. 625, regarding the note of Prof. Piazzi Smyth, Nature, vol. xx. p. 602, induce me to send an extract from my observing-book on those spots, together with some observations of them by Herr Hartwig, assistant to the observatory.

My observations of the sun are made with a rather small telescope, aperture of object-glass by Reinfelder and Hertel, of Munich, 74mm., with Merz polarisation eye-piece, power 55, images very fine, colourless.

1879.	M.T. Strassb. h. m.	
October 6	... 0 0	No spot on the sun.
,, 7	... 0 10	On the following limb two great regions of faculæ, with extremely narrow black spots in them.
,, 8	... 1 0	The group of faculæ, seen yesterday, contains to-day three great spots, with double nuclei; besides that there is a fourth system of three or four smaller spots with penumbra.

I did not look at the sun on the following days. The observations of Herr Hartwig are made by projection and with the heliometer of the observatory. By this instrument the polar and equatorial diameter of the sun has been measured every day since April, 1876, clouds permitting. It was during this series of micrometric measurements that Herr Hartwig made his remarks.

	Sid. T. Strassb.	
October 6–7	... 12 50	The sun appears without spots.
,, 7–8	... 12 25	Sun without spots; very bad definition.
,, 8–9	... 12 10	Beautiful group of spots near the following limb.
,, 10–11	... 12 15	Same group of spots, as seen the day before yesterday. Four very great spots; the following, which had *two* nuclei, like the others, has to-day *three*.
,, 12–13	... 13 10	Double spot on the middle of the disk; group of spots on the following limb.

Afterwards the clouds did not permit the sun to be seen for a week. It appears from these observations, that this first great display of solar activity after the minimum of spots, entered the disk October 6-7; it passed off, as Mr. Christie remarks, October 21.

A. Winnecke

Strassburg Observatory

Subject-Indexes

Most of those engaged in scientific work will probably agree with the views on this subject put forth by Mr. Wheatley in Nature, vol. xx. p. 627. There can be little doubt that a complete subject-index of scientific literature, in the sense in which it is generally understood, could not be compiled, and that the result of an attempt to do so would be as useless as it would be cumbrous, for the obvious reason that in a given paper, much valuable work is recorded which served only as a means to the end treated of; this work, therefore, lies hidden under a title which does not even remotely refer to it.

On the other hand, the compilation of lists of papers on particular subjects is fraught with no great difficulty, and would be of very great value. While the preparation of such minor indexes founded on the Royal Society Catalogue may be left to private enterprise, great advantage would, I think, be derived from some united action in the matter. I have myself made considerable headway with a classified list of papers on the subject which chiefly interests me, and which perhaps is best named Molecular Physics. This work necessitates my going through the whole catalogue for the sake of comparatively few papers, and I am further obliged to copy out the titles of, and references to, the papers I require. Now, if a movable copy of the Royal Society's Index were made as suggested by Mr. Garnett (NATURE, vol. xx. p. 554), and the different entries classified in sciences, these difficulties would be removed; Mr. Garnett, however, underrates the cost of preparing such a movable index, which would be large enough to deter many "gentlemen with leisure" from undertaking it. This work, therefore, must be carried out either by the Royal Society, or by a committee of those who take an interest in the subject; when completed the index could be distributed among those willing to undertake the subsequent arrangement in subjects.

There is another suggestion which I should like to make before closing this letter. Every month as it slips by adds rapidly to the enormous accumulation of scientific papers; unless these are catalogued and classified immediately they are published, the subject catalogue will never be satisfactory. What is wanted, then, is the publication (say every quarter) of a *complete* list of the scientific papers published during that period. I am aware that, as mentioned by Mr. Garnett, many such lists now appear, but none of them can be trusted as complete records.

If, however, a list were published "by authority" (for example, by the British Museum or the Royal Society), scientific men all over the world would send the titles of their papers to be entered in it, and it would soon be recognised that those who did not do so would stand a chance of rendering their work useless to those who travel after them along the same paths.

Science Schools, November 3 F. D. BROWN

Easter Island

IN the very interesting review of Mr. Wallace's "Australasia," in NATURE, vol. xx. p. 598, there is a passing reference to some views of my own concerning the stone images of Easter Island. The nature of the inferences that may be drawn in this case is not, I think, generally understood; and without wishing to give the subject more importance than it deserves, I should be glad if you could allow me space for a few words upon it.

Any positive ideas about the people who made them can hardly be got from the images themselves. They are rudely carved and ugly, and no existing race attempts to make anything really like them. But they are very numerous and very large; many of them weigh twenty tons, some probably two or three times as much. They have been quarried from a volcanic hill, conveyed several miles, and set upright upon pedestals, on massive stone terraces of great length. Work of this kind requires a definite amount of labour and strength. The amount available depends on the population. The population of a solitary island inhabited by savages is strictly limited by its area; the area of Easter Island is not more than forty square miles. There is, I believe, no known example in which an island of this kind supports, in an uncivilised state, more than fifty persons to the square mile. This is double the usual limit among savages.

Two thousand, therefore, would be the extreme limit of the population of Easter Island, unassisted from without; it has not more than half this number at present. In a population of 2,000 there are about 500 adult males, and we are to consider whether the work could have been done or even thought of with this amount of physical strength. It is, doubtless, quite impossible. A much larger number of people, or the help of civilised appliances, must necessarily have been at hand; but neither of these could be at hand without external help, and this could only reach the island across two thousand miles of ocean.

This is the really important point in this chain of inferences. We are led by what I think are inevitable steps to the conclusion that when these images were made there was a nation somewhere whose ships navigated the Pacific Ocean in such a manner that Easter Island could for a long period be supported as a colony.

I will not speak here of the anthropological bearings of this inference. Let me, however, enter a gentle protest against the sentence in which your reviewer speaks of "the accepted scientific position that primitive man was savage."

No doubt this is at present the belief of the majority of those who express their views; but there are names of great weight on the other side, and, considering what our actual knowledge of "primitive man" amounts to just now, it is rather hard upon science to make her responsible for our speculations.

November 3 ALBERT J. MOTT

Animals and the Musical Scale

IN a criticism in the *Examiner* of a book of mine on the "Theory of Music," the writer says:—

"We can hardly agree with Dr. Pole's view as to the essential artificiality of the diatonic scale, especially in the light of many facts collected by Mr. Darwin and other good observers. It is now almost certain that several of the lower animals have a very fair notion of the scale, and employ notes almost, if not quite, identical as to interval with our own."

If any of your readers can bring forward well authenticated facts of the kind they will be very interesting.

Athenæum Club, October 29 WILLIAM POLE

John Miers

IN your notice of the late venerable botanist, Mr. John Miers, in NATURE, vol. xx. p. 614, it is stated that "to the last he disbelieved in the action of the pollen and of the pollen-tube in the formation of the embryo-plant."

It is possible that the writer may have had some further warrant for this statement than the views published by Mr. Miers in his memoir on *Myostoma* (*Trans.* Linn. Soc., xxv. pp. 461-475 (1866), but it is scarcely borne out by them.

Mr. Miers's position as there expressed is that "it is not the pollen-tube, but simply the fluid-material contained in the pollen-grain, and emitted from its tubes, which is the direct agent in the process of fertilisation."

Whatever may be thought of this view, it is far from justifying the strong statement that in supporting it Miers "disbelieved in the action of the pollen." HENRY TRIMEN

October 28

[It would certainly have been more explicit had we added the word "tube" to pollen. At p. 468 of the paper cited by Dr. Trimen, Mr. Miers remarked "that the very important fact alluded to (the impact of the pollen-tube on the embryo-sac and the consequent fertilisation of the ovule) has not yet been satisfactorily proved." This was written in 1866. In the same paper "we have it demonstrated that in this case (Myostoma) the theory of the application of pollen-tubes for the fertilisation of its ovules is distinctly disproved."—ED.]

The Howgate Arctic Expedition

CAPT. HOWGATE, U.S.A., having for some years past fruitlessly endeavoured to obtain the comparatively small grant of 50,000 dollars from the American Government, for the purpose of carrying out his peculiar scheme of Arctic exploration, by forming a colony of active and experienced men, with a few families of Eskimos, at the coal-bed discovered some years ago in Lady Franklin Bay, Smith Sound, lat. 81° N., has determined to equip a private expedition on a smaller scale with this object.

A screw-steamer of about 140 tons (cargo measurement) has been bought for Capt. Howgate in the Clyde, has been refitted there, but not strengthened for ice navigation, which is to be done at Washington, and will, wind and weather permitting, sail for America on Thursday, November 6.

As most of your readers probably already know, Capt. Howgate's intention is that the explorers, instead of living on board ship, shall pass the winter in wooden houses taken out on purpose in frames, to be set up near the coal-seam, the party to remain in this locality for two or more years, watching a favourable opportunity of smooth ice or open water to push northward, and occupying their time usefully in making scientific observations, which are still much wanted in that far north region. Balloons, the telegraph, and probably the telephone, may be brought into use. J. R.

Intellect in Brutes

I AM in possession of an intelligent pointer dog, not quite two years old. The manner in which he makes his exit from the garden brought forcibly to my recollection Prof. Möbius's experiment with a pike, as narrated by Mr. Romanes in his article "Animal Intelligence" in the *Nineteenth Century* for October 1878, p. 659. A pike took three months to learn that he could not reach a minnow separated from him by a sheet of plate glass, and after its removal he never afterwards attacked the minnow. As Mr. Romanes says: "the firmly-established association of ideas never seems to have become disestablished." My pointer seems to arrive at an established association of ideas as fixed as the pike, a fact extremely interesting, considering that the dog is much higher in the scale of life than a fish.

The dog, when young, could only escape out of the garden through a small and difficult gap between the gate-post and the fence—a rose one. Some months ago a spar was broken out of the gate, and though the hole thus made was from the ground upwards, and quite large enough to allow of the passage of a large dog through it, yet it never took advantage of it. About a month ago a friend presented me with a young dog of the same variety, and it *at once* discovered the hole in the gate and went through it. But the older dog continues still to use the old gap between the post and the fence, and singularly enough it will see its companion pass through the hole in the gate, and it will even put its head through the vacant space and then turn aside and painfully crawl through the fence gap, which as a young dog it had discovered and used.

The discussion concerning the intelligence of the lower animals carried on in NATURE has interested some of us here. The following, regarding the gnawing of lead by rats, may perhaps interest your readers. Capt. Moir of the 99th Regiment, at present stationed here, showed me three bullets, still in the cartridge (for the Martini-Henry rifle), half eaten away by the rats, at Fort Chelmsford, Zululand. The rodents had made their way into the haversack in which the cartridges were, cut the strings tying the packet of cartridges, tore the brown paper off in which they were rolled, and then nibbled at the balls. These cartridges are made up in thin brass—which in no case was gnawed at. Nearly the longitudinal half of the exposed part of one bullet was eaten away; they had eaten into half the bullet, crossways of another cartridge, and in the third case they had nibbled off the point of a bullet.

It cannot be supposed that they nibbled for nibbling's sake; doubtless the smell of the grease in the cartridges attracted their attention to the haversacks, and the smell of the grease behind the bullets led them to attack the bullets—the only vulnerable point. JAMES TURNBULL

Grey Town, Natal, September 8

P.S.—There is a rat in Natal which, so far as I can gather, frequently carries its young ones before they are covered with hair; the little things cleave to the teats with mouth and feet. Gilbert White mentions that he once met with such an instance in England. I have not secured a specimen of this rat, though I have seen it once, and once only.—J. T.

Centipedes and Bees

As a postscript to Dr. Hutchinson's letters, I offer the following:—

The centipede does not "bite" at all—it makes tiny incisions with its numerous feet, which in themselves cause trifling inconvenience; but, when alarmed, it drops into each some kind of venom that causes intense inflammation (the *modus operandi* I now forget, but a medical friend explained it very clearly). I once had a centipede's nest in or near my bath-room, no less than eleven of different sizes having been killed there. Our first knowledge of them was derived from an infant child of the female servant, who, having been left on the floor there, was found crying and writhing beyond all soothing. When brought to me the child was feverish and restless, the *left* hand specially hot; on removing the little jacket, the fore-arm was found greatly swelled and inflamed, with two rows, less than half an inch apart, of pricks showing white on the delicate brown flesh. Ipecacuanha and eau de luce soon subdued the pain, but it was days before the child was well again. Several other persons also suffered from them, but only in one case was the line of pricks clearly traceable. Once, stooping to take up a water-pot, I felt a little *froissement* about the thumb; looking down, I perceived a centipede fully four inches long, which deliberately crawled across my hand near the knuckles, causing no pain, but a most unpleasant titillation, which continued for some time, though I put the hand in cold water immediately. On another occasion, seeing a centipede on the naked foot of one of the women, I called out to her, "Roho mut" (do not stir), and she similarly escaped all serious injury, while an application of warm oil very quickly removed all irritation. Of course it is only when crawling straightforward and undisturbed that the line of pricks can possibly be detected. On disturbance the animal shrinks up, curls round, and brings a number of them into one spot; at least such was the case the only time I ever *saw* a centipede do mischief; and the same appeared probable on other occasions when I saw merely the after-result.

I remember once, in the jungles of Rohilkund, one of our line of elephants brushed down a bee's nest from an old tree. Some of the nearest men were immediately stung; the servant behind me instantly wrapped me in a shawl I had beside me, then wrapped himself from head to foot in his large Kummerbund, as did all the other men, and off we went at speed to a small river not far off, where the elephants (who had not escaped) plunged themselves to their very backs, as the only mode of getting rid of their little assailants.

I may add that a small black scorpion common in the Dehlie division is very venomous. I have myself seen a case in which its "strike" was nearly fatal to a shepherd of about fifty years of age. MEMORIA

Bone-Sucking—A Habit of Cattle

THE habit of bone-sucking in cattle (NATURE, vol. xx. p. 457) is not peculiar to Natal. The learned Archbishop of Dublin, Dr. Whately, many years since made a most interesting communication to the then existing Dublin Natural History Society on this subject, and stated his observation that animals addicted to bone-sucking invariably fell into an unhealthy state unless the bone was removed from the field. There is a scarcity of limestone, as Mr. Donovan suggests, with us to account for this "bad habit," for such the Archbishop considered it.

Dublin W. FRAZER

IN response to the letter of Mr. H. C. Donovan (NATURE, vol. xx. p. 457), in relation to the habit of cattle in the colony of Natal *chewing bones*, I beg leave to state that many years ago, in a monograph on "Geophagy," I had occasion to put on record a similar habit among the cows in one of the Southern Atlantic States of the United States (*vide Southern Medical and Surgical Journal*, new series, vol. i. pp. 417–444, August, 1845). From this paper I quote (p. 442–443) the following extract bearing upon the question:—

"In confirmation of the importance of inorganic principles in the food, I will here adduce a remarkable fact which has repeatedly fallen under my own observation: The cows which live on the extensive savannas and pine-barrens lying on the north side of the Altamaba River, in McIntosh County, Georgia, subsist upon very coarse species of grasses, which are probably deficient in some of the phosphatic or calcareous ingredients essential to healthy nutrition, for these animals are constantly observed to *chew bones*. They frequently remain stationary for hours, with the head elevated to prevent the saliva from escaping from the mouth; they will, by constant trituration, gradually reduce the bony mass to a very small size, when it is rejected as an unmanageable morsel. The cattle in this section of the state are usually rather lean, and cows brought from the fertile plantations in the neighbourhood, if allowed to subsist on what they can procure in the savannas and pine-barrens in the course of a year or two become equally thin, and ultimately fall into the habit of *eating bones*. I have not been able to ascertain whether these animals indulge in this habit to a *greater extent* when they are in a state of *pregnancy* and when they are giving *milk*, but it appears reasonable that the increased demand for mineral matters under such conditions of the economy would call for a proportionate supply. The intelligent instinct which prompts these animals to seek for a diet so extraordinary must originate in an inadequate supply, in their impoverished aliment, of some of the inorganic principles (probably the phosphatic salts) essential to a proper nourishment of the osseous structures."

Berkeley, California, October 4 JOHN LECONTE

Earthquake in China

THE north of China has been very unfortunate of late. Famine has raged in the provinces of Shantung, Shansi, Shensi, and

Honan within the last three or four years, and, in a less severe form, in one or two of the adjoining provinces. Shansi is still suffering. And now the south-east of the province of Kansah has been visited by a destructive earthquake. The *Peking Gazette* of the 22nd of August states that a memorial has been received from Tso Tsung-t'ang, Governor-General of Shensi and Kansuh, reporting that on June 29 a slight trembling was felt at *Chieh Chow*, and at other sub-prefectures and districts within the province of Kansuh. This trembling, which occurred at first on alternate days and afterwards continued for several successive days, did not entirely cease until July 11. The earthquake would appear to have reached its height on the third day; for Governor-General Tso reports that on July 1 there was a violent shaking accompanied by a noise. A temple, several official residences, and many dwelling-houses were completely destroyed, and many persons were killed and injured.

In the Imperial edict Tso Tsung-t'ang is directed to send officers to the scene of the calamity to hold an investigation into the matter and afford relief to the sufferers. A. H.

Canton, September 13

Vertical Shafts in the Chalk in Kent

In the current number of *Good Words* there is a pleasant, gossiping paper by the Rev. J. G. Wood, giving an account of the curious well-like shafts found in the chalk about Erith. They are 40 feet to 100 feet in depth. Mr. Wood states that the sides show traces of having been wrought with picks made of deer antlers. He appears to accept the theory of local archæologists that the shafts were executed in "prehistoric" times, in the quest for flints for weapons or for some less obvious purpose.

Under any circumstances I should be loth to dispute the view of so competent an authority, and in this instance I have no local knowledge to guide me; but I should be grateful if some of your readers would satisfy me on the following point:—Is there any instance of similar excavations which have been conclusively proved to be the work of savages ancient or modern? I know of none within my own personal experience.

Burrows on the "adit" or "gallery" principle, *i.e.*, more or less horizontal, can be carried surprisingly far, so long as the roof does not fall in. We see this in the abodes of certain quadrupeds. But, to carry down a *vertical* shaft a few feet in diameter to a depth of 40 feet to 100 feet from the surface, even in a soil as favourable as chalk, appears to me to involve recourse to mechanical appliances not yet observed in use among primitive races. If I am wrong in this matter, the mode of excavation pursued by these rude shaft-sinkers certainly affords interesting matter for study. H. M. C.

London, November 1

THE FUNCTIONS OF UNIVERSITIES

We reproduce with pleasure the following extract from an article on this subject from the *Times* of Friday last, in connection with Prof. Max Müller's address at the Birmingham Midland Institute:—

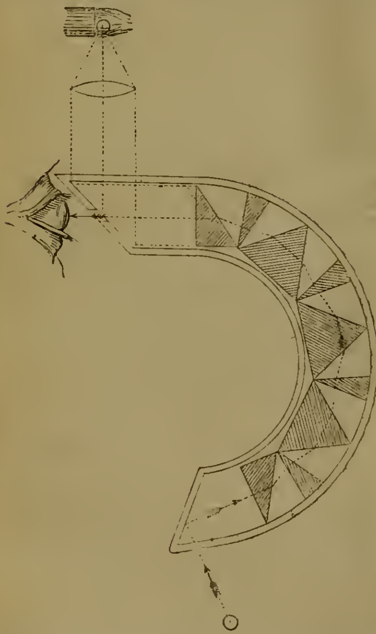
It would doubtless be unjust, as Prof Müller points out in his address, to attribute the lack of spontaneity, the tendency to mechanical uniformity in academical studies, exclusively to the influence of an elaborate system of examinations. Examinations are clearly necessary, as he justly contends, even though they are no better than a necessary evil; but they are rather means than ends, and they clearly become mischievous when they corrode and destroy the true spirit of academical life. Prof. Müller, a German professor in an English university, whose opinion is on that account entitled to peculiar weight, draws a favourable contrast between English and foreign universities; the former, he says, are free and self-governed, and that gives them an unrivalled position in spite of all their faults. The remark is true and appropriate, especially as a rejoinder to the hasty and ill-considered criticisms of Prof. Helmholtz in his rectorial address at Berlin, delivered some time ago. But the corporate freedom of the English universities, is, unhappily, not inconsistent with a good deal of personal bondage. Let us contrast, for instance, the career of a graduate of a German university with that of an English Fellow of a college. The former, as soon as he has passed the necessary examinations for his degree, is perfectly free to follow his own bent. Even in taking his degree he is entitled to claim it, partly at least, on the ground of some dissertation which he has written containing the results of his own independent study and research. If he elects to follow an academical career, he becomes at first a Privat-docent, and has to attract pupils, not by his power of preparing them for a particular examination, but by his command of all the available knowledge in a special branch of study, and by his capacity for enlarging its bounds. If he is called to be a professor, it is because he is known to be master of his subject, and to be keeping himself on a level with the march of knowledge in relation to it. The English graduade may have all the aspiration to follow this career of true academical freedom; but his pupils for the most part have no higher object than to pass an examination, and it is his business to prepare them for it. Any knowledge that he posseses beyond the range required for that purpose becomes a useless burden to him. The results of fresh research necessarily find their way but slowly into examination papers, and consequently the teacher at an English university, if he studies at all, is bound to study, not for himself, but for his pupils. He must learn all that they want to know, and he must put his knowledge into the form which will be most readily available for their purposes. Hence, if he has time to write at all, he writes summaries of history, essays in philosophy, or prepares a handy edition of a portion of a classic commonly read in the schools. A learned and scholarly edition of an author unrecognised in our somewhat narrow classical curriculum, a history like Grote's or Gibbon's, a philosophical work like the "Essay on the Human Understanding," or the "Critique of Pure Reason," are works hardly now to be looked for from a resident English graduate. Professorial work, of course, is different; it is beginning now to be recognised that it is the business of a professor to study widely and deeply and to advance the bounds of knowledge. But if the coming generation of teachers, the professoriate of the future, is to be confined to the range of a rigid and cramping system of examinations, narrow in their content, but all-embracing in their extent, what hope is there for that academic freedom, for that bracing spirit of living knowledge, of active thought, of ever-advancing study which, as Prof. Müller tells us, it is the true function of a university to foster and keep alive?

The truth is, perhaps, that our universities are a little too careful of the functions they so admirably discharge of finishing schools, a little too unmindful of those higher duties to which Prof. Müller's address forcibly calls attention. All that they do is done well, but there is still one thing needful. "That is the true academic stage in every man's life when he learns to work, not to please others, be they schoolmasters or examiners, but to please himself; when he works for sheer love of work in and for the highest of all purposes—conquest of truth." How many of our English University students ever reach this stage at all? That they learn much and learn it well cannot be doubted, that they are examined much and are examined well is equally indisputable. But we should be very sorry to see the Universities complacently resign the function of making scholars in favour of that of testing the attainments of schoolboys. We are very far from arguing that examinations can be dispensed with altogether. They have their purpose, and it is a very necessary purpose to fulfil. It is their indirect results in stereotyping academical effort, in extinguishing academical freedom, in discouraging wide study, in checking individuality, and in repressing spontaneity, rather than their direct results, that we have to fear The evil is no slight one, and we fear it is still on the increase. "Unless," said Mill, "individuality shall be able to assert itself against the yoke of public opinion, Europe, notwithstanding its noble antecedents and its professed Christianity, will tend to become another China." Prof. Müller would persuade us that our Universities are a safeguard against this catastrophe. But when China is mentioned in connection with education, examinations are suggested by an irresistible association. If, therefore, England is to escape the fate of China, it is not only encouraging to reflect that the most conspicuous modern building in Prof. Müller's own University is the new Examination Schools.

DESCRIPTION OF AN INSTRUMENT FOR EXPLORING DARK CAVITIES WHICH ARE INACCESSIBLE TO DIRECT LIGHT

AN electric lamp has recently been proposed for surgical and dental operations.[1] Some years ago I designed an instrument for illuminating the dark cavities of the body which would, I think, be very serviceable in connection with an electric lamp.

This instrument consists of a series of prisms arranged somewhat as in the corona employed for spectrum analysis. The accompanying woodcut will be sufficiently intelligible



without any detailed description. The different prisms are of glass of such refractive indices as to secure achromatism, and the rays of light are bent round corners, so as, finally, to reach an external observer.

In most cases one or two such prisms will be sufficient, but any number may be employed so long as the loss of light from absorption, superficial reflection, and other causes is not so great as to defeat the object in view by destroying the distinctness of the image.

THOMAS STEVENSON

[1] *Engineer*, March, 1879.

IMPROVEMENTS IN BLEACHING

A METHOD of applying the ordinary bleaching agents (hypochlorites) in a new way has been invented by Count Dienheim de Brochocki of Paris. Instead of immersing the goods to be bleached in an ordinary "chloride of lime" vat, and subsequently souring, the inventor treats bleaching-powder with an acid and simultaneously passes air through the mixture, so that chlorine and hypochlorous acid vapours are mechanically carried off; the resulting gases are passed through an alkaline solution in such proportions as to saturate part or the whole of the alkali, or to supersaturate it at will. The resulting liquid is said to be sufficiently stable to be kept without change for two or three months; it can readily be prepared of a density of 30° Beaumé, and acts as a bleacher without requiring any acidulation, and for many purposes is said to be superior to the ordinary bleaching-vat.

To this liquid the fanciful name "chlorozone" has been given, the inventor asserting that the oxidising power of a given quantity of bleaching-powder is *increased* by this treatment through the fixation in the product of some of the oxygen of the air used as carrying agent; the which oxygen he conceives to be liberated in the form of ozone in contact with the goods to be bleached! Although no experimental proof of the truth of this somewhat novel proposition appears to have been vouchsafed to the scientific world, yet it would seem that the new product has at least some practical advantages over the older bleaching agents, as it is used to a considerable extent in Paris, whilst works for its manufacture on a large scale have been recently erected at Warrington by Messrs. Nath. Holmes and Partners.

HERING'S THEORY OF THE VISION OF LIGHT AND COLOURS[1]

III.

IN the sixth and last memoir the author develops the part of his theory which has probably excited the most interest, namely, that of the vision of *colours*. He devotes his first section to the *mode of classification* of colours, and as this is not only the most important part, but differs materially from the generally received views, it is desirable to give its substance pretty fully.

He explains that, as he has based his general theory on what are naturally and physiologically two simple sensations, white and black, so he proposes to base his treatment of colours on the "natural system of colour-sensations." He then has to seek what the simple natural sensations of colour are, neglecting in this classification all consideration of the physical properties usually connected with them. He inquires, therefore, what simple colour-sensations there are. Taking the six usually admitted, violet, blue, green, yellow, orange, and red, he finds that two, namely, violet and orange, are obviously compound sensations; for in violet of every hue there can be distinguished clearly a mixture of the two sensations, blue and red; and similarly in orange there can always be traced the elements of red and yellow. The other four colours are red,[2] green, blue, and yellow. None of the sensations known by these names contain, when pure, any semblance of another colour-sensation. These four, therefore, may with perfect correctness, as was pointed out by Leonardo da Vinci, be considered as simple or fundamental colour-sensations. On this account they have received special names, not borrowed from any coloured natural objects.

All other colour-sensations than these may be called mixed or compound sensations, as two elements can always be discovered in them; but it is a fixed principle

[1] Continued from vol. xx. p. 639.
[2] This, however, is not the spectral red, which contains a mixture of yellow.

that *more than two simple colours* can never be evident in the same mixture.

There is also a natural peculiarity in the capabilities of the various simple colours for combining with each other. Red will combine with yellow or blue, but not with green, *i.e.*, red and green can never be both distinguished in the same combinations. Similarly, yellow will combine with red or green, but not with blue. Green will combine with blue or yellow, but not with red; and blue will combine with red or green, but not with yellow. In other words, we find the natural law that *on the one hand Red and Green*, and *on the other hand Blue and Yellow*, are never visible together in the same combination; they are incapable of combining together. What the cause of this is it is impossible to say. It is customary in books on physics to say that red and green, or blue and yellow combined, make white; but this is only true when by red, green, &c., are meant ether vibrations, and not physiological sensations; for to insist that red *plus* green makes white in the same sense that red *plus* blue makes violet would be contrary to common observation, for in pure white there is no trace of any colour-sensation whatever. It must, therefore, be something in the natural connection of these colours with our sense of vision that makes these combinations incompatible with each other; and for the sake of using a short expression for this relation, the author proposes, in consideration of their so-to-speak inimical relations to each other, to call red and green, or blue and yellow *opposite*, or *contrary*, or *antagonistic colours* (*Gegenfarben*).[1]

The combination of any simple colour-sensation with that of another (not antagonistic) gives a sensation of a different *hue* (*Farbenton*), and the hue will vary according to the proportions of the components. Thus different proportions of red and blue will give different hues of violet, and so on. The whole scale of these may be conveniently expressed by a "colour circle." Divide a circle into four quadrants, and at each point of division put one of the four simple colours, arranging the antagonistic ones diametrically opposite to each other. The intermediate portions may then be filled in with compound hues, passing in regular gradations from one of the simple colours to the next adjoining on either side. Such a circle, if supposed to be divided into very minute gradations, will contain all possible hues of colour. And every *hue, both simple and compound, will have, diametrically opposite to it, its natural antagonistic colour*.[1] Now every possible hue of colour may appear in many different states of "purity," or, as it is often called, "saturation." These various states are called by the author "nuances," and they are caused by the mixture with the hue in question of various proportions of black and white, *i.e.*, various degrees of the black-white sensation. Thus red may be mixed with black, white, medium gray, light gray, or dark gray, every grade giving a different nuance of the red hue.[2] The different hues and the different nuances of each taken together will comprise all colour-sensations possible.

The pure colour-sensations are unknown to us; what we experience are always nuances containing white or black. The fact that some colours, and some parts of the spectrum, appear so much brighter than others is due, the author asserts, to the fact of the former containing more white. He conceives that if the pure colour-sensations alone could be experienced they would all be of equal brilliancy, and would probably have the same degree of luminosity as the medium gray; for as each colour-sensation must be considered as an independent one, there is no reason for attributing to any of them the particular effect that we are accustomed to connect with whiteness in particular.

The varieties of colour-sensation admit of being expressed in a formula. Varieties of hue may be expressed by the proportions of each colour they contain; thus $\frac{\text{Blue}}{\text{Red}}$ or $\frac{\text{Red}}{\text{Blue}}$ will express all varieties of violet; the *blueness* of it will $= \frac{\text{Blue}}{\text{Blue} + \text{Red}}$, and the *redness* $= \frac{\text{Red.}}{\text{Blue} + \text{Red.}}$

The nuance of a hue, or its degree of purity, is expressed by the ratio the weight of the pure colour-sensation bears to the whole weight of the combination; thus the purity of a nuance of Blue $= \frac{\text{Blue}}{\text{Blue} + \text{White} + \text{Black}}$. Thus, suppose a red is mixed with double its weight of medium gray, then there are equal weights of each sensation, and the purity will be

$$= \frac{1}{1 + 1 + 1} = \frac{1}{3} = 0{\cdot}33.$$

For a compound hue, for example, violet, the purity will be $= \frac{\text{Blue} + \text{Red}}{\text{Blue} + \text{Red} + \text{Black} + \text{White}}$. For example, suppose the weight of the blue and red sensations are 4 each, the white 1, and the black 3, forming a dark nuance of violet, the purity

$$= \frac{4 + 4}{4 + 4 + 1 + 3} = \frac{8}{12} = 0{\cdot}66.$$

The author further forms an estimate of the *brightness* or *luminosity* (*Helligkeit*) of a nuance by the formula

$$\frac{\text{White} + \frac{1}{2}\,\text{Colour}}{\text{White} + \text{Black} + \text{Colour}}.$$

Thus in the former of the above two examples, the luminosity will be

$$= \frac{1 + \frac{1}{2}}{1 + 1 + 1} = \frac{1}{2}.$$

In the latter

$$= \frac{1 + \frac{8}{2}}{1 + 3 + 8} = \frac{5}{12}.$$

[1] The following observations of Sir John Herschel (extracted from his Report on my paper on Colour Blindness, presented to the Royal Society in 1856) strikingly confirm the views expressed by Herr Hering:—

"It is as necessary to distinguish between our sensations of colour and the qualities of the light producing them, as it is to distinguish between bitterness, sweetness, sourness, saltness, &c., and the chemical constitution of the several bodies which we call bitter, sweet, &c. Whatever their views of prismatic analysis or composition might suggest to Wollaston and Young, I cannot persuade myself that either of them recognised the *sensation* of greenness as a constituent of the sensations they received in viewing chrome yellow or the petal of a marigold on the one hand, and ultra-marine, or the blue salera, on the other; or that they could fail to recognise a certain redness in the colour of the violet, which Newton appears to have had in view when he regarded the spectrum as a sort of octave of colour, tracing, in the repetition of redness in the extreme refrangible ray, the commencement of a higher octave too feeble to affect the sight in its superior tones. Speaking of my own sensations I should say that in fresh grass or the laurel leaf, I do not recognise the sensation either of blue or yellow, but something *sui generis*; while on the other hand I never fail to be sensible of the presence of the red element in either violet or any of the hues to which the name of purple is indiscriminately given; and my impression in this respect is borne out by the similar testimony of persons, good judges of colour, whom I have questioned on the subject

"It seems impossible to reason on the joint or compound sensation which ought to result from the supra-position in the sensorium of any two or more sensations which we may please to call primary.

"Declaring red and green to be primary sensations, and yellow a mixture of them [is] a proposition which needs only to be understood to be repudiated—quite as decidedly as that the *sensation* of greenness is a mixture of the *sensations* of blueness and yellowness, and for the same reason; the complete want of suggestion of the so-called simple sensations by the asserted complex ones.

. . . .

"From these premises it would seem the easiest possible step to conclude the non-existence of yellow as a primary colour. But this conclusion I am unable to admit in the face of the facts (1) that a yellow ray incapable of prismatic analysis into green and red, may be shown to exist, both in the spectrum and in flames in which soda is present; and (2) that neither red nor green, as sensations, are in the remotest degree suggested by that yellow in its action on the eye.

"Whether under these circumstances the vision of normal-eyed persons should be termed trichromic or tetrachromic, seems an open question."—*Proceedings* of the Royal Society, vol. x., 1859-60, p. 72.—W. P.

[1] Such a circle has been published by Chevreul, but the colours are arranged somewhat differently, the antagonistic ones not being opposite to each other.—W. P.

[2] In technical language mixtures of a colour with white are called *tints*; with black, *shades*; but this nomenclature is imperfect, according to the author's view, as the various nuances are considered by him to contain black and white together.—W. P.

The luminosity of a pure colour will thus be $=\frac{1}{2}$, and if mixed with an equal quantity of white, it will be

$$=\frac{1+\frac{1}{2}}{1+1}=0·75\,;$$

that of pure white being 1.

After these preliminary explanations the author proceeds to develop the chief features of his theory of colour-sensation, adopting the principles previously laid down as applicable to black and white only. He expresses the chief points in two propositions :—

1. There are six fundamental sensations of the visual substance, arranged in three pairs. These are—

Black and white.
Blue and yellow.
Green and red.

2. Each of these pairs corresponds to a dissimilation process and an assimilation process of a special kind, so that the visual substance is subject to chemical change, or change of matter, in a threefold way.

The three kinds of change may be either connected or independent; the latter is the simplest supposition, and the author finds it convenient to assume that there are *three different components* of the visual substance, which be considers as corresponding with the three pairs of sensation, and which may, in short, be spoken of as the black-white, the blue-yellow, and the red-green substances respectively.

These three substances are not all present in equal quantities ; the black-white one is much more richly provided in the visual organs than either of the others, and the latter are not present in equal amount.

As in the black-white substance, both dissimilation and assimilation go on, the former corresponding to the white and the latter to the black sensation ; so the same processes take place in the two other substances, but with much less activity, whence the weight of the six fundamental sensations is very unequal ; relatively great in the black and white ; relatively less in the four colours. The author does not venture to pronounce which of a pair of colours corresponds to the D and which to the A action.

All rays of the visible spectrum have a dissimilating action on the black-white substance, but the different rays in different degrees. On the blue-yellow or the red-green substance certain rays alone have a D action, certain others an A action, and certain others no action at all. Thus each of the three substances has, so to speak, its own particular sensation-spectrum ; and in the actual impression of the spectrum these three overlap or intersect each other.

The spectrum of the black-white substance is the brightest in the yellow, and diminishes on both sides.

The spectrum of the blue-yellow substance consists of two parts, one yellow and one blue, which are separated by a spot which is lightless for this substance ; this is the place of the pure green.

The spectrum of the red-green substance consists of three parts, one green in the middle, and one red at each end, giving two spots which are lightless for this spectrum, *i.e.*, the place of the pure yellow and that of the pure blue.

Thus the total spectrum of the visual substance has three distinguished physiological points, where, in addition to the white, only one fundamental colour is visible, viz., yellow, green, or blue. The real red is very small in the spectrum, for the spectral red contains much yellow. The first part of the spectrum from red to pure yellow is thus a mixture of white, red, and yellow ; the second, from yellow to green, is a mixture of white, yellow, and green ; the third, from green to blue, of white, green, and blue ; the fourth, from blue to the end, of white, blue and red. In the pure yellow, green, and blue, only these colours mixed with white are seen.

Mixed light appears colourless, when it acts, on the blue-yellow or the red-green substance, with equal D and A power, for then both effects neutralise each other and the action on the black-white substance alone appears. For this reason two objective kinds of light, which, when mixed, give white, are not *complementary* but *antagonistic;* they do not produce the white by their combination, but merely destroy each other and leave visible the white which was already there.

The *excitability* (*Erregbarkeit*) may vary, doubly, on each of the three substances in the same manner as before explained, so that one and the same objective light-mixture may not only appear lighter or darker, but varying in colour according to the proportions present of the six kinds of excitability, giving various conditions (*Stimmungen*) of the visual organ.

Suppose the eye to have been long at rest, so as to be in what has been called the neutral condition (the D and A-actions being equal in regard to all three of the visual substances), the total sensation will comprise the two opposite colour-sensations of each colour-substance, as well as the white and black sensation, but the latter will be much the stronger, and more predominant, as each of the colour-sensations will neutralise its opposite one, *i.e.*, the red and green will neutralise each other, and so will the yellow and blue. This neutralising effect, however, does not take place in regard to the black-white substance, because the assimilation causing the black sensation is not produced by any direct rays ; if there were any solar rays causing A-action in the black-white substance, then solar light might, under certain conditions, be invisible, like an equal mixture of blue and yellow, or red and green. Hence the resulting total sensation, when the eye is at rest, is the mixture of white and black, called neutral gray.

Now if, in this condition, we allow the light of any one of the simple spectral colours, say green, to fall on the eye, it strengthens the already present green sensation, and also the white one. The result is a mixed sensation, formed of green, with a considerable mixture of white, and also with some mixture of black, already existing in the neutral gray. Thus it is that even the spectral colours never appear pure, but always obviously contain white and black impurity.

Pigmental colours are still more impure, as they reflect mixed light, in which only certain rays are more or less weakened. To the colour-action of those rays which are hereby unneutralised by antagonistic rays, is added not only the action of such rays on the black-white substance, but also the action of the whole remaining neutral-mixed light which only acts on the black-white sensation.

Mixed light which gives us a beautiful colour-impression may, if colourless light be added, appear entirely or nearly colourless, because the original colour-sensation is already mixed largely with colourless light. Even the spectral colours quickly lose their force and become pale and whitish, when the vision is steadfastly fixed for a time on one of the dark lines, for the excitability of the colour-substance is quickly lowered, while that of the black-white sensation retains its power.

In general the conditions are very unfavourable, in ordinary vision, for the powerful production of colour ; for both on the light and the dark parts the colour-sensations are rendered strongly impure, if not almost entirely suppressed by the black-white action. In the darkened eye, in which the latter has less power, the colour-conditions are more favourable, and hence the after-images are often highly coloured. The most favourable conditions are where the black-white substance has been fatigued by dazzling light, and hence the after-images in such cases often show colours almost more powerful than even those of the spectrum, where, in the original objects, scarcely any colour was appreciable.

It must be always borne in mind that every visual sensation, however it may appear, is really a mixture of all the six fundamental sensations. That one of the six, which has relatively the greatest weight, gives the character and name to the mixed sensation. If any one fundamental sensation is so strong in predominance over all the others, that the latter are not distinguishable, it approaches the idea of purity, which, however, in reality can never exist.

When the visual organ has been for a long time protected from any external stimulus, it assumes, more or less perfectly, that neutral condition in which the assimilation and dissimilation, as well as the D-excitability and the A-excitability are equal for all the three visual substances.

In this state, in order that a mixed light should produce a colourless impression, it is necessary that this light should have an approximately equal assimilating and dissimilating moment, by which is meant the product of the stimulus and the excitability. Such mixed light may be called objectively colourless light.

But the same light will appear, say, greenish, if the red-green substance is no longer in the neutral condition, but has its green excitability greater than that of the red. For in this case the A and D-moments will not be equal, and a small difference will exist to the advantage of the green.

Now when a part of the previously neutrally tuned visual organ has been stimulated by coloured light, the condition of this part will become so altered that the excitability for the perceived colour diminishes and becomes less than the excitability for the opposite colour. Under these circumstances any mixed light which, in the neutral condition appeared colourless, will now appear coloured with the opposite colour. And if a part of the visual organ has been affected, say, by the action of green light, on looking at a blue or yellow surface, the blue or yellow will appear tinged with red.

The phenomena of simultaneous colour-contrast and of colour-induction are explained in the same manner as for the corresponding phenomena in black and white.

It has been seen that by the white illumination of any part of the visual organ, the other parts of it, and particularly those adjoining, are, by the indirect action of the stimulus, darkened; or the sensation of black is intensified; and in a similar way, under the action of coloured light on any part, the sensation of the opposite colour is strengthened in the adjoining parts.

As a consequence of this the relations of excitability are altered; for, according to this theory the sensation of any colour implies also a change of those relations to the disadvantage of this colour and to the advantage of its opposite. If, then, light be allowed to fall on the whole retina, which, under a neutral condition, would be colourless, it now appears coloured; the colour on the previously excited part will be the opposite colour (successive contrast), while that around it will be the same colour as that previously observed (successive induction). In fact, all the phenomena explained for white and black may be, in this way, transferred to the colour-sensation.

The author makes some further remarks on the Young-Helmholtz theory. He admits that the attempt of Young to reduce the great variety of colour-sensations to a small number of physiological variables was a most important step in advance, but he considers that if, as before explained, every psychical result must correspond to some physiological process, the number of fundamental colour-sensations ought, as has been often urged, to be increased to four, and that separate physiological sensations ought to be allotted to white and black. But he considers the great defect of the theory to lie in its only acknowledging *one* kind of excitability, excitation, and fatigue, namely, that which he denotes by D, and that it ignores entirely the antagonistic relations of certain rays to the visual organ; hence it regards the production of white out of "complementary colours" as a result of their mutual combinations, and not of their mutual extinction.

He also remarks on the difficulties of explanation of many phenomena, on this theory, and in particular on the inconsistencies it causes in the attempted explanation of colour-blindness, as shown in the most modern literature on the subject.

In conclusion he gives some remarks on the chief points of his theory, which it may be instructive to repeat here.

The theory, although immediately dictated by a free and unbiased analysis of the visual sensations, is essentially based on certain fundamental principles, taken from the acknowledged phenomena of organic and psychical life, and it is by these principles that the author's views are brought into connection with the doctrines of physiology generally.

With respect to the doctrine of light and colour, the first thing to mention is the natural system of visual sensations, founded on their internal similarity; and further, the grouping of the six fundamental sensations in three pairs of opposite colours.

Next comes, as of fundamental importance, the appreciation of the visual sensations as the psychical correlatives of the nutritive processes, or changes of matter in the visual substance, which leads to the separation of the D and A sensations, and further, to the principle that every D sensation implies a decrease, every A sensation an increase of the visual substance. Corresponding to the three pairs of simple or fundamental sensations are assumed three kinds of D and A processes in the visual substance and three kinds of specific D and A excitability. The colourlessness of mixed light formed out of "complementary" rays, is explained by their antagonistic relations.

Further, here, for the first time the proof is methodically and comprehensively produced that the separate parts of the nervous visual substance are in internal functional changing relationship (*Wechselbeziehung*), which is to be regarded as reciprocally connected with the change of matter; for when $\frac{D}{A}$ is greater on a stimulated part, it is less in the surrounding parts, and *vice versâ*; so that after the stimulus the excitabilities of both parts change in opposite directions.

These propositions and their consequences afford the means of explaining the various phenomena mentioned, but it often happens that several explanations are possible for one and the same phenomenon, and that the decision between them must be reserved for more detailed inquiry. What we immediately appreciate in a visual sensation is the ratio of the corresponding D and A processes to each other, for this determines the *quality* of the sensation. A change of sensation gives only an indication of the change of this ratio, and not of the changes of its two components. Then it is that we have so often the choice between an increase of assimilation and a stoppage or decrease of dissimilation, and *vice versâ*. But the theory itself gives means of determining these, by further and more detailed and intricate investigations; and the author promises future communications by which the details will further be supplied, without as he hopes, any material alteration of the principles he has laid down.

WILLIAM POLE

THE "PARASOL" ANTS OF TEXAS: HOW THEY CUT AND CARRY LEAVES: ORIGIN OF CASTES BY EVOLUTION

IN Mr. McCook's recent investigation (NATURE, vol. xx. p. 583, and *Proc.* Acad. Nat. Sci. Phil., 1879, p. 35) he stated that he observed carefully both the mode of cutting and the system of carrying cut portions of oak-leaves at Camp Wright, and at a vegetable garden near Austin, Texas.

To investigate successfully he found it best to thrust small branches of live-oak into one of the mounds described, near the "gates." These were soon withdrawn, and seen to be covered with "cutters" busily occupied. It was thus possible to examine them at work by the light of a lantern, as it will doubtless be remembered that night is the busiest time with these active ants, supplying their minuteness with a most effective shelter.

The "cutter," usually an ant belonging to the caste next below the "soldier" in size, first grasps the leaf with outspread feet, and begins to cut into its edge by a scissors-like action of her sickle-shaped toothed mandibles. Thus she naturally proceeds, with steady motion, until the mandibles have clipped off a portion of the leaf, having a circular edge, clean cut. The feet turn as the head turns. The cutter sometimes drops, with the piece just cut, to the ground; but probably, if possible, retires when the piece has dropped, to continue her professional occupation. Mr. McCook found at the foot of one tree a pile of cut leaves, to which clippings were continually being added, dropped by the cutters. The carrier at the foot took them up and carried them to the nest. The loading of the cuttings is thus accomplished: the piece is seized by the curved mandibles, the head is raised, the piece is thrown back by a quick motion, seeming to be lodged on its edge within the deep furrow that runs along the entire median line of the head with the exception of the clypeus, and supported between prominent spines on the edge of this furrow and on the prothorax.

The young saplings near the mound at Camp Wright were found almost entirely stripped of leaves by these ants. The great tree (live-oak) near by was in parts stripped to the very top. In beginning work on a tree the cutters seem to aim first at the topmost leaves. They prefer trees with a smooth leaf; they eat grapes, radishes, &c., and can take celery, beet, young maize, and wheat, plum leaves, honeysuckle, and jessamine. Strangely enough, they do not like lettuce, paper-mulberry, figs, cedar, except the buds, when very hard up in winter. A nurseryman, on whose grounds Mr. McCook witnessed the ants at work and the scene of their former exploits, told him that they even entered his desk-drawers, and carried away part of his chewing-tobacco. At another plantation Mr. McCook saw an immense column of the ants engaged in plundering a granary of wheat.

One of the most interesting questions for evolutionists centres undoubtedly in the causes and mode of continuance of the castes or differentiated forms of species like this ant. The worker-castes are sterile, and produced from eggs laid at different periods by the female; and as to a blending of castes by intermediate forms, nothing has yet been seen or proved in the case of the cutting-ant, after careful examination by the microscope. The lowest castes of minims, in all individuals Mr. McCook examined, with special reference to the mouth-organs and eyes, had the same structure in equal definiteness and perfection, as the larger castes. Consequently, Mr. McCook again finds no way of comprehending how natural selection could have produced or preserved or improved these castes. May I suggest that we know as yet too little of the whole life-history of social animal communities, to say nothing of their past history in time, their conditions during long series of years, and the reaction of each community on its surroundings, to assert that any hypothesis of evolution admissible as a *vera causa* in one case is inadmissible in another? We are but on the threshold of the study of the influence of social laws and conditions upon human communities; how can we expect to understand the influence of society and common interests upon specialisation in ants? Yet there are even now several possible ways of imagining the influence of variation and changed conditions to have aided in producing castes. May it not be that the comparative study of *ant-communities* of the same species, or of different species of the same genus will at length furnish a key much more valuable than we yet know? How is it that nations of man rise and fall, increase or decrease? Are not all men of one species? Why are there so many castes? If we cannot answer these questions perfectly, why be dismayed if we quarrel about terms as to the intelligence or reason displayed by various animal forms? There is nothing to be done but for men to wait, study to comprehend the nature of proof, and then patiently investigate. The explanation of all difficult problems will, if we are to judge by the history of science, be very simple, much simpler and more illuminating than the acrobatic or the prejudiced intellects would have us believe.

G. T. BETTANY

NOTES

THE exhibition at Croydon, held in connection with the Congress of the Sanitary Institute of Great Britain, has a peculiarity attached to it which, though it has its advantages, is a disadvantage to the visitor. The peculiarity is that the awards of the judges will not be made known till the day of closing, viz., November 8. At most exhibitions visitors have their attention drawn to objects of high merit by the announcements of the honours the judges have awarded; but here, and this, too, on subjects often affecting their own health, visitors can, even if they care to take that trouble, only form their own opinions, guided by the skilled advocacy of the attendants at the different stalls. If all the objects announced in the catalogue as "essential," "indispensable," "infallibly safe," and "the only ones of the kind made," are really so, then the practical application of sanitary science in households is in a lamentably backward state, even in particulars where those who are our leaders in sanitation would least expect it. It can hardly be supposed, however, that all the exhibits shown have been admitted with the sanction of the Council as illustrations of the subjects discussed at the Institute. There are, for example, mus c stands, clocks, sausage mincers, billiard registers, weighing machines, mechanical toys, flower scissors, electric pens, nickel-plated goods, pantographs, bells, telephones, china cements, "lightning" knife sharpeners, &c. Some of the exhibits are made on principles that have been repeatedly denounced; for example, filters so closed that the filtering medium cannot be easily and frequently changed are now by our most experienced observers admitted to be unsafe, yet there are some in the exhibition. Traps of certain construction have been likewise denounced, yet they are shown. Ventilators of patterns generally regarded as practically useless, and so-called disinfectants which are only deodorisers, are shown. It might, perhaps, have been well had the exhibition been called one of "Sanitary and unsanitary appliances," and then the visitor would have been put on his guard not to believe in everything shown there. Mr. F. P. W. Essie, C.E., has contributed part of a collection of the materials on which his paper on the dangers of bad plumbing (read at the Congress) was based. It is intended as an unsanitary exhibition, and shows in an alarming manner how some so-called sanitary appliances may become a positive source of danger. Each specimen exhibited "has been associated with death and with disaster in some shape or other." It is a pity no handbook or any kind of guide other than the unclassified list of entries in the catalogue has been prepared. We may be able to return to the subject next week when noticing the list of awards.

AN article in the last number of the *Revue Scientifique* contains an interesting account of Mont Ventoux (1,928 metres high), and of the scheme for erecting a meteorological observatory thereon. The project, which has been prepared by M. Morard, under the direction of M. Bouvier, includes, first, the construction of a carriage road, which will render the summit accessible at all times. The total length will be 19 kilometres.

The observatory will be placed at the very summit of the mountain, on a platform of rock. It will consist of a small round tower, constructed to resist the most violent winds. Every means will be taken to establish an equilibrium of temperature between the inside of the tower and the outer air. The dwelling-house will be built a little lower, on the south slope, and thus sheltered from the mistral which is extremely violent on the summit of the mountain, and indeed has given to the mountain its name of *Ventoux*. A covered gallery of 11 metres will connect the house with the tower, access to which will thus be easy, even in the midst of snow and storms. At the instance of Admiral Mouchez rooms will be reserved in this house for scientific men, who may come in summer to carry on researches in astronomical physics, for which the limpidity of a Provençal sky is so favourable. The difficulties of execution would not appear to be very great, and, in comparing the situation of the future observatory with that of the Pic du Midi, General Nansouty has gone so far as to compare the summit of Ventoux to a sort of earthly paradise. The necessary expenses are calculated at 150,000 francs, and to this all the chief towns of the South-East have already contributed handsomely, their municipal councils having the intelligence to perceive the great practical benefit to be derived from such an observatory.

THE project of erecting a meteorological observatory on the top of the Ballon de Gervance, in the department of Haute-Saone, is progressing favourably. A fortress is being built on this elevated site, and will be finished next year. The garrison will very probably have the care of meteorological observations. A telegraphic line has been already established between the intended station and Belfort.

M. BISCHOFSHEIM is leaving for Nice with M. Garnier, the architect of the opera, and M. Lœwy, the sub-director of the Paris Observatory, in order to inspect the site on which he intends to erect the new observatory, on which he is to spend a sum of 60,000*l*., as we mentioned in our notes some months ago. Before determining on the details of his plan, M. Bischofsheim and his scientific and artistic advisers are to visit the most celebrated observatories of Austria, Germany, and England during this winter.

KING HUMBERT, of Italy has sent a donation of 20*l*. to a committee organised to obtain subscriptions for erecting a statue to Galvani at Bologna. Galvani was born in that city in 1717, where he was a professor in the University; he died in 1798.

THE *Journal Officiel* publishes a decree organising, at the Observatory of Paris, the School of Astronomy of which we announced, a few months ago, the imminent creation. The pupils are to be appointed by the Minister of Public Instruction rom pupils of the Normal or Polytechnic Schools, or graduates in the mathematical sciences. They must be more than twenty-five years of age. They are to receive 6*l*. a month during two years, and reside in the observatory. They will be obliged to follow courses of lectures at the Sorbonne and Collége de France. The Astronomers of the Observatory will give them special instruction. After having passed their examination, they will be appointed *aides-astronomes* in any of the Government observatories, with a salary of 10*l*. monthly. During their stay at the observatory they will practise calculations, meridian, and physical astronomical observations. *Elèves libres* will be admitted under a certificate of efficiency.

MR. C. L. WRAGGE, F.R.G.S., of Cheadle, has presented to the town of Stafford an excellent collection of specimens obtained by him in his travels in various parts of the world, and which will, no doubt, prove of great value to all those interested in geology and natural history.

IN the Cassel State Library, as well as in the Archives at Hanover, Dr. Gerland has succeeded in discovering a whole series of important original letters, hitherto not known, from the pen of Leibnitz, the philosopher, and of Papin, one of the inventors of practical applications of the power of steam.

RUSSIAN papers publish the project of the Exhibition of Manufactures and Fine Arts, which will be opened in 1881 at Moscow. We learn that the Moscow Anthropological Society and the University propose to take an active part in it, and to give to the exhibition a scientific value.

WE learn that in the month of January, 1880, an artistic and scientific exhibition will be opened in Algiers. It will be the first which has been ever held in the colony.

THE Society of Anthropology of Paris has received, at its last meeting, a letter from Felyx-Denys-Rapontayabo, a native King, in the Gaboon, who, having been educated in the Catholic mission, is a tolerably good French scholar. His Negro Majesty is sending to the Anthropological Society the skeleton of a gorilla, and volunteers to send any scientific documents which may be required.

IN his last report from Saigon, Mr. Consul Tremlett alludes to his having been ordered by the Foreign Office to procure and send home a quantity of the bark known as *hwang-nao*, which during the past four or five years has been exported from Tongking to Trinidad, and there seems to have proved efficacious in cases of leprosy. The tree from which it is obtained is hardly known except to the missionaries, and is only found in the mountain forests of the north of Annam.

A VIOLENT shock of earthquake is reported to have occurred in West Cumberland at 5.30 A.M. on Saturday week. A vivid flash of lightning was seen at the same time. The shocks of earthquake in the southern districts of Hungary, some lasting from forty to fifty seconds, continue in a north-easterly direction, and keep the population in a state of alarm. A shock of earthquake in the direction from south-west to north-east, was felt at Ekaterinodar, Caucasus, on October 9, at 8h. 55m. P.M.

THE Municipal Council of Paris has decided that artificial cold should be applied to the mortuary, in order to keep corpses in a state fit for public inspection and possible recognition for a longer period. In compliance with that decision a Commission, presided over by M. Vauthier, an engineer of the Ponts-et-Chaussées, who resided long in England, has been appointed to report upon the several ice-manufacturing machines. The work of the Commissioner is by no means an easy one. The pneumatic process is not, so far as we are informed, to be brought into the competition. The ammoniac, the chloride of methyl, and the sulphurous acid processes are then to be brought under consideration. The two last methods are now exhibiting at the Champs Elysées Palace, and the ammoniac process is used in the largest Parisian ice-house, the "Glacière du Bois de Boulogne."

A RETURN by the Director of Administrative Statistics at Vienna (based on the latest census of the great European states) shows that out of 102,831 persons who lived over ninety years, 42,528 were men and 60,303 women. The longevity of women is yet more apparent when we consider the numbers of human beings who attain and live beyond 100 years. In Austria, there were 229 women centenarians to 183 male ditto; in Italy, 241 female to 141 male; in Hungary, 526 female to 524 male, &c.

IN a recent Consular Report on the trade and commerce of Benguzi the sponge fishery is described as being entirely in the hands of Greeks belonging to Kalimnos, Hydra, and other islands, who annually frequent the coast of the Gulf of Sidra during the months of August and September. This branch of industry affords employment to upwards of 200 small vessels. A diving apparatus is used in fishing for sponges; the produce during the season is between 25,000 and 35,000 sponges. A duty of 40*l.* is levied by Government on each diving apparatus and 10*l.* on every vessel not carrying that appliance. The produce of the sponge fishery last year was estimated to be worth about 15,000*l.*, and was exported chiefly to England.

MESSRS. FRANCIS AND CO., of Hatton Garden, have recently devised an extremely useful telegraphic arrangement for ships, by which instant communication is given by the captain or officer of the watch to the helmsman. For the navigation of rivers and small waters such means of rapid telegraphing with the man at the helm must be invaluable, as in an instant an order can be given, and that, too, with absolute certainty. A leading and important feature in this new invention is that the signals to every part of the ship can be given from the one instrument, which is in form like a handsome capstan, with the commutators so arranged horizontally around its head that it may be worked by any one without the least instruction.

A COURSE of elementary lectures in continuation of a description of the solar system will be delivered in the theatre of Gresham College, Basinghall Street, London, E.C., on the evenings of November 11, 12, 13, and 14, by the Rev. E. Ledger, M.A., F.R.A.S., Gresham Professor of Astronomy. The lectures will be delivered at 6 o'clock P.M., and will be free to the public. They will be illustrated by means of a lime light.

As we have announced, the three Parisian telephonic companies have entered into a working arrangement, and are busy settling the details. In consequence of this fusion the subscriptions have ceased to be received, the future common price having not yet been agreed upon. It is certain that it will be dearer than the cheapest, and cheaper than the dearest. According to every probability 600 francs a year for a single line.

THE gold discoveries in the north of New Caledonia are reported to be turning out very valuable.

FROM Japan we hear that the manufacture of sulphuric acid is now being extensively carried on at the Osaka Mint, and large quantities are exported to China.

THREE boa-constrictors, found in the Chinese island of Hainan, have lately been presented to the Botanical Gardens at Hong Kong.

WE learn from a report on the trade and navigation of New York for 1878 that grape-sugar is being largely manufactured at Buffalo, three large factories have been established for the manufacture of glucose in a solid and liquid form, 200,000 to 300,000 bushels of corn being used in them per month. This product has a ready sale and is largely exported to Europe and other countries, and the business is said to be a very profitable one.

THE principal papers in the Thirteenth Annual Report of the Aëronautical Society are on the Flight of Birds, by Mr. Brearey and Mr. H. Sutton.

THE report of the meeting of October 17 of the Eastbourne Natural History Society contains a paper "On the Additions to the Fauna and Flora of the Cockmere District during the past year," by Mr. F. C. S. Roper.

THE additions to the Zoological Society's Gardens during the past week include a Weeper Capuchin (*Cebus capucinus*) from South America, presented by Mr. A. Sargent; a Silver Pheasant (*Euplocamus nycthemerus*) from China, presented by Mr. R. Moon; three Common Boas (*Boa constrictor*) from Bahia, presented by Mr. W. Young; a Bosman's Potto (*Perodicticus potto*) from West Africa, four Pied Wagtails (*Motacilla yarrellii*), British, purchased.

OUR ASTRONOMICAL COLUMN

MINOR PLANETS IN 1880.—In the first half of the ensuing year three out of the four older minor planets, viz, *Ceres, Pallas,* and *Vesta* will come into opposition while not far from perihelion, and consequently their angular diameters and brightness will be about as great as they ever can be, thus :—

Pallas in opposition on	Jan. 12	will be in perihelion on	Feb. 23.
Ceres ,, ,,	Feb. 12	,, ,,	Feb. 18.
Vesta ,, ,,	June 2	,, ,,	June 19.

At opposition the brightness of *Pallas* will be 6·8m., that of *Ceres* 7·3m., and that of *Vesta* 6·0m.

Perhaps advantage may be taken of the favourable conditions attaching to the positions of these planets to ascertain if they do really present measurable disks as has been stated by Lamont in the case of *Pallas*, and by Secchi in that of *Vesta*. Lamont, soon after the mounting of the 11-inch refractor at Munich, on a night of exceptional clearness, found that *Pallas* presented a defined disk, which at the mean distance of the planet from the sun would subtend an angle of 0″·51, which would correspond to 1″·41 at the distance unity. Again, Secchi observing on nights near the opposition of *Vesta* in 1855, noted a disk a little less than is presented by Jupiter's first satellite, or about 0″·8, which at the earth's mean distance from the sun would subtend 1″·01. There is a third instance in the case of one of the more-recently discovered planets, *Iris*, which at the close opposition in the winter of 1866, was measured by Mr. Talmage with Mr. J. G. Barclay's 10-inch refractor at Leyton; he found the apparent diameter 0″·96, or the diameter at distance unity 0″·89. Hence we should have for the real diameters 630 miles for *Pallas*, 450 miles for *Vesta*, and 400 miles for *Iris*, dimensions beyond those which have been attributed to them on other grounds. The south declinations of *Pallas* and *Vesta* will render them fitting objects for examination at Melbourne should Mr. Ellery be disposed to try the powers of his great reflector upon them. *Ceres* will be well observable in this hemisphere.

While writing upon minor planets it may be mentioned that their number has now been increased to 207; a circular from Prof. Peters, of Kiel, notifying the discovery of four new ones at Clinton (New York) and at Pola, by Prof. C. H. F. Peters and Herr Palisa.

THE RED SPOT UPON JUPITER.—Dr. O. Lohse, of the Physical Observatory at Potsdam, who has watched this planet regularly during the last nine years, mentions that on June 5, when his observations of the present year commenced, the red spot was of an intensity of colour to be perceived at the first glance at 15h. m.t., when it was near the eastern limb. The sharp outline and the form of the spot appearing to offer an advantageous opportunity for another determination of the time of rotation, numerous estimations and some measures of its position and size have been made at Potsdam. Dr. Lohse does not refer to any suspicion of proper motion, of which we have heard elsewhere, but, on the contrary, states that, with the rotation-period, 9·9221h., added on to the epoch 1879, September 27, at 9h. 48·3m., Berlin M.T. (or 8h. 54·7m. G.M.T.), the successive times of transit of the middle of the spot over the central meridian may be obtained. From sensible variation in the intensity and tint near the centre and limbs of the planet he conjectures the superposition of very dense gas or vapour. As the spot exhibits remarkable permanence, it may be also observable next year, and thus be the means of fixing the period of rotation with precision. Dr. Lohse further notes that this remarkable appearance upon the disk of Jupiter takes place at the time of recommencement of activity in the solar atmosphere.

A STANDARD CLOCK AT THE OBSERVATORY, STRASSBURG.—Those who give attention to horological matters will note with interest a communication from Prof. Winnecke, Director of the Imperial Observatory at Strassburg, on the performance of a clock constructed for that establishment by Hohwü, of Amsterdam. The observed rates between 1875 and 1878 are exhibited in tabular form, and are compared with rates calculated from a formula which Dr. Schur has investigated, viz. :—

$$\text{Daily rate} = \overset{\text{s.}}{0\cdot000} + \overset{\text{s.}}{0\cdot0125}\,(b - 750) - \overset{\text{s.}}{0\cdot0110}\,(t - 20),$$

where b is the height of the barometer in millimetres and t the temperature in the clock-case expressed in degrees of Celsius. The tabular statement (*Ast. Nach.*, No. 2,282) is much too long to be reproduced here, but we make the following extract showing the observed and computed rates applying to the two-months' interval, May 3–July 3, 1877; in the first column are the daily rates given by the observations, and in the second those resulting from the above formula:—

	s.	s.
May 3–11	– 0·07	– 0·02
11–25	0·00	+ 0·01
25–31	– 0·04	– 0·04
May 31–June 8	+ 0·03	+ 0·06
June 8–15	– 0·04	+ 0·01
15–19	+ 0·20	+ 0·23
19–22	– 0·15	– 0·09
22–26	+ 0·10	+ 0·11
26–29	+ 0·09	+ 0·05
June 29–July 3	– 0·05	– 0·04

Dr. Winnecke remarks that upon the experience in the interval 1875–78 he believes the performance of the clock has not been hitherto excelled, and congratulates himself upon the possession of a work of art.

PHYSICAL NOTES

WHO did discover the attraction caused by the vibrations of sounding bodies? Prof. Guthrie and Herr Schellbach of Berlin, discovered it independently of each other nearly ten years ago. But Guyot had observed the phenomenon before them; and in a paper in the *Philosophical Magazine* for 1849, by Mr. Reuben Phillips, on the "Electricity of Steam," the attraction caused by vibration is recorded as a new fact.

THE transverse vibrations of metallic cylinders open at one end have been recently studied by Herr Fenkner, at Marburg (*Wied. Ann.*, No. 9). The following results were arrived at: The vibration-numbers of the tones of such cylinders are independent of the height of the cylinder. The vibration-numbers of the corresponding tones of two such cylinders are inversely as the squares of the circumferences (or radii), and they are directly as the thicknesses of metal.

PROF. TÖPLER, of Dresden, is well known to physicists by his researches on singing flames and by the induction electric machine which bears his name. Töpler's machine, of which several examples were shown in the Loan Collection at South Kensington in 1876, resembles in form the more familiar machine of Holtz, and is based upon similar principles. Prof. Töpler is at present engaged upon the construction of a larger machine having twenty rotating plates; and which is capable of generating much larger quantities of electricity. This machine bears a close resemblance to the variety of Holtz machine shown before the Physical Society a few months ago by Mr. W. J. Wilson, and to that recently constructed by Mr. Ladd, which also had a number of plates rotating on a common axis.

APPARATUS for projection, like the magic-lantern, always gives inverted images. Most commonly this causes no inconvenience, for one can invert the object; but there are cases in which this cannot be done, and the only resource is to rectify the image. To obtain this result, M. Duboscq (*Journal de Physique*, October) has recently conceived the idea of receiving the rays which would go to form the inverted image on a prism with total reflection. Suppose an isosceles rectangular prism, placed with hypothenuse parallel to the optic axis of the lens by which the rays from the object are made convergent, and so as to receive the cone of rays on one side; refracted in the prism, the rays reach the hypothenuse at an angle greater than the limiting angle, are totally reflected, and sent to the second side of the prism, where they are refracted at the same angle as on entrance, and then go to the screen, forming an image which corresponds in position to the object. As it may be desired to rectify the image in some other plane than the vertical, it is found advantageous to mount the prism in a tube forming part of the projection-apparatus, and capable of being turned round the direction of the ray.

IN a recent memoir on the plasticity of solid substances (*Rev. Scient.* xi. 1879), Signor Marangoni, with reference to Bottomley's experiment dividing ice with a wire, groups plastic substances in two classes. Those of the first class can be cut in two with a metallic wire like ice, and they can also be considerably deformed. Such are plastic clay, fresh soap, camphor, black pitch. Substances of the second group give two lamellæ on the two sides of the cutting wire, which then come out of the slit, become notched and bend over, resembling leaves; to this class belong vegetable Japanese wax, dry Marseilles soap, tallow and stearine, but above all, yellow wax and paraffin. [The occurrence of these phenomena depends largely on the diameter of the wire and on the temperature. For yellow wax, wires of ¼ to 1 mm. diameter, for paraffin ½ to 0·9 mm. are necessary. With the former, the leaves are formed between – 8° and 40°, with paraffin (melting at 43·5°) only up to 15°. To produce the lamellæ, different weights should be hung to the wire in different cases. The lamellæ are very similar to those separated from rails when a locomotive with strong brake applied, goes quickly down a steep incline.

THE forms produced in the phonograph by utterance of the Italian alphabet are studied in a recent paper by Signor Fautrier (*Atti del Aten. Ven.* [3], I., 1879). The vowels uttered in the A note of the violin (435 vibrations) gave generally three-pointed groups, presenting certain differences. With regard to the consonants, it appeared that with the exception of *l*, *m*, *n*, and *r*, which give characteristic impressions, they only modify the form of the impression of the following vowel, and especially at its limits. Signor Fautrier adds some general considerations, especially on the intensity of the "klangs" given by the phonograph, and the theoretical significance of the apparatus.

M. GASTON PLANTÉ, whose researches on voltaic electricity, especially on the construction of secondary batteries and on the phenomena of their discharge have been from time to time laid before the readers of NATURE, has just published the first instalment towards a second volume. The forty pages or so of this *brochure* treat of the effects obtained with M. Planté's rheostatic machine.

DR. KÖNIG, the well-known constructor of acoustical apparatus has just completed a new instrument which promises to be of great interest and importance. Dr. König has long maintained, in opposition to the theory of Helmholtz, that the "combinational" or "difference" tones produced by the simultaneous sounding of two simple tones of different pitch are the result of very rapid "beats." The new instrument, which has not yet been seen outside M. König's *atélier*, is a kind of modified syren which puts the question at issue to a direct and crucial test.

WE learn that Prof. Silvanus Thompson is engaged upon a monograph upon the subject of Binaural Audition, which will embrace the whole existing literature of the subject. The work will not be published before next spring.

THE magnets employed in Gower's form of the Bell telephone are of unusual strength. It is stated that the steel of which these magnets are constructed is made from the iron of Alvarre, which, though a particularly bad iron for most purposes, makes a steel unsurpassed for magnetic apparatus.

THE phenomena which occur when the retina is struck by intermittent coloured light (alternating with total darkness) have been recently studied by Signor Cintolesi (*Ann. di Oftalmol.*, II. and III., 1879). With a certain velocity of intermissions the field of vision appeared at first still and regular in the colour of the active light. The state is gradually changed, and, *e.g.*, red passes by orange, yellow, and green, into a saturated blue-green, after which there is a return by the same colours to red, and so on in periodic change. This phenomenon of a periodic change with the complementary colour the author also describes in the cases of green and blue. The velocity of intermissions must reach 0·11 sec. for red, 0·14 for green, and 0·15 for blue light. In his theoretical views Signor Cintolesi has recourse partly to the Young-Helmholtz hypothesis, partly to Plateau's oscillation theory, and partly also to the photo-chemical properties of the retina.

IT has been noted recently by M. Jannetaz that, if a fine needle be turned round on a cleavage plate of gypsum (1 mm. to 2 mm. thick) so as to produce a small hole, and then be gently pressed into the plate, a separation occurs, surrounded by Newton's colour-rings, and having the form of an ellipse. The major axis of this ellipse makes an angle of 49° with the fibrous fracture, and its length is to that of the minor axis as 1·247 to 1. This ellipse has the same orientation and relative size as that of the propagation of heat in gypsum. Further, the larger axis corresponds with the direction of greatest resistance to bending, and the greatest elasticity.

EDISON'S new electromotor, with which he proposes to drive sewing-machines, watchmakers' lathes, and other light machinery, has an armature resembling that of a Siemens dynamo-electric generator, but placed longitudinally between the limbs of a horse-shoe-shaped electro-magnet. A similar disposition was previously employed by M. Marcel Deprez in the excellent little electromotors shown by him before the French Physical Society last year.

In the latest pattern of telephone transmitter sent by Mr. Edison to this country, the button of compressed carbon derived from paraffin-smoke has been abandoned in favour of another device. A small rod of ordinary hard carbon, of the quality used in producing the electric light, is mounted behind a mica disk and adjusted in loose contact with a light spring faced with platinum. This arrangement is therefore nothing more or less than a *microphone* attached to the back of a disk which receives the vibrations of the voice.

At a late meeting of the Académie des Sciences, M. Wardon made a suggestion to substitute nickel for steel as a material for compass needles. M. Wardon adopts a circlet of the metal of a form similar to that devised by M. Duchemin. When the apparatus was submitted under the direction of the Ministère de la Marine to a comparative trial with that of M. Duchemin, it was found to be decidedly inferior for nautical purposes; for the oscillations of the magnetised circlet are extremely slow, owing to the comparatively feeble intensity of magnetisation of nickel.

GEOGRAPHICAL NOTES

At the last meeting, October 15, of the Russian Geographical Society, the Secretary, M. Sreznevsky, read a detailed report on the geographical work done during the past summer. After having spoken of the gallant geographical feat of Prof. Nordenskjöld, he sketched the results of the expeditions of Col. Prshevalsky, MM. Potanin, Alferaki, and Pyevtsoff, and of the expedition engaged in exploring for the Central Asian Railway. As to ethnography and statistics, the secretary mentions the researches by M. Kuznetsoff in Western Russia, by M. Syrkou in Bulgaria, the anthropological researches of M. Meredlenovsky in the Crimea, M. Polyakoff in the Ural Mountains and Caucasus, M. Kibalchich on the banks of the Dnieper, and M. Miclucho-Maclay in Australia. As to this last, the Society engaged him to return to Europe, for the publication of the very rich results of his explorations, but he prefered to take part in a zoological exploration undertaken by Australian naturalists. The pecuniary position of M. Maclay is a very critical one. After having undertaken his extensive travels without sufficient means, he has received from the Society about 7,000 roubles, which sum was certainly quite insufficient to meet the great expenses necessitated by these travels. Now he has contracted debts for about 15,000 roubles at the Singapore bankers, and the Society seeks private subscriptions, the means for paying these debts, in which it is supported by the opinion of the whole of the Russian press. Finally Prof. R. Lentz made a communication on the labours of the International Conference in the Meteorology of the Polar regions. The Geographical Society will take an active part in the organization of the meteorological stations in these regions.

The *Moscowskiya Vyedomosti* has received the following information as to the Amu-darya expedition, dated Katty-kourgan, October 19. At Termez the expedition was divided into two parts: one has gone in boats down the Amu to Fort Petro-Alexandrovsk, the other through Surkhan and Rafiuaghan rivers to the Vaksh river. The results of the expedition are important: it has explored the Amu-Darya throughout its length, and its two branches, the Vaksh and the Pyandj rivers, for fifty miles above their junction. The topographers have prepared maps of these parts of the two rivers, and completed the maps of the Amu by several details; several latitudes and longitudes are determined astronomically, and zoological collections obtained. A levelling of the Amu is made up to Chardjuy. We notice the appearance of a Russian work by M. Lokhtin, "The Amu-Darya River and its former Connection with the Caspian." It contains a description of the river, a sketch of the historical data as to the Amu, and a review of the hypotheses as to the causes of the changes of its bed; it is accompanied by a map. The third, fourth, and fifth volumes of the "Report of the Amu-Darya Expedition," contain reports by M. Zuboff on hydrographical works in the lower parts of the Amu-Daria; by M. Dorandt, on the astronomical, magnetical, and hydrometrical measurements; and by Prof. Schmidt, on the slime of the Amu River.

The death, from paralysis, in India, is announced, of Major Herbert Wood, author of a well-known work on the Aralo-Caspian Region, on the hydrography of which he contributed several papers to this journal.

The last number of the *Isvestia* of the Russian Geographical Society, contains the proceedings of a meeting of the Society in October, 1878, and several interesting papers:—By M. Prshevalsky, on the observations of Dr. Richthofen; by K. Scharnhorst, on the barometric measurements of heights in Central Asia; by M. Mayeff, on the upper parts of the Amu-Darya, according to the description of Ibn-Dast; and by M. Miclucho-Maclay, on the Agomes Islands. The notes contain information as to the travels of MM. Prshevalsky, Nordenskjöld, and Grigorieff. In the note by Colonel Scharnhorst, on the barometrical measurements of heights made by M. Prshevalsky during his journey to Lake Lob-Nor, the measurements being calculated by comparison with barometrical observations at Nukus and at Omsk, the heights of which above the sea-level are exactly known from geodetical measurements, they are trustworthy, and the error does not exceed 100 feet. The height of Tashkend, calculated by comparison of six years' barometrical observations with those made at Omsk, Kazalinsk, Nukus, Petro-alexandrovsk, Baku, and Astrakhan, is 1,516 feet. The other places of general interest are: Kuldja, 2,080 feet; the passes across the Narat and Yuldus Mountains, 10,370 feet and 10,040 feet; the junction of Khabtragay and Baltangay Rivers, 5,320 feet; the town of Kurl, 3,240 feet; Lake Lob-Nor, 2,500 feet; Lake Sayram, 6,920 feet; and Guchen, town, 2,310 feet.

We are glad to notice the appearance of an "Annuaire for Turkestan" (*Turkestanskiy Kalendar*) for 1880, which contains much useful information as to the mineral riches of the country, its meteorology, financial situation, and statistics, besides a route-map and a map of the general-governorship of Turkestan. We learn from this Annuaire that Turkestan possessed in 1877 only thirty-five schools, with 1,848 scholars.

The November number of the Geographical Society's periodical contains three short papers: Notes on the Topography of the Sierra Nevada of Santa Marta, U.S. of Columbia, by Mr. F. A. A. Simons; Exploration of Oregon in 1878 by the Wheeler Survey; and Pévtsof's Expedition in North-West Mongolia, by Mr. E. D. Morgan. The first-named is illustrated by a map, which is not particularly well lithographed. The geographical notes, however, are the chief feature of the number. The Dutch Arctic Expedition claims the place of honour, and two pages are devoted to Dr. Holub's career. There is also a long account of the native territories south of the Zambesi, abridged from a report to Sir Theophilus Shepstone, which embodies information hitherto unattainable, and the more valuable as it has been revised by Dr. Holub. The exploration of the Swat River by the *Mullah* is recorded. The concluding thirteen pages are taken up with notes on new books and new maps, the map part bearing a close resemblance to a catalogue.

Mr. Stanford has published a new Library Map of the World, on Mercator's projection. The size is 5 feet by 3 feet, and has several new and admirable features. The currents in the ocean are shown by strong blue waved lines. The areas occupied by these currents, which are chiefly caused by the great periodical winds, have an oscillating boundary or limit, as waved lines are better calculated to indicate this, than the firm and sharply defined lines frequently used. A few of the lines in each current have arrow heads to indicate the direction. Figures in blue upon these waved lines, give the maximum and minimum rates in nautical miles per twenty-four hours. These are selected, we believe, from innumerable observations that have been registered and examined by Captains Evans and Hull of the Hydrographic Department, and published in their invaluable "Wind and Current Charts." The drift currents in the Indian Ocean and China Sea change with the Monsoon winds, and in the chart they are shown as they flow during the south-west monsoon, which blows from April to September. The trade and monsoon winds are named over the map in red letters, and the areas over which they generally blow are tinted in colours. The areas over which north-east winds blow are coloured blue, the areas for south-east winds pink; other areas are differently coloured in accordance with the particular direction of the winds which blow over them. A graduated scale at either side of the chart shows the sun's progress to and fro between the tropics; to the left of the chart the sun's vertical action may be traced as he proceeds northward to the Tropic of Cancer, and to the right, his return journey southward to the Tropic of Capricorn. Dates are given at intervals of five days, the intervening days being indicated by small red dots. In spare spaces to the north of the chart, small inset maps have been drawn to give the completion of the geography in the Polar areas, and upon these will be found, indicated by colour, the average summer limit of open water as far as known. The curves of equal magnetic variation are also shown upon these small maps, and the spots known as the magnetic poles are named. The northern limit of woods, beyond which trees are unknown, is shown upon the small map of the Arctic regions. The principal ocean mail routes are shown by broken black lines, and upon the longer lines the names of ports of departure and arrival are named. The number of days, the average of numerous voyages is noted on each line, and the distances in nautical miles from port to port are also given. The submarine telegraph cables are shown by strong black lines with dots at short intervals, and the various cables to the United States are identified by having their dates attached. The land is coloured politically giving the most recent territorial divisions, and a bright red colour is reserved for British possessions, which enables the reader to see easily how frequent are the stepping stones of British territory over the face of the earth. Altogether it will be seen this map is well calculated to serve a great variety of useful purposes; its execution is all that could be desired.

DR. NACHTIGAL has received a telegram from Malta to the effect that Herr Gerard Rohlfs's expedition, having reached and explored the Kufara Oasis, was there set upon and plundered. Herr Rohlfs and Dr. Anton Stecker were consequently compelled to return to Benghazi, though they hoped to receive help and compensation from the Turkish Provincial Government.

TRÜBNER AND CO. will shortly publish a new work on Madagascar, under the title of "The Great African Island: Chapters on Madagascar," by the Rev. James Sibree, jun. The work will contain a popular account of recent researches in the physical geography, geology, and exploration of the country, and its natural history and botany; and in the origin and divisions, customs and language, superstitions, folk-lore, and religious beliefs and practices of the different tribes. It will contain physical and ethnographical maps.

GEOLOGISTS will be glad to learn the appearance of a trustworthy map of mines in Russia in Europe by Prof. W. Möller, "Carte des Gites miniers de la Russie d'Europe."

WE notice in the last number of the *Bulletin* of the Belgian Geographical Society a paper on the colour of eyes and hair in Belgium, by M. Vanderkindere, with maps: on the Zambeze, by M. Wauters; and the quarterly report on the demographical and medical statistics.

THE Church Missionary Society a short time back entertained the idea of establishing a sanatorium on the west coast of Africa, and the matter, it may be remembered, caused some discussion between their adviser, Capt. R. F. Burton, and the Rev. T. J. Comber, a Baptist missionary, at one of the Geographical Society's meetings last session. It was proposed to place the sanatorium on Mount Cameroons, which rises to a height of over 13,000 feet, just in the angle of the Gulf of Guinea, opposite Fernando Po. Two agents of the Society accordingly proceeded thither in the missionary steamer *Henry Venn*, and ascended the mountain to the highest peak. Their report was favourable to the suitability of a spot some 7,500 feet high, known as Mann's Spring, but to build a residence there and cut a road to it would, it appears, cost more than the Society can afford in order to recruit the health of their missionaries.

UNDER the heading of ethnography, a paper by Père Petitot, on the Asiatic origin of the Indians of Arctic America is commenced in the current number of *Les Missions catholiques*.

THE great work undertaken by the Russian Geographical Society under the title of "Works of the Ethnographical and Statistical Expedition to South-Western Russia" is now completed. The whole work consists of seven volumes, in nine fascicules, or nearly 4,800 pages, and it contains abundant most useful information as to those countries which afford so great an interest by the variety of their population.

WE notice the appearance of the following important works recently published by the Russian Geographical Society:—(1) The eighth volume of its *Memoirs* (*Zapioki*), which contains a "General Sketch of a Theory of Constant Marine Currents," by Colonel Schilling, and a "Note on the New Map of Persia," by General Stebnitzky, with the map itself, which is one of the most important acquisitions to the exact cartography of Asia during recent years.—(2) The fourth volume of the translation of Ritter's "Asia," being the description of the Altay and Sayan Mountains within the limits of the Russian Empire, with a very important appendix (far larger than the original work itself), by MM. Potanin and Semenoff, being a *résumé* of all new information acquired from 1832 to 1875.—(3) "The Kashgar Land" (*Kashgaria*), an historical and geographical sketch, of the country, of its military forces, industry, and trade, by M. Kuropatkin, with additions of General Stubendorff and M. Sreznevsky.—(4) "A Journey to the Holy Land of the Prince Radzivil-Sirotka during the Years 1582 to 1584," published and annotated by M. Hildebrandt; and (5) The two first volumes of a "Catalogue of the Library of the Geographical Society," containing books on mathematical, physical, and general geography. The importance of this catalogue will be realised by all those who know what a number of works appear in Russian on the geography of Russia and Asia, and how difficult it is to know them. We notice with pleasure that the catalogue contains detailed indexes of all papers that have appeared in the publications of the Geographical Society. An important work, being the description of M. Potanin's journey to north-western Mongolia is already in the press.

CELESTIAL PHOTOMETRY

THE volume of the annals of the Harvard Observatory just issued is one of great importance to astronomical science, as the new director, Prof. Pickering, has included in it the photometric observations which have lately been carried on with so much vigour. The first chapter is devoted to a description of the forms of instruments—many of them new—which have been employed, and in this notice we shall limit ourselves to an analysis of this part of the volume.

The first instrument employed was constructed by attaching a Nicol to a double-image prism in such a way that it could turn freely around its axis. By a graduated circle and index, the angle could be measured to tenths of a degree. When two bright objects were viewed through this instrument, two images of each were formed by the double-image prism, either of which, by turning the Nicol, could be made as faint as was desirable. Whatever their relative light, the faint image of the brightest could thus always be reduced to equality with the bright image of the faint object. The true relative brightness is then deduced from the angle through which the Nicol is turned.

This form of photometer may be used without a telescope in the comparison of bright stars which are sufficiently near each other, but the loss of light is large. By Fresnel's formula for the reflection of light, each of the four surfaces of the prisms will reflect four per cent. The amount they would transmit, were there no other losses, would therefore be $(\cdot 96)^4 = \cdot 849$. This supposes that the faces of the Nicol are perpendicular to its axis. If made of the usual form, the loss would be still greater. The unavoidable defects of the surface, dust, absorption, and the reflection at the surface of the balsam cementing the prism, reduce still further the transmitted light. About ·80 will remain under favourable circumstances. Since the prism forms two equal images, only one half or ·40 can pass into each, and when the two images are reduced to equality, their brightness will be only ·20 or ·40 of that of the fainter object. For any but the brightest of the heavenly bodies, it is accordingly necessary to increase the light by means of a telescope.

The following general remarks occur on this form of instrument.

"Since the relative positions of the Nicol and double-image prism are unimportant, either might be placed in front of the object-glass, between the object-glass and the field-lens, between the field-lens and eye-lens, or between the eye-lens and the eye. Unless the double-image prism is placed in front of the object-glass, two images of the latter will, in general, be formed, giving two emergent pencils, both of which must pass without loss into the eye. There is danger that on moving the eye one or other of these pencils will be partially cut off, thus reducing the brightness of one of the objects. If the two images to be compared are brought very near together, this is less likely to occur. On the other hand, at least one of the images of a double-image prism is not achromatic; and, if the prism is placed in front of the object-glass, the colour becomes very marked. In this case, also, it becomes difficult to obtain a prism having such flat surfaces that the images will not be distorted, since any irregularities are magnified by the full power of the telescope. If the two images are separated by a distance d, any two stars at about this interval may be brought together, so that any star may be compared with all those on the circumference of a circle having a radius d. With a large prism in which d equalled about $3°$, an attempt was made to compare β and ρ *Persei* and β and γ *Lyræ* by placing the prism in front of the objective of a telescope having an aperture of about 10 cms. A direct measure of the variations in brightness of the above-named variable stars might thus be obtained. This plan was abandoned, owing to the colour of the images.

"There is one other position of the prism, that where the eye-piece forms its image of the objective, in which the emergent pencil will remain undivided. This is, however, the exact point at which the eye should be placed; and, moreover, the

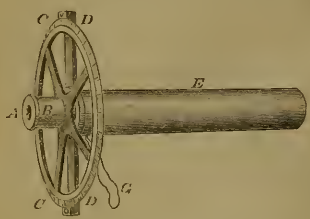


FIG. 1.

interval between the images cannot, in this case, be altered. Good results were obtained by placing the prism a little nearer the eye-piece, as in the first of the instruments described below. The advantage of placing the prism between the eye-lens and field-lens is that it is less likely to reduce the field of view. As this plan is open to the double objection of dividing the emergent pencil and keeping the images always at the same distance apart, it has not been employed in the following observations.

"The fourth position for the prism is between the field-lens and objective. It then separates the emergent pencils by an amount increasing with its distance from the objective, but, on the other hand, the interval between the images is proportional to its distance from the focus. Whatever, therefore, is the interval between the two stars, within certain limits, their images may always be made to coincide by first turning the prism and

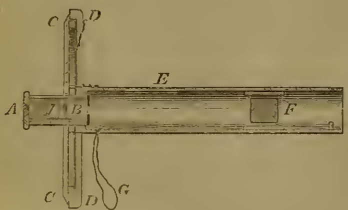

FIG. 2.

then sliding it along the axis of the telescope to the proper distance from the focus. A prism may therefore be used, in which the separation is small, and thus the two images of the objective may be rendered nearly coincident.

"The position of Nicol is comparatively unimportant. Since it must turn without moving the double-image prism, it is more convenient to place it between the latter and the eye. It was, accordingly, sometimes placed between the eye-lens and the eye, and sometimes between the field-lens and eye-lens."

We now come to the instruments.

The first observations were made with an eye-piece having a Nicol between its two lenses and with the double-image prism between this eye-lens and the eye. The observations made with this apparatus are regarded as preliminary; a second photometer was constructed, in which the Nicol and double-image prism were both placed in front of the eye-lens, the Nicol being next the eye. One marked advantage of this instrument, was that the circle instead of the index, turned with the Nicol. The labour of reading was thus much reduced. The Nicol was also replaced by a double-image prism, with the advantage that the field of view was less obstructed. With this form, however, the great number of images formed by successive reflections, when a bright object was observed, rendered it sometimes difficult to determine which should be compared.

A much simpler arrangement was used later. It consisted of two concentric tubes, one carrying a graduated circle, the other two indices. In the first of these tubes, a double-image prism was inserted; the other, which was held next the eye, carried a Nicol. This photometer was used without a telescope

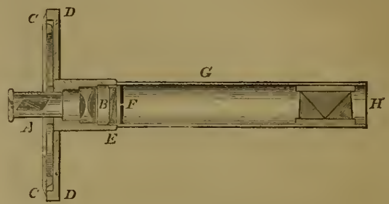

FIG. 3 (Scale [illegible]).

to compare the relative brightness of Saturn and Mars, and Jupiter and Venus. A tube was attached to this photometer, so that the light should always pass nearly normally through the prisms. When the objects were sufficiently bright, and within a few degrees of one another, good results were thus obtained, but the colour of the images, and their want of symmetry, was a serious objection when a great difference in light was to be measured.

After an experience of some months with these instruments, certain improvements suggested themselves, and still another photometer was constructed, represented in perspective in Fig. 1, and in section, on a scale of one-fifth, in Fig. 2. In both figures, B represents the eye-piece, in front of which is

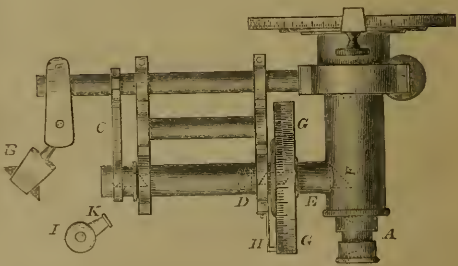

FIG. 4 (Sca le [illegible]).

inserted a Nicol, A. A circle, divided into degrees, is attached, and turns with the eye-piece. The indices D D are fastened to the tube E, which slides into the telescopes. F is a rochon prism, which was used instead of a double-image prism of spar. As it consisted of quartz, the separation of the images amounted to somewhat less than $1°$, so that the emergent pencils overlapped each other by nearly three quarters of the diameter of each. The apparatus had, moreover, the great advantage that the images were precisely alike and nearly achromatic. The prism was placed in a tube, which could be drawn towards or from the eye-piece by a cord G. Attaching this photometer to a telescope, and directing it towards a star, the latter appeared double; and the interval between the components might be altered at will.

These photometers could only be used for comparing objects very near together, as double stars, or satellites. For greater intervals, another device was tried. Two achromatic prisms of small angle were placed in front of the telescope, so as to cover the central portion of its object-glass. Two images of any object would thus be formed, separated by an interval dependent on the angle of the prisms and on their relative positions. By turning one or both of the prisms, the directions of the two images may be altered at will, and their distance varied between the sum and the difference of the angular deviation of the prisms.

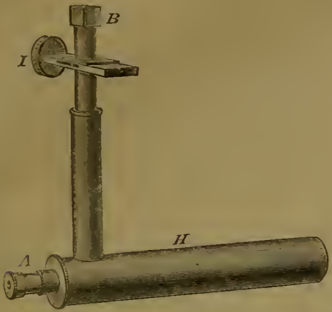

Fig 5

After bringing the images near together, they could be compared by one of the photometers described above. This method was tried with two circular prisms, having a diameter of 4·4 cms., and producing a deviation of about $1^{\circ}\cdot 3$. A telescope was used having an aperture of 10 cms. The light of any objects nearer than $2^{\circ}\cdot 6$ could be measured with this instrument. The constant, or proportion of the light transmitted by the prisms, was easily determined by comparing, by the photometer, the two images of the same object. This instrument, like those previously described, has the great advantage that both objects are seen under the same magnifying power, and therefore closely resemble

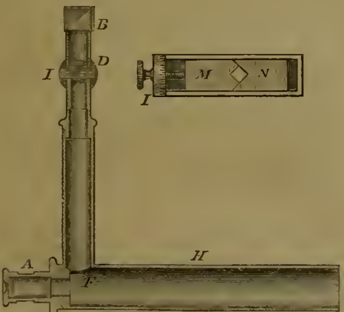

Fig.

each other, even when the condition of the air is not good. This plan cannot be used for large intervals, since, if the angles of the prisms are large, the images will be coloured by the secondary spectrum, and it would also be difficult to find the objects. With a large telescope, the prisms could not be reached easily by the observer, and the large diameter required would be an objection to their use.

The idea suggested itself to Prof. Pickering, that such photometers might be used to compare the colours of the components of double stars, by measuring *the relative light of different portions of their spectra*. A combined spectroscope and photometer, shown in Fig 3, was devised. A is a Nicol, placed in front of the eye-piece B. The graduated circle C C is attached directly to the tube carrying the Nicol; and the indices D D are fastened to the tube G, which slides into the telescope. H is a direct-vision prism, by which the images of the stars are converted into linear spectra. F is a diaphragm placed at the focus, and having a slit in it ·02 cms. broad, parallel to the edges of the prism. It is, therefore, perpendicular to the spectra, and permits a short portion of each to pass through. These appear as two stars, of a colour which may be varied with the position of the objects observed, as regards the axis of the telescope. Their relative light was measured by forming two images of each, by a plate of Iceland spar, E, which was used instead of a double-image prism, since the rays were not parallel. The light was then measured by turning the Nicol.

All of the photometers described above are open to the objection that the loss of light is very great. Under the most favourable circumstances only ·20 to ·40 of the light is used; so that, with the large telescope of aperture 38 cms., faint objects appear no brighter than with a telescope having an aperture of 18 to 24 cms., with a common eye-piece. To remedy this objection which was greatly felt during the observations of the satellites of Mars, a class of photometers of wholly different form was tried.

In these the image of some bright object, assumed as a standard, is reflected into the field of the telescope, and its light reduced by a known amount, until it is no brighter than the object to be measured. An unobstructed view of the latter is obtained meanwhile, with an eye-piece of the usual form. The first of these instruments is represented in Fig. 4.

The image of the faint object formed by the telescope is viewed by the eye-piece A. The light of the bright star taken as a standard, passes outside the telescope, and falls upon the prism B, by which it is reflected through the objective D of a small auxiliary telescope, and falling on the prism F, is brought into the field of view. The faint object is thus seen in one half of the field with the full aperture of the telescope; while the bright standard appears in the other half of the field, its image being formed by the small telescope. C and E are two Nicols, of which E may be rotated, and the light passing through it reduced at will. G G is a graduated circle, attached to the tube carrying D and E, and measuring the reduction of the light by an index H, which is fixed. The whole photometer may be turned around the axis of the large telescope, the tube carrying the prism enables the latter to rotate around the axis of the auxiliary telescope, and, finally the prism may be tipped around an axis parallel to its edges. Either two of these motions enable the observer to bring any object into the field of view of the small telescope. Practically, the second and third motions were used for the purpose. The first of these movements was reserved almost exclusively for the purpose of placing the prism so that it would conceal the bright star or planet with which the faint object was to be compared, when their distance apart was small. Otherwise, its light as seen in the large telescope, would be so intense as to interfere with the proper estimate of the light of the faint object. I is a lamp, by which the half of the field covered by the prism F may be illuminated, so as to render it as bright as the other half of the field. A piece of blue glass, K, served to vary the colour of the light.

Great difficulty was experienced in obtaining good images of bright stars with the small telescope, on account of the Nicols used. Since the rays passing through E are convergent, aberration is caused by the obliquity of its faces, even if they are plane and parallel. Hence the Nicols were removed, and a new form tried. The lenses of a double-image micrometer being taken out, two V-shaped pieces of brass were attached to the slides carrying the divided lens. A square hole, or "cat's eye," was thus formed, whose dimensions could be altered at will, by turning the micrometer screw. This arrangement is shown in M N, Fig. 6. Placing it near the objective D, Fig. 4, the light was varied by changing the aperture of the small telescope. All these instruments, however, were heavy, difficult to adjust, and not easily removed and replaced. These defects were remedied by still another form, represented in perspective in Fig. 5, and in section, on a scale of one-fifth, in Fig. 6. The same letters are used as in Fig. 4, for the corresponding parts. The faint object is viewed with the eye-piece A, while the light of the bright object, passing outside of the telescope, is reflected by the prism B into the object-glass D, whose aperture is varied by the screw I, which moves the plates M N. Finally, the prism F throws the light into the field of A. The whole is attached to the tube H, which slides into the end of the telescope. This photometer is light, can be easily removed, and by a suitable adapter may be attached to any telescope. As it forms a single piece, the adjustments are little liable to be disturbed.

In some observations, especially during twilight or moonlight, errors were apprehended from the comparative darkness of that half of the field covered by the prism F. This prism was replaced in other forms therefore by a piece of parallel glass. They were then called photometers E' and J. The reflected stars they formed were much fainter, and double, one image being produced by each surface of the glass. Still these instruments had the advantage that the field was unobstructed, and the star to be measured might be placed in any desired position, as regards the standard.

The latter class of photometers can be used only in the measurement of faint stars. If the image of the object seen in the large telescope is brighter than that formed by the auxiliary telescope, no setting of the Nicols or micrometer screw will render them equal. This difficulty was obviated by using the photometer shown in Fig. 4, removing the Nicols, and replacing its eye-piece by the concentric tubes referred to in an early part of this analysis. The images of the same object, seen in the large and small telescope, were first compared, and the constant thus found was used in reducing the observations of other objects. The advantages of this photometer are that stars of greatly different brightness and in different parts of the sky may be compared; but the loss of light is great, and the images are seen under different magnifying powers.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Board of Natural Science Studies have recommended a new set of regulations for the Natural Sciences Tripos, to take effect as regards the first part of the examination, in the Easter Term of 1881, and as regards the second part in Easter Term of 1882. In effect it is intended to provide for a class list in general natural science honours in June each year, founded on aggregate knowledge shown by candidates in the first part of the examination, provided no credit is given in a subject unless the candidate has shown a competent knowledge of that subject. Each of the three classes is to be arranged in alphabetical order. The general arrangement of subjects and practical work has already been settled, but the details will no doubt invite attention. The working of Regulation 6 is rather curious. "In the first part of the examination there shall be a practical examination, either written or *vivâ voce*, or both, in such subjects as the Board of Natural Science Studies shall from time to time determine, provided that in all those subjects in which there is no such practical examination, one or more of the questions in the printed papers refer to objects exhibited at the examination." Regulation 7 states that there is to be a practical examination either written or *vivâ voce*, or both, in each of the eight subjects of examination in the second part. Regulation 14 proposes that, in arranging the class-list for the second part of the examination, the examiners shall have regard to general knowledge and ability as well as to special proficiency in one or more subjects. No candidate shall obtain a first-class for proficiency in one subject unless he show a competent knowledge of some cognate subject. When Human Anatomy is taken as the principal subject, either Zoology and Comparative Anatomy, or Physiology, be taken as a necessary cognate subject. Regulation 15 includes the following:—In each case of giving a first-class in the second part of the examination, the examiners shall specify the subjects for which the candidate is so placed, or the reason for specially distinguishing him.—A discussion in the Arts School on the proposed regulations for the Natural Sciences Tripos (on October 31), was opened by Mr. Sedley Taylor expressing great doubts about the desirability of giving such a prominent place to human anatomy in an honours examination. He read to those present the opinions of three eminent physiologists and anatomists specially obtained by himself on this point, and they were, on the whole, against the proposed regulation as unnecessary, if human anatomy were to be taught in the only way in which it could fairly enter into the Tripos, for its general and not its professional value, while usually the memory work involved was enormous, and such as to be of quite technical character. Dr. Humphry strongly supported the regulations and the distribution of subjects, as a method of aiding in preserving a scientific study of human anatomy. Dr. Paget dissented strongly from this view, not as a means of discouraging the study of anatomy, but to lessen the strain of constant change by questions which went to the root of the matter. He believed no sufficient settlement could be expected unless or until the Tripos was divided into two—biological and non-biological; it was unwieldy and unmanageable in its present state. Surely it was not impossible to frame some division of subjects which might secure this and be found workable. Mr. Balfour did not agree with the way in which human anatomy was regarded as so far apart from the anatomy of all other animals as to gain such distinctive marks, while no such division was made in physiology. Mr. Trotter thought it would be quite impracticable to enter upon the discussion of the Tripos at present, and that it would be impossible to divide the subjects into biological and non-biological. The geologists would object. Mr. J. N. Langley testified to the difficulty men often found in choosing or combining their subjects. Mr. Bettany strongly supported Dr. Paget's projected division of the Tripos into two, but with this difference, that men who gained a degree in the first part of the Tripos, as now proposed, in the "comparatively elementary" parts of the subjects, should be allowed to gain their final class in either biological or non-biological subjects, without such complex and often uncertain or vague regulations to puzzle candidates.

THERE can be little doubt as to the health of Cambridge being good, and the increasing confidence in Cambridge as a place of education, in view of two facts, viz., that the death-rate during the Michaelmas quarter has been only at the rate of thirteen per thousand, per annum; including only six deaths from the seven principal zymotics; and that the entry of freshmen at the colleges this year is the largest ever known, having increased by at least one hundred. It is the more incumbent on the university or the colleges, to see that space for exercise, recreation, study, and sleeping are fully provided for every undergraduate, and to take an active part in preventing disorderly men from remaining to vitiate others; and it is equally the duty of every wise man not to tempt our youth into overstrain of body and mind.

MR. PATTISON MUIR, Caius Prælector in Chemistry, lectures on the Metals this term, and also on Advanced Systematic Chemistry to Tripos candidates. Professors Liveing and Dewar have issued a notice of great importance to those desirous of prosecuting researches in chemistry. The new rooms added to the Chemical Department will enable them to accommodate a limited number of students who have had the necessary training and are desirous of prosecuting chemical research or of acquiring skill in special branches of chemistry. Applications for permission to prosecute researches must be made personally to the Professors, and all investigations must be subject to their approval. Mr. A. Scott, B.A., Prof. Dewar's assistant, will have the general superintendence of this part of the laboratory.

A COURSE of practical instruction in Experimental Physics will be given in the Cavendish Laboratory during this term. The course will be adapted to the requirements of beginners, and demonstrations will be given daily at times to be arranged with the members of the class. Thus again one of the most necessary classes is to be provided, but we trust Mr. Garnett's energies in this department will not be overtaxed.

OXFORD.—In a congregation to be held on November 18, the amendments to the proposed statute respecting degrees in Natural Science will be considered. As the proposed statute now stands, scholars in the Faculty of Natural Science may offer for Responsions Greek and Latin, or Greek or Latin with either French or German, and shall also be examined in arithmetic, the elements of plane geometry and algebra up the binomial theorem. An amendment has been proposed by Prof. Rolleston to substitute the elements of deductive logic for algebra beyond proportion. In moderations (first public examination), Prof. Rolleston proposes to insert deductive and inductive logic as an alternative for algebra. Candidates will be obliged to offer either Greek or Latin, with either French or German, and will be examined in the theory of logarithms, Euclid, trigonometry as far as the solution of plane triangles, and elementary mechanics. The council have proposed amendments abolishing those clauses granting the rights of Masters of Arts to Masters of Natural Science, since counsel's opinion has given it to be beyond the power of the University to grant such privileges to a new faculty. The council will accordingly propose a decree authorising the Vice-Chancellor to take whatever steps may be necessary to obtain the power of conferring on Masters in Natural Science the rights and privileges at present enjoyed by Masters of Arts.

The statute providing that there shall be two examiners in each of the three branches of the natural science school will come into operation this term. The three new examiners will be Dr. Odling in Chemistry, Prof. Ray Lankester in Biology, and Mr. W. N. Stocker, Brasenose, in Physics.

Dr. Acland, Regius Professor of Medicine, will give a public lecture at the Museum, November 20, on the new hospital at Baltimore, U.S., and its relation to the medical studies at the Johns Hopkins University, and to general medical education.

Mr. C. J. Baker, of Manchester Grammar School, has been elected to the Physical Postmastership at Merton College.

THE Board of Trinity College, Dublin, have elected Dr. Alexander Macalister to the Professorship of Anatomy, and Chirurgery, in Dublin University, vacant owing to the resignation of Dr. B. McDowel. Prof. Macalister still retains his Professorship of Comparative Anatomy, but resigns the Professorship of Zoology and the Directorship of the Zoological Museum. The election to the former of these posts we observe is fixed for an early day in this month ; the nominators are the members of the academic council of the University of Dublin, with a veto on the person nominated by the board. The election to the Directorship of the museum is in the hands of the board, and to this the person elected has always been the professor of zoology. The yearly emolument from both posts is between 300*l* and 400*l*. a year.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 9.—Questions in molecular physics figure largely in this number. Herr v. Wroblewski inquires into the nature of absorption of gases, by a kinematical method, inferring from the phenomena of motion of gases diffusing in absorbent substances, the condition in which they exist in these. The phenomena in caoutchouc are studied, and the author concludes, *inter alia*, that the absorption of protoxide of nitrogen, carbonic acid, and hydrogen by caoutchouc is a purely physical process, and the gases retain, after absorption, their gaseous state and all characteristic properties. The constant of diffusion of a gas depends only on physical properties, and chiefly its specific gravity, being approximately inversely proportional to the square root of this ; but the specifically lighter gases show greater constants than this relation expresses. The constant for protoxide of nitrogen and carbonic acid increases with increase of temperature, and at 10° C. is fifty times smaller than that for carbonic acid in water. A caoutchouc membrane is to be conceived as a porous plate endowed with gas-condensing and rarefying powers (the gas moving through the pores).—M. Chappuis investigates the condensation of gases on a glass surface by a similar method to Magnus's, viz., measuring the expansion between two exactly known temperatures, of a certain volume of gas at constant pressure in contact with a large glass surface, and inferring the original volume of the gas. The numerical results for hydrogen, air, carbonic acid, sulphurous acid, and ammonia, from 0° to 100° and 180°, are given, and utilised in determining the absolute coefficient of expansion at constant pressure (a slight correction of the former determinations being necessitated by the phenomenon in question). Magnus's statement that at 100° there is no condensed gas layer on a glass surface is shown to be incorrect in the case of ammonia.—A paper by Herr Schleiermacher treats of the quantity of liquid condensed on a moistened body. The author rejects Wilhelmy's numerical values for the condensation, and considers that, in determining the specific gravity of a liquid, if one be content with an accuracy of 0·002 per cent., the influence of condensation may be neglected ; in general the coefficients of condensation would be, at the most, of the order of 0·00001 $\frac{\text{g}}{\text{sq. ctm.}}$.—The specific heat of water is anew determined by Herr Heinrichsen, who arrives at the number 1·071 (for 100°) ; this stands about midway between Regnault's result, 1·013, and Jamin's, 1·122. (Stamo got 1·125, and Münchhausen 1·030.)—Herr Koch finds that the oxygen-polarisation of platinum and palladium increases the friction of these metals to a glass surface coated with water or dilute sulphuric acid.—Mr. B. O. Peirce, jun., shows from experiments how greatly the electromotive force of gas elements depends on the nature of the electrolyte.—Herr Edlund, replying to a criticism by Herr Dorn, gives experimental evidence that the electromotive force in passage of liquids through tubes depends directly on the velocity, and not on the pressure ; also that it is inversely proportional to the cross-section ; and explains the facts observed by the unitarian theory.—Herr Fenkner expounds some laws of transverse vibrations of metallic cylinders open at one end.—Remaining papers :—Researches on anomalous dispersion of light, by Herr Sieben.—Researches on the height of the atmosphere, &c. (continued), by Herr Ritter.—On the electromotive force of the Grove element in units of Siemens and Weber, by Herr Riecke.

THE *Journal of the Royal Microscopical Society*, vol. ii. No. 6, October, contains the *Transactions* of the Society.—On a new species of Cothurnia, by John Davis ; with Plate 20. Cothurnia is a genus of stalked infusoria very closely allied indeed to Vaginicola. Mr. Davis's new form is apparently very correctly referred to it ; but if so, his species is not a rotifer, and, we presume, does not possess a mastax. The infusorian is described as much smaller than its lorica, and is so figured when contracted ; this is not characteristic of a rotifer.—On some causes of Brownian movements, by Dr. W. Ord. Observations suggested by the study of *Amphipleura pellucida* mounted in Canada balsam, by lamp-light and sun-light, with various objectives, by Col. Woodward.—On Abbé's experiment on *Pleurosigma angulatum*, by Col. Woodward.—On new species and varieties of diatoms from the Caspian Sea, by Dr. A. Grunow ; translated, with additional notes, by F. Kitton ; with Plate 21.—The Record of current researches relating to invertebrata, cryptogamia, and microscopy. This record forms a most valuable portion of this journal. It occupies over 100 pages of this number, and, as far as one can judge, the notices give a very fair epitome of the papers quoted. The attempt to make this record a complete one of the invertebrates and of cryptogams is praiseworthy, but it seems to us that our yearly zoological and botanical records already do this in a fairly perfect way. Would it not be better that this bi-monthly record should confine itself to those papers of special interest to the microscopist. In this record references to papers of the type of Fischer on *Voluta musica*, Norman on Solenopus, or Pfeffer on Philippine pteropods, might be omitted. Only those who have worked at compiling bibliography know the great labour and skill required to keep up such a record ; and certainly the editor of this journal deserves the special thanks of all workers with the microscope.

THE *Gazetta Chimica* (fasc. vi. and vii.) contains the following papers :—On the chlorides and oxychlorides of tungsten, by U. Schiff.—On a method of preparing economically the bibasic citrate of quinine, by F. Dotto-Scribani.—Researches on *Satureja juliana*, by P. Spica.—Chemical researches on the salts obtained from the mother liquors of the salt works of Volterra, by A. Funaro.—Chemical analysis of a Chilian chrysocolla, by N. Pellegrini.—On a singular decomposition of the chlorhydrate of phenyl-ethyl-amine, by M. Fileti and A. Piccini.—On some neutral ammonia salts (citrate, phosphate, photosantonate), by F. Sestini.—New experiments on resinous substances, by G. L. Ciamician.—On the isomeric nitrosalicylic acids, by U. Schiff and F. Masino.—On the pretended artificial tannic acid, by P. Freda.—On piperidine, by R. Schiff.—On the action of cyanide of potash on the ammoniacal derivatives of chloral, by R. Schiff and S. Speciale.—On the crystalline forms of anglesite from Sardinia, by Q. Sella.—On the forms of crystallisation of some substances belonging to the aromatic series, by R. Panebianco.—On lithofellic acid and some lithofellates, by G. Roster.—Chemico-mineralogical researches on the lavas of the volcanoes of the Ernici in the Valle del Sacco (Rome), by S. Speciale.—On the discovery of nitric acid in the presence of nitrous acid, by A. Piccini.

THE *Rivista Scientifico Industriale* (Nos. 17 and 18).—From these numbers we note the following papers :—On a new method for determining the distribution of magnetism in magnets, by Prof. G. J. Agostini.—On the electromotive forces developed by saline solutions of different degrees by concentration with the metals which form their base, by A. Eccher Dall' Eco.—On the temperature of the voltaic arc and of the positive and negative polar extremities of the carbons during the production of the electric light, by Prof. Rossetti.—On the decomposition of chlorhydrate of ethyl amine by heat, by M. Fileti and A. Piccini.—On the preservation of dragon flies with fading colours, by Prof. Pietro Stefanelli.—On a new hydrometer for measuring the water supplied to steam-boilers, and called "Isaghidrometro" by its inventor, Sig. Massarotti.—On the work which can be performed by the beams of certain aquatic motors, by Cesare

Modigliano.—On a palæontological discovery made at Montegazzo in Fellina (province of Reggio-Emilia), by Prof. A. Ferreti.—On some recent communications made to the Paris Chemical Society, by the Editor.—On the filling of a barometer tube in vacuo, by Prof. Damiano Macaluso.

THE *Archives des Sciences physiques et naturelles* (September, Geneva) contain the following papers of note:—Review of the principal publications on physiological botany during 1878, by M. Marc Micheli.—On xylic acid, its preparation and compounds derived from the same, by MM. E. Ador and Fr. Meier.—Note on the last report of the Council of the Royal Astronomical Society (London), by Prof. Gautier.—Analysis of some recent works relating to the topography and the constitution of the moon, by M. Rapin.—Account of the sixty-first meeting of the Swiss Naturalists' Association, on Aug. 12–14, 1878. The remaining contents of the number consist of mere extracts from papers published in other serials and relate all to chemistry.

La Natura (vol. iii., Nos. 16 and 17) contains the following papers of interest:—On the intensity of electric currents and of extra-currents in the telephone, by G. Farraris.—On the correction of mercury thermometers, by C. Ferrari.—Observations made during the earthquake of August 9 last, by A. Serpieri.—On two new meteorological works, by C. Ferrari.

SOCIETIES AND ACADEMIES

LONDON

Mineralogical Society of Great Britain and Ireland, October 21.—Dr. M. Forster-Heddle, president, in the chair.—The following papers were read:—On the mineralogy and geognosy of the Orkney Islands, by the president.—On a probably dimorphous form of tin, by Dr. C. O. Trechmann.—On some Cornish tin-stones and tin-capels, by J. H. Collins, F.G.S.—Experiments on the elasticity of minerals, by John Milne.—On a peculiar pasty form of silica from Leadhills, Scotland, by Andrew French, F.C.S.

PARIS

Academy of Sciences, October 27.—M. Daubrée in the chair.—The following papers were read:—Notice on the life and scientific works of M. Dortet de Tessan, by Admiral Paris.—On the galvanic oxidation of gold, by M. Berthelot. This refers to Grotthuss's observation of the dissolving of gold-wire when used as positive pole in sulphuric acid traversed by a current. The attack is not due to formation of persulphuric acid, but solely to the influence of the current and contact of the electrode with the electrolysed liquid.—Decomposition of selenhydric acid by mercury, by M. Berthelot. He observed such decomposition when the substances had been in contact with each other a few years.—Note on the development of railways in Brazil, by Gen. Morin. Two maps from the Emperor were shown. The total length of railway in operation in the provinces of Rio de Janeiro, St. Paul, and Minas Geräes, is 2,882 km.; in construction, 1,751 km.; total, 4,633 km. From 1,000 km. to 1,200 km. of the working lines have a broad gauge of 1·60 m.; the rest, for local traffic, a gauge of 1 m. The mountain chain near the sea in Rio de Janeiro presented great difficulties, but beyond, the railways lie in long and fertile valleys.—Critical reflections on experiments concerning human heat, by M. Hirn.—On the gymnastics of M. Zander of Stockholm, by M. Norström. This is a system of mechanical and passive gymnastics, machinery worked by steam being used to move the limbs of the subject in various ways (the force being suitably proportioned). M. Larrey remarked on the complicated and expensive nature of the apparatus, and desired scientific data as to the effects obtained.—Result of researches made with a view to find the origin of estival reinvasions of phylloxera, by M. Faucon. The principal cause he considers to be carriage by the wind (inferred from the result of fixing a sheet of oiled white paper on a board at the top of a post facing the wind). Other causes are passage of the insect on the surface of the ground, and the presence of eggs.—On the appearance of mildew or false American oïdium in the vineyards of Italy, by M. Pirotta.—Determination of longitudes, latitudes, and azimuths in Algeria, by M. Perrier. He shows that the probable error of each definitive result is about one-tenth of a second of an arc.—Specific heats and points of fusion of different refractory metals, by M. Violle. The specific heat of iridium grows regularly with the temperature, and the formula gives 1950° (of the air-thermometer) as the point of fusion. The specific heat of gold hardly varies up to 600°, then gradually increases towards the point of fusion, 1035°. Other points of fusion: silver, 954°; copper, 1032°, palladium, 1500°, platinum, 1775°.—Chloride of lime battery, by M. Niaudet. The positive electrode is a zinc plate in a solution of chloride of sodium. The negative, one of carbon surrounded by fragments of carbon and chloride of lime in a porous vessel. All the combinations produced are soluble, and the battery remains an indefinite time at rest without being used up. The electromotive force at first is over 1·6 volt.—On the combinations of phosphuretted hydrogen with hydracids, and on their heat of formation, by M. Ogier.—On erbine, by M. Clève. He recognises M. Soret's priority, and the identity of the substances he himself called *holmium*, with M. Soret's X.—Complementary note on commercial trimethylamine, by MM. Duvillier and Bursine.—On ordinary cellulose, by M. Franchimont. This refers partly to dehydration of cellulose with sulphuric acid (chloride of zinc did not decompose cellulose).—On glucose, by M. Franchimont.—On the transmissibility of human rabies to the rabbit, by M. Raymond. Two rabbits were inoculated with blood and saliva (respectively) from a hydrophobic person. That inoculated with saliva showed signs of rabies four days after, and soon died. Pieces of its salivary glands (got thirty-six hours after death) were introduced into two other rabbits, who also died (paralysed), but without passing through a violent stage.—Researches on Daltonism, by MM. Macé and Nicati. They aimed at comparative measures of the quantities of light perceived in different parts of the spectrum by the Daltonian and the normal eye. Curves were got corresponding to the three varieties of Daltonian eye. The descent of the curve in the green the authors think they have been the first to prove certainly. No simple relation between visual activity and intensity of light was ascertained.—On the origin of the toxical properties of the Indians' curare, by M. Du Lacerda. None of the vegetable or animal juices often added by the Indians to the product of Strychnos have the effects of curare, and *Strychnos castelnœ*, also, *S. triplinervia*, are found to give curaric effects fully.—Experimental researches on human heat during rest in bed, by M. Bonnat. In all seasons the minimum of the body-temperature (observed in the rectum) is between midnight and 3 A.M. At Nice, in winter, the minimum is rarely under 36°·3; in summer, 36°·4 or 36°·5. From 3 A.M. the temperature rises till 9 A.M. (becoming, *e.g.*, 36°·9 in winter). The maximum is between 2 P.M. and 4 P.M., and from 9 P.M. the temperature slowly falls to the minimum. From 9 A.M. to 9 P.M. in winter the variations do not exceed three-tenths or four-tenths of a degree C.; in summer they may reach six-tenths.

DEMONOLOGY AND DEVIL-LORE

Demonology and Devil-Lore. By Moncure Daniel Conway, M.A., B.D., of Divinity College, Harvard University, Cambridge, U.S.A. Member of the Anthropological Institute, London. With numerous Illustrations. 2 vols. 8vo. (London: Chatto and Windus, Piccadilly, 1879.)

THESE two volumes carry us back to the period when existing creeds were embryonic, and when primitive man was creating his religion from his environment. The lights of heaven, animal and vegetable life, the elements and natural phenomena supplied the raw material of mythology, and received embodiment as anthropomorphic deities. Mr. Conway premises the inexactness of speaking of the worship of stock and stone, of insect and reptile as primitive. He expresses his belief that these only acquired intrinsic sanctity when the origin of their imputed sacredness was lost—the progress of ideas being from the far to the near, and not from the near to the far. Macaulay has attributed a monotheistic faith to the first inhabitants of Greece. Chalmers has done as much for China, and Mr. Brown, in his great Dionisiak Myth, has stated his conviction that "there is no gradual evolution in human thought, and that the earliest stages of religion and worship were infinitely superior to those which succeeded them." But whilst he endorses these opinions, Mr. Conway must remember that they are not shared by other competent authorities. Dr. Goldziher, for instance, stoutly maintains that religion was painfully evolved from mythology, and that polytheism has been the invariable precursor of faith in a single God. In this conflict of opinion we are as unprepared to decide whether worship rose from the idol to the Deity, or sank from the pure religion of a golden age into the vagaries of a degraded mythology, as we are to determine whether an adoration of the generative powers preceded or grew out of that of the sun. In the present state of our knowledge we must be content to suspend our judgment; but in examining Mr. Conway's work we must remember that it rests upon a theory which at least is not proven.

The undefined pantheism of primitive awe, says Mr. Conway, gradually melted into dualism, and the varying aspects of the Almighty as distributor of good and evil caused his separation into distinct embodiments of these principles. This is doubtless, in a sense, perfectly true: "theism is found side by side with unconscious pantheism, of which it is only an expression," and the Jew had in Jehovah a distributor of the evil as well as of the good before he evolved, or inherited, the conception of Satan. We are, however, inclined to believe that the first supernatural power which forces a conviction of its existence upon the mind of the savage is that of evil, and that the idea of a beneficent being is both subsidiary and of later occurrence. First, the embodiment of evil is feared and propitiated; next, when invoked successfully for the destruction of the worshipper's enemies, he begins to exhibit (to his worshipper at least), an amiable phase of his character, and the conflicting elements which thus come into play form the germs of the rival entities of God and Devil.

The first volume of the work, which is in two sections, deals with the Demon and its development into the Dragon, whilst the second volume is devoted to the Devil. This latter volume is filled with the theological conceptions which originated and developed the personification of abstract evil. These are scarcely suited for discussion in our pages, and for an account of their subtle gradations we must refer our readers to the book itself. The demon, however, is not theological but natural; it is a being the harmfulness of which is not gratuitous, but incidental to the gratification of its desires. It is the embodied expression of the natural obstacles with which savage man found himself obliged to contend, and hunger, heat, cold, wild beasts, the warring elements, darkness, disease, and death were the causes to which it owed its birth. It was to propitiate the hungry demon that sacrifices were instituted: in the hope that such offerings might satisfy the insatiate appetite of the monster to which not only human hunger and privation, but also eclipses were held to be due. Here we may offer an explanation, omitted by Mr. Conway, which throws light upon the character of this devourer of the sun and moon. From the most remote antiquity the two points at which the ecliptic and the moon's orbit intersect each other were called the head and tail of the dragon. As these are the points at which eclipses happen we see at once why astronomers fabled the existence of a monster which devoured the sun and moon. Once started the progress of the myth was easy, and after many varying phases the hunger fiend found its later developments in the form of the ogre and the vampire. Mr. Conway says that the visible consumption of sacrifice by fire in part originated the belief that it was the element of fiends, but it appears—on his theory that the progress of thought was from the far to the near—more probable that the sun having been the primary object of worship lent its characteristic of heat to some of the abstractions to which it gave rise. This class of demon was modified as the painful action of intense heat, in the desert sand, in sunstroke, and in drought, was observed by man. The worship of the sun in heaven would pass easily into the worship of his natural representative of fire on earth. In opposition to light and heat we find darkness and cold personified, and trace in such tales as the descent of Ishtar to Hades and the deaths of Baldur and Adonis the grief of man for the loss of the sun.

A propos of cold Mr. Conway reminds us that hell, which we are accustomed to regard as unpleasantly warm, really means a place of fireless darkness—fire being far too agreeable in northern latitudes to be regarded with disfavour, and he traces the superstitious desire for burial to the south side of a church to a wish for proximity to the happy abodes of Brimir and Sindri—fire and cinders! This passage is instructive, apart from its humour, for it teaches us how in the constant revolution of opinion the god of to-day is the fiend of the morrow, and how, as Mr. Fiske has pointed out, the German Abgott sums up in a single etymology the history of the havoc wrought by the monotheistic idea amongst the ancient symbols of Deity. To this degradation certain later forms of demon were due, and it is thus that the gipsy language retains as the word for God that which we employ as the appellation of the devil.

Mr. Conway passes in review the myths which spring from lightning, as the blasting-eye of Siva, the dart of Rudra, the spear of Odin, and the sword of St. George; and treats of the typhoon caused by the passing of the bob-tailed dragon and the various embodiments of whirlwind and waterspout, of sand-cloud and flood. He next proceeds to deal with the animal demons; and here, whilst we find much amusing folk-lore, we are surprised that he has not worked out that degradation of deities to which he himself alludes, and which might here be so effectively produced. Thus, although we have a suggestion of association between the hare and the moon, due probably to the resemblance of their Sanskrit names, and a statement that the lion is a symbol of majesty and of the sun in his glory reached in the zodiacal Leo, we have no hint of the extremely important change from the worship of the bull to that of the lamb due to the precession of the equinox, which brought a different sign for adoration at the vernal equinox, and which caused, in all probability, the substitution of the Pascal Lamb for the worship of Apis; this feast of the *transit* having its remembrance at the present day in the hot *cross* bun. Similarly we have no explanation of the association of the ass, the cock, and the goat with phallic ritual, though their association with the most holy rites of that creed could not fail to have diabolised them in the eyes of adherents to succeeding faiths. The Pleiades, the Succoth Benoth of the Chaldeans, were represented by a hen gathering her chickens under her wings; and we are surprised that Mr. Conway, who rarely loses an opportunity for startling the orthodox, has not here found a parallel to Christ's lament over Jerusalem. He has an interesting notice of the wehr-wolf, which was seemingly suggested by Mr. Fiske's excellent little work, "Myths and Myth-Makers," a volume to which, if we mistake not, Mr. Conway is much indebted. The animal kingdom thus furnished its quota of demons, and we are shown how every force which could be exerted injuriously in claw, fang, sting, or hoof, was pressed into the service of evil.

Hostile races were demonised of old, just as is the kidnapping white man of to-day amongst the black races of Africa. The varying physique of contending nations may have originated the myths of giants and dwarfs. A small people possessed of superior intellectual powers would scarcely fail to impress their huger opponents; though we must not lose sight of the gigantic features which are so frequently associated with solar heroes, and which may, perhaps, suggest a more satisfactory explanation. With our recent experience of famine in India, we shall have no difficulty in understanding the dread in which its embodiment was held, nor the adoration of the Hindu for the rain-giving Indra. Yet Mr. Conway justly laments that this adoration has taken the form of temple building throughout the land, for the offering of a worship impotent to arrest the famine demon, whose course might have been stayed had the expenditure thus lavished been devoted to observatories—since modern science has pointed out the relation existing between sun-spots and years of scarcity. He at the same time reminds us that we are more intent upon scaring our own people with the hell and devils which we have inherited from our pagan forefathers, than in endeavouring to remedy the demoniacal vice, infamy, and misery by which we are surrounded. We cannot follow Mr. Conway through his long and interesting catalogue of the other natural features which have been demonised—the mountain steep, the gloomy night, the mysteries of disease and of death—this he has worked out with great care, and a *résumé* of these sections would fail to afford an idea of their interest. These natural obstacles personified and demonised by man having played their part, shrunk, as he advanced in civilisation, from their terrible proportions, to make way for more general forms expressing comparatively abstract conceptions of physical evil.

On the one hand stood moral man, on the other unmoral nature. Man had by this time discovered that moral order in nature was represented solely by his own power; the good gods were now respected only as incarnate in men, whilst the active powers of evil remained hateful and hurtful to man, each becoming more purely a demon, and passing on to become a devil. Man in his growing culture gave a more symbolic cast to those representations, which had hitherto been purely naturalistic, and those semi-metaphysical conceptions were evolved which Mr. Conway classes under the general heading of dragon. In this class come the chimæra and sphinx, huge worm and serpent, Behemoth and Leviathan. Finally, the terrible conclusion that evil is a positive and imperishable principle in the universe—the notion of remorseless fate—of arbitrary will to which every human agony is attributable, detached from universal organic necessity, gave birth to the stupendous conception of embodied abstract evil in the person of the devil.

Only those who have attempted an investigation similar to the present one of Mr. Conway can appreciate the patient labour incident to the collection of widely-scattered materials and the mass of varied reading necessary to fit the author for his task, and we are happy to bear witness to the evidences of careful preparation with which these volumes abound. It is to be regretted that his excellent matter is frequently enveloped in rhetorical embellishments which render the comprehension of his meaning difficult. Mr. Conway's style of writing is characterised by recapitulation, want of concentration, and a constant parenthetical introduction of matter only collaterally related to the subject in hand, which render parts of his book far from easy reading. His explanations of the formation of legendary characters and of myths appear to us at times somewhat strained, and he leans unduly upon the metaphysical aspect of the question to the exclusion of those archæological and astronomical explanations which would have so greatly enhanced the value of his work. He has indeed dealt with phases of folk-lore, and has shown how physical and material wants were crystallised as entities, but he has, in our opinion, failed to make out, as he might have done, the genealogy of the infernal powers, and to cite those explanations which a knowledge of the astronomy of the ancients so constantly affords. In illustration of our remark, we may instance his treatment of one of the most important myths, that of Bel and the Dragon. He mentions that Bel is lord of the surface of the earth, including the atmosphere, and quotes long translations from tablets, giving accounts of the conflict as it w known to the Babylonians. He compares Bel's sword with that mentioned in Genesis as turning every way to guard the tree of life; he tells us that the Bel whom Milton saw was Cromwell and the dragon the serpent of English oppression; and that to the Jews the power of Christendom came to be represented as the reign of Bel. But out of all this he obtains nothing further than an identification of Bel with Michael in the Apocalypse. This is sufficiently provoking when we remember the astronomical and cosmical facts which underlie the story. Were we possessed of no further evidence than that afforded by the great pyramid, we should be at no loss to perceive the anxious care with which the heavenly bodies were observed by the ancients. A star-group which specially claimed their attention was the Pleiades. The Pleiades above the horizon were the celestial, and below it the infernal gods. The period of their culmination, typifying appropriately a deliverance from Hades of the departed, has been dedicated, throughout the Old and New Worlds, to the worship of the manes of ancestors. This festival survives in our All Saints Day the accompanying feasts of Hallow-e'en and All Souls, originating in the imperfection of ancient observations. Wanting instruments of sufficient accuracy to determine the exact time of culmination, the ancients, by extending their devotions over three days, secured a due celebration of the sacred epoch. One act of this solemn period was lighting the sacred fire. The *Times* of November 4 records that Her Majesty was graciously pleased to assist at that holy rite, and witnessed the burning in effigy of a witch, personification of the evil power. This fire, the Bealltainn or Beltin, was the fire of Bel, and celebrated his ascension to the zenith, whilst his adversary, the dragon, was cast down to the nadir. In the rising of the Pleiades, at the time that Scorpio sank below the horizon, we may see the victory of Bel over the Dragon—a victory always negatived, as autumn gave place to winter, and ever renewed as winter was succeeded by spring, the alternating success of the combatants being fitly recorded in a joint worship. When we remember the identification of the Cherubim with the Bull, and of the Seraph with Scorpio, we perceive that their continual cry is but another expression of the eternal struggle. Again, in a mystic sense, we must remember that in Babylonian mythology Bel was Saturn, the oldest and chief god, the great spirit of antiquity, the ancient of days, God of Heaven, Life God, Lord of the Cycles, Chronos, Eternal God. His emanation was light, and in his character of sun god he was the creator—Demiurgus and Logos—and in this phase he combats and overcomes Tiamat or evil chaos, as the heavenly spirit in Genesis broods over the abyss of darkness—this idea is reproduced in another Babylonian legend, in which Bel cuts the woman Omorka, or primitive matter, in halves, and forms heaven and earth of the pieces. We can readily understand that on the promulgation of the doctrine that the gods were originally men whose virtue had raised them to the skies, the heroic deeds of Bel were related as those of a giant over natural foes, and that the first of the gods became the first man, equivalent to Adam. And so we find that, in company with his wife Beltis (Eve), he preceded the antediluvian rule of the ten zodiac gods. But Bel was, as the highest abstraction of deity, himself hermaphrodite, and in that sense active heaven and passive earth—light and darkness. He is thus the dragon-slayer and the great serpent itself, a fact which will account for the two personifications being the objects of a joint worship equivalent to the linga-yoni worship of India.

To the getting up of the work we have nothing to object except as regards the illustrations, which, though fair, scarcely reach that standard which the excellence of the text deserves. Debited, however, with any faults which it may contain, a large balance remains to the credit of its learned author, and if he has not succeeded in producing an exhaustive treatise upon his subject, his volumes are undoubtedly a most valuable contribution to Demonology, and we trust they may meet with the success to which they are unquestionably entitled.

OUR BOOK SHELF

Fauna der Gaskohle und der Kalksteine der Permformation Böhmens. Von Dr. Ant. Fritsch, Band i. Heft i. (Prague, 1879.)

THE accomplished professor of zoology, in the university of Prague, publishes in this part, which consists of ninety-two folio pages and twelve beautiful plates, descriptions of the sections of the rocks whence the fossils were derived, lists of the fossils, and a careful *résumé* of the literature of the extinct amphibia, which are usually jumbled up together under the term Labyrinthodontia. The most valuable part of the work is an elaborate description of the new forms which abound in the strata overlying the Silurians, in a region where the Pilsner district may be considered typical. The Gaskohle there yielded a very rich fauna and flora of twenty-one new labyrinthodont species, some Orthacanthoids and species of Xenacanthus, Acanthodes, and Palæoniscus; besides Estheria, portions of Orthoptera and Julus. The plants named by O. Feistmantel were numerous and the few typical Permian forms are:—*Equisetites contractus, Neuropteris imbricata, Odontopteris obtusiloba*, and *Schlotheimi, Asterocarpus Geinitzii, Schützia anomala*, and *Walchia piniformis*. With these are Sigillaria, Stigmaria, Volkmannia, Calamites, Lepidodendra, &c. The new amphiban genus Branchiosaurus is represented by five species in the whole district, Sparodus by two, Hylonomus by the same number, and there is a form called Dawsonia. In noticing the family Branchiosauridæ Dr. Fritsch draws attention to the necessity of allowing the name Stegocephali to replace that of the Labyrinthodontia for the order, as the labyrinthic condition of the teeth is not seen in skulls in which the supra-occipitals are two distinct ossifications, where there are post-orbital and supra-temporal bones, as well as well-developed epiotics, a sclerotic ring being present. The family just alluded to are broad-headed salamander-looking things with smooth teeth with large cavities. They have short ribs, vertebræ with relics of the chorda, and the parasphenoid is in the shape of a broad plate, which narrows in front. The skin is covered with delicate ornamented scales, and the remains of branchial rays are present. One of these, *Branchiosaurus salamandroides*, already described by the author, is carefully illustrated, and is a form well worth studying. Its osteology is plainly given, and the remnants of the breast plate and of the shoulder girdle and pelvis also. The new genus Sparodus has remarkably broad bones, which may be vomers, which carry numerous conical teeth, and the fore part of the parasphenoid is short and broad, and the palatines have a row of teeth on them. Allied to *Hylerpeton*, Owen, and *Batrachiderpeton*, Hancock, Sparodus has about seventeen teeth in the lower jaw on either side and the front ones are double the size of the others. The genus Dawsonia, allied more or less to *Hylonomus*, Dawson, is also one of those broad frog-headed salamandroid-looking branchiate amphibia. The sculpturing of the head plates is remarkable, and there appears to be a new bone interpolated behind the post-frontal. Beneath, the vomers have teeth, and so have the long part of the pre-sphenoid, the outer portions of the pterygoids, the palatines, superior-maxillaries, and the pre-maxillaries. The clearly written book is made all the more valuable by the introduction of Miall's reports to the British Association on the labyrinthodonts, and it is pleasing to note the author's graceful recognition of the assistance, he has had in his work from British palæontologists.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

An Account of some Marine Animals met with *en route* to the Cape September 21, 22

I AM commanded by my Lords Commissioners of the Admiralty, to transmit herewith a copy of a letter from the commanding officer of H.M.S. *Crocodile*, giving an account of some marine animals met with *en route* to the Cape, which may be of some interest to the readers of NATURE.

Admiralty, November 10 ROBERT HALL

H.M.S. *Crocodile*, Simon's Bay
September 30, 1879

SIR,—I think the following statement may be of some scientific interest, and have the honour to request that it may be attached to my letter of proceedings of this day's date.

Between the Lat. of $\left\{\begin{matrix} 5^\circ\ 53' \\ 9^\circ\ 48' \end{matrix}\right\}$ S., and Long. $\left\{\begin{matrix} 5^\circ\ 44' \\ 7^\circ\ 32' \end{matrix}\right\}$ E., and between the hours of moon setting and daylight on the nights of September 21 and 22, the condensers were continually heating, and the vacuum gauge suddenly dropping to zero.

On examination of strainers, it appeared that the inlet to the sea-water was choked with a marine animal to an extent that necessitated stopping and clearing four times on the night of the 21st inst., and five times on the night of the 22nd inst.

On referring to Dallas's "Natural History," the description given of the Pyrosoma, class Tunicata, order Ascidia, corresponded in all apparent particulars to the specimens I fished up from alongside and took from off the strainers. Those on the strainers were, of course, much flattened by the pressure, and those that had passed through were much attenuated.

The luminosity of the creatures was very great, and of a most brilliant sapphire colour. I have, &c.,

(Signed) F. PROBY DOUGHTY, Captain

To Commodore Richards, A.D.C., Cape of Good Hope

Easter Island

As the reviewer of Australasia in NATURE, vol. xx. p. 598, I must ask space for a few further words with regard to Rapanui. Mr. Albert J. Mott draws conclusions with regard to the ancient navigation of the Pacific Ocean and a former condition of high civilisation of the erectors of the stone images, which will not be admitted by any scientific ethnologist. The difficulties attending the erection by savages, or very slightly civilised people all over the world, of large stones has been greatly overrated. In the case of the stone images of Easter Island, the latest observer, M. A. Pinart, who has paid great attention to this very question and published the fullest account of the matter, together with a series of excellent illustrations, finds no difficulty in accounting for their erection. He writes as follows:—" L'ensemble de ce vaste atelier de statues gigantesques les unes entièrement terminées les autres à l'état d'ébauche et en voie d'exécution nous permet de nous rendre compte de la façon dont le travail était accompli, et de la manière dont elles étaient érigées et mise en place après leur complet achèvement. L'exécution de ce travail qui de prime abord parait considérable, qui à tout étonné les voyageurs et *suggère de nombreuses hypothèses*, est cependant d'une grande simplicité."

M. Pinart then goes on to explain how the sculptures were always cut out on rocks considerably inclined, and slid down hill to the place assigned, where they were tilted by means of an inclined plane of earth and stones built up, into holes dug deep enough to bury all but the head of each statue. I must refer readers wishing for more detailed information to M. Pinart's paper, "Voyage à l'Ile de Paques," *Le Tour du Monde*, 1878, p. 225, No. 927, for drawing my attention to which I am indebted to the librarian of the Royal Geographical Society, Mr. Rye.

The population of Easter Island was by some earlier voyagers estimated at as high as 1,500. It may have been greater, and as many as 500 men would certainly not be required for the erection of any of the images. There was undoubtedly a good deal of wood in the island in old times, and thus rollers and levers would be made use of. The trees of the island have now been exterminated by the inhabitants. Palmer speaks of a peculiar gesture of the modern Rapanui natives which he compares with certain features in the images. It is the opinion of experts that the general appearance of the sculptured faces is decidedly Polynesian, as far as mode of artistic treatment is concerned. Mr. Mott's conclusion that the existence of these images proves that a nation formerly existed which navigated ships to Easter Island at regular intervals, and kept the place going as a colony, will be regarded as simply absurd by any one who knows anything of the science of navigation. So small and so isolated an island as Rapanui could only be reached by navigators who had a very advanced knowledge of astronomy and navigation, and were provided with instruments of great precision, and who had determined the position of the island on maps with exact correctness. No Chinese, Japanese, Indian, or Arab navigators could have hit on the island except by accident. An exact determination of longitude, as well as of latitude is involved in the matter. A mere knowledge of the compass with even as good information concerning its variations as we now possess would not avail. The island was discovered by Roggeveen on April 5, 1722; in 1764 Commodore Byron, with two ships, sought for the island in vain; in 1766 Bougainville, with two French ships of war, sought for it also in vain; in 1767 Capt. Cartaret made the same attempt with a similar result. It was only on March 11, 1774, that Capt. Cook found the island again, and Mr. Mott would have us believe that persons who were by the undoubted evidence of their artistic capabilities and method of treatment of the human figure in sculpture, savages, were able to accomplish, as often as they wished, a feat of navigation which baffled some of the best European navigators of the eighteenth century. Even at the present day so difficult is the determination of longitude to persons not specially trained as expert navigators that the island of Bermuda, and even the Virgin Islands have been more than once reported as "gone down" by merchant captains who could not find them.

With regard to Mr. Mott's "gentle protest" against my statement that "the accepted scientific position is that primitive man was savage," no protest, whether gentle or otherwise, will alter the fact that such is the case; but it is quite superfluous to enter into a discussion here on the general theory of evolution, in accordance with which that position is maintained.

H. N. MOSELEY

Silurian Fossils in the Curlew Mountains

I BEG to state that the paragraph which occurs in NATURE, vol. xx. p. 641, that Silurian fossils have been found in beds amongst the Curlew Mountains "supposed to be old red sandstone," is not quite correct. It was very well known in this office that the beds containing the fossils were of the Silurian formation—though erroneously included within the boundary line of the old red sandstone in the Survey Map, sheet 76. Since the map was engraved, the district to the north and east has been surveyed, and a large fault was discovered, ranging in the direction of the spot where the Silurian fossils have been found. The occurrence of this fault explains the presence of the beds with Silurian fossils within the area of the tract coloured as old red sandstone. There is, therefore, nothing in the announcement in your paper of the slightest novelty, and I have only to state that if the writer of the paragraph had communicated with myself previously to "rushing into print," he would have received such information as would have prevented him giving publicity to a statement which however literally correct, is erroneous in essence.

EDWARD HULL,
Director of the Geological Survey of Ireland

Geological Survey of Ireland, Dublin, November 6

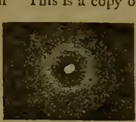
Lunar Ring

WHILE experimenting on the actenic power of lunar light on August 30 last (period of full moon), at 9.30 P.M., I obtained, with a minute-and-a-half exposure, a photographic negative of the moon, which shows a distinct and well-defined ring or glory around it which was not visible to the naked eye on looking directly at the moon in a clear and cloudless sky, nor was there any halo on the ground glass of the camera, nor on the lens, at the time of observation This is a copy of it from the negative.



I used no clock-work arrangement with the camera, but allowed the moon to traverse the plate, and I have since then taken several photographic observations under various conditions. I have taken the moon in all her phases, with long and short exposures, in clear and cloudless sky, and never could get a ring even faintly defined. I have also heated the camera and screwed the cold lens into it, carried it into a colder atmosphere in order to produce condensation of dew. I have placed two small separate openings in front of the lens; on one occasion I dusted puff-ball spores upon the lens; on another I breathed warm breath upon it, but never got anything but decided burr, which was always densest near the limb of the moon and gradually tapered away towards the circumference like a bright light seen through a thick fog, but no appearance of ring. I have also taken observations when scud was passing rapidly over the moon, when perfect prismatic halos were visible to the naked eye, but no ring was ever impressed on the photographs; nothing more than a haze, such as that produced by breathing on the lens. The next full moon (September 29) was totally obscured, so that I failed to get an observation then; but last evening (October 29), at 10 P.M., I was fortunate to get one fine, clear exposure of one-and-a-half minute, and was pleased to see a clear and well-defined ring rise up on the plate during development, similar in every respect to that obtained on August 29, showing clearly that this unusual appearance is dependent upon the position of the moon in her orbit, she being in opposition when she manifests ring-giving power and shows us a crown. But why is this? What is the cause of this unusual, and, I believe, hitherto undescribed, appearance? Why should this ring be invisible to the naked eye and yet give a luminous impression on a photographic plate? Why should it appear only at full moon period and not at any other phase? Can it have any connection with what Mr. Newall saw round Mars through his huge telescope? If the moon had an atmosphere similar to that of the earth, and a star of some magnitude were occulted by the moon at that particular time, it is possible that its light in passing through the lunar atmosphere might be refracted so as to show a corona round the moon; but it is pretty generally acknowledged that there is no atmosphere surrounding it, therefore there can be no refraction.

It might be that the solar rays in passing through the upper regions of the earth's atmosphere are so defracted that the ultra-violet rays (though invisible) are thus rendered visible.

It is also possible that the doubly-reflected lunar light (the ashy light), in passing back to the moon from the earth, encounters on its passage the reflected solar rays from the moon, arresting and nullifying in proportion to its strength, so much of the light proceeding from the moon thereby causing a clear space around the moon-limb, a region of inertia, while the reflection from the disk of the earth, being larger than the moon's reflecting disk, will show itself as a ring on the outer edge of the neutral zone, much in the same manner as two heliographic reflectors would act if they were so arranged as to throw their respective reflections directly into and upon each other, the one being small and the other larger, just as the moon is the smaller and the earth the larger body, the smaller body reflecting a smaller, brighter light, while the larger body would reflect from its broader disk a less brilliant light with a feebler force, yet not so feeble as to prevent it arresting an amount of force equal to itself.

GEORGE BERWICK

Sunderland, October 30

[Dr. Berwick's explanation appears scarcely sound for it involves the assumption that a ray of light meeting another can arrest it; and also it involves the visibility of such rays while traversing space. We would remark that faint halos due to atmospheric causes are often seen almost masked by the brightness of a full moon, and the photograph being over-exposed, so far as the moon is concerned, does not show the relative actinic brightness of moon and halo. Would Dr. Berwick try further experiments with shorter exposures, and also ascertain from a number of photographs how far on either side of full moon a halo can be photographed, and whether it is always present during similar periods?—ED.]

Phosphorescence

A FEW days ago my attention was drawn to the phosphorescence of some fish (haddock) just received from the coast. The light was most brilliant about the fins and inside of the fish, which had been gutted. A spectroscope of low dispersive power showed all the light to belong to the green part of the spectrum. Approximate measures gave 557·5 (mm.) and 488·4 as the extreme wave-lengths, the part from 557·5 to 503·4 being somewhat brighter than the remainder, with a feebly indicated maximum at 527·6.

In the hope of getting a brighter spectrum the fish were washed in as small a quantity of water as possible. This water became highly phosphorescent, and when agitated in a bowl, gave beautiful luminous caustics, but neither in the bowl nor in a glass trough, nor in a tube of half-inch bore, did the liquid give a brighter spectrum than that afforded by the fish.

A large bubble of air was inclosed with the liquid in the tube. When the tube was violently agitated, it became luminous from end to end; if then held vertically, the light rapidly faded except near the top of the liquid, but on suddenly inverting the tube, the bubble of air slowly ascended, causing the whole contents of the tube to phosphoresce very brilliantly. This was a most striking phenomenon. After the lapse of some nine hours, the liquid had almost entirely lost the power of giving light.

RALPH COPELAND

The "False Dawn"

FOR some time past certain considerations had led me gradually to infer that the "False Dawn" of the very extensive literature of Islām, whether Arabic, Persian, or Turkish, &c., and whether prose or verse, is another name for the "Zodiacal Light." No dictionary yet published so explains it.

I submitted my ideas and reasons to a number of English and foreign astronomers and linguists. All expressed their concurrence in those views; but direct proof of their correctness was not at once forthcoming. Recently, however, through the kindness of the Hydrographer to the Admiralty, a most obliging effort was made to solve this question by Capt. Wharton, commanding H.M.S. *Fawn*, now cruising in the Sea of Marmora. The method employed by that officer, and its conclusive result, cannot be better described than by giving his own words as follows:—

H.M.S. *Fawn*, Tuzla Bay,
September 26, 1879

Dear Capt. Evans,

For the information of Mr. Redhouse, I have to tell you that I can satisfactorily answer his question as to the false dawn of the Turks.

On the morning of the 20th instant, at 3.30 A.M., I went to a mosque at Buyukdere, and interviewed the Imaum, who, on being asked for the "fejri kyāzib,"[1] at once pointed out the zodiacal light, then brightly shining in the east. . . . There can be no doubt as to the coincideuce of the two.

Yours sincerely,
W. J. L. WHARTON

[1] "Fejri Kyāzib" is the Arabic expression for "the false dawn."

This preliminary philological question being thus irrefragably settled, I wish to bring to the knowledge of English and western astronomers the fact that, though the zodiacal light was first distinctly noticed in England in 1661, and named in France by Cassini, in about 1683, the "false dawn" was known to the Arabians in the days of Muhammad, who is said by the commentators in the 183rd verse of Chap. II. of the Qur'ān, to have there legislated on the subject as follows, when he instituted the diurnal fast of the Ramazan in the second year of the Hijra (A.D. 624):

"And eat and drink until the lighter streak of the dawn shall become distinguishable unto you from the darker streak."

Commentators, and, after them, the most highly esteemed Arabic dictionary, the Sihāh of Jawhari, who died in A. H. 397 (A.D. 1006) explains the expression "the lighter streak," as meaning "the true dawn," and, "the darker streak" as signifying "the false dawn."

Here, then, is incontrovertible proof that the zodiacal light, under its Arabic name of "the false dawn" was explicitly mentioned 650 years, and implicitly, 1,000 and odd years, before western observers had noticed the phenomenon. This is a point deserving special consideration by all who may in future write a history of the progress of discovery in respect to the zodiacal light. To how much older a time than that of Muhammad, a knowledge of the light may be hereafter traced, is a question that I leave with confidence to those who so fruitfully investigate the fragmentary records of antiquity. I should imagine that no one will suppose Muhammad was the first to take notice of an appearance that is, at times, much brighter than the "milky way."

Another suggestion has also arisen in my mind, of a far wider interest, in connection with my discovery. It is this:—

Modern western Sanskrit scholars have inclined to the idea that the high *plateau* of Pamir, which separates Chinese from Independent Tartary, and the Indus from the Jaxartes, was the primeval cradle of the whole Aryan race. Physically and historically, this hypothesis seems to be utterly untenable, though my reasons would be out of place here. The zodiacal light would appear to confirm my objection.

From the latitude of Pamir, the zodiacal light is a very conspicuous object there, and sure to be noticed by a nation of shepherds, nomads, warriors, and commercial caravan travellers. Had the various Aryan races all come from Pamir, they would have brought thence a knowledge of the zodiacal light, as they all brought the word "yoke" with them from the land whence they radiated. How comes it, then, that in ancient times as in modern, no Aryan, not even after Alexander had nearly reached Pamir, and the Ptolemies had reigned in Egypt for centuries, ever observed or mentioned this phenomenon? My conjectural answer is this: The Aryan race came originally from a northern land, where the zodiacal light is rarely and but dimly visible, radiating from thence as they have done all through the historical period, and as their rearmost representatives, the Slavs, are persistently striving to radiate still to climes more favoured than their own. J. W. REDHOUSE

London, November 5

The Caudal Disk

THE following may throw some light on the use of the caudal disk possessed by many of the Uropeltidæ (*vide* NATURE, vol. xx. p. 538):—

When in the Wynaad, in September, 1875, I captured, at the foot of the Nilgiri Hills, a Silybura, referred, I think, by Col. Beddome to the species, Nilgiriensis. This snake I took down to Mangalore, and kept alive until the succeeding March, when it was unfortunately killed by ants. When caught it was working its way through grass by the road-side, and made violent efforts to escape, striking my hand repeatedly with the pointed terminal scales, by throwing back its tail. I am uncertain whether to view this action as defensive or not. It may have been the result of the snake's struggles, but it is noticeable that the movement was vertical and not horizontal.

I had but few opportunities of investigating the matter, for in a few days the snake became so used to being handled that it would make no efforts to escape.

It was kept in a box filled with earth to the depth of some six inches, and during day-time never was to be seen, but at night came to the surface regularly, and was then much less sluggish than in the day. When taken out of the earth, it would at once commence to bury itself by forcing its pointed snout downwards, and alternately expanding and contracting the thick anterior portion of the body. The motion was exactly that of a worm, and the posterior portion of the body and the tail were dragged slowly after by longitudinal contraction, and were not actively used. During the burrowing process there were occasional pauses of that part of the body above ground, but from the movements of the earth it was evident that the snake was still progressing. So sensitive was the skin that the gentlest breath would hasten the withdrawal of the body, but so soon as the caudal disk was level with the surface the snake would retain it in that position for a long time, sometimes half an hour and more. The numerous keels on the scales of the disk carried a certain amount of earth; the disk invariably remained in the same plane as the ground's surface, exactly filling the hole, and it was therefore almost impossible to detect the snake, without close examination.

These facts suggested to me the idea of the disk being protective, and I therefore, on numerous occasions, unearthed the snake and watched it burrow, always with the same result—the steady withdrawal of the sensitive portion of the body, and the retention of the disk at the surface for a longer or shorter period.

I do not know what are the chief enemies of Uropeltidæ, but possibly certain carnivorous birds prey on them. If so, it is conceivable that the earth-covered disk would secure the snake and its hole from observation, until the head had worked sufficiently far underground to admit of the tail being at once withdrawn, beyond reach of beak or claw. This is quite possible from the power these snakes possess of extending themselves, a power well displayed if one of them be held firmly in both hands. E. H. PRINGLE

P. and O. S.S. *Pekin*, Gibraltar, October

Intellect in Brutes

THE Duke of Argyll in his "Reign of Law" was, I think, the first who promulgated the dictum that man is the only tool-making animal. As far as I can ascertain, this assertion is admitted by developmentists, yet it is undoubtedly true that the Indian elephant makes two *implements*, or forms and alters certain things so as to adapt them specially to fulfil definite purposes, for which, unaltered, they would not be suitable.

One evening soon after my arrival in Eastern Asam, and while the five elephants were as usual being fed opposite the Bungalow, I observed a young and lately caught one step up to a bamboo-stake fence and quietly pull one of the stakes up. Placing it under foot, it broke a piece off with the trunk, and after lifting it to its mouth, threw it away. It repeated this twice or thrice, and then drew another stake and began again. Seeing that the bamboo was old and dry, I asked the reason of this, and was told to wait and see what it would do. At last it seemed to get a piece that suited, and holding it in the trunk firmly, and stepping the left fore-leg well forward, passed the piece of bamboo under the armpit, so to speak, and began to scratch with some force. My surprise reached its climax when I saw a large elephant leech fall on the ground, quite six inches long and thick as one's finger, and which, from its position, could not easily be detached without this scraper, or scratch, which was deliberately made by the elephant. I subsequently found that it was a common occurrence. Leech-scrapers are used by every elephant daily.

On another occasion, when travelling at a time of year when the large flies are so tormenting to an elephant, I noticed that the one I rode had no fan or wisp to beat them off with. The mahout, at my order, slackened pace and allowed her to go to the side of the road, where for some moments she moved along rummaging the smaller jungle on the bank; at last she came to a cluster of young shoots well branched, and after feeling among them, and selecting one, raised her trunk and neatly stripped down the stem, taking off all the *lower* branches and leaving a fine bunch on top. She deliberately cleaned it down several times, and then laying hold at the lower end broke off a beautiful fan or switch about five feet long, handle included. With this she kept the flies at bay as we went along, flapping them off on each side every now and then.

Say what we may, these are both really *bonâ fide* implements, each intelligently made for a definite purpose.

S. E. PEAL

A COCHIN-CHINA REMEDY FOR LEPROSY

A NOTE in NATURE (vol. xxi. p. 19) refers to a remedy for leprosy, obtained from Cochin-China, but the origin of which is imperfectly known. Its name is given as *hwang-nao.* In Mr. Consul Tremlett's Report (For. Off. Repts. No. 21, p. 1237) it appears as *hoang-nau.* We have taken a good deal of trouble about this drug at Kew, and the inclosed extract from the Kew Report for 1877, p. 31, contains all that has been positively ascertained about it at present:—

"*Hoâng-nan, a Supposed Remedy for Leprosy.*—Mr. Prestoe, Superintendent of the Trinidad Botanic Garden, has drawn my attention to some accounts given in *Les Missions Catholiques* for 1875, describing the surprising efficacy of a drug, the produce of a plant found in Cochin-China, in the treatment of leprosy and rabies. The plant is known by the name of Hoâng-nan, and the description, which is of the vaguest kind, represents it as a climber, and its bark as the efficacious portion.

"M. L. Pierre, the Director of the Botanic Garden at Saigon, has obtained an imperfect specimen of the Hoâng-nan, and informs me that he identifies it as a new species of *Strychnos*, which he has named *S. gautheriana*, in honour of the ecclesiastic who first gave the virtues of the Hoâng-nan a wider publicity.

"M. Pierre adds some remarks which appear to me worthy of placing on record:—'The bark of *Strychnos nux-vomica* is regarded in Cambodia and Siam as a poison no less certain than that extracted from the seeds. The natives have remarked the fact, which is also believed to hold good in the case of cinchonas, that the bark has the most powerful properties when it has been covered with moss or otherwise protected from the action of light.' In collecting the bark great attention is paid in consequence to the circumstances under which it has been produced." W. T. THISELTON DYER

SOME POINTS IN THE HISTORY OF SPECTRUM ANALYSIS[1]

A PHYSICAL problem begins like a rivulet. At its first introduction it is small and seemingly unimportant—constantly however, as it winds along it receives accessions from various quarters until at length it becomes a mighty river that is finally merged in the unfathomable ocean. This course is followed by all such problems. Each begins small—grows broader and will finally bear us on to the unknown if we trust ourselves to its guidance.

I need hardly remind you that the demonstration of the decomposition of white light was one of the triumphs of the illustrious Newton. But like other problems it had its small beginning. We find in one of the earliest memoirs of the Royal Society, a paper on "The Genuine Method of Examining the Theory of Light and Colours," by Mr. Newton. Here he asks amongst others, the following questions:—

(1) Whether rays that are alike incident on the same medium, have unequal refractions?

(2) Whether rays endued with particular degrees of refrangibility, when by any means separated, have particular colours constantly belonging to them, viz., the least refrangible scarlet, the most refrangible deep violet, the middle sea green; and others other colours?

(3) Whether colours by coalescing do really change one another to produce a new colour, or produce it by mixing only?

(4) Whether a due mixture of rays, endued with all variety of colours, produces light perfectly like that of the sun? and he ends by remarking that the most proper and direct way to a conclusion is to determine such queries by experiment. Then follow some objections to the theory of light and colour, by the Rev. F. Pardies and Mr. Newton's reply to these objections. Into the nature of these however, it is not my purpose to enter. Let me rather adopt Newton's suggestion and bring the experiment itself before you.

You are all, no doubt, familiar with the operations of the photographer, and as a matter of fact you know that when the light from a natural object is made to pass through his lens an image of this object is impressed upon the sensitive plate placed at the focus at the other side of the lens.

If the natural object be a friend's face you obtain his photograph, if it be a tree, you get the image of the tree, if it should be a bright slit of light or a bright wire you would get the image of the slit of light or of the wire. Now here we have a slit which is rendered luminous by an intense light thrown upon it, and if we place a photographer's lens before it we shall obtain an image of the slit. You see the image thrown upon a screen and you see moreover that the light is white; it is in fact the electric light which illumines the slit. For the machine by which this light is produced our college is indebted to the generosity of Mr. Wilde. But my object is not now to discuss the electric light, but to show you that it is white and like the light of the sun—since, as you see, its image on the screen is white. Let us now interpose a prism or train of prisms between the lens and the screen. These prisms will do two things. In the first place they will bend the rays towards the base or thick part of the prisms so that in order to catch the image the screen must be moved in this direction. But in the second place they will bend some rays more than others;—if the slit be lighted by pure red light it will be least bent, if by orange, this will be more bent than the red, if by yellow this will be more bent than the orange, then follow green, blue, indigo, and violet, the latter of which is most bent.

Now if the light behind the slit be a mixture of red, orange, yellow, green, blue, indigo, violet, we shall have a series of images of the slit overlapping one another, and forming a long ribbon of light of which the portion least bent will be coloured red and that which is most bent will be violet. Let us now see what we get from the light we are using. Here you see we have all the colours of the rainbow, red, orange, yellow, green, blue, indigo, violet, and therefore our light must contain all these; but our light was white like that of the sun and thus you see we are entitled to say that white light is composed of a mixture of these various colours.

In fact what we have done by the prism has been to separate these various constituent rays from one another and throw one on one part of the screen and the other on another part. But now if we make these various constituents to dance so quickly before our eyes that we get a united impression of the whole, we shall imagine once more that we have white light. We separated the rays in space—let us now combine them in time—and you see the thing is white. We have thus demonstrated the composition of white light after the way by which the chemist proves the composition of water, first decomposing it by the battery into oxygen and hydrogen, and then causing these two gases once more to recombine. I will now remind you that light consists of waves or undulations given out by the luminous body. These waves take place in a medium called ether, surrounding us all, in which they proceed with incredible swiftness. The light given out by a luminous particle may thus be compared to the note or notes given out by a bell. In solids and liquids however the particles are so closely packed together that they may be likened to a number of different bells all tied together in such a way that the total mass is capable of giving out every, or almost every, variety of note. From an incandescent solid or liquid body, when sufficiently hot, you thus get every variety of light, and

[1] Being an address delivered by Dr. B. Stewart, F.R.S., at the opening of the present session, to the Natural Philosophy Classes at Owens College.

it is particles of carbon, probably in the solid state, that in the electric light afford us every variety of ray so as to enable us to get from them a continuous spectrum. When, however, we go from solid and liquid particles to those of a gaseous nature, we find the various molecules so far apart that each one is unconstrained by its neighbour; it is thus like a bell left to itself, in which case it gives out its own peculiar kind of light just as a bell, left to itself, will give out its own peculiar note. I will now show you on the screen the various rays or luminous notes given out by particles of incandescent vapour of silver.

We thus see what is the spectroscopic difference between solids or liquids, and gases, the former when sufficiently heated giving out a continuous spectrum consisting of all different rays of light, the latter a discontinuous spectrum consisting of only a few different rays.

The next point to which I will call your attention is a very important one. A particle when cold or comparatively cold absorbs those very rays which it gives out when hot. Now it is known that incandescent vapour of the metal sodium, gives out under certain conditions a peculiar monochromatic yellow light, which we call the double line D. This light is so strictly monochromatic that all bodies under its illumination appear either yellow or black, as you will see by the following experiment.

Now suppose we take the electric lamp, the carbon points of which, as you already know, give out all kinds of light, and suppose we place between these points a piece of metallic sodium; while this sodium is in the act of being volatilised, and its vapour comparatively cold, you will see that it will stop one particular kind of light, and will thus cause a black line. When, however, the vapour is sufficiently hot, this black line will be changed into a bright yellow one. You thus see that when we have an incandescent body which gives us all rays, and when between it and the eye we insinuate some comparatively cold sodium vapour, we get a certain definite black absorption line.

Now the curious point is that the sun's light gives us this black line, so that if I could replace the electric light by the sun, I should have a black line thrown upon the screen in the very position where you saw it when the sodium was introduced.

This means that between the source of the sun-light and the eye, we have sodium vapour in a comparatively, remember only comparatively, cold state, and as this vapour is certainly not in the earth's atmosphere, it can only be in the atmosphere of the sun. I need not tell you that although colder than the particles beneath it which give us sun light, it must be in reality very hot. The discovery that there was vapour of sodium in the atmosphere of the sun was due to Stokes, and it has since been found out by Kirchhoff that we have black lines in sun light corresponding in position with the bright lines of iron vapour, the bright lines of hydrogen, the bright lines of magnesium vapour, and the bright lines of many other elements, and we may therefore assume as Kirchhoff assumed, as a first and approximative hypothesis, that the vapours of iron, magnesium, hydrogen, &c., as well as that of sodium exist in a comparatively cold state in the atmosphere of our luminary;—more recent work by Huggings and others has shown that the same remark applies to the atmospheres of many other stars.

You thus see that there are two ways by means of which the chemical composition, or rather perhaps the atomic structure of bodies may be indicated by the spectrum. At a comparatively low temperature this structure will be indicated through the lines that are absorbed or rendered black, while at a comparatively high temperature it will be indicated by the bright lines that are given out.

Thus at a comparatively low temperature a solution which contains blood will indicate the presence of this substance by certain very peculiar black lines. Blood, however, is easily decomposed by a high temperature, and accordingly when such is applied we no longer get the bright equivalents of these black lines, but something very different, namely, the bright lines of iron, and of those other elements into which blood is decomposed as the temperature is raised. In short when raising the temperature of a substance its black lines will be converted into bright ones only in those cases where no molecular change has taken place between the two temperatures. Even in the case of elements like sodium Roscoe and Schuster have shown that the absorption spectrum at a low temperature is different from, and more complex than, the radiant spectrum at a high temperature, and other elements have been tried in this way by Lockyer and others with similar results. We may imagine with much propriety that the molecule of sodium vapour at a low temperature is a larger and more complex structure than it is at a high temperature, where the splitting up or dissociating agency of heat has been freely employed.

We come at last to the important question which it is my object to discuss. Has a study of the spectrum thrown any light on the ultimate constitution of matter, or is it likely to do so?

You are aware that chemists and physicists have begun to speculate as to the possibility that the so-called elements may be in reality nothing more than combinations differing in numbers and in tactical arrangement, of some one kind of primordial atoms.

This idea was first entertained by Dr. Prout, the well-known physician and chemist. He pointed out that the atomic weights of the so-called elements are very nearly all multiples of the half of that of hydrogen, so that the various elements may possibly be looked upon as formed by a grouping together of certain atoms of half the mass of the hydrogen atom.

M. Stas, the distinguished Belgian chemist, instituted a laborious series of experiments with the view of testing this doctrine. He came to the conclusion that the atomic weights of the various elements were not precisely multiples of the half of that of hydrogen, there being greater differences than could possibly be accounted for by errors of experiment. His researches, however, seemed to show that in many cases there was a very near approach to Prout's imagined law. But here we must bear in mind the great difficulty, or indeed impossibility, of obtaining substances absolutely free from all impurities (indeed Dumas showed that oxygen forms part of the silver with which Stas worked), so that we may be excused from imagining that Stas has settled the point in the negative. We are thus driven to look to the spectrum as a likely means of throwing some light on this very interesting and important speculation.

Let us now, therefore, endeavour to realise what would be the behaviour of the spectrum if the so-called elements were not capable of simplification, and also what would be its behaviour if they were, and then find with which of these two hypotheses the true behaviour of the spectrum agrees best. Now if the elements were absolutely simple bodies, we might still expect that the molecule of vapour of an element would be at a low temperature more complex than at a high one, and would therefore give out a more complex spectrum. As, however, the temperature was made to rise we might expect ultimately to obtain a certain spectrum which would represent the simplest mode of vibration of that element, and which would thenceforward remain, however much higher the temperature should be made to mount. Lockyer has written much on this point and given many facts in support of this view.

And again we should have no reason for supposing that the lines of the ultimate spectrum of one element should coincide in position with those of the ultimate spectrum of another element. If therefore we had a mixture of all the elements, and subjected this mixture to a very high temperature, the resulting spectrum under the supposition that each element is really an element, would never be simpler than the combined spectra of the various elements.

On the other hand, if the elements were really compounds of some one primordial atom, we might expect that a very high temperature would split up their atomic structure, and simplify their spectra, so that at an enormously high temperature a mixture of all the elements might nevertheless give us a very simple spectrum. We might likewise expect that different elements might split up into common constituents, so that at a very high temperature the spectra of these elements would have certain lines in common.

It is in the larger masses of the Universe, the sun and stars that we must look to find a mixture of all kinds of matter at very high temperatures, and when we have a brilliant bluish-white star containing a large proportion of the more refrangible rays we have every reason for supposing this star to be at a very high temperature. Now such stars exhibit an extreme paucity in the black lines which appear in their spectra, in which there is hardly anything else than certain prominent lines seen in the spectra of hydrogen, calcium, magnesium, and sodium. Lockyer, who has devoted great attention to this subject, argues therefore as follows. If it be true that as a rule the atmospheres of the whiter and presumably hotter stars contain fewer elements and those of the smallest atomic weight and that as stars diminish in whiteness their atmospheres rise in complexity of structure this undoubtedly tells in favour of the power of high temperature to split up the so-called elements. He has quite recently carried this reasoning into another field. The Fraunhofer lines give us the integration of the absorptions of all the strata of the solar atmosphere. Now spot phenomena occur in a restricted stratum of this atmosphere, and this stratum is low and therefore hotter than the overlying portions. We can tell the spectral lines special to a spot by their widening, and the number of lines widened is small in comparison with the Fraunhofer lines. Here again we have simplicity brought about by high temperature in the low levels in the sun as in the stars hotter than the sun.

Let us now ask whether the spectra of the various elements have or have not certain lines in common. It used to be imagined that they had not.

When, however, they have been examined under great dispersive power there has been found reason to qualify this assertion. There are certain lines in the spectra of each element which appear long and thick, their predominant notes as it were, and it has been found that while such a line for instance is exceedingly prominent in some one element other elements appear to possess it, only not nearly so prominently. Lockyer's argument from this was that, on the assumption that the elements are truly elementary, the line in the other elements was caused by traces of impurity. He has, however, recently had reason to believe that there are coincidences between the spectra of the various elements not of this nature. There are coincidences of lines which are not the prominent lines of any one spectrum and they give no signs of that variability of brightness that might be expected to characterise lines due to impurities. These lines he has called basic lines. As may be readily imagined in a branch of knowledge which is so new we shall have long to wait for facts. Hence we cannot test this conclusion by referring to the spectra of stars. But Lockyer has already shown that we can test it by means of the spectra of sun-spots, and here the facts are certainly in support of it. The basic lines are more prominent in the spectra of spots than in the spectrum of the sun generally, and further they are more prominent at epochs of sun-spot maximum than during times of minimum.

But we must have a clear conception of what we mean when we suppose that the so-called elements are split up at a very high temperature.

If we apply a very powerful source of electricity we obtain certain peculiar lines from the vapour of calcium.

Now if we could (like the Demon of Maxwell) catch hold of and segregate—put into a box as it were all these minute entities that give us this suspicious line at a high temperature, and further if we could keep their high temperature up I think it is probable that we might obtain something which is not calcium, or at any rate, something simpler than the molecule of calcium as this appears at lower temperatures. But we are not yet able, and perhaps we may never be able, at an ordinary temperature to present the chemist with some other substance derived from calcium which is not calcium.

To conclude there seems little doubt that spectrum analysis will, as it advances, throw great light on the ultimate constitution of matter and it therefore justifies the remarks which I made at the commencement of this lecture.

THE SWEDISH NORTH-EAST PASSAGE EXPEDITION

DESPATCHES have been received by Mr. Oscar Dickson, of Gothenburg, from Prof. Nordenskjöld, giving an account of the wintering of the *Vega*, down to April 1; letters from Lieut. Palander and other members of the North-East Passage Expedition have also been published, some of them bringing down the narrative to a later date. From these we gather the following particulars:—

The *Vega* was frozen in on September 28, in 67° 7′ N. lat. and 173½° long. W. from Greenwich, at the northernmost extremity of Behring's Straits. The land in the neighbourhood forms an extensive slightly rolling plain, bounded on the south by gently-rising hills, which, farther into the interior, are said by the natives to reach a considerable height. The plain is occupied to a large extent by lagoons separated from the sea by low sandy beaches. When the *Vega* was frozen in, the ground was covered with hoar frost and frozen, but still free of snow, so that it was possible to form some idea of the flora of the region. Close to the beach, compact beds of *Elymus* were intermixed with carpets of *Halianthus peploides*; next there stretched a poor level gravelly plain, only covered with a black lichen, *Gyrophora proboseidea*, and some few flowering plants, amongst which *Armeria sibirica* was the most common. South of this, again, was a tract occupied by lagoons and small lakes, whose shores were covered with luxuriant vegetation, consisting of grasses and *Carices*. On the neighbouring high ground, where the soil, derived from weathered strata of gneiss and dolerite, is richer, the vegetation is marked by greater variety. Here were thickets of willows, extensive carpets of *Empetrum nigrum*, and *Andromeda tetragona*, and large tufts of a species of *Artemisia*. Here were found also the frozen remains of the red whortleberry, the cloudberry, *Taraxacum officinale*, and other plants peculiar to the high north. In an excursion to the interior on October 8, Lieut. Nordquist observed that on the driest parts of the *tundra* the most common plants were *Aira alpina* and *Poa alpina*; on the lower places, *Glyceria, pedicularis*, and *Ledum palustre*. *Petasites frigida* and a species of *Salix* occurred everywhere, the latter growing in large compact masses covering spots several hundred square feet in extent, the bushes in some places being 3 to 4 feet high.

In the neighbourhood of the *Vega's* winter quarters there were six small encampments, numbering from three to twenty-five tents each, inhabited by Tchuktches to the number of about 200. With these natives there was much friendly intercourse. They were allowed free access to the deck from which, though covered with a multifarious variety of articles, they did not remove the smallest trifle. They were not, however, altogether to be depended on in the statements they made regarding the articles they offered for sale. Thus, on several occasions what were represented to be hares were found to be dead foxes skinned and with the head and feet cut off, and the natives expressed great astonishment at the instant discovery of the deception. When they had acquired a taste for European food, they bartered drift-wood and the bones of the whale for ship-biscuit, and the quantity distributed partly in this way, partly as gifts, was so considerable as to contribute in no small degree to mitigate the famine that threatened to break out among the natives in mid-winter. None of them were Christian, nor could any of them speak any European language, except one or two who could say a couple of words in English or a word of salutation in Russian. Lieut. Nordquist studied their language with such zeal and success, that in a fortnight he could make himself pretty well understood. He has collected materials for a comprehensive vocabulary.

When the *Vega* was frozen in, the sea next the coast was covered with newly-formed ice, too thin to carry a foot-passenger but thick enough to prevent a boat from making any way. On October 3 the Tchuktches walked on board over the ice. Up to the 10th there were weak places between the vessel and the land, and a blue sky in the east still indicated open water in that direction. On the 13th it was ascertained that a belt of drift ice-fields, compactly frozen together, at least thirty kilometres in breadth, lay between the *Vega* and the open sea. The thickness of the newly-formed ice was measured by Lieut. Bruzewitz, with the following results:—

The Thickness of the Ice

On December 1	56	centimetres.
,, January 1	92	,,
,, February 1	108	,,
,, February 15	120	,,
,, March 1	123	,,
,, April 1	127	,,
,, May 1	154	,,
,, June 1	154	,,
,, July 1	103	,,

For a distance of about six kilometres from the shore the ice lay all winter nearly undisturbed, but farther out it was in continual motion. So-called polynia, or open places, says Nordenskjöld, probably occur here all the year round, and in favourable weather accordingly we could see almost constantly a blue water-sky from true north-west to east. A southerly wind in a few days brought the open water within a few hours' walk of the vessel. It then swarmed with seals, which indicates that it was in connection with a sea always open. The neighbourhood of such an open sea probably accounts for the fact that in the fields of drift-ice that surrounded the vessel there was not a seal-hole to be seen. On January 1 Lieut. Bove reached open water by a four hours' walk. From the fact that from a hummock five metres high he could see no boundary to the open water towards the north-east and north, and from the extent of the water-sky in that direction, he concluded that the breadth of the open water was at least thirty-five kilometres. The depth at the edge of the ice was twelve fathoms, the temperature $-2°$ C. The water ran at a considerable speed right from the coast (from south-south-east), apparently a tidal current. The open water swarmed with seals. No polar bear, no walrus, and no birds were seen.

During the long-continued severe cold in the month of January, in the course of which the temperature several times fell below the freezing-point of mercury, the sea appears to have frozen completely for a great distance from the coast. but by February 7 mild weather again commenced, with variable and southerly winds. The same day a faint water-sky was seen at the horizon. Some kilometres to the east the beach was free of ice, and from the heights on land the seamen observed a high sea in the blue streak of water which bounded the horizon. The open water thus appears to have been very extensive. The statement of the natives that it extended to Behring's Straits was perhaps correct.

The temperature during the wintering was as follows:—

	Minimum. °	Maximum. °	Mean. °C.
October	− 20·8 ...	+ 0·8 ...	− 5·21
November ...	− 27·2 ...	− 6·3 ...	− 16·59
December ...	− 37·1 ...	+ 1·2 ...	− 22·81
January	− 45·5 ...	− 4·1 ...	− 25·05
February	− 43·8 ...	+ 0·2 ...	− 25·08
March	− 39·8 ...	− 4·2 ...	− 21·65
April	− 38·0 ...	− 4·6 ...	− 18·93
May	− 26·8 ...	+ 1·8 ...	− 6·97
June	− 14·3 ...	+ 6·8 ...	− 0·60

On two occasions the barometer was uncommonly high, viz.,

December 22, 6 A.M. 782·0 (0°) mm.
February 17, 6 A.M. 788·1 (0°) mm.

The lowest atmospheric pressure observed before April 1 was on

December 31, 2 A.M. 728·8 (0°) mm.

The weather during the winter was exceedingly stormy, and the direction of the wind near the surface of the earth was almost constantly between north-west and north-north-west. But in a stratum of air at no great height there prevailed, to judge from the motion of the clouds, a similar uninterrupted current from the south-east, which when it occasionally sank to the surface of the earth, brought with it heat and comparatively dry air. This is explained by Behring's Straits forming a gate bounded by high hills between the warm atmospheric area of the Pacific, and the cold area of the Arctic Ocean. The winds must here arrange themselves approximately according to the same laws as the draught in the door-opening between a warm and a cold room. The cold stream of air must go below, and the warm above. The mountain heights which the natives say are to be found in the interior of the Tchuktch Peninsula, besides, contribute to the heat and dryness of the southerly and south-easterly winds. For they give to the winds which pass over their summits the properties of the "föhn." The coldest winds have come from south-west to west, that is, from the Siberian Plain. On the existence of two currents of air which, at a certain height above the surface, contend with one another for the mastery, depends again the speed with which the sky in the neighbourhood of Behring's Straits suddenly becomes cloudy and again completely clear.

Nordenskjöld remarks that the fall of snow was not particularly great, but as there was no mild weather of any continuance during the winter, so that the snow was never covered with any continuous crust, a considerable portion of the snow remained so loose that it was carried backwards and forwards by the least puff of wind. With a storm or strong breeze, the snow was carried to higher strata of the air, which was so filled with the fine particles, that it was impossible to distinguish objects at the distance of a few yards. But even when the wind was light and the sky clear, there went on a constant snow-storm a few inches in height along the surface of the ground in the direction of the wind, and so principally from north-west to south-east, carrying an immense mass of water in a frozen state over the north coast of Siberia to more southerly regions, and playing a sufficiently important part in a climatic respect, among others as a carrier of cold to the most northerly forests, to deserve the attention of meteorologists.

The most remarkable observations which the wintering of the *Vega* has yielded appear to relate to the aurora. Our voyage happened in one of the years, writes

Nordenskjöld, of which it was known beforehand that it would be a minimum aurora year. Just this circumstance has, however, allowed me to study, in a specially suitable region, this natural phenomenon under uncommonly favourable circumstances. For here the luminous arches, which also in Scandinavia generally form the starting-points of the ray-auroras, have shown themselves undimmed by the more splendid forms of the aurora, and one could thus devote one's self to collect observations towards a clearing-up of the right nature of these arches undisturbed by accidental accompaniments. Referring for details to a paper he has sent home for publication in the *Transactions* of the Swedish Academy of Sciences, he goes on to say that the aurora, during the winter 1878-79 never appeared with the splendid bands or draperies of rays so common in Scandinavia, but always in the form of faint luminous arches, which remained unaltered in position hour after hour and day after day. They were *constantly* visible when the sky was not clouded nor their feeble light dimmed by the rays of the sun or the full moon. The conclusions Nordenskjöld draws from numerous measurements of the height, extent, and position of these arches are, that our globe, even during a minimum aurora year, is ornamented with a nearly constant corona or circle of light, single, double, or multiple, whose inner edge during the winter of 1878-79, had a height above the surface of the earth of about $\frac{8}{100}$ of the earth's radius, whose centre, the "aurora pole," was situated on the radius of the earth which touches the surface about 81° N. lat. and 80° W. lat. (Greenwich), and which, with a diameter of 0·3 of the earth's radius, extended itself in a plane at right angles to the radius of the earth which touches the centre of the circle. This circle of light stands in the same relation to the ray- and drapery-auroras of Scandinavia as the trade-winds and monsoons in the south to the irregular winds and storms of the north. Its light is never distributed into rays, but resembles that which passes through obscured glass. When the aurora becomes stronger the extent of the circle of light is altered, double or multiple arches are visible, generally lying in the same plane and with a common centre, and rays are thrown out between the different bows. Arches are seldom seen lying irregularly to or crossing one another. The area within which the *common arch* is visible (on the supposition that it can no longer be distinguished when its altitude is only 4° above the horizon) is bounded by two circles drawn upon the earth's surface with the aurora pole as the centre, by radii revolving round it at angles measured on the earth's circumference of 8° and 28°. It touches only to an inconsiderable extent lands inhabited by peoples of European origin (the northernmost part of Sweden, Norway, Finland, Iceland, and Danish Greenland), and even in the middle of this area there is a belt passing over the middle of Greenland, the south of Spitzbergen, and Franz Joseph's Land, where the *common bow* commonly forms only a faint "veil" of light in the zenith. This belt separates the regions where the luminous arches are seen mostly on the southern from those where they are seen mostly on the northern horizon. In the area nearest the aurora pole only the smaller, in the middle of Scandinavia only the larger and less regularly formed coronas are visible. But in the last-mentioned region, as in Southern British America, the aurora-storms and the ray- and drapery-auroras become common. The region where the aurora occurs in its most developed state is to be sought for near the circle which, with the aurora pole as a centre, is drawn on the surface of the earth with a radius at an angle measured at the earth's circumference of about 24°.

The tidal observations, when compared with other series made in the Arctic seas, give important indications regarding the distribution of land and sea in the Polar basin. The greatest range at the *Vega's* winter-quarters was only eighteen centimetres, which shows that the sea north of Behring's Straits forms a marine basin of limited extent, connected with the ocean only by sounds. The variations in the height of the water, produced by winds, were much greater. They amounted nearly to two metres. Still greater irregular changes in the position of land and sea appear to have occurred within the memory of man. For the Tchuktches were at one time afraid that the Swedes would cause inundations along the coast. This appears to show that the sudden changes in the position of the earth which are well known in the volcanic regions farther south had extended so far noth. As most of the Tchuktch villages are situated close to the sea, one of the mighty waves which earthquakes give rise to would completely destroy an immense number of them.

The magnetical observations made during the wintering, in an observatory built of ice and snow, which, being necessarily on land, was at a very inconvenient distance from the vessel, consisted of (1) absolute determinations whenever opportunity offered; (2) observations of the changes in the strength and direction of the magnetic forces made along with necessary absolute determinations every hour between November 27 and April 1; (3) five-minute observations on the 1st and 15th of every month from and including January 15.

With reference to the natural history of the region in which the *Vega* wintered, Prof. Nordenskjöld states that it is very poor in the higher plants and fungi, but lichens are abundant. The number of insects and other invertebrate land animals was very small. Land- and fresh-water mollusca were completely wanting. Of coleoptera only twenty species were found, belonging principally to the families *Carabi* and *Staphylini*, with two *Curculiones* and *Chrysomelæ*, and the other orders appeared to be equally poor, with the exception, perhaps, of the *Diptera* and *Podurida*. On the other hand the sea-bottom, though covered with a stratum of water always about 2° C. below the freezing-point, swarmed with a large number and a great variety of the lower animal types, of which the dredging-boat almost daily made a rich collection in the channel, which opened early in summer in the neighbourhood of the vessel. Prof. Nordenskjöld expected that the same avifauna would be found with little variation in all the Polar lands. Experience has, however, shown that this is by no means the case, the Tchuktch peninsula being quite an exception. Birds here occur in much fewer number, but in a much greater abundance of types than in Novaya Zemlya, Spitzbergen, and Greenland, and the bird-world in its entirety has thus quite a different stamp. The birds common on Greenland, Spitzbergen, Novaya Zemlya, and the coast of North-west Siberia, *Larus glaucus*, *eburneus*, and *tridactylus*, *Harelda glacialis*, *Somateria spectabilis*, *Plectrophanes nivalis*, *Phalaropus fulicarius*, and *Tringa maritima*, the common raven and several other species, are found here. But in addition to these the following uncommon birds are met with:—The American eider, the common eider, *Somateria mollissima*, being absent; a greyish-brown goose with bushy yellowish-white feathers round the neck; a swan-like goose, white with black wing-feathers, a species of *Fuligula* marked in white and green with a fine black-velvet head, the beautifully-marked, uncommon *Larus Rossi;* a little brown snipe with a bill widened spoon-like at the point; several beautiful singers, among them *Sylvia Eversmanni*, which for some days visited the coast in great flocks, probably on their way to breeding-places farther north, or waiting till the bushes in the interior should be free of snow. A portion of the purely Scandinavian species here exhibit some variations in colour-marking and size.

The mammalia are also more numerous than in other places visited by the Swedish expeditions. According to Lieut. Nordquist the most common mammal is the hare. It differs from the common Scandinavian mountain hare by its greater size (its weight often rising to

14 lbs.) and by the nasal bone not diminishing so rapidly in size. The mountain fox (*Vulpes lagopus*, L.) is very common. The common fox (*Vulpes vulgaris*, Gray) appears also to be common. A red fox, shot in October, differs considerably from the common, and approaches the mountain fox in several particulars. The fox's food during winter appears to consist of hares, ptarmigans, and lemmings. Of lemmings three species were met with, *Myodes obensis* (the most numerous), *M. torquatus*, and *Arvicola obscurus*. The Tchuktches state that a little mouse also occurs, which Nordquist supposes to be a *Sorex*. The two lemmings often showed themselves above the snow during winter, which was not the case with *Arvicola obscurus*. The wolf was seen only twice. The wild reindeer was also uncommon, traces of them having been seen only once. Traces of the land-bear were also seen, and the natives stated that they were not uncommon in summer. The marmot (*Arctomys*) occurs in abundance. An animal described by the natives as living by the banks of streams is supposed to be the common otter. Two weazel-skins were obtained from the natives. It is not certain whether the ermine occurs there. Only two marine mammals have been seen during the winter, the Polar bear and the ringed seal (*Phoca fœtida*). The latter is caught in great numbers, and along with fish and various vegetables forms the main food of the natives. Of land birds there winter in the region only three species, viz., *Strix nyctea*, *Corvus corax*, and *Lagopus subalpina*. The last-mentioned is the most common. On December 14 two large flocks of ptarmigan, one numbering about fifty, were seen about ten miles from the coast. The raven is common at the Tchuktch villages. Its first egg was obtained on May 31. The mountain owl was seen for the first time on March 11, but according to the natives, it is to be met with all winter. In open places on the sea there occur during winter, according to the natives, two swimmers, *Uria Brünnichi* and *Uria grylle*. Besides these there possibly winter on the sea a species of *Mergulus* and one of *Fuligula*, a specimen of the former having been obtained on November 3, and of the latter on March 9.

(*To be continued.*)

GALILEO AND THE APPLICATION OF MATHEMATICS TO PHYSICS[1]

TWO hundred and ninety-eight years ago to-day (November 5, 1581) Galileo Galilei, then a boy between seventeen and eighteen, matriculated as a medical student in the University of Pisa. At that time Medicine was perhaps the least satisfactory of scientific studies, and though his family had influential professional connections, the empirical maxims and the semi-metaphysical reasons by which they were supported never caught the young man's fancy or satisfied his intellect. We first hear of him listening outside the door in which Ricci, the Court mathematician of Florence, who happened to be spending some time at Pisa with the Grand Duke, taught the pages a little Euclid. For a couple of months Galileo neglected his medicine, and greedily absorbed his Euclid through the key-hole till he found some chance opportunity of introducing himself to the Professor, who was delighted with his new pupil. Ricci presented him with a volume of Archimedes, and the great mathematician and physicist of Syracuse became the spiritual father of the young Italian student. In spite of the straitened circumstances of his family, and the chances of fortune that awaited him in a decorous prosecution of his regular medical studies, he deserted them, and attached himself to Ricci.

Watching one day the long swing of a lamp hung from the roof of a church, we are told that he noted the times it took in oscillation after oscillation, and found that though the arc through which it swept died down till it was scarcely visible, the time it took from each farthest right hand point to the succeeding farthest left hand point of its sweep was always the same. He applied the knowledge he had gained at once to the more accurate measurement of the regularity of the pulse beats. The observation of the student, and the immediate practical application of it, was the sure forerunner of the greatness of the man. He knew that Science is Measurement three centuries before Comte laid it down as the definition of mathematics, or Marks had been born to caricature the maxim in his diploma picture.

At that time the Peripatetic philosophy was dominant over Europe, and tyrannized in Italy. The followers of Aristotle naturally travestied the errors of their master. In his own time Aristotle was a genuine observer of nature, and, as Galileo afterwards said of him, he would have been the last to dispute a fact because it contradicted his preconceived opinions. His followers, who were not observers, had constituted a universe on high *a priori* principles. They taught that there were two great classes of things perishable and terrestrial, one heavy, tending by an irresistible law of their essential nature to the mathematical centre of the universe, the other light, and tending irresistibly away from it. Things imperishable and extra-terrestrial moved by a like necessity in everlasting circles round the centre of all things. A body of 2 lbs. weight, having more tendency to the centre than a body of 1 lb., must fall faster, and acquire a greater velocity in an equal time. With *a priori* principles like these observation was superfluous. Galileo questioned them and put them to the *examen rigorosum* of experiment. The explanation of the isochronism of the larger or smaller swings of the pendulum lay in the fact that though when the moving lamp started from a higher point it had further to fall—it began to fall more nearly perpendicularly and faster, and it swept through its larger arc with a greater velocity at every point. When he took two such pendulums of equal length, to the end of one of which a lamp weighing 1 lb. was fastened, and to the end of the other a weight of 2 lbs., Galileo found that their times of oscillation were the same.

The Peripatetic dictum of the greater gravity of heavier bodies was in contradiction with this simple fact. Galileo took the two weights to the top of the hanging tower of Pisa, and let them fall. They fell at the same or practically the same instant. Though the simultaneous thud of these two weights on the ground was the death-blow of the Peripatetic assumption, it was not enough to convince teachers who had grown grey in teaching it. But a moment's thought now will serve to show us not merely that it is so, but why it must be so. Instead of the mass of 2 lbs., imagine for a moment that the 2 lbs are made up of two single pound weights, each identical in shape and material with the other mass of 1 lb., and that all three drop together. All three will come to the ground together. If the two pound weights are made to adhere to each other by ever so thin a film of glycerine, there will be no strain on the film, and they will not separate. If an imaginary section is cut through a single mass of two pounds there will equally be no strain or shearing force along that section. The tendency of the two single lbs. downwards is twice as great as that of the 1 lb., but it has to move two masses instead of one. Ten runners who keep abreast of each other do ten times the work of an eleventh runner on the other side of the course. Man for man, each does the same work, and each man's work has the same effect in producing the racing speed of each. An imaginary or real thread might tie the ten together, but there would be no strain on the thread, which would not snap, if their rates of running were the same.

Galileo often returned to the pendulum, and completely

[1] An Introductory Lecture, by William Jack, M.A., LL.D., F.R.S E., Professor of Mathematics in the University of Glasgow, formerly Fellow of St. Peter's College, Cambridge.

established the laws of its motion in ordinary small oscillations. He showed that though the weights at the end of the string have no effect on the times of oscillation the length of the string has, that these times are twice as long for a string four times as long, three times for one nine times as long, and always in the proportion of the square roots of the lengths. In proving this he had to investigate motion along a slope or Inclined Plane, and it was he who first showed that whatever the incline, the speed acquired by a body moving on it depends not on the amount of

The Leaning Tower of Pisa.

ground it has covered on the plane itself, but on the vertical drop between its starting point from rest, and its position at any moment. The pendulum moves along an arc of a circle, and something very like that arc would be got by drawing instead of it small chords of the circle from point to point in it successively. The smaller these successive chords become the nearer the sum total of them is to the arc, and the motion of a heavy particle constrained to move down them is substantially the same as that of the bob at the end of the pendulum. These successive chords are so many inclined planes, and the movement of the weight down the entire series, is identical with the swing of the bob in the arc. More is necessary to establish this completely than Galileo was able to supply. In passing from plane to plane the particle must be supposed to make a slight rebound at each, a rebound which is less for each, according as the change of slope from one to the other becomes less and less, but the number of the planes, and therefore of the rebounds, increases in the same proportion as the slope of each to each diminishes. To reduce the swing of the bob in its arc to the fall of the mass down the planes it is necessary to show that the effect of this great number of small rebounds is negligible, and Galileo had not advanced far enough in the Fluxional Calculus to show it.

The principle that the speed at any point of the downward slope depends only on the vertical drop between the two positions of the particle, is true independent of friction which lowers the speed attained in a constant proportion. But it would have been difficult to establish the truth stated in this way by ordinary experiment. What is the speed attained, and how are we to recognise it? As the body goes downwards it is increasing in speed from moment to moment. It is easy to time a railway train running at a uniform rate. When the first quarter milestone he notices flies past him, a passenger sees, let us suppose, that the second hand of his watch is at 5 seconds, while at the next quarter milestone it is at 20, at the third 35, at the fourth 50. Every one of these equal intervals is swept over by the train in 15 seconds, or a quarter of a minute. The train is going at the regular rate of a quarter mile per quarter minute, or a mile a minute, or sixty miles an hour. Had the intervals of time noted been different, the problem would obviously have been much more complicated. Let us suppose that the two first 5 and 20, are as before, that the next is 40, and that at the fourth the second hand of the watch has again come round to 5 seconds past the minute. In that case the first quarter mile interval is done in 15 seconds, the next in 20, the third in 25. If the rates were uniform for each interval these figures would give us sixty miles an hour for the first quarter mile, forty-five miles per hour for the next, thirty-six miles an hour for the third. The train is slackening speed, and these are the average rates during the time spent in covering each of these quarter miles. But the train does not drop suddenly from one to the other, and nothing in nature does so. Point by point it has a different rate, and the question, What is the rate at any point? is not easily answered. How, then, are we to measure the rate of speed at a point when that rate is constantly changing? We must seek some necessary consequence of any law of change which we suppose, and we must transform the question, the answer of which it is difficult to verify, into one which it will be easy to subject to an experimental test. Galileo appealed to mathematics, and showed that if his theory, that the velocity depends on the vertical drop, be true, the amount of the vertical drop must be four times as great for two seconds, and nine times as great for three seconds, as for one second, and he set himself to compare the real with the theoretic result.

Let us consider what seems a simple thing, a fall in space, where there is no inclined plane at all. What is the amount of fall for so many seconds? The difficulty in answering accurately is that for even a short time the fall is very large. It is of no use distinguishing between a fall of 16 feet, for instance, and one of 20¼ feet, if the times of description, which are 1 second and 1⅛ second, are too nearly the same to be distinguished by our measurement of time. In Galileo's day the measurements of time were only beginning to be a little delicate, chiefly through his own discoveries, and an error of ⅛ of a second in measurement is obviously easy to make, when one of 4 feet is not easy. In the simpler case of free fall, therefore, Galileo could not compare spaces and times conveniently, because his measures of space were so much more accurate than those of time. The experimental test can be more readily applied to the inclined plane because the fall is slower and there is no other vital alteration in the conditions of the problem.

It is necessary to form some hypothesis about the law which the falling body obeys, to deduce the mathematical consequences of that law, to select one of them which admits of an immediate and satisfactory experimental verification. This was what Galileo did. He believed that the force on the falling body was probably due to the mass of the earth, and that it was at least likely that it would be the same all through the motion, as the particle all through it is practically equally far from the centre of that mass. A constant force must be measured by its constantly producing the same effect in the same time, and the first obvious effect of any force on a falling body is, like the effect of getting up steam on a locomotive, the change of speed which it produces from moment to moment. If this be uniform—so much extra speed put on every second—there must be some way of connecting mathematically the easily measurable spaces and times instead of the less practicable but more direct speeds and times, and the question whether the result and the theory at the back of it agree can be tested over and over again by experiment. The two answers do agree, and they agree in every case. The theory, therefore, is right, unless some other theory about the effect of forces can be found to lead to the same result. The hypothesis about the earth force, that when a body falls from rest its speed will be increased by the same amount in every equal time interval, and that the speed of any body will be increased just as much as that of any other, is a true hypothesis. A 10 lb. weight falls neither faster nor slower than a 1 lb. one. If the earth alone be acting on both, a feather falls as fast as a guinea. It is so in vacuum, though in ordinary air, of course, it is different. A force always the same, producing, that is to say, always the same amount of change of speed in the same time, is acting on every equal particle of matter at the earth's surface. To test this theory we can appeal practically to the inclined plane, rough or smooth. The force on a body falling along it at any moment bears a fixed proportion to that in a free fall; a very small proportion, if the plane has only a very slight slope. Obviously the length of the line along such a plane, down which a body runs in a second, is a very small proportion of that of the free fall in the same time. In the latter case, what to Galileo's power of measuring time was an almost imperceptible difference involved a very marked difference in the spaces gone through, so that it was difficult to verify the law. In the former the spaces needed to be measured for experiments lasting even a few seconds become reasonable. In three seconds a body falling freely from the top of a steeple 144 feet high would fall to the bottom, and it would only take five seconds to fall down Tennant's stalk, but it is easy to make a plane such that a body will only fall down 14 feet along it in three seconds.

It was in connection with his investigations of motion on a plane that Galileo laid down the principle that perhaps serves best as the basis of the theory of balancing forces, the principle of what is called Virtual Velocities. Every one is familiar with it, in the ordinary maxim, that what is gained in speed is lost in power. In the board laid across a fallen tree, on which children see-saw, the lighter child is put at the extremity of the longer arm. With a plank, 12 feet long, a child 50 lbs. weight will be balanced against one 70 lbs. weight when the plank rests on the tree 7 feet from the light child's end, and 5 feet from the heavy one's. When they swing, the amount of swing is proportional to the distances from the fixed point. If the plank moves, so that the child at the 7 feet end rises through seven inches, the other goes down through five. In every case like this, where forces are in equilibrium on a system, we can imagine a motion given, every point moving according to the geometrical circumstances. Let us imagine such a motion. When two forces act on a system and keep it at rest, multiply the space through which the point of application of each force moves, referred to the line in which the force acts, by the measure of the force. When there is equilibrium the resulting quantities are equal and of opposite signs. The one child weighing 50 lbs. rises vertically through 7 inches, and we may call the product 350 inch-lbs. upwards. The 70 lbs. child moves in the same time 5 inches downwards, and the product, which is 350 inch-lbs. downwards, is equal and opposite to the other. If there is equilibrium it must always be so; if it is so there must be equilibrium. It was to Galileo that we owe this most fruitful of statical principles. It can easily be extended to the case when any number of forces act at any number of points on a body or a system, but it was not till a century later that John Bernouilli could state it in all its generality, or show how admirably it serves as a sufficient basis for the whole theory of equilibrium.

These laws of falling bodies and of virtual velocities marked the greatest advance in mechanical science since the world began. The nature of the earth's common action on all bodies at its surface had, in fact, been ascertained. The question that had been put directly to nature had been completely answered, and the answer was final.

The Peripatetics had a singular notion of what they called Inertia. According to them, a body had a natural tendency to move at a given speed straight towards the centre of the earth if it were heavy, and straight away from it if it were light. The continuance of that natural motion, in that direction, at that speed was ensured by inertia. Strike the body in that or in any other direction, and an immediate change takes place, but it is a change which disappears if the body is moving in a vacuum. In ordinary air it is kept up, because the air behind, from which the body is suddenly taken away when it is struck, instantly closes up, and strikes it like a spring which has been let go. At every new position it leaves air, and air springs after it to keep it going. As far as it was then possible, Galileo worked out the consequences of this theory and those of his own, which was that stated in Newton's first Law of Motion—that except where any external force operates, motion in any direction at a certain rate will continue indefinitely in that direction at the same rate. The result was that the old theory was proved to be wrong. As with the first law of motion, so with the second. It is substantially this, that when a force acts on a particle in motion, it produces the same effect in changing that motion as it would if, before it began to act, the body were at rest. Suppose a particle moving with a speed which may be described as 10 feet per second northward and 8 feet per second eastward. Let a force suddenly act on it, the effect of which is to change its rate of going to 17 feet per second northward and 13 feet per second eastward. The amount gained is an addition of speed of 7 feet per second northward and 3 feet per second eastward. Imagine the same force acting on a particle identical with the former, but initially at rest. It will make that particle begin to move from rest at the same rate of 7 feet per second northward and 3 feet per second eastward which it gained in the former motion. The effect in changing rate has been the same as if the body had been at rest, and the whole effect on the eastward direction has been the same as it would have been had there been nothing to affect it in a northerly direction.

It was through the combination of these two principles that Galileo was able to solve another and more difficult problem. Until they were verified by the success of millions of predictions founded on them, they were not so much principles as theories or hypotheses. A fulfilled prediction of any complicated phenomenon raises the hypothesis on which it has been explained to the dignity of a probable truth. Let a bullet be started in an oblique direction at a certain speed—we can predict, by applying these two principles, the way in which it will move and the course it will follow. Let us take one which is sent off at a rate of speed compounded of 32 feet per second vertical and 20 feet per second horizontal. At every point of its path, it will keep both these rates except so far as gravity changes them, and gravity will do by it as a moving body just what it would do by a body starting from rest. To the latter it would give a downward speed of 32 feet per second in a second. In a second it will give just enough downward speed, therefore, to annihilate the upward speed of the bullet. After a second, it will have ceased to have any upward speed, but it will go on with the horizontal speed of 20 feet per second. In its first second the bullet has moved away from its starting-point 20 feet in a horizontal direction and 16 feet upward, because a fall of 16 feet from rest is needed to generate that velocity of 32 feet per second downward, which is wanted to destroy the upward velocity of the amount with which it started. At the end of the first second it has reached its new position by a certain path. Till the bullet comes to the ground again another second will suffice, during which it will fall through 16 feet vertically, and acquire a speed of 32 feet per second downward as it started with 32 feet per second upward, and it will move horizontally 20 feet further from the starting-point. When the second second closes, the particle has again reached the ground by a path which is the left-handed facsimile of that by which it rose.

There are thus three measurable things, all consequences of our fundamental laws. Does the bullet rise 16 feet? does it strike the ground 40 feet away from where it started? does it take 2 seconds to do it in? Nature answers that all these things are so. If we take some means of making the bullet record or picture its path on a board or paper we shall have a still completer answer to the question. Galileo's mathematics were enough to show him that if these two laws were true the curve described must be a parabola—except so far as it is slightly modified by the resistance of the air—and the parabola calculated is the parabola described. Such a proof is all but conclusive. Every point in the path really found has thus been predicted as the mathematical consequence of these two laws, and when this prediction is repeated and confirmed in every experiment, doubt vanishes, the laws are securely established, and the secret of nature has been found.

(*To be continued.*)

JAMES CLERK MAXWELL, F.R.S.

JAMES CLERK MAXWELL, whose premature death on Wednesday last week, science has to deplore, was born in 1831, being the only son of John Clerk Maxwell, Esq., of Middlebie. His grandfather was Captain James Clerk of Penicuik, whose two sons were the Right Hon. Sir George Clerk, Bart.. of Penicuik, and the above-mentioned, John Clerk Maxwell. Captain James Clerk was a younger brother of Sir John Clerk of Penicuik, and on the death of the latter Sir George Clerk succeeded to the estate of Penicuik, while John succeeded to the estate of Nether Corsock, part of the Middlebie estate, which had come into the family through marriage in a previous generation with Agnes Maxwell. Along with this estate John Clerk assumed the family name of Maxwell. When James Clerk Maxwell was eight years old, his mother died, and his father, who had been called to the Scotch Bar, but never practised as an advocate, lived a retired life, devoting himself to the care of his estates, and of his son.

James Clerk Maxwell was educated at the Edinburgh Academy, where he gained the Academical Club Medal for Geometry in 1845, and the Silver Medal for Mathematics in 1847. In 1848 his mother's brother, John Cay, of Edinburgh, took him to see William Nicol, who showed him the colours exhibited by polarised light after passing through unannealed glass, &c. This visit seems to have given the first impulse towards his researches in optics. On his return he constructed a polariscope with glass reflectors. The framework of the first was of cardboard, but a superior article was subsequently constructed by him in wood. Small lenses mounted in cardboard were employed when a conical pencil of light was required. By means of this instrument he examined the figures exhibited by pieces of unannealed glass which he prepared himself, and with a camera lucida, and a box of water colours, he reproduced these figures on paper, taking care to sketch no outlines, but to shade off each coloured band imperceptibly into the next. Some of these water-colour drawings he forwarded to Nicol, and was more than repaid by the receipt shortly afterwards of a pair of prisms prepared by Nicol himself. These prisms were always very highly prized by Prof. Maxwell. Once while at Trinity the little box containing them was carried off by his bed-maker during a vacation, and destined for destruction. The bed-maker died before term commenced, and it was only after a very diligent search that they were found among the late bed-maker's effects, which had been set aside as valueless. After this event the prisms were most carefully guarded, and about three weeks ago were deposited, at Professor Maxwell's request, in one of the show cases of the Cavendish laboratory. The study of the figures exhibited by unannealed glass in polarised light drew the attention of Clerk Maxwell more particularly to the equilibrium of elastic solids, a subject on which he has done some very valuable work.

After leaving the Edinburgh Academy James Clerk Maxwell entered the University of Edinburgh, where he soon won the esteem of Kelland, Forbes, and Gregory, under whom he studied and worked. In October, 1850, he came to Cambridge, entering at Peterhouse. At this time his father does not seem to have been very sanguine respecting the advantages to be derived from a Cambridge course, but his opinion of the University rose considerably when in 1854 the examiners showed their appreciation of his son by making him Second Wrangler, and bracketing him as first Smith's Prizeman. Clerk Maxwell's first term in Cambridge does not seem to have been a very happy one. The Peterhouse men were all classics or pure mathematicians, and he could get no sympathy in his physical work. Finding himself comparatively without friends at the end of the term, he consulted his father and his college tutor, and by their advice migrated to Trinity on December 14th, 1850, where, having a much larger number to select from, he not only found congenial spirits, but soon became looked up to as their leader by a set of admiring followers. In 1852, while an undergraduate at Trinity, he stayed for a few weeks at a country vicarage in Suffolk with the Rev. C. B. Taylor, a brother of a college friend. While there he was attacked by a serious illness, and the care and kindness with which he was nursed by Mr. and Mrs. Taylor never faded from his memory; it so impressed him with the power of love that it formed an important factor in the formation of the Christian character which all who knew regarded with an admiration akin to worship.

As above stated James Clerk Maxwell graduated as Second Wrangler and (bracketed) first Smith's Prizeman in 1854, having previously been elected a Foundation Scholar of his College. In 1855 he became a Fellow of Trinity, and in 1856 obtained the Professorship of Natural Philosophy in Marischal College, Aberdeen, which appointment he held till the fusion of Marischal College and King's College, when he, with other Professors, received a pension from the Crown. In 1858 he married Katherine, a daughter of Principal Dewar of Marischal College, thus vacating his fellowship at Trinity. In 1860 he succeeded Prof. Goodeve as Professor of Natural Philosophy and Astronomy in King's College, London, but after the death of his father he retired in 1865 to his estate in Scotland, where he subsequently carried out his father's plans for completing the house and offices at Glenlair. In 1871 he was invited by the Senate of the University of Cambridge to accept the Chair of Experimental Physics which had just been created, and on October 25th, 1871, he delivered his inaugural lecture as Professor of Experimental Physics in the University of Cambridge. At first the most important part of his work consisted in arranging the details of the Cavendish Laboratory which the Duke of Devonshire had offered to present to the University, and the building of which was personally superintended by Prof. Maxwell from first to last. The whole of the arrangements which render the Cavendish Laboratory so admirably adapted for Physical investigations, are due to the care and forethought of Prof. Clerk Maxwell. When the building had been completed and formally presented to the University, the Duke of Devonshire further signified his desire to provide it with a complete equipment of apparatus, and all this was procured under the personal supervision of the Professor. In 1872 he was elected Honorary Fellow of Trinity College, Cambridge.

During last winter Prof. Maxwell did not enjoy his usual health. In the spring he was unable to carry on his work with his accustomed vigour, but when he left Cambridge for Scotland his friends supposed that with mental rest and physical exercise his health would be restored, and did not regard his indisposition as other than temporary. In Scotland, however, his health did not improve, he suffered much pain and was unable to take his usual food. At length by the advice of his medical attendants, and of Prof. Saunders of Edinburgh, one of his former fellow-students, he returned to Cambridge in the beginning of October. Under Dr. Paget's care he at first made considerable improvement and some hopes were entertained of his recovery. He, however, gradually became weaker, and when Dr. Humphry visited him in conjunction with Dr. Paget, it was plain that medical skill could only alleviate his suffering. He died at noon on Wednesday, November 5th, having retained the conscious possession of all his mental powers to the last.

General invitations were sent to all members of the electoral roll of the University to assemble in Trinity College Chapel at 4·30 P.M. on Monday, November 10th, and were numerously accepted, especially by heads of houses (including the Vice-Chancellor), and by professors. About 4·45 P.M., the service was commenced by Mr. Stanford playing the "Dead March" upon the organ. The remains of the late Professor were then carried into the chapel, preceded by the choir and the first part of the Burial Service read. This was followed by the Anthem "If we believe that Jesus died and rose again, even so them also which sleep in Jesus shall God bring with him. . . . . Wherefore comfort one another with these words." After the service the assembly followed the body to the great gate, whence it was conveyed to Scotland to be interred in the family burying-place at Corsock, Kirkcudbright.

Prof. Maxwell was appointed Foreign Honorary Member of the American Academy of Arts and Sciences of Boston in November, 1874; Member of the American Philosophical Society of Philadelphia in October, 1875; Correspondent in the Mathematical Class to the Imperial Academy of Sciences, Göttingen, in December, 1875; Honorary Member of the New York Academy of Sciences in December, 1876; Associate of the Amsterdam Royal Academy of Sciences in April, 1877; and Corresponding Member of the Imperial Academy of Sciences, Vienna, in August, 1877. He was Fellow of the Royal Societies of London and Edinburgh, and of the Cambridge Philosophical Society, and a large contributor to the Transactions of each of these. In 1872 he was created Honorary LL.D. of Edinburgh, and on June 21, 1876, he received the honorary degree of D.C.L. at Oxford.

In 1860 the Rumford Medal of the Royal Society was awarded to Prof. Clerk Maxwell "for his Researches on the Composition of Colours, and other Optical papers." In his address on the presentation of the medal, Major-General Sabine alluded to Prof. Maxwell's calculation showing the connection of the "mechanical strains to which elastic solids are subjected under certain conditions with the coloured curves which those solids exhibit in polarised light." He then alluded to the colour-top of Prof Maxwell, and the colour-equations obtained from it, as well as the light it throws upon colour-blindness, concluding with these words:—"These researches for which the Rumford medal is awarded lead to the remarkable result that to a very near degree of approximation all the colours of the spectrum, and therefore all colours in nature, which are only the mixtures of these, can be perfectly imitated by mixtures of three actually attainable colours, which are the red, green, and blue, belonging respectively to three particular points of the spectrum."

While Professor of Physics at King's College, London, Maxwell was engaged as a member of the British Association Committee in the determination of the Absolute Unit of Electrical Resistance, and it was the comparison of electrical units which attracted a great part of his attention during his tenure of his Cambridge Professorship. He always spo e very highly of Faraday's "Experimental Researches," which he read very early in life, and to which he attributed some of his most useful ideas on electricity and electro-magnetism. In Clerk Maxwell Faraday found a mind constituted after the same plan as his own, but with the advantage of a mathematical training, which has made Prof. Maxwell capable of interpreting Faraday's bold realisations to the mathematical world. For Clerk Maxwell's own views of Faraday the reader may be referred to the article "Faraday," in the ninth edition of the "Encyclopædia Britannica."

It is impossible in a sketch like this to give anything but the most superficial view of a character so noble in all its aspects as that of Clerk Maxwell. As a professor he was wonderfully admired by those who were truly his disciples. He had not the power of making himself clearly understood by those who listened but casually to his pithy sentences, and consequently he was not a so-called popular lecturer; nor was he a most suc essful teacher of careless students. But when he had those about him who could enter into his mind, and, receiving the golden truths from his lips, could alloy them in such a way as to make them acceptable to the ordinary student, no better teacher could be desired, even for the most elementary instruction. His wonderful imagination was of great value, not only in supplying illustrations for didactic purposes, but in suggesting analogies and opening up new fields for research.

The pages of *Blackwood's Magazine* can testify to his talents as a poet; his sense of humour and his ready wit formed remarkable features in his character, in fact he seldom talked for many minutes without provoking at least a smile. (Some of the reviews lately contributed by him to NATURE may serve as illustrations.) He was well versed in all the literature of the day. and seemed to have investigated on his own account every system of philosophy. He took great interest in passing events, though he never indulged in political discussions. As an experimentalist he was too well known to require description; in that region of science which was his *par excellence*, viz., the domain of Molecular Physics, he stands without a rival. But there were other sides of his character which outshone even his scientific attainments. Such complete unselfishness and tender consideration as he exhibited for those around him, and especially for those under his control, are seldom to be met with. During the eight years that he held the chair of Physics in Cambridge, he never spoke a hasty word, even to his attendants. His self-sacrificing devotion to those he loved was the marvel of his friends. Though he never entered into theological controversy, and only occasionally in his scientific writings indicated in a sentence or two the side he took in questions which have recently been brought prominently before the public by some of the more popular men of science, those who had an opportunity of seeing into his home-life knew him to be an earnest Christian. About three weeks ago he remarked that he had examined every system of Atheism he could lay hands on, and had found, quite independently of any previous knowledge he had of the wants of men, that each system implied a God at the bottom to make it workable. He went on to say that he had been occupied in trying to gain truth, that it is but little of truth that man can acquire, but it is something to "know in whom we have believed." His simple Christian faith gave him a peace too deep to be ruffled by bodily pain or external circumstances, and left his mind free to the last to contemplate all kinds of questions of general interest. One day not long before his death he had been puzzling himself for some time in vain endeavours to discover why Lorenzo ("Merchant of Venice," Act v. scene 1), whose character was at least far from noble, says to Jessica—

> "Look how the floor of heaven
> Is thick inlaid with patines of bright gold:
> There's not the smallest orb which thou beholdst
> But in his motion like an angel sings,
> Still quiring to the young-eyed cherubins;
> Such harmony is in immortal souls;
> But whilst this muddy vesture of decay
> Doth grossly close it in, we cannot hear it.'

We may quote one other example illustrating how the speculative character of his mind remained to the last. About five or six days before his death, when he was suffering from such extreme weakness that he could say very little, after lying motionless with his eyes closed for some time, he presently looked up and remarked, "'Every good gift and every perfect gift is from above, and cometh down from the Father of lights, with whom is no variableness, neither shadow of turning.' Do you know that is a hexameter?

'πᾶσα δόσις ἀγαθὴ καὶ πᾶν δώρημα τέλειον,'

I wonder who composed it."

His knowledge of hymns and hymn-writers was very extensive, and he took great pleasure during his illness in reciting from memory some of his favourites among the writings of Richard Baxter, George Herbert, and others.

To attempt to give any adequate idea of his contributions to science in a sketch like the present would be but to mislead the reader. His great work on "Electricity and Magnetism," the second edition of which is now in the press, is the admiration of mathematical physicists. More generally known are his treatise on the Theory of Heat, and his little text-book entitled "Matter and Motion" which was published by the S.P.C K. One of his earliest papers on the "Theory of Rolling Curves," was communicated to the Royal Society of Edinburgh by Professor Kelland, and read on February 19, 1849, when Clerk Maxwell was an Edinburgh student barely eighteen years of age. His paper on the "Equilibrium of Elastic Solids," above alluded to, was read before the same society on February 18, 1850. His paper on the "Transformation of Surfaces by Bending" was read before the Cambridge Philosophical Society on March 13, 1854, about two months after taking his degree. This was followed in December, 1855, and February, 1856, by papers on "Faraday's Lines of Force." In 1857 he obtained the Adams Prize, in the University of Cambridge, for his paper on the "Motions of Saturnian Rings." His paper on the "Theory of Compound Colours, and the Relations of the Colours of the Spectrum," which was chiefly instrumental in gaining the Rumford Medal, was read before the Royal Society on March 22, 1860. His "Dynamical Theory of the Electromagnetic Field," including a brief sketch of the Electromagnetic Theory of Light, was read before the Royal Society on December 8, 1864. The results of Clerk Maxwell's experiments on "The Viscosity and Internal Friction of Air and other Gases," were made known to the Royal Society in the Bakerian Lecture read, February 8, 1866. Then follow his Royal Society papers "On the Dynamical Theory of Gases," in May, 1866, and "On a Method of Making a direct Comparison of Electrostatic with Electromagnetic Force, with a Note on the Electromagnetic Theory of Light," in June, 1868. Lately he took great interest in Graphical Statics, and contributed a long paper "On Reciprocal Figures, Frames and Diagrams of Forces," to the Royal Society of Edinburgh, in December, 1869. Among his most recent papers are a paper on "Stresses in Rarefied Gases arising from Inequalities of Temperature," read before the Royal Society on April 11, 1878, and a paper on "Boltzmann's Theorem," read before the Cambridge Philosophical Society. It would take too long to enumerate his articles and reviews published in the *Philosophical Magazine* and in NATURE. His contributions to the ninth edition of the "Encyclopædia Britannica" include the articles "Atom," "Attraction," "Capillary Action," "Constitution of Bodies," "Diagrams," "Diffusion," "Ether," "Faraday," and "Harmonic Analysis." "Harmonic Analysis" was the last article he wrote.

One of the most remarkable of his works is the recently-published volume of the Electrical Researches of the Hon. Henry Cavendish, of which Prof. Maxwell is the editor. The MSS. are in the possession of the Duke of Devonshire, and are now at Chatsworth. They were entrusted by him to Prof. Maxwell shortly after the completion of the Cavendish Laboratory. Some of Cavendish's experiments were repeated by Prof. Maxwell with all the appliances of modern apparatus, and others were carried out by his pupils.

Most of the apparatus which he employed in his researches has been presented by Prof. Clerk Maxwell to the Cavendish Laboratory, together with many of his books. He always regarded the laboratory with great affection, and the University owes much to his liberality. One of the most interesting pieces of his handy-work now preserved in the laboratory is a plaster model of Prof. Willard Gibbs's thermodynamic surface, described in the fourth edition of "Maxwell's Theory of Heat." All the lines on the surface are drawn by his own hand, many of them being mapped out by placing the surface obliquely in the sunshine and marking the boundary between light and shade. Another valuable model constructed while Prof. Maxwell was at Cambridge is his dynamical illustration of the action of an induction coil in which two wheels represent by their rotation the primary and secondary currents respectively, the wheels being connected through a differential gearing to which a body of great moment of inertia is attached, the rotation of which represents the magnetism of the coil. A friction break represents resistance, and a spring may be attached to the secondary wheel to represent the capacity of a condenser placed in the secondary circuit. Among other valuable pieces of apparatus presented by Prof. Maxwell to the laboratory are the receiver, plates, and inertia bar employed in his researches on the viscosity of air and other gases, his colour-top, portions of the "colour-box," including the variable slits, with the wedge or measuring their width, a polariser and analyser made of thin films of stretched gutta percha, the mechanism for illustrating the motion of Saturnian rings, a real image stereoscope, and the dynamical top, whose moments of inertia about three axes, which are at right angles to each other, can be so varied by means of screws that the axis of rotation can be made that of greatest or of least moment of inertia. When the axis of rotation is the mean axis, the motion of the top is, of course, unstable. When Prof. Maxwell came to Cambridge in 1857 to take his M.A. degree, he brought this top with him from Aberdeen. In the evening he showed it to a party of friends in college, who left the top spinning in his room. Next morning he espied one of these friends coming across the court, so jumping out of bed, he started the top anew, and retired between the sheets. The reader can well supply the rest of the story for himself. It is only necessary to add that the plot was completely successful.

Prof. Clerk Maxwell's papers will be placed in the hands of Prof. Stokes, who is one of his executors, in order that they may be published or catalogued and preserved in such a way as to be readily available to those wishing to consult them.

The death of James Clerk Maxwell is a loss to his University and to the world too great for words. He rests from his labours, but his works will follow him.

WM. GARNETT

NOTES

THE following is the list of officers to be proposed at the anniversary meeting of the Royal Society on December 1:—President—William Spottiswoode, M.A., D.C.L., LL.D Treasurer—John Evans, D.C.L., LL.D., V.P.S.A. Secretaries—Prof. George Gabriel Stokes, M.A., D.C.L., LL.D., Prof. Thomas Henry Huxley, LL.D. Foreign Secretary—Prof. Alexander William Williamson, Ph.D. Other Members of the Council—George Busk, V.P.L.S., Prof. Arthur Cayley, LL.D., Major-General Henry Clerk, R.A., Edwin Dunkin, F.R.A.S., Augustus G. Vernon Harcourt, F.C.S., Sir Joseph Dalton Hooker, C.B., K.C.S.I., D.C.L., John Whitaker Hulke, F.R.C.S., Lieut.-General Sir Henry Lefroy, C.B., William Newmarch, Inst. Fr. Corr., Prof. Alfred Newton, M.A., V.P.Z.S., Prof. William Odling, M.B., V.P.C.S., Sir James Paget, Bart., D.C.L., William Henry Perkin, Sec. C.S., Charles William Siemens, D.C.L., John Simon, C.B., D.C.L., Prof. John Tyndall, D.C.L., LL.D.

A MEMORIAL strongly recommending Lord Rayleigh's election (if he can be induced to become a candidate), to the Professorship of Experimental Physics at Cambridge, is in circulation. Lord Rayleigh's merits for such an appointment are perfectly well known to our readers. We understand that his election will be supported by many of the professoriate.

WE are pleased to hear that Prof. Sir Wyville Thomson is now much better, and able to conduct the correspondence in connection with the *Challenger* work.

THE death is announced, at Florence, of Miss Martha Charters Somerville, the only surviving daughter of Mrs. Mary Somerville, in her sixty-sixth year. Miss Somerville enjoyed a pension of 100*l*. a year, in recognition of the services rendered to science by her mother.

THE Royal Institution Christmas Lectures will be given by Prof. Tyndall. The subjects will be Water and Air.

ON Tuesday night Dr. W. W. Hunter, the Indian Director-General of Statistics, delivered a lecture at the Philosophical Institution of Edinburgh, on the subject of "What the English had done for India." Contrasting the present English condition of the country with what it has become, since we have had to do with it, Dr. Hunter showed that the improvements in the land, and in the lot of the people had been immense. We need not refer here to the purely governmental improvements which have been made, by the substitution of a good government for a bad, or for no government at all. The peace and security which the poorest native now enjoys was unknown before. Much of the improvement which has taken place has been due to the introduction of science and its results into India. As the *Times* puts it in a leader on Dr. Hunter's address:—"A country which, in the natural course of things, seemed fated to be long shut out from the light of civilisation, or to receive tardily a few rays, was admitted at once into the full blaze of noonday. Other nations have been doomed to work out their civilisation with painful striving. But, thanks to her association with the West, India has had no such novitiate to undergo. All that Europe could teach or give has been made free to her without trouble or price. She has had no centuries of painful waiting, but has stepped at once into possession of all the accumulated intellectual wealth of the West. This has already borne fruits, and more must follow. Our Indian fellow-subjects are being rapidly familiarised with our language and books, and they eagerly drink in modern ideas. They study our philosophers, and talk with more or less intelligence of Mr. Darwin or Mr Herbert Spencer. The names of our chief scientific men are as well known at Agra or Poona as in London. Our schools and colleges are the little leaven which will not fail to leaven the whole mass. The old intellectual idols and prejudices are already prostrate or tottering; and even were there no traces of a bridge or a road to tell of our sway, its history would be imperishably written in the intellectual revolution which we have swiftly effected."

DURING the last four years, *Science News* states, very little has been heard of the observatory to be built in California from the gift of Mr. James Lick, and the public has very generally supposed that nothing would come of the project. But there are now signs of a renewed activity on the part of the trustees, and evidence of an intention to carry the project through without further delay. In August last, Mr. S. W. Burnham, of Chicago, the well-known observer of double stars, was invited to spend a month or two on Mount Hamilton, with his telescope, in order to test the suitability of the mountain as a site for the proposed observatory. His reports were so favourable that Prof. Newcomb, on whose recommendation he was chosen for the work, visited the place himself in September. Both these gentlemen speak in the highest terms of the excellence of the astronomical conditions. Not only is almost every night perfectly clear, but, according to Mr. Burnham, bad seeing is almost unknown. Every night is such a one as he would consider superb at Chicago, and would only meet with two or three times a year. He discovered during his stay a number of new double stars, in portions of the sky which are further south than can be thoroughly examined in the comparatively bad atmosphere of stations this side of the Mississippi. The result of this exploration will give both the trustees and the public a new interest in the project, and it is supposed will lead the former to push the work on as rapidly as possible. If, as both the astronomers who have examined the site seem to suppose, its atmosphere is finer than that of any existing observatory, the result will be that the most powerful telescope in the world will be under the finest sky for employing its utmost capacity.

M. FEIL, the Paris glass-founder, has just received an unusual number of orders for large discs for the following observatories:—Pulkowa Observatory, 80 cm. diameter; Nice Observatory (Bischofsheim's gift), 76 cm.; Paris National Observatory, 73 cm.; Vienna Observatory, to be worked by Grubb, 70 cm.; Mr. Hilger for England, 52 cm.; and M. Salmocroghi, of Milan, 52 cm. The Nice Observatory object-glass will be worked by MM. Henry Brothers.

ON Thursday, November 4, took place at the French Ministry of Public Instruction, the first general meeting of the delegates of the Meteorological Commission. M. Jules Ferry was in the chair, and he prefaced the discussion by some remarks on the zeal exhibited by delegates and expressed the confidence felt by the Government in the ultimate success of so many efforts. M. Hervé Mangon, the president of the Council of the Central Bureau, read a report on the work accomplished since the institution was created, and directed attention to a number of useful questions which up to that moment had been too much neglected. All the resolutions proposed which had been discussed in preliminary meetings were accepted. A number of delegates delivered addresses asking for the erection of new stations and the improvement of certain departments.

THE French Minister of Public Instruction has appointed a commission for arranging all the collections now located in the Trocadero, and creating out of these valuable elements an ethnographical museum.

UNDER date Rome, Sunday night, the *Daily News* correspondent telegraphs:—"Galvani in the act of touching with two different metals the lumbar nerves of a vivisected frog; such is the monument, admirably executed in marble, which his native city, Bologna, has this day dedicated in her busiest street to the great discoverer of animal electricity."

IT is stated that the Bell Telephone Company have taken the first steps to bring an action against the Edison Telephone Company for infringement of patent in respect of the microphonic transmitter of hard carbon employed in the latest form of instrument. This transmitter, which is almost identical with the Blake microphone used by the Bell Company, is claimed by Edison, under the name of the *Inertia Telephone*, as one of the earliest forms of his carbon telephone.

THE programme of the Society of Arts for its 126th session has just been issued. It gives a list of the papers and lectures for the session, so far as they have been arranged. The following are the papers to be read at the evening meetings previous to Christmas:—November 26, "Suggestions for Dealing with the Sewage of London," by Major-General H. Y. D. Scott, C.B. F.R.S. December 3, "Apprenticeship: Scientific and Unscientific," by Silvanus P. Thompson, D.Sc., Professor of Applied Physics at University College, Bristol. December 10, "Art Vestiges in Afghanistan; the Results of some Recent Explorations in the Jellalabad Valley," by William Simpson. December 17, "The Panama Canal," by Capt. Bedford Pim, R.N., M.P. The dates of the papers after Christmas are not announced, but the following are among the subjects to be treated:—"Domestic Poisons," by Henry Carr; "Gas Furnaces and Kilns for Burning Pottery," by Herbert Guthrie, C.E.; "The Utilisation of Slag," by Charles Wood; "Art in Japan," by C. Pfoundes; "The Trade and Commerce of the Yenisei," by Henry Seebohm; "Modern Autographic Printing Processes," by Thomas Bolas, F.C.S.; "The History of the Art of Bookbinding," by Henry B. Wheatley, F.S.A.; "Art Ironwork," by J. W. Singer; "The History of Musical Pitch," by A. J. Ellis, F.R.S.; "The Recent History of Explosive Agents," by Prof. Abel, C.B., F.R.S.; "Ireland and its Resources," by C. G. W. Lock: "The Future of Epping Forest," by William Paul, F.L.S. Three courses of "Cantor Lectures" are to be given. The first course is by Dr. Charles Graham, F.C.S., F.I.C., Professor of Chemical Technology at University College, London, on "The Chemistry of Bread and Bread-making;" the second on the "Manufacture of India-rubber and Gutta-percha," by Thomas Bolas, F.C.S.; the third by R. W. Edis, F.S.A., on "Art Decoration and Furniture." The first meeting of the session will be held on the 19th inst., when the opening address will be delivered by Lord Alfred S. Churchill, chairman of the Council.

DR. HINCKS's "History of the British Marine Polyzoa," upon which he has long been engaged, is nearly ready for publication; it will form two volumes, uniform with the same author's "Hydroid Zoophytes," and will be fully illustrated by drawings of all the known British species and more remarkable varieties of this hitherto almost undescribed class. The work will be published by Mr. Van Voorst.

MESSRS. BUNNY AND DAVIES, of Shrewsbury, have published a "Guide to the Botany, Ornithology, and Geology of Shrewsbury and its Vicinity," edited by Mr. W. Philips, F.L.S.

THE freedom of the Leathersellers' Company has been conferred on Prof. Owen.

ON November 3, at 7.45 P.M., a magnificent meteor was observed at Strassburg, in the vicinity of Jupiter, travelling southeastwards. The duration was four to five seconds. The meteor was coloured green, and left behind a luminous track.

IN his just published report on the trade of Newchwang, in Southern Manchuria, Mr. Consul Adkins mentions that he has in his possession a specimen of lead ore found in the neighbourhood, which contains about 90 per cent. of metal, and also one of copper from the same locality which is almost equally rich. An attempt is being made to get authority to work these mines with foreign appliances. There is an abundant supply of excellent coal close to the veins of metal, and were the mining industry once fairly started, the prosperity of Newchwang and the whole province would, in Mr. Adkins's opinion, become remarkable.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mr. Thos. G. Anderson; a Common Barn Owl (*Strix flammea*), British, presented by Mr. F. Bagnall; a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, a Mona Monkey (*Cercopithecus mona*) from West Africa, a Malbrouck Monkey (*Cercopithecus cynosurus*) from East Africa, deposited; two Moustache Monkeys (*Cercopithecus cephus*) from West Africa, an Axis Deer (*Cervus axis*) from India, a Quebec Marmot (*Arctomys monax*) from North America, a Common Weasel (*Mustela vulgaris*), British, two Boatbills (*Cancroma cochlearia*), two Variegated Bitterns (*Ardetta involucris*) from South America, a Common Night Heron (*Nycticorax griseus*), British, purchased.

METEOROLOGICAL NOTES

IN the *Meteorology of England* for the quarter ending June 30, Mr. Glaisher gives some interesting notes of the cold weather up to that date. The mean temperature of London for the quarter was 49°·5, being the lowest which has occurred during the corresponding period since 1837. The unusually protracted cold weather set in on October 27, 1878, and for the eight months ending June, 1879, the mean temperature was only 41°·6, being lower than any which has occurred in the present century since 1813-14, when the mean temperature of these eight months was only 40°·4. It was during this cold period that the Thames was frozen over and a fair held between London and Blackfriars Bridges. Mr. Glaisher appends a very valuable table showing the mean temperature of the eight months ending June for each year from 1771-72, from which it appears that five colder periods than that of the present year occurred towards the end of last century, viz., 40°·9, in 1794-95, 41°·2 in 1788-89, and 41°·3 in 1783-84, 1784-85, and again in 1796-97. The more frequent occurrence of a higher temperature during the colder half of the year in recent years as compared with what prevailed in the end of last century is pointed out. During the first six months of 1879 the rainfall about London has been exceptionally large, amounting to 17·30 inches, which is larger than has fallen in these months any year since 1815.

IN the *Transactions and Proceedings* of the Philosophical Society of Adelaide, South Australia, for 1877-78, there is an interesting paper by Mr. H. H. Hayter, Government Statist of Victoria, on the infantile mortality of our Australian colonies, based on the statistical returns from 1866 to 1877. During these twelve years the rates per annum of the mortality of infants under one year of age in proportion to 1,000 births were 155 in South Australia, 128 in Queensland, 125 in Victoria, 106 in New South Wales, 101 in New Zealand, and 100 in Tasmania. In each of the years South Australia stood at the top of the list, except in 1877, when the rate of its infantile mortality was slightly exceeded by that of Queensland. From a detailed statement of the causes of deaths of infants in South Australia for the three years 1873-74-75, it appears that of the 3,641 deaths which occurred during these years from all causes, no fewer than 2,249 were occasioned by bowel-complaints and their complications. The whole of this question, which is a vital one as affects the future of such of our colonies as are characterised by high summer temperature, can only be satisfactorily investigated by weekly or monthly statistics of deaths of infants from all causes taken in connection with the mean temperature and humidity of the air during the time. Thus the different summer temperatures and humidities of these colonies explain by far the larger proportion of the differences in the rates of their infantile mortality. All the differences, however, are not to be thus explained, and it is the investigation of these and the tracing of them to their causes which would likely lead to the adoption of improved sanitary and domestic arrangements.

WE have received from the Scottish Meteorological Society a communication from Mr. Thorlacius, their observer in the north-west of Iceland, in which he states that the spring there was stormy and cold, but that, in direct contrast to what has prevailed in the British Islands, the summer had been very fine and warm up to the date of writing (September 23), and the rainfall very small during June, July, and August. Pastures had, in consequence, suffered much, and the hay crop turned out to be generally a very poor one. This has, however, been to some extent counterbalanced by the admirable state in which the hay harvest has been secured, so that most can look forward to the coming winter without uneasiness, even though it should prove severe. Since April they have heard nothing of the Greenland ice, always a subject of no little anxiety in these parts, the ice having fortunately kept away from the coast of Iceland. The Danish man-of-war schooner *Ingolf*, Capt Mourier, cruised this summer close to the coasts of Greenland, but could effect no landing, owing to a belt of ice he could not force his way through, which lay along the shore for a distance of from twelve to sixteen miles. The Captain sailed along the coast, taking several bearings by the way, from Stewart's Island to Cape Dow, or from 69° to 65° 30′ lat. N., thus sailing in a south-westerly direction along the coast of Greenland, which lies opposite the north-west of Iceland, at a distance of about 120 nautical miles. This shore has not been previously explored, no one having probably ever had an opportunity of getting so close in shore before. The strait between Iceland and Greenland was this summer, which very rarely happens, quite open for navigation, except the inconsiderable belt of ice immediately outside the coast of Greenland. Capt. Mourier had special instructions from the Danish government in regard to this exploration, and it is considered likely that the explorations on this little-known coast will be resumed. These meteorological and geographical facts are important in relation to the more southerly course than usual recently taken by our European storms, and the easterly and northerly winds resulting therefrom, to which we owe the all but unexampled cold dull weather of the last twelve months.

THE "Results of Observations in Meteorology, Terrestrial Magnetism, &c., made in Victoria during 1876," under the superintendence of R. L. J. Ellery, have been received. The methods of making and reducing the observations are detailed at length in the preface. The chief feature of the Report is its purely statistical character, there being no attempt to state the outstanding points of interest in the meteorology of the year in this part of Australia. To some extent, however, this want is compensated for by there being given with each month's detailed results the averages for that month of pressure, temperature, humidity, and rainfall, calculate from all previous observations in the office—together with particularly full data of electrical phenomena, hail, snow, frost, fogs, hot winds, storms of winds, and heavy rainfalls of half an inch and upwards within the twenty-four hours at the thirty-eight rain stations over the colony.

These hot winds are not merely of local interest to the colonists, but of general interest in matters affecting the atmospheric circulation of the continent of Australia, and as affording facilities to the meteorologists of that region in the study of whirlwinds and other cyclonic movements, the correct theory of which science has still to propound. The frequency of these hot winds at Wilson's Promontory, the most southern point in Victoria and completely enveloped by the sea, is noteworthy, as also the instance which occurred on March 14, when on the surface the wind was cool and damp, whereas a hot wind was blowing 50 feet high on the lighthouse balcony. The discussion of the wind observations is a valuable piece of work. These show an excess of atmospheric movement in the warmer months and during the hottest hours of the day, the velocity of the wind in summer increasing from 7·13 miles an hour from 2 to 3 A.M. to 15·97 miles from 2 to 3 P.M. During 1876, which was remarkable for the absence of sun-spots, the aurora australis was only seen once, viz., between 3 and 4 A.M. of April 26 at Kyneton.

GEOGRAPHICAL NOTES

THE Germans have so deservedly earned a distinguished reputation as scientific geographers, that it is quite pleasing to catch one very seriously tripping in geographical matters. In Philip Leopold Martius's "Das Leben der Hauskatze und ihrer Verwandten" (Weimar: B. F. Voigt, 1877), in the part of the work treating of the varieties of the domestic cat, appears (s. 61) the following extraordinary statement: "Die schwanzlose Katze von der Insel Man *im stillen Ocean* wenn nicht das *Kap Man auf Borneo* darunter zu verstehen, ist wohl noch nie zu uns nach Deutschland gekommen, obgleich sie auf der Katzenausstellung in London einst vertreten war." The author goes on to express his earnest wish that a pair of these great rarities, Manx cats, may be procured and exhibited at some zoological garden. Manxmen will hardly thank him for placing their native isle in the Pacific Ocean and confounding them with Polynesians, but the suggestion as the result of ponderous research that after all perhaps such a place as the Isle of Man does not exist, but that its mythical development has arisen from a mistake as to a cape of the same name in Borneo is too delicious altogether, and so ingenious and thoroughly German that it must needs be recorded for the benefit of the readers of NATURE.

DR. NACHTIGAL, has communicated to the Berlin Geographical Society full particulars as to the misfortune lately suffered by Gerhard Rohlfs' expedition in North Africa. Rohlfs and his companions, who were plundered and detained while exploring the Kufara Oasis, and compelled to return to Bengazi, were relieved by the intervention of the Foreign Office under assurance that complete reparation would be made them. The explorers' travelling effects, along with gifts sent by the German Emperor for the Sultan of Wadai, require to be supplemented and renewed, though it is almost certain the expedition will still be able to proceed in accordance with its previous plan. Dr. Lenz, it was announced at the same meeting, had lately gone to Morocco on a geological survey, which he would subsequently extend eastwards into the Sahara.

AT the opening of the Geographical Society's Session on Monday last, the Earl of Northbrook, the president, briefly reviewed the work of travellers and geographers during the past few months, and spoke in very eulogistic terms of Prof. Nordenskjöld's great achievement. The most noteworthy feature, however, in the address, was the statement that news had been received that morning from the expedition despatched by the African Exploration Fund Committee to the head of Lake Nyassa. Nothing had been heard of its whereabouts since the death of Mr. Johnston, except a rumour as to its progress, gathered by an Arab from native sources, and lately communicated by Dr. Kirk through the Foreign Office. Mr. Thomson reports that he has arrived, within comparatively few days' march of the lake, in the country of Uhehé. Lord Northbrook read some interesting extracts from Mr. Thomson's journal which will, no doubt, soon be published by the Society. Mr. Clements R. Markham then read a summary which he had drawn up of a paper on the exploration of Central Sumatra, prepared by Prof. P. J. Veth, President of the Dutch Geographical Society. One of the main results of the late Dutch expedition, was the discovery that the Jambi River, which should be known by its native name of Batang Hari, was navigable for nearly 400 miles. It was announced that at the next meeting a paper would be read which had been written by Captain A. H. Markham, descriptive of his Arctic cruise during the summer in the *Isbjörn* and of the work of the Dutch Expedition in the *Willem Barents*. Captain Bruijne, its commander, has kindly promised to attend the meeting. Lord Northbrook also stated that hopes were entertained of Dr. Emil Holub being able to give an account of his remarkable journeys in South Central Africa on January 12.

IN an account which he has sent home to the Church Missionary Society, of the tribes on the road to Mpwapwa, Mr. J. E. Last tells us that the third tribe from the coast is that of the Wanguru. In going from Saadani to Mpwapwa caravans pass through the southern limits of their country. These Wanguru seem to be a scattered people, but they are found in great numbers living among the mountains north of Kwa Masengo, one of their chief villages. There they cultivate the ground on a large scale, growing rice plentifully and all the common native produce; ginger is found in great abundance. They also grow a great deal of tobacco, and three native medicines not known among other tribes. One is the seed-pod of the *mdaha*, in form very like a piece of rough stick, and when ground it is very hot to the palate. The other two are vegetable fats produced from seeds, and are much in vogue as medicines at Zanzibar, as well as on the coast and inland. The French Roman Catholic mission have had a station among this tribe for some little time.

NEWS has been received from Zanzibar that another expedition has started from Bagamoyo for the interior. It is despatched by M. Lavigerie, Archbishop of Algiers, and consists of eighteen Europeans, of whom six are laymen. Their object is to reinforce the Algerian missionary stations at Ujiji and at King Mtesa's capital. The expedition is under the leadership of the Abbé Guyon.

THE new number of *Les Annales de l'Extrême Orient* contains papers on the Belep group and the fauna of the Indian Archipelago, the former of which is illustrated by a map.

THE fame of the newly discovered sapphire mines in Siam is so great that great numbers of Burmese and Shans are said to be flocking thither. The mania appears also to have attacked part of the European community in Rangoon.

THE November number of *Petermann's Mittheilungen* contains a reduced copy of the geological map of India from Medlicott and Blanford's "Preliminary Sketch." The narrative of Dr. Regel's journeys in Central Asia is concluded, and is followed by an interesting account of the trade and industry of Werchojansk and Kolymsk circles, in North-East Siberia, and an eclectic article on the region about the sources of the Santa-Cruz, in Patagonia, with a map illustrating Moreno's journeys in 1876-7. There is also a map accompanying the paper on Dr. Regel's journeys.

AMONG the papers in the September number of the *Bulletin* of the Paris Geographical Society, the one of most scientific value is Commander Perrier's lecture on the measurement of longitudes in France. M. Ed. Cineré describes his journey in South America, mainly the United States of Columbia, in 1875-6. There are two interesting letters on the Oxus question, by M. Woeikoff, with a note by M. Vivien de St. Martin, and a paper by the Abbé Durand on Père Dupayrett's journeys in South Africa. There is also an interesting unpublished letter of Dagelet, the astronomer attached to the expedition of La Perouse.

THE general council of Constantine (Algeria) has appointed a commission for determining the *tracé* of the Transaharian railway. It has been already determined by the commission to publish a *projet*, by M. Peltreau, on the section from Constantine to Juggurt by Biskra and Oued Birh.

IN the last session of the Geographical Society of Paris a very interesting discussion took place on the possibility of using elephants from India in South African exploration. It was considered more advantageous to try to use the native elephants after being trained on the Indian method. It was stated that a number of African elephants had been also sent to India in order to be tamed there. M. Soleillet remarked that elephants can nowhere be met in India except in well-watered places, so that they must be used in Africa, in countries offering some analogy with such regions where they can live without difficulty.

M. PAUL SOLEILLET will leave very shortly for St. Louis (Senegal) in order to proceed on his intended journey to Segou-Sokkoro and thence to Timbuctoo. He has received funds from

M. Ferry, the Minister for Public Instruction, enabling him to take with him a trained botanist. In his last address before the Geographical Society of Paris he entered into many interesting details showing that the negro populations of the region he is to visit were half-civilised races susceptible of intercourse with European nations.

The public subscription for M. Miclucho-Maclay gives very good results. On November 1 the sum had already reached, at the *Golos* office alone, above 2,786 roubles (about 278*l*.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The anniversary dinner of the Cambridge Philosophical Society is to take place in the new hall of Pembroke College on November 29, at 7.15, under Prof. Newton's presidency. The occasion will be clouded by many memories of Professors Maxwell and Garrod.

The Botanic Gardens Syndicate are to obtain plans and estimates for the erection of a curator's house in the Garden.

There is much questioning as to Dr. Power's justification for regarding the coming changes as a "revolution," especially in laying down the office of Vice-Chancellor. A reform in which the University concurs to a great extent can hardly be regarded with such grave anxiety. Dr. Power, in the speech referred to, said that the new comparative anatomy buildings had been for a considerable period in use, although the dispute as to the respective liabilities of the University, the architect, and the contractors for the accident to the roof and floors is not yet settled. The recent addition to the rooms for human anatomy had proved satisfactory. Dr. Power again warned the University of the rapid rate of increase of permanent expenditure and the very uncertain nature of the income, depending so largely on the fees and dues from members of the University. He acknowledged that the department of chemistry had been existing on a starvation allowance, and that some professors and lecturers had been paying heavy expenses out of their own pockets rather than make fresh demands on the already overburdened finances of the University.

Dr. E. H. Perowne enjoys the singular felicity of having become Master of Corpus Christi and Vice-Chancellor in one year. Mr. G. F. Browne, the senior proctor, desires to maintain strongly the college system as against the lodging-house system, especially in regard to discipline. But this would not involve any diminution in the urgent need for more thorough University science teaching, and the more complete recognition as a duty, of banishing the mere schoolboy and the idler, or the mere athlete, to the schools or elsewhere, instead of employing such ability as is here set to lecture in the ABC of subjects.

At Christ's College it is proposed to give open scholarships and exhibitions in natural science for entrance in October, 1880, by examination on Friday, March 19, and following days. He must show that he will probably be able to pass the "Little-go" at latest by the end of his third term of residence. A candidate may gain a scholarship for mathematics or classics in combination with natural science. No candidate will be admitted who has kept any actual terms by residence, but there will be no limitation of age. In mathematics there will be papers in Euclid, algebra, plane trigonometry, and conic sections, geometrical and analytical. Candidates for natural science scholarships must all take chemistry, and also either physics or biology in addition. The principles of spectrum analysis are included in theoretical chemistry, physical measurements and manipulations in physics; also statics, dynamics, optics, heat, and electricity; in biology the conditions are exceedingly well stated, as—*Physiology*: Fundamental principles of the chief physiological processes of plants and animals; general histology of their principal organs; *Morphology*: Fundamental principles of morphology as illustrated by forms representing the principal classes of the vegetable and animal kingdoms; principles of the classification of plants and animals; practical microscopical examination of the various tissues; dissection and description of typical plants and animals. The examinations will be held in common with those at Emmanuel and Sidney Sussex Colleges, as before.

The last Report of the Board of Natural Sciences Studies was to be offered for confirmation to-day (Thursday), at 2 P.M., and it was expected to be non-placeted, although it might be carried on a division.

PROF. BURDON-SANDERSON announces that he will begin a course of weekly lectures at University College, Gower Street, to ladies, on physiology, on Friday the 21st, at 4 P.M. The first lecture will be public.

MR. P. R. SCOTT LANG, M.A., B.Sc., F.R.S.E., who has for some years been assistant to the Professor of Natural Philosophy—Prof. Tait—in the University of Edinburgh, has been appointed by the Queen to the chair of mathematics in the University of St. Andrews.

MR. MARK FIRTH has signified his wish to found a chair of chemistry in connection with Firth College, Sheffield. He proposes to invest a sum sufficient to produce an annual income of 150*l*., and this, together with the fees of students, will amount, it is believed, to a sufficient sum. Mr. Firth proposes that the appointment shall be first filled by Dr. Carnelly, Owens College, Manchester.

THOSE of our readers interested in the higher education of girls may be glad to know that a Calendar of Queen's College, Harley Street, has been published.

THE *Golos* learns, according to the *Times* Berlin correspondent, that the Russian Government intends thoroughly changing the statutes of the University of Dorpat, in Livonia, that strong bulwark of German science and culture. Among the proposed alterations now under consideration in the Imperial Council, the chief one aims at restricting certain liberties hitherto enjoyed by German-speaking students and subjecting them to police surveillance similar to that now in force at all other Russian Universities.

SCIENTIFIC SERIALS

The American Journal of Science and Arts, October.—An examination of the chemical composition of amblygonite, by Mr. Penfield, leads him to give a new and more simple formula for the mineral. He shows that the hydroxyl group in amblygonite is isomorphous with fluorine.—From general geological sections in Iowa, Mr. McGee concludes that residuary clays and others of equal compactness were passed over by a thick ice-sheet with or without serious disturbance, and that the plane of contact between glacial drift and subjacent residuary clay is not always clearly defined.—Mr. Dale describes a peculiar fault at Rondout.—The first portion of a research, by Mr. Gibbs, on the vapour densities of peroxide of nitrogen, formic acid, acetic acid, and perchloride of phosphorus, is given, and the two remaining papers are from English publications (Crookes on radiant matter, and Draper on oxygen in the sun).

The American Naturalist, October.—John A. Ryder, an account of a new genus of minute pauropod myriapod (with figures).—Wm. Barbeck, on microscopical fungi attacking our cereals.—C. L. Herrick, fresh-water entomostraca (describes and figures *Diaptomus longicornis*, n.sp.).—S. K. Lum, notes on the thrushes of the Washington Territory.—John Ford, the leather-turtle.—S. L. Frey, Were they mound-builders?—Recent literature: Proceedings of scientific societies.

The American Quarterly Microscopical Journal, vol. i. No. 4.—Prof. S. A. Forbes, on some sensory structures of young dog-fishes.—Dr. C. L. Anderson, spores with a spore glossary.—Dr. J. J. Woodward, on the oblique illuminator, and on a new apertometer.—F. H. Wenham, on Prof. Smith's apertometer.—John Mayall, on measuring aperture.—R. Hitchcock, aperture, angular and numerical.—J. D. Hyatt, on the tongue of the honey-bee.—Thomas Taylor, on oleomargarine and butter.—W. C. Hubbard, Haeckel *v.* Virchow.—Prof. Stowell, the origin and death of the red blood-corpuscle.—B. Eyferth, on the simplest forms of life.—An announcement from the publishers states "that the existence of the *Quarterly* ceases with this number." The editor found that it would be impossible for him to give the journal the necessary supervision during the coming year, hence the necessity of this suspension.

Journal of the Franklin Institute, October.—Prof. Thurston here publishes an investigation of the strength of American timber, several varieties of which (white and yellow pine, locust, black walnut, white ash, white and live oak) were submitted to testing machines in the Stevens Institute. The results show that American timber has a constructive value equal, if not decidedly superior, to European timber. (The numbers were almost invariably higher than those of Barlow, Tredgold, or

Lastett.) Timber yields, under all forms of stress, to an extent about proportional to the load.—Mr. James Smith sketches a plan for water-supply of Philadelphia, viz., a gravity-supply by aqueduct from Perkiomen.—A modification of Tisley's compound pendulum, by Mr. Queen, of Philadelphia, whereby the motions and figures may be exhibited on a screen to large audiences, is described, and there is an account of the zinc veins and works of Lehigh Valley.

Bulletin of the United States Geological and Geographical Survey of the Territories, vol. v. No. 2, September.—J. A. Allen, on the Coatis (genus Nasua, Storr).—Dr. Coues, on the present status of *Passer domesticus* in America.—Dr. Peale, on the Laramie group of Western Wyoming and adjacent regions.—A. R. Grote, on Lithophane and some new Noctuidæ (describes many new species).—Dr. A. White, Palæontological Papers, No. II., on carboniferous fossils from Colorado, Arizona, Utah, and Wyoming, and on cretaceous corals from Colorado (describes several new species).—F. V. Hayden, the so-called Two-Ocean Pass.—E. D. Cope, on the extinct species of Rhinoceridæ of North America, and their allies.—Dr. Coues, second instalment of American ornithological bibliography.

Bulletin de l'Académie Royale des Sciences de Belgique, No. 8.—M. Plateau here defends, at some length, his theory of the superficial viscosity of liquids in opposition to the theory of Signor Marangoni, who, without denying a viscosity proper to the surface and different from that of the interior, thinks its influence (*e.g.*, in retarding the movement of a needle on the surface) very small in comparison with that of other causes, especially, in liquids which can be inflated in large bubbles, the *elasticity* of a layer of impurity (*imbrattamento*) arising from exposure in the air, while in liquids like water and most saline solutions, changes in tension, through alteration of the surface and changes in curvature of the menisci at the sides of the needle, &c., are operative.—M. Petermann writes on the presence of grains of *Lychnis githago* in alimentary flour, and indicates a method of detecting it.—There is also a paper on the quartziferous diorite of Champ-Saint-Veron (Lembecq), by MM. Poussin and Renard.

Journal de Physique, October.—On the inscription of meteorological phenomena, particularly electricity and pressure, by M. Mascart.—On the rectifying apparatus of M. Duboscq, by M. Bertin.—On a phenomenon similar to Peltier's phenomenon, by M. Bouty.—A regulator of temperature, by M. Benoit.

Cosmos, 5 Heft, August.—Prof. Dr. Schultze, history of the origin of the "Despising" of Nature.—Ernst Haeckel, on the common relationship between the ctenophora and the medusæ, with an account of a form connecting the two groups. This extraordinary form is beautifully figured.—Dr. Mehlis, the barrowfield near Hagenau and its probable epoch.—Henry Potonié, Alexander Braun's attitude towards the theory of descent.—Short notices and criticisms.

THE *Nyt Magazin for Naturvidenskaberne* (Christiania, vol. 24, pt. 4, and vol. 25, pt. 1).—From these parts we note the following papers:—On the geology of the Folge Fon peninsula, by T. Ch. Thomassen.—On the ornithology of Madagascar, by Leonhard Stejneger.—On microline, a new species of triclinic potash-feldspar; its optical, crystallographical, and chemical characters, by A. Des Cloizeaux.—On the insect fauna of Dovrefjeld and the Gudbrands valley, by W. M. Schoyen.—On the changes which some plants undergo in northern latitudes by Prof. F. C. Schübeler.—On the occurrence of iridium in northern minerals, by S. Wleugel.—On dislocation lines in the so-called Skrimfjeld, by O. E. Corneliussen.—Diary of a journey in the Trysil district, by L. Meinich.—Account of a botanical tour in Hardangervidden, by N. Wille.—On some contact rocks of the Christiania Silurian basin, by A. Penck.

THE *Verhandlungen der k.k. geologischen Reichsanstalt* No. 12, Vienna) contains the following papers:—On the miocene deposits at the south-western margin of the Galicio-Podolian Plateau, by J. Niedzwiedzki.—On the tertiary formation at the eastern slope of the Vogelsberg, by H. Bücking.—On the pliocene mammal-fauna of Hungary, by Th. Fuchs.—On the Flysch question, by the same.—On the geological objects exhibited at Teplitz and relating to the Teplitz basin, by R. Raffelt.—On the marginal mountains of the Vienna bay, by Franz Toula.—The number further contains the following eports of geological excursions undertaken by different members f the Reichsanstalt, viz.: by Dr. O. Lenz from Eastern Galicia, by Dr. Edmund von Mojsisovics from Bosnia, by E. Tietze from Eastern Bosnia, and by Dr. A. Bittner from the Herzegowina.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, November 6.—Prof. Allman, president, in the chair.—Mr. W. H. Twelvetrees (of Orenburg, Russia) was elected a Fellow of the Society.—The President, in opening the session, briefly alluded to the demise of Mr. W. Wilson Saunders and Mr. John Miers, whose scientific and official labours in connection with the Society have been well appreciated.—Mr. W. T. Thiselton Dyer exhibited and made remarks on some photographs of vegetation, including *Cinchona Ledgeriana*, in the Botanic Garden of Buitenzorg, Java.—Mr. D. Morris, recently returned from investigating the coffee-leaf disease of Ceylon and South India, read a paper on the structure and habit of *Hemileia vastatrix*. He supports the Rev. R. Abbay's statements as to the destructive character of the fungus and its evident gradual extension over the coffee-producing regions of the East; he even expresses fears of its ultimately being carried to the West Indies and Brazil;—2,000,000*l.*, the estimated annual deficiency in Ceylon alone, is no mean sum to be debited from the revenue and interests of the planters. Mr. Abbay has described the spores as attached to the inner surface of the orange yellow sporanges (a notion opposed to received ideas respecting free cell formation); but Mr. Morris's observations are opposed to those of the former. The author explains the hitherto puzzling dark brown bodies beneath the sporanges as composed of closely interwoven threads of mycelium. During February, March, and April, both bark and leaves are everywhere covered exteriorly by mycelial filamentous threads which reproduce by germinating spores. In the wet weather these do not enter the stomata. It is in this stage that conidial growth supervenes according to Abbay (secondary spores of Thwaites), but the author has failed to substantiate this phase, though starved plants on glass slides raised conidia. It is during the filamentous stage before penetration that remedial agents—dusting with sulphur and lime, &c.—have a chance of being effective; but a serious disturbing element offers in the large area of abandoned crop still continuing to propagate the fungus.—Dr. F. Day read a paper on the instincts and emotions of fish. Biologists of late have been less attracted by the faculties of fish than of other animals, and even Cuvier's estimate of their total want of intelligence has been quite recently quoted as authentic. The author combats this notion, and, from his own experience and data afforded by other writers, claims evidence of emotions and affections. He shows they construct nests, transport their eggs, protect and defend their young, exhibit affection for each other, recognise human beings, can be tamed, manifest fear, anger, hatred, and revenge, utter sounds, hide from danger, betake themselves for protection to the bodies of other animals, and have other peculiar modes of defence, leave the water for food, and even different families combine for attack and defence. Their faculties, notwithstanding, are greatly subordinated and modified compared with those of higher races of the vertebrata.—The Rev. G. Henslow read a paper on the origin of the (so-called) scorpioid cyme. He pointed out some errors in deducing this from the dichotomous cyme: 1. Opposite pairs of bracts, being successively in planes *at right angles*, the resulting sympode would be a volute, and not a helix. 2. The position of the bracts (when present, as in *Borago*) are not opposite the flowers. 3. There are always *two* rows of flowers, not a single one. 4. The appearance of a flower in the fork between the two branches of the inflorescence (as in *Myosotis*) is not usual, and is due to the adhesion between the terminal and the highest axillary raceme. This has given rise to a false impression of dichotomy. 5. Authors have hitherto confounded the "true scorpioid raceme" (Henslow) with spicate degradations of sympodial inflorescence. He refers it to the indefinite system, and explains its origin by a new principle of phyllotaxis, which he first discovered in *Lagerstromia*, viz., in resolving opposite and decussate leaves into alternate, instead of their lying on a continuous spiral line, the line *oscillates* through three-fourths of a circle, and if a line be drawn from flower to bract, it will represent the so-called scorpioid cyme of Boragineæ.

Chemical Society, Nov. 6.—Mr. Warren De la Rue, F.R.S., President, in the chair.—The following papers were read:—On the transformation products of starch, by C. O'Sullivan. In this paper, which was originally presented to the Société Chimique de Paris on June 18, the author criticises the results published by MM. Musculus and Gruber, pointing out some errors into which they had fallen. He reasserts the fundamental facts of his former paper, viz., that starch splits up under the influence of malt extract in four principal ways. The author also investigates the action of malt extract on the products of the above reactions. He inclines to the belief that the dextrins are not a series of polymers, but rather a series of bodies of the same molecular weight, the molecules being arranged differently as regards one another, the molecules being arranged in groups all dependent on one another.—Note on the formulæ of the carbohydrates, by Dr. Armstrong. The author discusses the various formulæ of glucose, and inclines to that which represents glucose as being an aldehyde and a penthydric alcohol; the cane sugars are probably related to the glucoses as ether is to alcohol. The author discusses the probable arrangement of the molecules in starch, and arrives at a conclusion differing from that of O'Sullivan.—On a new method of determining sulphur in coal, by Teikichi Nakamura of Tôkiô. The author mixes intimately one part of finely-powdered coal with three or four parts of sodium carbonate and ignites very gradually, so that no smoke or odorous gases escape; a white or reddish ash is left, which is treated with water, &c.—On the bromine derivatives of β naphthol, by A. J. Smith.—On the dissociation of ammonia iron alum, by J. S. Thomson. Dilute neutral solutions of ferric salts, when heated, deposit a basic salt; this dissociation can be prevented by the addition of dilute sulphuric acid. By using sulphuric acid of known strength, the author has studied the subject quantitatively. A solution of ammonia iron alum containing more than 1 grm. in 14·37 cc., does not dissociate; this dissociation begins in more dilute solutions, and increases regularly with successive additions of water; ammonia and potash salts increase the dissociation.—On α methyl oxysuccinic acid, the product of the action of anhydrous hydrocyanic acid upon aceto-acetic ether, by G. H. Morris.—Demarçay described an uncrystallisable acid obtained as above, whose baryta salt was unstable. The author has repeated the experiments, and obtained a well-crystallised acid melting at 108°. The barium salt is stable when boiled with water.—On the action of phosgene on ammonia, by H. J. H. Fenton. The author has examined the white amorphous substance obtained in the above reaction, and extracted guanidine and urea quite identical with ordinary urea.—On the rehydration of dehydrated metallic oxides, by C. F. Cross. The author has obtained various anhydrous basic metallic oxides by igniting the hydrates. These oxides, when exposed to a saturated atmosphere, absorb water up to a definite limit of a molecular character. The investigation includes oxides of aluminium, chromium, cobalt, iron, and copper.—On alizarin blue, by G. Auerbach. The author gives the method of preparing and purifying this substance; when pure it forms brown, shining needles, melting 268°–270°. He has also prepared various salts and bromo derivatives; the actions of zinc dust, chlorine, and acetic anhydride were studied. In constitution the author thinks the body must be closely related to the aldehydines of Ladenburg.

PARIS

Academy of Sciences, November 3.—M. Daubrée in the chair.—M. Mouchez presented the last published volume of *Annales de l'Observatoire de Paris*, giving observations made in 1876. He stated that the Ministry of Public Education had decided that a certain number of astronomical students should be admitted to the Observatory for two years' instruction and practice, after which those found fit should be appointed as assistant astronomers in government observatories.—Nautical instructions on the coasts of Algeria, by M. Mouchez. The volume he presented describes first the meteorology, then the physical character of the coast.—Experiments with an inverted syphon having two horizontal branches, capable of raising water without a movable piece to considerable heights relatively to that of waves, or to exhaust at considerable depths relatively to the hollow of waves, when a retaining valve system is added, by M. De Caligny.—On some pathological states of the tympanum, causing nervous phenomena, which Flourens and De Goltz attribute exclusively to the semicircular canals, by M. Bonnafont. Displacement of the tympanic membrane away from or towards the internal wall of the tympanic cavity (*e.g.* in the latter case, by a concretion of wax or polypous excrescence), causes, through the chain of small bones, variations of pressure of the liquids in the vestibule and semicircular canals, with consequent giddiness, staggering, &c.—On the abnormal spectrum of light, by M. De Klercker. Two hollow glass prisms having the same angle (25°) and filled with alcohol, are placed on the stage of spectroscope with their refringent angles in opposite directions; the image of the slit is not deflected. To one prism are then added crystals of fuchsine; the original image then divides into two parts, one going to the right and widening into a distinct regular spectrum of the less refrangible rays; the other remains in the same place without widening, and takes a blue-violet colour. M. De Klercker attributes the effect to the different amount of retardation by molecules of different species in the solution.—On determination of the elements of a vibratory motion; measurement of amplitudes, by M. Mercadier. He uses a (so-called) vibrating micrometer.—Stomachic digestion and duodenal digestion; action of pancreatine, by M. Defresne. Hydrochloric acid in gastric juice is combined with an organic base which moderates its action and changes its properties. The acidity of mixed gastric juice, half an hour after ingestion, is no longer due to chlorhydrate of leucine, but to lactic, sarco-lactic, tartaric, malic, and other acids. The best reagent of this transformation is pancreatine. This difference in acidity of pure and mixed gastric juice becomes still more manifest in artificial digestion of nitrogenised food.—Result of researches into the origin of reinvasions of phylloxera, by M. Faucon. He contends for the superiority of submersion to insecticides, and indicates a method.—On uniform analytic functions in the neighbourhood of a singular essential point, by M. Picard.—On the ultra-violet absorption spectra of nitric and nitrous ethers, by MM. Soret and Rilliet. The known characters of the absorption spectra of metallic nitrates are not met with in nitric ethers. A solution of amylnitrous ether gives six absorption bands between H and R.—On a new stellar spectroscope, by M. Thollon. He uses two compound direct-vision prisms of special form (one in the collimator, the other in the telescope tube), whereby he seeks to reduce the loss of light as much as possible. The larger of the simple (or component) prisms has an angle of 100°, and contains a mixture of ether and sulphide of carbon; and two rectangular prisms of crown glass (one on either side) have faces parallel to each other and to the bisecting line of the angle of 100°.—On the tensions of vapour of saline solutions, by M. Pauchon. The value of coefficient a, in Kirchhoff's formula, varies continually with the concentration, in some cases increasing, in others diminishing.—On an electro-capillary thermometer, by M. Debrun. The principle is that mechanical action deforming a mercury meniscus like that in Lippmann's electrometer, produces a current.—On animal cellulose or tunicine, by M. Franchiment. The difference between animal and plant cellulose, if such exist, is not due to a difference of the groups $C_6H_{10}O_5$ forming it, but to a difference in the manner of their union.—Researches on the different modes of combination of phosphoric acid in the nervous substance, by M. Jolly. In the calf the brain is very rich in phosphorised elements; in the grown ox it is the spinal cord that contains most of them; and after alkaline phosphates, phosphate of iron is the most abundant.—On hairs and hairy glands in some kinds of Nymphcaceæ, by M. Heckel.—On the growth of stems of dicotyledonous trees, and on the descending sap, by M. Guinier. He thinks it is perhaps time to renounce the ordinary theory of descending sap.

THE DOUBLE STARS

A Handbook of Double Stars. By Edward Crossley, F.R.A.S., Joseph Gledhill, F.R.A.S., and James M. Wilson, M.A., F.R.A.S. (London: Macmillan and Co., 1879.)

Double Star Observations made in 1877–78 *at Chicago with the* $18\frac{1}{2}$*-inch Refractor of the Dearborn Observatory, &c.* By Sherburne Wesley Burnham, M.A. (From *Memoirs* of the Royal Astronomical Society, vol. xliv.)

IT cannot be said that a special work upon the double and compound stars has not been long a desideratum. Of the various branches of astronomical science the study of the double stars appears to have formed one of the most attractive to amateurs generally; so far as the reduction of the observations is concerned it involves little calculation, and the observations themselves are not laborious but admit of being proceeded with at intervals of leisure, with comparatively moderate appliances, at least in a large number of cases. Many of our amateurs have their daily duties and occupations in other lines, and seek relief in their evenings from the monotony of routine; the observation of the double stars upon a well-arranged list perhaps offers as favourable opportunities for rendering themselves really useful and for doing really good work in astronomy without the labour of one kind or another involved in several other classes of observation as it is possible to find.

The branch of astronomy to which we are referring has progressed as rapidly as others, and the observations of double stars and particulars relating to them have been scattered through a large number of astronomical publications, to consult which involves a great outlay of time and trouble, even if they are accessible without difficulty. The main purpose of the volume before us has been to present the great majority of measures of some twelve hundred double stars in a convenient form, with notes bearing upon binary character or other peculiarity, or, speaking generally, to furnish a history of each star. Part I. is introductory or explanatory, containing a brief historical notice and reference to those astronomers who have been most occupied upon the double stars, with particulars of the instruments employed, the adjustments of the equatorial, the micrometer and methods of observing with it, forms for registering measures and similar details. Part II., which possesses considerable value, treats of the calculation of the orbits of the revolving double stars, and in this division of the work the authors have been fortunate in being assisted by Dr. Doberck, who has a greater experience in this direction than any other astronomer of the day, and who has contributed in so important a degree to advance our knowledge of the elements of these revolving suns. Sir John Herschel's graphical process for determining the apparent orbit which is still of such material assistance towards more refined investigation is explained and illustrated (which is better still) by an application to Castor. This is followed by the calculation of an orbit by analytical methods, applied to σ Coronæ, the different steps being clearly defined, but these methods are necessarily much more laborious, and at present we do not seem to get the full advantage in many cases that might be expected from them. It will be no fault of Dr. Doberck's if the computer does not succeed in obtaining elements upon the principles he so well explains, which will continue to represent the motion of the star. Other causes frequently operate, however, which appear to render elements less satisfactory for *prediction* than might be expected, considering the refinement used in their calculation. The comparison of Dr. Doberck's orbit of σ Coronæ with observation affords a very close agreement. In the next three chapters Mr. Wilson enters upon relative rectilinear motion, the effect of proper motion and parallax on the observed angles and distances of a star optically double, and the errors and combination of observations.

Part III., "the Catalogue and Measures," prepared by Mr. Gledhill, is that which will be most frequently consulted. Considerable care appears to have been taken in the selection of the objects, and in the collection of the measures by various observers. A great amount of trouble must have been expended upon this portion of the volume, which is well brought up to date, and few facts of importance bearing upon the history of any object appear to have been overlooked, though such omissions must almost necessarily occur sometimes in a work of this character. There has evidently been the wish to make this part of the work as useful as possible to the amateur. Perhaps in a short supplement to another edition it may be desirable to reproduce the double star measures with the Königsberg heliometer, collected in vol. xxxv. of the Observations at that Observatory, the more especially as these volumes of observations have but a small circulation in this country; we miss most of these measures in the "Handbook."

An appendix contains the positions and measures of two hundred of Mr. Burnham's new double stars, placed at the service of the authors by the discoverer. Part IV. is bibliographical, and supplies a list of the principal works and papers relating to double stars and upon various forms of micrometer.

The volume is one which may be expected to find its way to the shelves of most amateurs and students of astronomy.

Mr. Burnham's important contribution to vol. xliv. of the *Memoirs* of the Royal Astronomical Society, contains (1) a catalogue of 251 new double stars with measures, and (2) micrometrical measures of 500 objects, amongst them some very difficult ones and a number of evident binaries.

At the time the Chicago Astronomical Society was organised in 1862, Messrs. Alvan Clark and Sons had still in their possession an object-glass of $18\frac{1}{2}$ inches aperture, which was then the largest in the world. Steps were taken to secure it, and, thanks to the energy of the Hons. Thomas Hoyne and J. Young Scammon, the latter of whom has been president of the Society from its organisation, the glass was secured for Chicago, and by means of a public subscription 18,000 dollars were raised for its complete mounting, and Mr. Scammon contributed 30,000 in addition for the building. Fortunately an observer equal to the use of so fine an instrument was at hand, and latterly Mr. Burnham has devoted it to the discovery of new double stars and the revision of an extensive list of known ones which appeared most deserving of attention. He remarks: "My work has been wholly a labour of love. During the business hours of every day I have been otherwise fully occupied, and hence my observations have been prosecuted often at the expense of rest, sleep, and recreation. I submit the results to the Royal Astronomical Society as the first contribution of the great equatorial of the Dearborn Observatory." Mr. Burnham had however published, between 1873 and 1877, *nine* smaller lists of new double stars, containing 482 in all; the present catalogue brings up the number to 733; indeed, his energy and success have been alike extraordinary.

In looking over this tenth catalogue of new doubles, many objects are noted which deserve more or less attention. η Piscium, a star of the fourth magnitude, has a companion of the eleventh at a distance of one second, and "there is no known pair among stars of this magnitude or brighter, with so close and minute a companion." Three stars have been found near the celebrated variable, *Algol*, all three closer than Schröter's companion; one of 12·5m. is distant only 10″·6 on an angle of 115°. There are also three new doubles amongst the Pleiades, and a much nearer companion to *Aldebaran* than that observed by Herschel and Struve. In an object in R.A. (1880·0), 21h. 1m. 25s., and Decl. +43° 12′, Mr. Burnham finds the most minute close pair known and terms it "a curiosity in double stars, if for no other reason;" it is too small for Argelander's *Durchmusterung*; the components are about equal and near 11m., distance 0″·4. There are two faint companions to Herschel's "Garnet-star" in Cepheus, and not the least interesting addition is a *comes* of 12·5m. preceding nearly on the parallel, by 0″·7, the star 85 Pegasi, which has large proper motion and a sensible parallax according to the investigations of Prof. Brünnow at Dunsink; as Mr. Burnham remarks the physical connection or otherwise of the faint star should be soon decided.

In the second catalogue, as we have stated above, there are many binary systems, the Chicago observations either confirming previous deductions or indicating new objects in motion. Mr. Burnham doubts the duplicity of *Atlas Pleiadum*, though Struve considered that confidence might be placed in his measures of 1827, an inference somewhat supported by Dr. Hartwig's observation on the occultation of the star by the moon in 1876. An examination of the interior of the trapezium of Orion, afforded not the slightest suspicion of any additional stars, and hence Mr. Burnham concludes that several faint objects supposed to have been seen within it, with smaller telescopes, have no real existence, and he expresses the same opinion as to recent suspected companions of the Pole-star. He shows good reason for inferring that one of the components of Σ 1058 is variable; the brighter star is missing in more than one catalogue where it might be expected to be found, and in 1878 a thorough search did not reveal any double star near its place, but in the early part of the present year he has been more successful and has measured the star on two nights, when the magnitudes were respectively 8 and 11. A reference to Mr. Burnham's notes will afford a number of other objects to which special interest attaches.

OUR BOOK SHELF

The Saidapet Experimental Farm Manual and Guide. By C. Benson. (Madras, 1879.)

THIS volume is published by the direction of the Madras Government, and consists of a Report by the Superintendent of the more important results obtained at the experimental farm since its commencement in 1865. An agricultural college has been recently added to the farm establishment, but this educational work lies beyond the scope of the present volume. Of the value of the work done on this experimental farm there can be no question; the Government money spent on it has been well laid out. If the miserable and profitless native systems of agriculture are to be improved, and the land made capable of supporting the rapidly increasing population, it must be by the adoption of the methods here recommended.

In the native agriculture the soil is stirred to the depth of 3 inches only, manure is seldom employed, and grain crops are generally the only ones cultivated; the land is thus reduced to its lowest limit of productiveness. Irrigation is also most wastefully conducted. Eight to twelve feet of water are consumed in the production of a single crop of paddy, the ground being turned into a swamp, and frequently becoming a source of disease to the surrounding population.

The improvements recommended are in the first place a deeper cultivation of the soil, by which its porosity and water-holding power would be increased, and the root development of the crop favoured. An English plough is said to cost twenty-five times the price of a native implement, but the work done is so superior that the increased outlay will be repaid during a single year's cultivation of twenty acres. Many soils also require draining. The rainfall in India is at certain times of the year extremely heavy (16 inches have been recorded at Saidapet in twenty-four hours); on such occasions undrained land becomes for a long period unworkable, and much precious time is lost. Judicious drainage will not diminish the water holding power of heavy land, but rather increase it by promoting the disintegration of the subsoil. Drainage is also greatly needed in many cases for irrigated land; without this the water may become stagnant and its good effect greatly diminished.

The next improvement demanded is the adoption of a proper rotation of crops, in which fodder crops should hold an important place. The experiments have shown that a large number of excellent fodder crops exist, which can be cultivated if need be all the year round. The fodder crops most strongly recommended are cholum (*Sorghum vulgare*), and guinea grass (*Panicum jumentorium*). Sugar cane, where well manured, affords an immense amount of excellent fodder. Paddy may also be often usefully cut while green, and a good supply of fodder thus obtained when the quantity of water available is too small to carry the crop to maturity. Horse gram (*Dolichos uniflorus*) may also be grown with advantage as a fodder crop, and four or five cuttings may be obtained in the year. Being a leguminous plant, rich in nitrogen, it is of great use in bringing poor land into condition, and may be ploughed in as a green manuring with excellent effect.

One great object of the growth of fodder crops is to enable the farmer to raise the condition of his soil by applications of organic manure; to increase the amount of humic matter in the soil is a most important step towards amelioration in such a climate as that of India. The fodder crops should be consumed by cattle, kept, at least during the night, in loose boxes, and the manure thus obtained returned to the land. Other manures recommended are steeped cotton-seed, salpetre, bones, and lime.

Until the condition of the land is raised by proper cultivation and manuring, a large number of improvements must remain impossible. Superior grain crops, and superior varieties of rice and cotton, can only be grown on good soil; on poor soil they at once deteriorate. The same may be said of live stock: the miserable native breeds are accustomed to starve during a part of every year; such treatment would be fatal to better animals. Until good fodder crops are grown, any permanent improvement in the breeds of farm animals is impracticable.

We might easily extend our notice of this useful volume; it is full of practical information, and must prove of great value to all engaged in agricultural operations in India.

R. W.

Grundriss der chemischen Technologie. Von Dr. Jul. Post. Part ii. (Berlin: Robert Oppenheim, 1879.)

WE have already noticed the first part of Dr. Post's excellent manual of chemical technology (see vol. xvi., 83), which made its appearance towards the end of 1876. Unfortunately, the completion of the work has been delayed by the severe and prolonged illness of the editor. The first portion was mainly confined to a description of the modes of manufacture of crude or intermediate products; the second part treats of the finished or final products. Objections might, doubtless, be raised against such a mode of treatment, but we question if, on the whole, a more systematic method of dealing with so complex a subject as chemical technology could have been devised. The entire work forms unquestionably one of the most, if not *the* most, complete repertorium of the existing processes of industrial chemistry that we know of in any language, and as such we can confidently recommend it to the notice of our chemical manufacturers. Dr. Post has been assisted by an excellent band of collaborators, many of whom are recognised as authorities on the subject of their respective communications. A due amount of space is usually devoted to a consideration of the theory of the various processes when this has been at all worked out; and the description of the mode in which these processes are actually carried into operation is facilitated by numerous diagrams and plans. Dr. Post is to be congratulated on the completion of an exceedingly useful work.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The November Meteors

THE cloudless sky from the morning of the 12th to the 15th, with the total absence of moonlight, afforded a most favourable opportunity for the observation of the meteors of the season. A constant watch was kept up at this observatory from 10 P.M. until daybreak of the 13th, 14th, and 15th, and the results show that the Leonids were considerably in excess of what they had been during the last few years.

The total number of meteors observed was 309, and out of these 104 radiated from the Lions, and 56 clearly indicated five principal radiant points. Four of the radiants were situated near the stars ϵ, γ, δ, and η Leonis, and the fifth was just below (31) Leonis Minoris. The position of this east point was very clearly marked by a stationary meteor of the 1st magnitude. Eighty-six of the meteors were of the 1st or 2nd magnitude, and nine others were brighter than 1st magnitude stars. The largest number of Leonids seen during a single hour was fifteen, from 4 to 5 A.M., on the 14th. S. J. PERRY

Stonyhurst Observatory, November 18

The Platysomid Fishes

I AM very sorry to find that my esteemed friend Prof. H. Alleyne Nicholson has, in the new edition of his "Manual of Palæontology" (vol. ii. p. 138, *note*) committed the mistake of quoting me as his authority for elevating the Platysomid fishes to the "rank of a distinct division of Ganoids." No such proposition occurs in the unpublished paper to which he refers, which was written to follow up the views which I expressed in my account of the structure of the Palæoniscidæ (Palæontographical Society, 1877), as to the abolition of the sub order "Lepidopleuridæ," necessitated by the demonstration of the fact that the Platysomidæ as a *family* are not really allied to the Pycnodontidæ, but are on the other hand so closely linked by ties of structure to the Palæoniscidæ, that, wherever the latter family is placed, thither the Platysomidæ must follow.

My paper on the "Structure and Affinities of the Platysomidæ" was read before the Royal Society of Edinburgh on May 5 of this year, and will in a few weeks appear in the forthcoming fasciculus of that Society's *Transactions*. Prof. Nicholson's mistake as to my views is obviously due to his having only had, and that on one single occasion, a very hurried glance over my proof-sheets. R. H. TRAQUAIR

8, Dean Park Crescent, Edinburgh, November 12

Voice in Fish

THE question as to whether fish have any so-called voice or means of intercommunication having some interest for your readers, I may relate that about six years ago, while engaged in a survey of the Disang River in Eastern Asam, I had occasion to sound by a line the depth of a pool called the "Deo Dubé" (or deep of the Demon).

While seated in a small *Rob Roy* canoe and very slowly drifting on the pool, I became aware of a number of large Mahsír (*Barbes macrocephalus*) moving about in the water below and around me. Sitting perfectly still I had the pleasure to see them gradually approach the surface and move about me at a foot or so distant, passing alongside, under and round the canoe carefully examining it, bow and stern specially. It may not be easy to guess a fish's *thoughts*, but from the manner in which they examined my symmetrical and grey coloured canoe they appeared to think it might possibly be a huge fish, and dead of course.

While watching their movements I was aware of a peculiar "cluck," or percussive sound—frequently repeated, on all sides, and coming from below, but close to me. Eventually I found that this was made by the Mahsír, and one—passing close along on my right, by itself, made several *distinct* sounds as it went on—that seemed answered by others to the left. If seated, say on the bank, the sound would be loud enough to be heard at 40 feet distance.

A large bivalve also is common in some parts of Eastern Asam that sings loudly in concert. A small *ant* also makes a peculiar thrice-repeated noise by scraping in unison on the dry leaves of its nest if it is disturbed. S. E. PEAL

Silurian Fossils in the "Lower Old Red Sandstone" of the Curlew Mountain District

YOUR correspondent in NATURE, vol. xxi. p. 32, on the above subject has evidently misunderstood the notice (NATURE, vol. xx. p. 641). The rocks in question, though belonging to what is generally known as the "Old Red Sandstone," contain Silurian fossils, which confirms the opinion of myself and others that the lower Old Red should be regarded as the upper part of the Silurian formation. G. HENRY KINAHAN,

President of the Royal Geological Society of Ireland

Dublin, November 17

The Paces of the Horse

A GOOD many ingenious contrivances have lately been invented by which to find out the true movements of the feet of the horse in its various paces, notably that described in "A Study on Locomotion" which appeared in NATURE, vol. xx. pp. 434, 468, 488.

My object in writing this letter is to challenge the assumption of all these experimenters that their diagrams should constrain artists to correct their representations of animals in motion.

When, for instance, Prof. Marey says of his diagrams, "these pictures are correct as regards the position of the members; it would be the artist's duty to add elegance of form," it is apparent to me that such a division of labour would never produce a picture. Take Fig. 16, for instance, representing the true position of the legs in galloping, and I venture to say no amount of elegance added would convey an idea of what the animal was doing.

I submit that the error which leads the experimenters so far is forgetting that the mechanism of the human eye has as much to do with the matter as the movements of the horse's feet.

Confining my argument to the gallop, I contend that the conventional extended attitude is true artistically, though it never actually takes place whilst the horse is at this pace. The eye (as is sufficiently proved by the need of machinery for finding out the actual motions of horses' feet) does not obliterate and receive impressions sufficiently quickly to trace the three paces in the gallop; but it can note the fact that at some moment during each bound, each of the four reach this extreme point. Now the feet are twice as long at this point as at any other, that is to say, the passing out over and returning along the last inch is for the eye a pause at the extreme. It is no more doubtful that a galloping horse should be painted as it usually is, than that a swinging pendulum can only be suggested by drawing it at one or other extreme of its excursion. An artist could no more use Prof. Marey's diagrams in the way it is assumed he should, than he could represent a rolling wheel if he took no liberties with the apparent position of the spokes; but confined himself by remembering their true places and numbers, which of course are the same as when the wheel is at rest.

It is true that a galloping horse might also be represented with all its legs gathered under it, but this is not done, because, as I agree with Prof. Marey, "it is the artist's duty to add elegance of form;" whilst I dissent from him when he allows himself to be convinced that "the greater part of the horses [of Phidias] are represented in false attitudes" because the odograph says so.

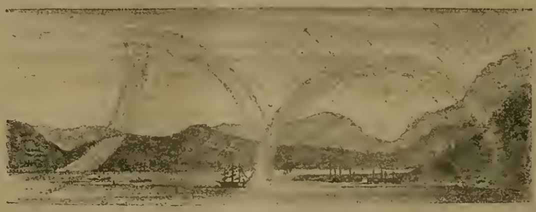
Edinburgh, November 12

A Curious Rainbow

I send you a rough sketch of a curious rainbow group seen in Gareloch about 8.25 A.M. on October 20. I would have written sooner but I delayed till I had obtained sketches from several different sources. I only saw the junction of the two bows at C, that being the only part of Row Bay visible from my standpoint, but several observers saw the whole group as I have drawn it. The sea was quite glassy, so that the inverted rainbow A must have been formed by the sun's rays reflected from the water. The wind was just beginning to rise and some scudding showers were passing up from the Firth of Clyde from the south-west,



Road to Kilcreggan. Roseneath. Row Point. Pier. Row.
A B C D

but the bay was quite calm. The bow D was perfectly full and bright, while B died away at its highest point. I can only imagine that B was formed by light reflected by some bright cloud, but I did not observe any bright enough. The view is nearly north-west. As I have never even among our Scottish hills seen such a combination of rainbows, I think the description may have some interest for some of your readers. The hill to the right is Knapps Hill, and is 2,000 feet high and three and a half or four miles distant.

Woodbourne House, Helensburgh, November 4

How Snakes shed the Skin

In Nature, vol. xx. p. 530, Dr. H. F. Hutchinson, amid some interesting facts about snakes, says: "I have never witnessed the process of skin-shedding, nor, I believe, has any observer." The Doctor then ventures an ingenious, though incorrect, hypothesis of his own. In the *American Naturalist* for January, 1875, *i.e.*, vol. ix. No. 1, under the title, "The Pine Snake of New Jersey," I gave an article embodying the results of several years' study of *Pituophis melanoleucus*, in which the process of exuviation is described as witnessed by myself. Herewith is an abstract. The few words interpolated for the sake of clearer exposition are put in brackets.

Near the close of September, 1873, at 1 P.M., looking into the box, I saw that the female snake had started the skin from her head. It was a little torn at the snout, and I found that the head and a little of the neck were denuded. The denuding process was going on, but very slowly. Doubtless the chief difficulty was in starting the skin, and I felt sorry that I did not see the start. The neck was very slowly becoming divested of the old cuticle, which, at first glance, had a sort of back-creeping aspect. What surprised me was the fact that there was not the least friction in the process; that is, there was no rubbing against any exterior object. It really did look as if an invisible power was drawing the skin back upon itself. [Looking closely, I caught the secret. There was a systematic alternate swelling of the body at the neck of the skin, thus stretching it, and making a shoulder in front of the neck, each swelling pushing the loosened skin a little backward.] The old skin at this time is very moist and soft, and any swelling of the body stretches and loosens it. So soon as the exuviation has reached the part of the body containing the larger ribs, this doffing of the old suit proceeds more rapidly, and with a singular system. It is done just in this way: Exactly at the place where the skin seems to be moving backward, a pair of ribs expands. This action enlarges or puffs out the body, and by stretching loosens the skin at that place. In this movement both ribs in the pair act at the same time, just as the two blades of the scissors open together. Now comes a second movement of this pair of ribs, in which action the two ribs alternate with each other. One of them—say the one on the right side—is pushed forward and made to slip out of and in front of the constriction made by the swelling, when it immediately works backward, that is, against the neck of the double receding skin. Now the left rib makes a like advance, and in a similar manner presses backward. [Thus for every increment of exuviation, or backward movement of the inverting skin, three actions occur with rhythmic method; the expanding of one pair of ribs, the intumescence of the body at that spot, and the pushing back of the skin by the alternate action of each rib.] Thus the final action of each pair of ribs is not synchronous, but alternate, and has a notable sameness of movement and result with that of the alternate hitching of each side of the mouth when swallowing a large prey. Indeed, swallowing, with a serpent, is a misnomer, for that laborious hitching is not more a pushing of the prey down the gullet than a drawing of the body over it. The Western man said he always felt better after getting himself round a good beef-steak. With the serpent this is a literal fact; it puts itself outside of its victim. So with that singular costal action it seems to push the skin backward; but this is an illusion, for it actually pushes itself forward, pulling the skin out as itself advances out of the skin, thus with each movement or advance lengthening the inverted cuticle behind; that is, the old hose everts or evolves itself forward, though it appears as if by some occult force to be pulled on itself backward.

The ribs of a serpent, which extend nearly throughout its whole length, are very much smaller near the neck and near the tail. At both these parts exuviation is much slower than where the larger ribs have play in the process. This rib action produced an automatic movement of the snake on the floor of its box, and across the folds of its companion, which kept as still as if it were dead. This involuntary movement of the reptile's body was almost imperceptible. All told, it might have been through two feet of linear space. But the exuviated skin was nearly six feet long. This movement seemed much greater than it really was. It was emerging from a tubular case, which was doubling upon itself for a while, the inner or unevolved part shortening as it moved forward with the body; the outer, or evolved part lengthening as it moved backward from the body. The cast-off skin is presented inside out, so that every scale is now seen on its under or concave side, and this is also true of the eye-scales. To all this there is one exception: the last scale of the tail is a hollow pyramidal or four-sided spike. This, for plain reasons, is not everted. When the shedding has reached this scale a sharp shake of the extremity is sufficient, and the unverted spike is left inside of its everted skin. The entire process of exuviation, allowing five minutes for the part that I did not witness, took thirty-five minutes.

Let me add that in poor health a snake has a hard time in getting off its old coat. I could detail an instance wherein the process took three months. The old skin adhered stubbornly to the new one, and was only removed by friction and by tearing off mere bits at a time.

SAMUEL LOCKWOOD

Freehold, New Jersey, U.S.

The "Hexameter," Πᾶσα δόσις ἀγαθὴ . . .

THERE is an obstacle in the way of regarding this passage (James i. 17) as a hexameter quoted by the Apostle from some poet, as the late lamented Prof. Clerk Maxwell is reported in Mr. Garnett's interesting notice of his life, work, and, not least, his character, to have suggested. The final syllable of δόσις is short, as the accentuation of πρᾶξις and similar verbal nouns proves. *Arsis*, as in "Βέλος ἐχεπευκές," Il. α, 51, can hardly be pleaded.

J. J. WALKER

University Hall, W.C., November 17

THE SWEDISH NORTH-EAST PASSAGE EXPEDITION[1]

DURING the wintering of the *Vega* large quantities of the bones of the whale were found on the beach. These at first were supposed to be the remains of whales that had been killed by the natives or by American whalers. On examination it was found that they must be sub-fossil. This was confirmed by the natives, who stated that no whale had driven on land in the memory of man. The remains were found to belong to four or five different species, of which *Balena mysticetus*, or a nearly allied type, was the most common.

Prof. Nordenskjöld investigated the formation of the strata of frozen earth several hundred feet thick which occur in Siberia as in Polar America. Along the coast of Siberia there is a stratum of water resting on the bottom of the sea which is several degrees below the freezing-point, so that a flask of the comparatively fresh surface water, when sunk into this stratum, begins to freeze. Stuxberg observed that the trawl-net often froze fast to the bottom. This was accounted for by the freezing of the fresh water which the net carried down with it from the surface. Nordenskjöld thinks that the mud carried down by the rivers into the sea as it sinks to the bottom carries with it fresh water adhering to the minute particles, and that this fresh water, like that carried down by the net, freezes at the bottom, forming thus a frozen stratum, which increases year by year until it reaches an enormous thickness. He is of opinion that a portion of the earthy layers of Siberia was formed in this way, although, he adds, he by no means considers this the only way in which such formations arose.

Along the whole coast, from the White Sea to Behring's Straits, no glacier was seen. During autumn the Siberian coast is nearly free of ice and snow. There are no mountains covered all the year round with snow, although some of them rise to a height of more than 2,000 feet. With one exception there were no rocks along the coast precipitous enough to be suitable breeding-places for sea-fowl, but a large number of these birds were seen during spring flying farther to the north.

During the voyage of the *Vega* from her winter quarters through Behring's Straits and farther south, Nordenskjöld searched for a tribe called Onkilon, said to be allied to the Eskimo, but without success. He found only reindeer-owning Tchuktches, and supposes that the name Onkilon, given by Wrangel to the old tribe inhabiting the coast and driven out by the Tchuktches, is probably related to the name Ankali, given by the reindeer-owning Tchuktches to the coast Tchuktches. Nordenskjöld states that English authors who refer Eskimo and Tchuktches to the same origin are mistaken. It was found that the inhabitants on the American side are pure Eskimo, with whom it was possible to carry on barter by means of the list of Eskimo words published in "Arctic Geography and Ethnology," London, 1875; but that the language spoken by the Tchuktches, of which Lieut. Nordquist collected about 1,000 words, is quite different, and probably allied to that of the Iranian races. On the other hand there is a complete correspondence between the household furniture of the Tchuktches and the Eskimo. It may be safely affirmed, he says, that these two neighbouring races have a greater number of identical articles in their tents than of common words in their languages.

The hills at Cape York on the American side were found to consist of crystalline schists without organic remains. Among the natives, who were Eskimo, there was a Tchuktch woman who said that Tchuktch tribes were settled on the American side between Point Barrow and Cape Prince of Wales. The Eskimo used, along with breechloaders, revolvers, and axes obtained from the Americans, bows and arrows, bone boat-hooks, and various stone implements. They were friendly and agreeable, and less given to brandy than the Tchuktches. There did not appear to be any chief among them. Complete equality prevailed, and the standing of the women did not appear to be inferior to that of the other sex. Among the stone implements were found arrow-heads and other articles of a species of nephrite so closely resembling the well-known nephrite from High Asia, that these implements were supposed to have actually come from that region.

A warm current, as in Europe, was found to flow along the north-western coast, and to create there a far milder climate than that which prevails on the Asiatic side. The limit of trees therefore lies a good way to the north of Behring's Straits, while the whole of the Tchuktch Peninsula appears to be devoid of trees. This is the case also with the land along the coast at Port Clarence, but a short distance inland there were bushes two feet high. Vegetation was generally luxuriant, and a great number of species were identical with, or nearly allied to, those of the Scandinavian north, among others the *Linnea*. Notwithstanding the luxuriance of the vegetation, the land invertebrates were much poorer in species than in the north of Norway. Thus only from ten to twenty kinds of beetles could be found, principally *Harpali* and *Staphylini*, and of land and fresh-water mollusca only seven or eight species. The avifauna was also rather scanty, and the dredgings in the harbour at Port Clarence, on account of the unfavourable nature of the bottom, yielded only a small number of animal and vegetable species.

The *Vega*, crossing to the Asiatic side, anchored in Konyam Bay on July 28. On the north shore of this Bay Dr. Kjellman added seventy species of flowering plants to the collection he had previously made. Here, too, were

[1] Continued from p. 40.

found the first land mollusca on the Tchuktch Peninsula. Nordenskjöld considers it probable that on the southern part of this peninsula there was in former times a little inland ice. On July 31 the *Vega* was anchored at St. Lawrence Island. Drift ice was seen for the last time. The quantity of ice carried by the Polar current through Behring's Straits is very inconsiderable, and it has evidently been for the most part formed along the coast. Not a single iceberg was visible, the whole of the ice seen being level and rotten "year's ice." St. Lawrence Island is inhabited by Eskimo, who having frequent intercourse with the Tchuktches, have adopted some of their words. The prevailing rock is granite, weathering readily, and thus giving origin to a very fruitful soil. Vegetation was exceedingly luxuriant, and rich collections of land and marine animals, lichens, and algæ were made.

The *Vega* next anchored off Behring Island on August 14. This island belongs to Russia, but the American Alaska Company has acquired the right of hunting, and maintains a station where skins, principally those of the *Otaria ursina*, are purchased. Between 50,000 and 100,000 of these animals are killed yearly on this and the neighbouring Copper Island. They yield the brown "sealskin" so much in fashion in recent years. Behring's Island is supposed to have been visited first by Behring, who, after being shipwrecked, died there in 1741, survived, however, by many of his companions, among others, by the talented naturalist Steller, who described the natural history of the island in a masterpiece that has seldom been surpassed. Since Steller's time great changes have taken place. The *Canis lagopus* then occurred in incredible numbers. Now they are so uncommon that not one was seen, and those that remain are not dark blue, but white, the skins being of little value. On the neighbouring Copper Island dark blue foxes are still found in considerable abundance. In 1741-42 Stellar and his companions killed here about 700 sea-otters. This animal, famous for its precious fur, is now quite extinct on Behring's Island. Of the sea-lion (*Otaria stelleri*), formerly abundant, only single specimens are to be found along with the sea-bear (*Otaria ursina*) on the rocky shores of the island, and the great sea-cow, the most remarkable of all the mammals formerly belonging to Behring's Island, is now completely extinct. Steller's sea-cow (*Rhytina stelleri*) was of a brownish colour, covered with hair which grew on a hide resembling the bark on an old oak. Its length, according to Steller, was sometimes as much as thirty-five feet and its weight nearly 50,000 lb. The female yielded abundance of milk, which, along with the flesh, resembled, and were even, according to Stellar, superior to those of the cow. The sea-cow fed on the abundant algæ along the coast in great herds. According to Middendorf, the last sea-cow was killed in 1768. Nordenskjöld, however, found a "creole" of mixed Russian and Aleutian blood, whose father had come to the island in 1777, and remembered the killing of sea-cows while they fed on seaweed at low water for the first two or three years (1779 or 1780) after his arrival. Nordenskjöld also found two men who had seen, about twenty-five years ago, a large animal corresponding to Steller's sea-cow. He also obtained two complete skulls of the animal and a quantity of bones sufficient to fill twenty-one large boxes and barrels. The sea-bear (*Otaria ursina*) is the only large animal that exists on the island in about as large numbers as in Steller's time. It is "preserved" by the Alaska Company, only a limited number being killed yearly.

The vegetation on Behring's Island was found to be exceedingly luxuriant, and the sea in its neighbourhood one of the richest in algæ in the world. Forests of algæ, sixty to a hundred feet high, grew in favourable situations, rendering dredging exceedingly difficult. Some of the algæ are used by the natives as food.

The small streams swarmed with a number of different kinds of fish, among them a species of *Coregonus*, a little *Salmo fario*, a middle-sized salmon with nearly white flesh and a purple skin, and another of the same length, but very thick, and with a hump on its back. Other species of salmon with deep red flesh are found in the larger rivers. Leaving Behring's Island on August 19, the *Vega* reached Yokohama on September 2 in good order and with every man on board in excellent health. There had not been a trace of scurvy during the whole voyage.

GALILEO AND THE APPLICATION OF MATHEMATICS TO PHYSICS[1]

II.

In dealing with the falling body I had to ask you to think what is the speed at any moment of a body which is changing its speed every moment, every half moment, every hundredth part of a moment or what we call continuously. It is easy to see that it has *some* speed at every point, and that the speed at every point is quite definite. I indicated a way in which we could fix this approximately, by taking the average speed over short intervals. A similar question is raised in considering the path of the projectile. Its direction changes from point to point. The bullet is shot towards the east, and, for the sake of picturing its path, I imagine the lines vertically upward to be called northwards, as on a vertical map. At first the particle starts off, let me say, in a direction N.N.E. When it has reached the top of its path it is going horizontally—due east—when it has got back to the level the Northing has been turned into Southing, and it is going S.S.E. In its upward motion it changes continuously from N.N.E. to E. At a certain position it is half a point more to the east and less to the north; further on, a point more; further on again, the Northing has disappeared. The path has curved away; it is curving away at every point of it. A particle moving at a uniform rate in a circle changes its direction; but at every point the amount of curvature or immediate bending away from the direction in which the particle moves at any moment is the same. In a small circle the curve bends away faster than in a larger one from the line which represents the direction of motion at any point, but in each separate circle the measure of bending must at every point be the same. How will it be in a different kind of curve, such as an ellipse, or the path of a projectile, a parabola? As the speed of falling changes from moment to moment continuously, the curvature changes from moment to moment.

In solving the problems of falling bodies and of projectiles, Galileo was essentially applying the principles of the Differential or Fluxional or Indivisible Calculus. If pure mathematics had attracted him as strongly as its application to physics, he would have thought these problems out, and would have founded the Fluxional Calculus, which is the glory of Newton and of Leibnitz. No doubt the world saw more in his great astronomical discoveries; in the telescope, which brought the moon thirty times nearer, and showed its mountains and the jagged edges of its gibbous side; in the discovery that Venus waxes and wanes with phases like the moon; in the four satellites of Jupiter, the famous Medicean stars, which showed the most restless activity of revolution round their central orb—an activity unprecedented in celestial bodies and discomposing to the Peripatetics, whose stately order of the heavens could not tolerate stars which behaved like sky rockets—of the curious double satellite of Saturn, which sometimes was even more bewildering, and went out altogether. It was the Ring, and Galileo gave what we now recognize as a very fair picture of it. No wonder that the man who first made the

[1] An Introductory Lecture, by William Jack, M.A., LL.D., F.R.S.E., Professor of Mathematics in the University of Glasgow, formerly Fellow of St. Peter's College, Cambridge. Continued from p. 43.

telescope a practical instrument could not lay it aside till he had exhausted what it had to tell him, or that his whole thoughts were turned from the mathematical and apparently abstract entities which we have been describing to discuss the system of the universe in the new light he had brought to bear on it. Yet the choice he made has proved to be wrong. It was through the door of mathematics—not through the tube of the telescope—that the discoveries of the true system of the universe were destined to pass. Galileo's facts made it practically certain that the Copernican theory was right, and that the sun was the centre of the orbit of each of the planets. Kepler enlarged these statements, establishing, by a patient industry that was never surpassed, that the orbits are ellipses nearly circles, with the sun in one focus—that the line drawn from sun to planet sweeps over equal areas in equal times—that the square of the time taken to describe a planet's orbit, divided by the cube of its mean distance from the sun, is a fraction which is the same for every planet of the system. Till Newton appeared to interpret them, these results were only statistical facts; and Newton himself could throw no light on them till he had invented the Fluxional Calculus and discovered the properties of an abstract fluent quantity, such as a speed or a curvature, which is continuously changing.

And yet how near Galileo came to the secret! We have seen that he was in fact compelled to deal with the fundamental problems of the Fluxional Calculus in discussing falling bodies and projectiles. It was his famous scholar Cavalleri whose Calculus of Indivisibles foreshadowed the Fluxional Calculus of Newton. It is difficult to say how much of Cavalleri's views were developed out of the note-books of his master's lectures and out of his own consideration of the problems that master had triumphantly solved. Like many of Galileo's pupils, he had published works of his own, in which it was doubtless difficult to separate what was original from what was borrowed. From about 1592 till about 1638—forty-six years—Galileo had published scarcely anything except on the planetary system. The inclined planes, the falling bodies, the pendulums, the cycloids, were so many problems worked out in his youth—during the early years of his professoriates at Pisa and Padua—scattered in students' note-books, and germinating in students' minds throughout the world. It was so with his theory of projectiles; and Cavalleri, who was one of his old students and his successor at the University of Padua, published the theory of projectiles without referring it to its real author. Challenged by Galileo, he allowed his obligations frankly, and their friendship was not interrupted. Cavalleri published his theory of indivisibles in Galileo's old age (1635), calling it "Geometria indivisibilibus continuorum nova quadam ratione promota," after he had apologised for his former awkward error. The shape of the new theory was Cavalleri's own—the impulse came almost certainly from the discoverer of the true theory of falling bodies and of projectiles.

We owe the theory of indivisibles to Cavalleri, and not to Galileo, partly, no doubt, because for the greater portion of his manhood his astronomical discoveries, and the discussions they brought with them, filled Galileo's mind almost exclusively; partly because for the last five-and-twenty years of his life most of his thought had to be spent on his relations with the Church, to which he was sincerely attached. In 1616 he was warned that the Copernican hypothesis was to be considered as false. Religious persecutions were not then unknown in Protestant countries, and people were tortured for witchcraft as well as heresy. But it was reserved to the Catholic Church in Italy to erect the Aristotelian doctrines and the Ptolemaic system into an article of faith. A century after Luther shook the world at Wittenberg, had brought dreadful days for mathematicians, physicists, and reformers, in Italy. When Galileo was a youth of twenty-three, two years before he was called to be professor at Pisa, Barozzi, who had occupied himself at Venice with the discussion of the asymptotes of curves, was believed to be guilty of dealing in sorcery and witchcraft, of casting lots, and of causing the drought which reigned in the Island of Cyprus. He was condemned by the Inquisition in 1587, partly because he had a great number of curious books and a wonderful collection of astronomical and mathematical instruments. Porta, the famous author of the "Magia Naturalis"—the reputed discoverer of the *camera obscura*,—was summoned to Rome to give an account of his opinions. Giordano Bruno was burned at Venice in 1600, hardly less for his daring speculations in religion than because he had attacked Aristotle and adopted the system of Copernicus. The aged Archbishop of Spalatro, de Dominis, to whom Newton attributes the successful explanation of the colours of the rainbow, died in 1624 in the prisons of the Inquisition, and all that death had left to the mercies of his persecutors was publicly committed to the flames. The skies of Italy were black with the smoke of these burnings, the air was heavy with suspicion and terror. The Inquisition tried men for heresies which had been denounced by unknown enemies, and the processes of moral and intellectual torture to which it subjected those who were brought before its tribunals were only more oppressive because the secret of their details was closely kept. Galileo wrote a letter to his friend and pupil the Jesuit Castelli, in 1614, copies of which were privately circulated, but which was not printed till twenty years later. In that noble writing he lays down with equal firmness and clearness the broad lines with separate scientific and religious thought, and shows himself deeply penetrated with religious as with scientific faith. A Jesuit father denounced it, another preached against him as a witness for the Copernican system. Though the great works he had hitherto published, that on the Solar Spots and the "Nuncius Sidereus" had neither of them committed their author to the Copernican theory of the universe, the Church resolved to anticipate and to forbid the support by the most illustrious of living astronomers of doctrines, which, whatever else might be said of them, were clearly fatal to the authority of the Peripatetics.

Galileo went to Rome (in 1616) to struggle for as much liberty as could be saved, but he was deeply disappointed with the result. He retracted nothing, because he had neither been tried nor convicted, but the officers of the Inquisition waited on him, and left him an official warning that it was not permitted to teach that the sun was the fixed centre of our system, and that the earth revolved around it. Silence was imposed on him; and it was only after the new Pope was appointed, who, as a Cardinal, had opposed the promulgation of this warning, that he ventured again to think of publishing his views. The book in which they appeared in 1632 was a three-cornered dialogue between a Ptolemaist and a Copernican, with a third person acting as a kind of half intelligent chorus. The arguments of the Ptolemaist were, of course, the weaker, as in Galileo's hands it was impossible that it should be otherwise. To secure the *imprimatur* of the censorship, he prefixed this statement to the book—"Within the last few years a salutary edict was promulgated at Rome, in which, in view of dangerous scandals, silence was enjoined on the supporters of the Pythagorean doctrine of the movement of the earth. Some have been rash enough to say that this dogma was not arrived at after a judicious examination, but was promulgated in passion and in ignorance, and it has been asserted that people utterly without practice in astronomical observations ought not to attempt, by a premature prohibition, to clip the wings of speculation. Hearing these complaints my heart burned within me, and I could not keep silence. Having been fully informed of this wise decision, I resolved to appear publicly before all the world, and to testify to the truth. I was at Rome at the time. I was listened to and praised by the most eminent prelates, and was at once acquainted with this decree. My purpose in this book is to show foreign nations that in Italy, and especially in Rome, as much is really known about these matters as anywhere else. I have gathered together my speculations on the Copernican system to show that all these things were known before the condemnation, and that we owe to Italy not merely doctrines for the salvation of their souls, but ingenious discoveries to delight the minds of men." The elaborate and somewhat overstrained courtesy of this preface availed as little to save its author from the terrors of the Inquisition as the imprimatur of the Papal censorship which he had procured beforehand. The Pope looked on the *soi-disante* hypothetical presentation of Copernicanism as a mere pretence. I need not repeat the well-known story of the great man's sufferings. After long months of mental torture, he was dragged before the sacred tribunal, and compelled to confess that he had been criminally negligent in stating too cogently the arguments for the Copernican system in the eagerness of intellectual debate, and in not sufficiently guarding the hasty reader against the force of arguments for what the Church had pronounced to be dangerous heresy. At the age of seventy the greatest discoverer—the most distinguished man in Europe—was threatened with torture to extract from him, if possible, the confession that he had had a malicious intention of unsettling men's faith in divine truth. It had been privately decided by the Pope that if the threat of torture failed, the Inquisition was not to proceed to the last extremity. Galileo knew nothing of this, but the threat did fail. For his rashness he was sent to the prisons of the Inquisition. He was released in a few days, but he was ordered to confine himself within four walls and his successive places of seclusion were marked out for him. His visitors were noted, and he was warned that an imprudent word might bring him back to the dungeons from which he was only respited on his good behaviour. Private orders were given to the censorship throughout Italy that he was not to be permitted to publish anything, not even to re-issue the treatises which first made him illustrious. It was a living death to which his judges had consigned him, and he was reduced to permit his friends to publish surreptitiously across the Alps the book which summed up the long work of his life in Mathematics, in Mechanics, in Hydrostatics, in Physics, so far as Physics were then possible. His greatest work, the "Discorsi e Dimostrazioni Matematiche," "on two new sciences," appeared in France, and, to save him from the risk of torture, the miserable pretence had to be put forward even there, that the manuscript had been taken away by one of his friends. In 1637, in his seventy-third year, he lost his eyesight; in 1641 he died.

The eight years during which the broken-hearted old man, from whose outward eyes the light of that universe, which he had done more than all his predecessors to reveal to men, was fast fading, were the most memorable in the history of modern science. Much of the work he published in them had previously been scattered over Europe by his pupils, but none of them all had his mighty sweep of thought, his noble style, his all-illuminating insight. Had his enemies succeeded in silencing him, had he been handed over to the rack at seventy, or prevented, as they meant he should be, from speaking once more *urbi et orbi*, for fear his words might shatter the system of Ptolemy or put an end to that worship of a traditional philosophy which he had conquered, and which was struggling to strangle him in its death throes, the world might have waited a century longer for Torricelli and Pascal, for Newton and Laplace. In these last years he is greater and maturer than ever. Banished from the skies by the jealousy of philosophers and priests, he comes back to earth and lays deep and sure those foundations of mechanics without which it was impossible to carry further the science of the heavens. His watchword was that phenomena must first be measured before the attempt to explain or to co-ordinate them. Physics and Astronomy can rest only on mathematics, and the secrets of that hand which laid the foundations of the world in measure are only to be learned by patient and exhaustive observation, and by thought built upon and not preceding it.

Let me give you one last illustration of his method in his invention of a heat measurer. Every one seems to know what is heat and what is cold. They are among the most familiar of our sensations. But my sensations may differ from yours. I may pronounce a body hot which you may call cold; and before Galileo's time there was no apparent way of settling the dispute except by declaring it a matter of taste, and agreeing to differ. He invented a measuring instrument—the progenitor of our thermometers. Imagine a flask with a bulb blown out at the end of it, and a long tube of uniform bore for a neck, such as we see in a thermometer. Let the bulb be partly filled with coloured water. Put the finger at the end to keep the water in; turn the tube upside down so that the bulb is at the top and the tube vertical. Plunge the end of the tube in a vessel of water, and then remove the finger. All the coloured water will not flow down into the vessel. If the bulb is surrounded by something warmer than itself, the level will fall till it nearly reaches the water in the basin; if it is surrounded by something colder, the level will rise. Galileo had found a phenomenon accompanying an increase or diminution of heat as unvaryingly as a shadow follows its substance. Like the shadow, this new phenomenon is measureable, and though it was too soon to say that the rise or fall in the tube was in any exact proportion to the diminution or increase of the surrounding heat, it was easy to establish the fact that a rise always meant a diminution and a fall an increase. It was not given to Galileo to discover those properties of air and gases which turn the thermoscope into the air thermometer, the most sensitive and accurate of heat measurers. Had he known them, he was far enough in the way which his pupil Torricelli followed to have discovered the barometer also, and to have measured the weight of a column of that great atmospheric ocean at the bottom of which man lives as the Bathybius is supposed to live at the bottom of the watery deeps. Even there his sagacity had divined the necessity of applying measurement to that horror of a vacuum which before his time had only been a philosopher's name for our ignorance of a cause.

I have certainly failed in my object to-day if I have not conveyed to you two truths which lie at the basis of modern science. It is the *first*, perhaps, with which I have most to do as a teacher, and you as students of pure mathematics. The sciences of measurement, the methods of measurement—sciences and methods which are abstract in form, but which are constantly applied to concrete things,—are the true keys to the sciences of experiment. It was in the apparently intricate abstractions of continuous change of velocity and of curvature, in the apparently curious considerations of the science of indivisibles, the beginnings of which we owe to Galileo, that Newton found that secret of the universe which transformed the life-long labours of Kepler, the great statist of astronomy, into the law of gravitation. The fascinations of astronomy, and the fatal chains which hung about his later life, like those which Samson had to bear when he made mirth for the Philistines, combined to deprive Galileo of the honours which awaited Newton. But that lesson need not be lost to us. My *second* lesson is that measurement—measurement even in its simplest form, mathematics, or, if you choose, arithmetic,—lies at the root of all our knowledge of nature.

If I have one word more to say about the great Florentine to my students, it will not be of the pity of it all, of the terror and the tragedy in which his life closed;

it will be to ask them to remember that he proved, what the greatest men have always proved, that it is possible to conciliate the most magnificent knowledge of mathematics or of any abstract science with all the culture of the time. Galileo was an admirable writer; he was a great musician; he studied Ariosto and Dante with intense love; he amused himself with comedy; he distinguished himself in painting. It is the commonplace of the history of great men—a commonplace better illustrated perhaps by the great names of Italy than by those of any other country—that greatness is scarcely compatible with a narrow concentration of intellect, even to one great family of subjects. Many of her great mathematicians were sculptors, painters, poets, masters of expression. But if the story of Galileo's life should guard you from falling into the Scylla of the eager student who thinks that he must dwarf his nature if he hopes to attain to eminence in a special subject—an error to which the pressure of our times renders him more and more liable—it is equally certain to save him from the Charybdis of the *dilettante* who forgets to choose that one of the objects attainable within the little compass of a man's life which is most suited to his faculties, and in attaining which he is most likely to succeed. Galileo repressed none of his great powers, and denied himself none of the intellectual delights which few men of his day were so able to enjoy. But the obstinacy with which he followed after mathematical and physical truth, from the day when he first listened, as a truant medical student, at the key-hole of a lecture-room to the professor of mathematics teaching the Grand Duke's pages, to that, nearly sixty years after, when the worn-out shell which had suffered so much was laid in that last darkness of the grave, warns us that greatness is never, and, I may add, success is seldom, won without an unfaltering perseverance in the pursuit of the main object of life. The last wish of the venerable old man, whose heart suffered as much from the cruelty which had cut him off, in a sense, from the outward communion of the faithful, as his intellect did when he was compelled, on his knees, to deny what he had proved to be the true system of the universe, was refused him. The Church below refused him burial in the Santa Croce at Florence, but it could not prevent the eyes that old age and suffering had blinded to the delights of his Italian earth from opening on the splendours of an immortality which no man has better earned.

WHO WAS PRINCE ALUMAYÛ?

SOME of our contemporaries, referring to the recent death of King Theodore's son, Prince Alumayû, speak of him as if he were an African of the ordinary Negro type. This is perhaps on the whole a fair gauge of the popular ideas still prevalent regarding the natives of the Dark Continent. Yet, though the standard is not of a high order, it must be confessed that in the present case some little confusion might well be pardoned, considering the many difficulties attaching to the subject of Abyssinian ethnology. Indeed it would be no easy matter even for a sound ethnologist to answer the question off-hand, who was Prince Alumayû? To do so accurately implies a clear knowledge of a very complicated problem, to the elucidation of which a few lines may be welcomed by the readers of NATURE, in connection with an event of some political importance and presenting a very striking parallel in more than one respect to the death of the late Prince Louis Napoleon in Zululand.

It may at once be stated that, whatever else he may have been, the young "Ethiopian," as he has been called, was in no sense an African Negro, and that matters will be much simplified if the "Negro question" be dismissed altogether from the present discussion. There no doubt is some true Negro blood in the lowlands, especially towards the south-west frontier bordering on Senaar; but in the Abyssinian highlands proper the Negro element seems never at any time to have been present, and at any rate King Theodore of Amhara was no more of Negro stock than are the Rajputs of Northern India. The types have nothing in common except the outward element of colour, though even here great differences prevail, and many of the Abyssinians, especially the women, are very fair. In all other respects—physique, language, mental qualities—the divergence is fundamental.

This statement applies not only to the ruling peoples of Tigré, Amhara, and Shoa—the "Habesh" proper—who are intruders, but also to the true aborigines whether settled or nomad, and who may, for convenience, be here collectively grouped as Agaü, the 'Αγαῦ of Cosmas (about 520 A.D.). The Habesh belong to the Himyaritic branch of the great Semitic family, and must have found their way into the country from the south-western parts of Arabia many hundred years before the Christian era. The Agaü are a section of the Hamitic family intermediate between the Gallas and Somâli of the south, and the Bisharas or Bejas and Egyptians further north. But Semite and Hamite, both originally no doubt one, are themselves mere varieties of the great "Caucasian" type, of which the Aryans are a collateral branch. It follows therefore that Abyssinia is peopled exclusively by races fundamentally distinct from the African Negro, and remotely allied to the fair European stock. Hence Prince Alumayû's affinities are, not with the black inhabitants of the Dark Continent, but with the light, swarthy, and dark peoples of Europe, South-Western Asia, and Northern India.

It will now be more easy to determine his position in the Abyssinian family itself. Although in this area the fundamental elements, as shown, are two only, Hamite and Semite, the intermingling of these elements, continued during a period of probably not less than four thousand years, and taking place under ever-varying conditions, has resulted in no little confusion, and the perplexity has in this case been further intensified by the elements of speech and religion. Thus, the Amharic people, for instance, are usually classed as "Habesh" proper, because of their language; for Amharna, notwithstanding many serious differences, is no doubt fundamentally related to the Tigrâi, the purest representative of the old Ghêz (Himyaritic), extinct since the fourteenth century. But it might not be difficult to show that the bulk of the Amharic[1] nation are ethnically of Agaü stock, though now speaking a modified Ghêz dialect imposed upon them by the conquering Semites from the north. At the same time the dominant race in Amhara is no doubt still more akin to the Semites than to the subject race. Hence the late Prince Alumayû, belonging to the royal blood of Amhara, must, on the whole, be regarded as of Habesh (Himyaritic) stock as well as speech.

Religion has been mentioned as a source of confusion, and an obvious case in point are the mysterious Falashas, who, because professing the Jewish faith, are popularly supposed to be of Hebrew nationality. Fortunately, Mr. Edward Hine has not yet got hold of them, and they have consequently not yet been identified with any of the lost tribes. Nevertheless, their position is sufficiently curious and interesting, though it may now be stated with some confidence that they are neither Jews, Israelites, nor Semites. In speech and physique they are a distinct branch of the Agaü (Hamitic) family, and can no more be converted into descendants of Abraham by the practice of maimed Abrahamitic rites than the adoption of Islám can transform the Chinese Panthays into Koreish Bedouins.

The subjoined scheme of the various races now in possession of the Habesh highlands may help to clear up

[1] The very word *Amhara* has been identified with the *Hamra*, the chief Agaü nation in the Takazzé valley and province of Lasta, Tigré.

the obscurity attaching to the subject of Abyssinian ethnology:—

Table of Abyssinian Races

Hamites. (Agaü Stock.)	*Mixed.*	*Semites.* (Himyaritic Stock.)
Aghagha, prov. Aghaumêder.	(Hamites & Semites.)	Tigré, N. and E. of River Takazzé.
Hamra, prov. Lasta, S. Tigré.	Bogos, extreme N.E.	Samhar, on coast near Massowah.
Falasha, mainly in Semyen.	Gongas, about Gojam.	Shoho, S.W. of Massowah.
Kwara, W. and N. of Aghaumêder.	Gurâgwe, extreme S.	Menza, N. of Hamasen.
Khamant, chiefly in Dembea.	Kunama, N.W. towards Taka.	Habab, Bediuh, Takwé, Marea, Barea, } N. & N.E. frontiers Tigré.
Fighen, S.W. from Lake Tsana.	Shoa, S.E. corner.	
Zalan, chiefly in N. Amhara.	Amhara, between the Takazzé and Abai.	
Witos, about Lake Tsana (?).	King Theodore.	
	Prince Alumayû.	

Of the languages three only are of any literary or political interest: *Ghêz*, still surviving as the language of the liturgy and Sacred writings, though scarcely understood even by the clergy; *Tigrâi*, its purest modern representative, current throughout the kingdom of Tigré and generally north and east of the Takazzé; *Amharna*, spoken with considerable dialectic variety in Amhara and Shoa. All are written in a peculiar syllabic character showing certain affinities to the Himyaritic rock inscriptions of Marah and other parts of South Arabia. Amharic employs seven additional letters for sounds not occurring in Ghêz or Tigrâi, making with the vocal modifications a total of 249 distinct symbols. This was the language of Prince Alumayû.

A. H. KEANE

COLOUR-VISION AND COLOUR-BLINDNESS

AS the notices of these subjects which have recently appeared in NATURE appear to me to do scant justice to the received theory, will you permit me to call attention to a portion of the evidence on which this theory rests?

The *Philosophical Transactions* for 1860 contain a paper by Prof. Clerk Maxwell, in which actual measurements are given of the quantitative relations between various colours, some of the observations having been taken by persons of normal vision, and others by a colour-blind person. The instrument of observation consisted of a species of spectroscope with three parallel slits, the widths of these slits, and also the distances between them being variable at pleasure. By this means three overlapping spectra are obtained, and any three spectral colours can be mixed in any proportions. The observations showed that any four colours as presented to the eye in a given spectrum are connected with each other by a definite colour-equation, such as—

$$3A + 4B = 2C + 6D,$$

which means that if the four colours A, B, C, D, as they exist in the given spectrum, are increased in intensity threefold, fourfold, twofold, and sixfold respectively, and then mixed two and two, the mixture $3A + 4B$ will present exactly the same appearance as the mixture $2C + 6D$. This is only another way of saying that colour as seen by normal vision contains three independent variables, or requires three numbers for its specification. Any three colours of the spectrum will serve as the three specifying elements; for example, if we employ A, B, and C to specify D, the specification will be—

$$D = \tfrac{1}{2}A + \tfrac{2}{3}B - \tfrac{1}{3}C.$$

Here we have one coefficient (that of C) with the negative sign. The three primary colours are defined to be those which will always have positive coefficients when they are employed as the specifying elements. In plainer words, all other colours can be exactly imitated by mixtures of the primaries, whereas, in the above example, the colour D cannot be imitated by a mixture of A, B, and C.

The points of the spectrum at which the three primary colours are found, will not necessarily be the points which most strongly excite the three elementary colour-sensations respectively. On the contrary, as a matter of fact, the two extreme sensations (called by Maxwell the *red* and the *blue*) are very feebly excited at the parts of the spectrum where they are purest, namely, at the extreme ends of the spectrum; and the middle sensation, which is largely adulterated with the other two even at the point where it is purest (namely, at a point in the olive green, which is, accordingly, one of the three primaries), has not a maximum of intensity at this point, but increases in intensity as the brightest part of the spectrum is approached, and attains its maximum (for the solar spectrum obtained with a flint glass prism), somewhere between the fixed lines E and D. The determination of the position of the middle primary in the spectrum, was made with considerable precision in the paper referred to; but the faintness of the two extremities of the spectrum rendered wide slits necessary in examining these regions, and thus introduced inaccuracy in determining the positions of the two extreme primaries, which in later publications Prof. Maxwell places at the very extremities of the spectrum.

The latter part of the paper of 1860 consists of a postscript containing observations made by a colour-blind person. The colour-equations found by direct observation are given, and are shown to agree with the supposition that the observer's vision was dichroic, the sensation corresponding to the extreme red being absent. The curves of intensity for each of the two elements in the vision of the dichroic observer are given, side by side with the three curves of intensity for the vision of a trichroic observer, all these being directly calculated from the observations, and the two dichroic curves appear to be practically identical with two of the three trichroic curves.

Dr. Pole's objection to the received theory appears to me to have no force except in so far as it is an objection to a name. The colour which the colour-blind see in the less refrangible half of the spectrum appears to be due to the excitement of the middle one of the three elementary sensations of trichroic vision. Persons of normal vision never get this sensation without large adulteration, and hence ordinary language contains no appropriate name for it.

Prof. Hering's theory of colours, as expounded by Dr. Pole (NATURE, vol. xx. pp. 479, 480) seems inconsistent with the fact (established by the observations of Prof. Maxwell, Lord Rayleigh, and other competent observers) that there is one definite colour-equation between any *four* colours. For Prof. Hering's theory assumes four elements of colour-sensation, R, G, B, Y, such that

$$R + G = 0, \quad B + Y = 0.$$

It would follow that, with the help of the minus sign, all colours could be specified in terms of R and B, and hence by writing down the specifications of any three colours, and employing the ordinary processes of elimination, a colour-equation could be obtained between the three colours. Prof. Hering's theory then leads to the result that there is a definite colour-equation between any *three* colours; in other words, that when any three colours are given it is possible to imitate one by a mixture of the other two. This result is so utterly opposed to fact, that a theory which leads to it cannot stand for a moment.

J. D. EVERETT

SOME OBSERVATIONS ON FLEUSS'S NEW PROCESS OF DIVING AND REMAINING UNDER WATER

I HAVE recently had two opportunities of seeing a new process of diving and of remaining for a long time under water, called, after its inventor, Fleuss's process. The peculiarity of it is that the diver takes down with him such a good and wholesome supply of air-food, that he is quite independent of any supply from above, so that there is no pumping required, and, indeed, no help whatever, except a signal-man and cord.

The experiment is being shown daily at the Royal Polytechnic Institution, and I am indebted to the managers for giving me the earliest notice of it, and for offering me every facility for observation. I am equally indebted to Mr. Fleuss for his readiness to carry out my wishes, and I am sure the readers of NATURE will be interested with the facts I have now to offer them.

Mr. Fleuss, the inventor of the apparatus, is a young Englishman, twenty-eight years of age, who has served, I believe, as an officer in the P. and O. Company's service. He has constructed the apparatus himself in a skilful but not very ornamental fashion, and he is his own diver. He went down in the apparatus, like a brave man, first himself, and he only, up to the present, has been down in it. He is a short slight man, of fair complexion, and very pleasing expression. He has a quiet and resolute enthusiasm which is quite refreshing.

The dress in which he descends under water is like an ordinary diver's dress. A helmet, a breast-plate, and the common water-tight armings and leggings. He bears on his shoulders a weight of 96 lbs., and his boots are weighted to 20 lbs. At twelve feet depth he moves comfortably in the water under this pressure. From the helmet there proceeds a light cord for signalling to the signaller above.

Before the helmet is fixed and the mask closed, it is seen that he wears, firmly tied over his mouth and nose, an ori-nasal mouth-piece, from which a breathing-tube of an inch bore proceeds downwards. This mouth-piece is, in appearance, just like the chloroform mouth-piece invented by the late Dr. Sibson, and afterwards added by Dr. Snow to his chloroform inhaler. For many years I used invariably the same kind of mouth-piece for administering volatile anæsthetics, but Fleuss's fits much closer, and is fixed more firmly.

When he is on the floor of the tank, Fleuss moves about as he pleases, apparently without any impediment whatever. He can pick up coins, he can sit down, and he can even lie down and get up again, a feat, I believe, entirely novel in diving. He breathes, he assures me, just as easily as when he is in the air and quite as freely, and from what I observed when he came out of the water from a long immersion, I have no doubt as to the correctness of his statement. He has some means of disposing of the products of respiration as well as of getting a continuous supply of air for respiration, since there is no escape of expired air from him into the water.

On the first occasion on which I witnessed the experiment Mr. Fleuss remained in the water twenty minutes. He came out quite free of any oppression. His pulse was steady, his breathing free, and his complexion natural. This was considered a short experiment, and on Saturday last, November 15, therefore, I asked to see it prolonged to an hour and to be allowed to follow it through all its stages. The request was immediately granted.

The diving-dress was adjusted on Saturday, at 6.33 P.M., and then Mr. Fleuss began to breathe from the apparatus. At this time his temperature was quite natural and his pulse was beating steadily at 68 per minute; the pulse was of good strength and tone. The temperature of the air was 51° F.; of the water, at the upper surface, 49° F. Fleuss said it was colder lower down, but the difference was not determined. He descended at 6.40 and remained under the water, at a depth of twelve feet, precisely one hour, namely, until 7.40 P.M. He walked about the greater part of the time, picked up pennies, and once or twice partly reclined on the floor of the tank. At the end of the hour he gave the signal to come up, the cold of the water having caused great numbness in his hands; he walked up the steps, carrying the heavy weights (116 lbs.) briskly, and was relieved, after a short delay, first of his helmet and then of his mouth-piece. At this point I found his pulse to be beating at 120 per minute and somewhat feeble, but the face was clear of any sign of asphyxia, though it was a little pale. His breathing was quite free. He attributed the quickness of the pulse to the labour of carrying the weights up the ladder, and no doubt correctly. Seven minutes later, the dress having been removed and warm clothing put on, I found the pulse to be ninety per minute, and the temperature of the body, taken from the mouth, to be 94° F., rather more than 4° below the natural standard. At twenty minutes later, that is to say, at twenty-seven minutes after release from the water, the pulse was eighty per minute, while the temperature had risen to 96° F.

At this stage I took an observation of the pulse with the sphygmophone. The three natural sounds were perfectly clear and in regular order, but the first or percussion impulse sound was extremely tremulous; the second or recoil sound was slightly tremulous; the third was clear.

I next took a sphygmographic reading of the pulse, in which all the events belonging to the natural pulse were distinctly marked. The impulse stroke was short, as was also the first descending stroke; the second ascending stroke was decisive, and the intervening lines between the third and the recurrence of the percussion stroke were shorter than is natural to Mr. Fleuss, as will be seen from the comparison of the two annexed sphygmographic tracings, 1 and 2.

1. Pulse tracing after one hour's immersion in water at 49° F. Temperature of mouth 96°, pulse beat 80 per minute. November 15, 8.15 P.M.

For the sake of comparison I took a subsequent tracing of Mr. Fleuss's pulse on the morning of Monday, November 17, after breakfast. His pulse was at 68 per minute, the same as it was on Saturday just before he entered the water. It will be seen to be a pulse naturally slow and steady, but not very powerful.

2. Tracing of pulse in its natural or ordinary condition under the same pressure. Beats 68 per minute. November 17, 10 30 A.M.

At fully seven minutes after his release from the water the pulse had come down to sixty-eight beats per minute, and the temperature had risen to 97° F. Ten minutes later still the temperature was 97°·6 F., eight-tenths of a degree below the natural. At this time my observations ceased.

The facts above narrated prove that, without assistance from above, a man who has had no previous experience of diving or of remaining under water can take down with him sufficient oxygen to live there easily for an hour. Mr. Fleuss assured me—and I see no reason to doubt him—that but for the cold he could have remained another hour and a quarter, and that he could easily arrange to remain four hours. Depth would make, he said, no difference as to breathing within the apparatus.

The mode by which the breathing is effected remains a secret, but is, he says, extremely simple. At my first observation, when he was under water twenty minutes only, I thought it possible that he carried down sufficient compressed air to live upon, and that he had a means for allowing the expired air to escape into the water. The later experiment shows me that this view was wrong. He could not carry down in the dress sufficient air to last him over an hour, and he does not seem to give out the expired air. I have no knowledge from him or any one how he breathes in the dress, and although I see how it could be effected, I think it right to leave it to Mr. Fleuss himself to describe the principle of his invention whenever he thinks, from his experiments, the fitting time has arrived.

In whatever way Mr. Fleuss gets breathing-room under the water, he has, without a doubt, achieved a great practical success. He has learned how to live independently for a long time shut off from all external access of air. He has learned, if I may so say, to become artificially amphibious, and if his plan succeeds, the cumbrous diving-pumps are done away with and the art of diving is vastly simplified.

Again, if he can live so long on the small reserve which he carries down with him in his dress, he has only to enlarge the dress, to expand it, that is to say, into a submerged vessel, to be able to go anywhere under the sea and do with intelligence what is now left to unintelligent mechanism. What such an intelligent direction might do with torpedoes it is not at all pleasant to contemplate.

The plan may be used for the purposes of deep-sea exploration, and the suggestion I made respecting my Salutlanders, that they sought for discoveries on the floors of the great oceans, may be so much nearer to accomplishment than the time which I assigned to it, that I may haply live to have the return laugh at what was called "the most visionary of speculative fancies." It is equally probable that the aëronaut may be able to rise much higher than he has yet done in this dress, or in a car specially constructed on a similar plan.

The apparatus may almost certainly be applied at once to another service very different in kind and on land instead of water. When a man can move about with an air-supply in his pockets, so to speak, he can go into fire as well as water. In a fire-proof non-conducting dress, provided with Fleuss's breathing apparatus, a fireman could enter a burning house, and without danger of suffocation go wherever the weight of his body could be borne.

Lastly, in wells charged with foul air, or in mines charged with choke-damp and other poisonous gases, the Fleuss apparatus will, I feel certain, prove of the greatest practical service, and I am happy in being the means of introducing it at length to the notice of my *confrères* in science.

BENJAMIN WARD RICHARDSON

NEW GUINEA[1]

BEFORE us lies one of the earliest published maps in which New Guinea is laid down. It belongs to Huygen van Linschoten's book of East Indian voyages, and was published in the year 1595, being derived largely from Portuguese sources. The map is turned on one side as compared with our present ones, so that at the top, on one hand, appears Japan, strangely shaped, and with the names of the cities curiously spelled, Meacum (the capital, Miaco, Kioto) and Tochis (Tokio?): whilst on the other hand lies New Guinea. At the foot of the map are Sumatra and the Bay of Bengal, and on the left hand China stands prominently upwards from the base of the map, with a camelopard walking about in its midst, regardless of the rules of geographical distribution. The north point lies to the left hand of the map, and the south to the right. New Guinea is represented as a very large and elongate island, the south coast being drawn without definite outline as unexplored, but with the Aru Islands duly shown lying off it. The great island is marked "Os Papvas," and at its eastern corner is the inscription "Hic hibernavit Georgius de Menezes." Although Antonio d'Abreu and Francisco Serraõ possibly sighted the New Guinea coast in 1511, Dom Jorge de Menezes must be regarded as the actual discoverer of the island. He was driven by the prevailing monsoon out of his course far to the eastward, when attempting to reach the Moluccas, from Malacca, by a new route round the north of Borneo in August, 1526. Having thus reached an island lying off the coast of Papua, he had to "winter" there, that is to say, to wait for the periodical change of the monsoon. According to Oscar Peschel, the island at which he remained, and which was called Versija, was very possibly one of those lying off Geelvink Bay. It is remarkable how very slowly our knowledge concerning New Guinea grew through the explorations of successive voyagers, since the time of Menezes until within the period of the last ten years, and even now it is quite startling to pick up a small octavo volume and find it jauntily entitled "A Few Months in New Guinea," as if New Guinea were as familiar and accessible a place as say Iceland or Norway, about which such little books are commonly written by enthusiastic tourists.

We are sorry, indeed, that Mr. Stone's book is so little, and would have been glad if it had been three times as long, and he had given us further details of all kinds

FIG. 1.—Vahu, a Motu youth.

concerning his most interesting sojourn amongst the Motu people of the coast, whose God dwells out over the sea, and the mountain-dwelling Koiaris, who believe the dread "Vata" inhabits the mountain summits.

It is close to the east end of New Guinea, and on its southern shore beneath the Owen Stanley range of mountains that the Motu country lies. Mr. Stone first made an excursion from Cape York, in the small mission steamer *Ellengowan*, up the Maikasa or Baxter River, the mouth of which, on the New Guinea coast, lies due north of the Cape, just on the opposite side of Torres Straits. The river was traversed for sixty-four miles, but then forked, and since both channels were too narrow for the steamer to turn in, further progress was stopped. At this distance even from the river's mouth, native plantations of yams, sugar-cane, and tobacco were found. A further distance of twenty-six miles was traversed in a small boat, and large numbers of the recently-discovered species of Bird of Paradise, *Paradisea raggiana*, were met with. The bird does not croak like the Great Bird of Paradise of the Aru Islands, "wauk wauk," but utters "a peculiar whistle resembling that of a man to his dog," and must

[1] "A Few Months in New Guinea." By Octavius C. Stone, F.R.G.S. (London: Sampson Low and Co., 1880.)

thus in its note come very near its more distant ally, the Rifle Bird of Cape York and New Guinea (Ptilorhis). As the small boat returned to the steamer it was greeted by the sweet strains of a "barrel-organ," brought in the hope that it "might please some of the natives." It is really appalling to realise that a "barrel-organ" has penetrated sixty-four miles up a river in New Guinea; and though we heartily wish the organs and their grinders were all in New Guinea, yet, did we regard matters from a missionary and philanthropical point of view, we should

Fig. 2.—Burning pottery in Anuapata.

have thought twice before attempting to demoralise the musical ears of the poor Papuans with such an instrument; or, perhaps, knowing the high ability of the Papuan race, we should have expected such a course to evoke hostility rather than to conciliate. But the missionary charm did not work; the natives kept well away from the barrel-organ: only one was sighted, and he promptly fled.

After a return to Cape York, Mr. Stone, with three assistant natural history collectors, Messrs. Hargrave,

Fig. 3.—Trading canoe or lakatoi.

Petterd, and Broadbent, proceeded again to New Guinea in the *Ellengowan;* and after touching on the way at Roro or Yule Island, where the natives cultivate fields of from five to thirty acres in extent, inclosed by fences six feet high; and at Purok on the main land, where the natives have a large circular market-place cleared of grass and trees, and periodically used by surrounding tribes, arrived at Anuapata (Port Moresby) amongst the Motu people on October 29, 1875. The arrival of the white men was not greeted with pleasure by the natives, because many of them had lately died of the measles introduced by the missionaries. The party at once erected their tent, and, proud of their nationality, and apparently taking a leaf out of Mr. Stanley's book, hoisted a union-jack at each end of the roof, and on a pole in front a banner with "Excelsior" upon it, thus apparently intimating that they intended to climb the neighbouring mountains if they could. They were soon beset by the natives, whose constant cry, corresponding to that of "bacshish," or the Fuegian "yammerschooner," is "kuku lasi"—"Won't you give me some tobacco?" The Motu people have an insatiable appetite for *trade* tobacco. In the evening there was a tremendous hubbub round the tent, and a hostile demonstration caused partly by a Polynesian Christian teacher, who, left in charge of the tent, had pointed a gun at would-be intruders, but also partly because the natives were not pleased at the white men persisting in remaining in their country contrary to their wish, and very naturally so, after the experience of the measles. But the natives were luckily afraid of the dark, and were frightened into submission by a display of rockets and of the power of dynamite. As a sort of set-off for thus frightening them almost out of their lives, great care was taken that they should not be corrupted by Sunday trading.

The natives have dogs which, like the Australian dingo, do not bark. The author wishes he had had a bulldog with him, for he describes the natives as "expert thieves, inveterate liars, and confirmed beggars," and feels sure

Fig. 4.—Native cradle.

that a dog which could bark would frighten them out o their wits. They ran away from a sheep landed from the *Ellengowan.* They have strict commercial instincts, and would "see you starve before they gave you food." Everything has to be bought with "trade gear." The natives are not cannibals, but were evidently acquainted with cannibalism, for, being firmly persuaded that all the tinned meats consumed by the white men consisted of human flesh, they expressed great disgust at the cannibal practices of their visitors. It is delightful to find the Papuan thus turning the tables on the pioneers of civilisation.

The Motu people seem on the whole very much bored by the presence of the missionaries, excepting when a chapel is formally opened, and there is a big feast in consequence. As they cannot dispose of their teachers in the usual way, perhaps in secret they pray for help to the cassowaries of which the author saw the foot-prints in the neighbourhood, for these voracious birds are, as the naturalist knows, far more at home in New Guinea than at Timbuctoo; but possibly even New Guinea cassowaries would require the traditional condiment, and matters have not as yet reached the hymn-book stage in Papua. A very amusing account is given of a missionary religious service at Anuapata. It appears that there are bold and contumacious sceptics amongst the Motu people who refuse to assimilate the Jewish cosmogony, and do not mind expressing their opinions freely in public.

"The service was held beneath a roof thatched with grass, supported on posts, open on each side, and fitted at one end with a low stage and reading-desk. Previously to the present occasion not more than two or three natives had ever attended, but, attracted, no doubt, more by curiosity than by any religious feeling, no less than three hundred, including men, women, and children, were now present, three-fourths of whom were compelled from want of space to remain outside. They appeared to know they ought to be quiet, and some of the eldest seemed to be listening, but the greater part were looking around them and evidently inattentive, apparently taking no interest in the proceedings. The small boys amused themselves by flinging pebbles at one another, making grimaces, or pulling a stray dog's tail, and sometimes the word koi-koi, meaning 'lie,' would be heard in reference to something the missionary was saying."

The Motu people express surprise in a curious and interesting way, namely, by drawing in their lower jaw and clicking their upper teeth with the thumb-nail of the right hand, very much the same gesture as the old European "biting of the thumb." They also express surprise by smacking their lips. The women are expert makers of pottery. The clay is worked into shape by hand over an earthenware mould, of course without any wheel appliance. The upper and lower halves of a vessel are made separately and afterwards joined. The pots are baked in an open fire on the sea-beach. They are of a brick-red colour when baked, and are made of three forms—the "ura," or cooking-pot, the "hordu," or water-pitcher, and the "nao," or bowl.

The natives start in every November with large cargoes of this pottery on a trading expedition a distance of two hundred miles up the coast; three or four of the largest canoes are lashed firmly side by side with rattans, and the compound craft thus produced is termed a lakatoi; some of these lakatois are propelled by a dozen square sails and others by a single huge elliptic-shaped sail, which is extremely picturesque in app.arance, but the cause of the peculiar form of which seems very uncertain.

In return for the pottery the natives receive sago, yams, taro, sweet potatoes, betel-nuts, and sugar-cane. The record of the undertaking of systematic long voyages, such as these by savages, is a very valuable fact, and helps to account for a rapid spread of cultivated plants, such as tobacco, for example, which doubtless originally reached New Guinea from America through Europeans. Whilst waiting for a start at Anuapata, the crews of the six lakatois from the neighbouring villages, composing the trading fleet, held regattas almost every day to while away the time and get into training. A terrible wailing was made by the womenkind on the day of actual departure, and many embraces between husbands and wives took place upon the beach, and there was much rubbing of noses; the women escorted the lakatois some distance in single canoes.

The mothers rock their babies by swinging them in a net bag suspended from a beam beneath the verandah, and the babies are often carried in these bags.

We cannot follow the author further in his account of the Motus, nor cite any of his interesting experiences amongst the Koiaris. The book is well illustrated throughout, and at the end is a short Motu dictionary, and shorter tables of eight other Papuan languages. The Motu people have a name for every different plant and bird, and for all the conspicuous stars. Numerals are given up to a million. We should almost be inclined to doubt the Motu conception of so high a number; possibly there may be some mistake in the matter. In the Koitapu language the numerals for eight and nine appear to be formed by subtraction from ten, and to mean (ten) less two and (ten) less one, as in the Admiralty Island language. The personal names for women are amusing indeed, the first two are probably intended as complimentary, but the remaining three can hardly have such a meaning; those cited by the author, when translated, mean "pig," "thief," "hungry," "frightened," and "bad."

A list of birds drawn up from the author's important collection by Mr. Bowdler Sharpe closes the book. The author seems to have little or no knowledge of natural history, since he repeatedly speaks of a Dugong as "a large *fish*," and further describes it as a "finny monster," and he imagines that the pig was introduced into New Guinea by Capt. Cook. His descriptions of birds, insects, and other animals seen are, however, interesting throughout the book. He gives some valuable information about the pigs. Some are kept tame by the natives, and some of them are very fine and fat; when young they are striped longitudinally, yellow, brown, and black, every other stripe being black; the stripes blend to a general dark brown tint as the animals get older. It is interesting to find that the Papuan pig exhibits the same markings as the European young wild boar so plainly. The natives have an ingenious way of catching the wild boar. When the boar charges, after being slightly wounded with a spear, a net with a very wide mesh set on a hoop-like frame is pushed over his head as he rushes forward. He gets his neck into one of the meshes, and with the large hoop about his throat, is helpless, and then easily killed.

We commend Mr. Octavius Stone's book to all classes of readers: there is not a dull page in it.

VERTICAL SHAFTS IN THE CHALK IN KENT

THE deep caves in the chalk in Kent while preserving a general form in a limited area, present certain differences amongst themselves, which enable us to trace something of their history as to time and object.

Those now most easily examined are the latest and best constructed. Though they are not dug at the present day here, there are many old ones that have been worked for chalk. These are distinguished by their irregular shapes and very wide shafts.

But there are fine examples now open of which North Kent has many having these general characters—a deep shaft, penetrating the soils (Woolwich pebble beds, Thanet sands and gravels) above the chalk, then the chalk itself from 2 to 5 feet, and widening out into a cave in the latter, mostly without effort at burrowing laterally, and when doing so keeping the shaft in the middle and the general shape of the cave as it were one area, with a due regard for the permanence of the roof. Some had pillars for this purpose left in the chalk, and there is one with four of them which are elegant in form and rounded. This cave being an excellent example of the kind, may be more particularly described. The shaft is 3 feet 3 inches in diameter (a common average), and passing through sand reaches the chalk at 51 feet; then penetrating it 2 feet widens out into an area of 49 × 38 feet, the sides cut into bays. Two pillars are left, one on each side of the shaft, and in continuation of it, still 3 feet apart, and there are two other pillars in the eastern part. The western part having no pillars has fallen in, and there is a large mound of sand and rubbish in the centre—but the height of the cave is 20 feet, perhaps 22 feet.

In this case the access to the chamber is perfect: the shaft is provided with foot-holes from 6 inches to 20 inches (occasionally) in lateral depth; these pass from the surface to the bottom of the central pillars at about 18 inches apart and opposite to each other, and it was easy a few years ago to descend and ascend without assistance, unless perhaps with that of a stick across the mouth of the shaft. Some of the shafts have foot-holes only to the point where they widen out below, when recourse was had to a pole or rope, of course.

Most of the caves are simpler than this, and the commonest form is a mere beehive sort of widening.

All these open caves appear to have been dug with iron picks.

At Greenhithe one has been lately found containing a large quantity of Romano-Brit'sh pottery, but it was dug with metal implements, probably of iron.

There are two caves at Crayford within 3 feet 3 inches of each other; they are exposed in the side of a chalk-pit connected with the brick-fields. One of them measured, from the surface to the chalk, about 18 feet; thence to the floor, 17 feet 6 inches. The floor was of flints, about 6 inches thick, which had been taken up at one part and piled in a heap on the other side of the cave; about a quarter of the area, an irregular oval of 18 feet diameter, had been so treated. From this floor rose an obtuse cone of sandy clay 6 feet high, washed in very slowly and evenly by the rain. In the cone were found flint flakes, and one worked scraper with a rough core, from which flakes had been chipped, but no pottery. Above this, coarser soil and lumps of chalk, with several sorts of broken pottery, very coarse, black, spongy pot, scarcely baked, containing a large quantity of crushed shells not calcined, and a few pieces of pot made with coarsely-pounded chalk—all these either without ornament or only finger-nail marked; then finer pot of Roman moulds, and fine black ware, with a Samian plate. All were accompanied by large quantities of the bones of domestic and food animals for about a foot, then coarse earth and bones to the surface.

From about the period of the Roman deposit until now we know the value, and it would not be excessive to date the commencement of the deposit of mud and the abandonment of the cave perhaps at half that period earlier.

On the walls of this cave there are no marks of the implement by which it was excavated, and the conclusion is that the blocks were prised out.

The cave adjoining this fell in early and was soon obliterated.

Before knowing of these caves flint flakes and two "pot boilers" were found on the surface.

Clusters of these pits are either huddled into small areas sometimes or are spread out into lines, and they are frequent in spots which, from the supply of water, must have been thickly wooded, and so difficult of access, or from the bleakness of the situation unlikely to be noticed.

There is a cluster at Bexley of thirty-five in about three and a half acres, and another of forty-four.

Some pits which are mostly filled up now, in the woods, are part of a system and are connected by banks and ditches, and the same banks with earthworks which are of a late stone age, and also with clusters of hut circles, and there is great probability that they served two uses—retreat and storage, and as pitfalls, as to the last with an ingenious contrivance in one instance for driving animals down a deep covered way, either past a pit or, by an arrangement of a simple barrier, shunting them into it for the use of the camp.

F. C. SPURRELL

PROF. GEIKIE ON THE GEOLOGY OF THE FAR WEST

ON Monday the 10th inst. Prof. Geikie reopened the class of geology in the University of Edinburgh by giving an account of his recent exploration of the western territories of North America. There was a large attendance of students and others.

The Professor, in the outset, reminded his students that last session he pointed out the remarkable lessons to be learned from the geology of the western regions of North America, more particularly in reference to the changes which had taken place on the surface of the earth from ordinary atmospheric causes. It was with special reference to those changes that he took a journey to the West. Had geology begun in those western territories, instead of among the old broken, gnarled, and contorted rocks of Europe and the east of America, its progress, at all events in some departments, would have been far more rapid than it had been. He had three objects in the expedition:—(1) To study the effects of atmospheric and river erosion upon the surface of the land; there being no region where these lessons could be learned with more wonderful impressiveness than in those great plateaux and table lands. (2) To mark the relation which the structure of the rocks underneath bore to the form of the surface. In this country and in Europe generally one was continually brought face to face with evidence of dislocations, protrusion of igneous rocks, contortions, and other complicated forms of geological structure which, save to experts in the subject, made it often difficult to realise how much of the present irregularity of the surface should be attributed to unequal waste by ordinary atmospheric causes, and how much to the direct effects of underground movements. The Western States and Territories of North America over which the strata, for thousands of square miles, retained their original horizontality, presented remarkable facilities for the investigation of this subject, and had already, in the hands of King, Hayden, Powell, Dutton, and others, furnished ample materials for satisfactory discussion. (3) To watch with his own eyes some of the last phases of volcanic action. He had been familiar with the phenomena of active volcanic vents as displayed in Italy and the Lipari Isles; but he was anxious to see some of those marvellous evidences of the gradual decay of a vast volcanic area so well displayed in the famous region of the Yellowstone. The Professor went on to give a brief account of his journey. He stated that he was accompanied throughout by a former student of the class, Mr. Henry Drummond, F.G.S., whose constant hearty co-operation had been one main element in the success of the expedition. His route first lay westwards by railway into Colorado. In crossing the prairies towards the Rocky Mountains he noted, in the few sections that occurred, soft grey cretaceous or tertiary clays and marls. Getting down at some of the stations, and looking at the ant-hills and burrows of the prairie dog, he found that the surface of the prairies was veneered with a thin coating of a pinkish, fine-grained sand, sometimes approaching to gravel, its colour being due to the presence of a great many small pieces of fresh felspar. It was clear that this mineral, as well as the quartz and occasional fragments of topaz, which he saw, did not belong to the strata on which they lay. In going west, the grains of sand, getting coarser, assumed the form of distinct pebbles, till, when he reached the mountains, they became huge blocks and boulders, evidently derived from the heights beyond. The cause of this wide diffusion of sand and gravel over the prairies was constantly present to his mind during the rest of the journey, and he took occasion on returning eastward to halt and make a more detailed examination of the subject.

The term "Rocky Mountains," he remarked, was a singularly unfortunate designation, under which had been included a great many independent and totally distinct mountain ranges. On most maps of North America a continuous line of lofty ridge was inserted down the axis of the continent and marked "Rocky Mountains." But no such ridge existed. The great plateau had been wrinkled by innumerable meridional folds which, dying out, were replaced by others. Some of these folds formed notable ranges of mountains with wide basins or plateaux between them. It was thus possible to cross the axis of the continent without traversing any mountains, rocky or otherwise. The line of the Union Pacific Railroad followed one of these natural routes. At its highest point (upwards of 8,000 feet), so little did the landscape suggest the altitude, that it had been found desirable to erect there a wooden placard with the title "Summit of the Rocky Mountains."

Crossing the Missouri River at Kansas City, and striking westwards to Denver, the Professor said he halted for a little while on the flanks of the great mountain range that formed the colossal bulwarks of the parks of Colorado. As seen from the prairies they rose in a picturesque line of peaks, visible in the clear atmosphere of these regions at an incredible distance, and looking at first like mere low islets, the greater part of their bulk being still hidden beneath the sea-like surface of the prairie. Composed of crystalline rocks these crests had been pushed as a great wedge through the cretaceous and tertiary rocks of the prairies, and had carried those rocks up with them in a grandly picturesque curve along their flanks. An excursion into some of the gorges or cañons by which the flanks of these mountains are trenched, brought to notice some interesting facts connected with the surface erosion of the district. He then found the source of the pink felspar sand of the prairie ; it had been borne down from this region, where great masses of pink granite, grey gneiss, and other crystalline rocks formed the core of the mountains, and were visibly crumbling into the same kind of pink sand and gravel. He found that the mountains had been covered with glaciers which had gone out into the plains and shed their huge horse-shoe shaped moraines where now everything was parched and barren.

Having crossed the watershed of the continent, he struck westward into the Uintah Mountains, one of the few ranges in that region that had an east and west direction. This range had been visited by Hayden, had been mapped by Clarence King and his associates, and its eastern end had been carefully examined by Powell. It formed one of the most remarkable elevations in North America. Unlike the other mountainous high grounds it possessed no great central core of crystalline azoic rocks, but consisted of a vast flattened dome of red sandstones, dipping steeply down beneath mesozoic rocks on either flank. The precise geological age of these sandstones had been a matter of dispute. King had regarded them as carboniferous. In their lithological characters they much resemble some of the old red sandstone of Scotland, while some of the more compact portions, recalled the red Cambrian sandstones of Applecross and Assynt. One feature of surpassing interest in the Uintah Mountains was the evidence of enormous denudation, continued through a protracted cycle of geological time. The horizontality of the strata along the central parts of the range was such that terrace above terrace could be traced by the eye for miles around any commanding peak. The rocks there had escaped crumpling and fracture to a remarkable degree. It could therefore be seen that the deep gullies and clefts, the yawning precipices and cañons, the wide corries and vast amphitheatres by which the surface was so broken up had been produced not by underground disturbances but by erosion at the surface. Most of this tremendous denudation had doubtless been effected by ordinary atmospheric action. The speaker described the disintegrating effects of the remarkable daily vicissitudes of temperature in this region, the action of wind, as well as of melting snow, and occasional torrents of rain. But he showed that the mountains had also nourished large glaciers, and that these, filling up the main valleys had protruded into the plains beyond. They had left behind them numerous lake basins, some ground out of the horizontal sandstones, others dammed up by fallen moraine *débris*.

Striking into one of the valleys, he found it crossed by beautiful horse-shoe moraines that had once formed a succession of lakes, of which the sites were now occupied by meadows. In these and other high grounds, however, it was the beaver, which, by its dams, converted even the small streams into a succession of shallow lakes. In most of these valleys there were hundreds of acres of bog land entirely due to the damming of the water by the beavers. The Uintah Mountains were flanked by ranges of low and sometimes fantastic hills, *mesas* or terraces, and isolated *buttes* or outliers, included under the general term "mauvaises terres" or "bad lands." This designation referred to the fact that the ground was everywhere crumbling down under the action of the weather, and nothing would grow upon it. The strata of these bad lands were flat or nearly so, and showed their lines of bedding with singular precision along the faces of the crumbling cliffs and slopes. They had an arid and almost ghastly aspect, grey, verdigris green and yellow, as they rose out of the sandy wastes at their base. It was from these strata that Prof. Marsh had obtained some of the marvellous reptilian and other forms which he had described from the eocene and cretaceous rocks of the West. Prof. Geikie narrated a ride through the forest lands of the mountains, and gave an account of how the party, benighted away from camp, had to pass the night without food on the bare ground, and how the forest around them caught fire.

The journey to the Yellowstone region was one of great tediousness and discomfort. Having letters from the Secretary of War and the Quartermaster-General of the United States, the party received every attention at Fort Ellis, where a pleasant day or two were spent, examining with the officers of the garrison the geology of the district. From this point the journey was performed on horseback and with a pack train of mules, the officer in command at Fort Ellis having furnished an outfit, scout and escort. The Professor gave a narrative of the traverse of the Yellowstone country, dwelling specially on the evidences of former successive periods of volcanic eruption, and on the proofs of intense glaciation to be observed in the ascent of the valley of the Yellowstone River. The tokens of a long period of volanic activity contemporaneous with the operations of the river, resembled those of Auvergne, but on a much larger scale. The mountains around consisted mainly of crystalline rocks such as gneiss, schist, and granite. The volcanic action appeared to have been chiefly confined to the valley. Sheet after sheet of lava bad been poured out, and these, one after another, had been cut through by the river. The edges of some of the lava plateaux could now be seen crowning the summits of steep slopes or even cliffs far above the level of the stream below. So great had been the general erosion that no distinct craters remained now visible. But what appeared to be the stumps of some of these, filled up with a coarse volcanic agglomerate, were here and there observed. The lavas offered a vast and tempting field of investigation, presenting as they did a great number of petrographical varieties. Some of the obsidians were particularly interesting in their pumiceous and spherulitic characters. The Grand Cañon of the Yellowstone, cut out of these volcanic masses, was described as perhaps the most marvellous piece of mineral colour anywhere to be seen in the world. It had been cut out of tuffs and lavas, showing sulphur yellow, verdigris or emerald, green, vermilion, crimson, and orange tints, so marvellous that, if transferred to paper or canvas they would be pronounced incredible and impossible ; the lecturer said he had spent a day in making a careful water colour study of this cañon, but he hardly expected to get any of his friends to believe in the truthfulness of his colouring.

During the ascent of the Yellowstone Valley the evidence of former extensive glaciation was abundant and conclusive. The party had hardly been in the valley a quarter of an hour when they descried, not far above the upper end of the first or lowest cañon, a large block among some mounds in the centre of the plain. This proved to be an erratic of coarse granitoid gneiss, lying among many others of smaller size. The mounds, manifestly moraines, curved in vast crescents across the broad plain of the Yellowstone. Further mounds and scattered blocks were noted in the ascent of this great expansion of the valley. On reaching the entrance of the second cañon, the Professor found it most exquisitely glaciated from bottom to top. It reminded him of the wonderful ice-polished precipice on the left bank of the Aar glacier, above the Grimsel. It was clear, therefore, that not only was this second cañon old; it was older than the glacial period; it had supplied a channel for the glacier that ground its way out from the mountains. Endeavouring to estimate the minimum thickness of the ice, he traced with the eye the glaciated surfaces up to the summit of the declivity—a height of at least 800, perhaps 1,000 feet,—and they evidently went still higher. In going further up the valley, he found that the blocks of granite and gneiss, dropped by the glacier as it melted, went far above 1000 feet. He got them on the shoulders of one of the great hills overlooking the valley 1,600 or 1700 feet above the plain. The ice, therefore, must have been not less than 1,600 or 1,700 feet thick, and must have passed across intervening ridges into adjacent valleys. It thus appeared that not only did glaciers occupy the valleys of this region, but that some of them were of such thickness as to deserve the name of ice-sheets, covering the whole surrounding region.

Leaving the Yellowstone Valley, the party struck through the forest, and after a two days' ride reached the Upper Fire-Hole Basin of the now famous geyser region. Prof. Geikie gave a general sketch of the aspect of this district, and described the operations of one or two of the geysers which he witnessed. After the long ride through an arid region and dusty wastes, he tried hard here to get a pool to wash in, but could find nothing below 212°, and the only chance of getting a warm bath was to find some hole where the water had had time to cool after flowing out of the hot crater. The whole ground was honey-combed with holes, each filled with gurgling boiling water. One geyser, affectionately and gratefully known as "Old Faithful," went off with wonderful regularity every 63 minutes; the others were more capricious. The singular depositions round the orifices of eruption and round the margins of the pools on the cones were referred to, and among other interesting phenomena an account was given of the "Devil's Paint Pot," a mud geyser, throwing out white and brilliantly-coloured mud, boiling like a great vat of rather thick pasty porridge, and surrounded with small mud cones, each of which had formerly been a point of emission.

In quitting the Yellowstone region, it was impossible not to reflect with admiration upon the labours of the explorers who had first made known the wonders of this remote and inaccessible region. The Reports of Hayden and his associates were found to be most trustworthy and useful. Nor could one forget the sagacity with which Hayden proposed, and the enlightened liberality with which Congress enacted, that for all time the Yellowstone Region should be a tract set apart as a national park for the instruction and recreation of the people.

On the way out of the mountains by Henry's Lake and the head of the Snake River branch of the Columbia River, the travellers came upon a party of armed Indians, who explained that they were out of their reservation on their way to a council of Indians in Montana. As the great outbreak of the White River Utes, who killed Major Thornburgh and his men, took place only about ten days or so later, and as there was then some excitement among the tribes to the West, the geologists, though pleased at the time to have seen the noble red man in his war-paint among his native wilds, came to think that on the whole they might congratulate themselves on having seen no more of him. Only last year the Yellowstone country was dangerous from roving bands of Indians, several lives having been lost in it. Leaving the Indians, who pursued their northward course in a bee-line, the travellers held westward along the edge of the vast basalt plateau of the Snake River—one of the most extensive lava fields in the world. A great plain, thousands of square miles in extent, had there been deluged with dark basalt. No cones or eminences appeared from which the lava migh have been poured. Perhaps the eruptions took place from open fissures. Here and there later cones had risen upon the plain, belonging, doubtless, to some of the later stages of the volcanic activity. Some of these cones still retained well-shaped craters.

Reaching eventually the basin of the Great Salt Lake, one of the first geological features that struck the travellers was the evidence of the former vast expansion of the Salt Lake. Lines of terrace ran as prominent features along the sides of the mountains, the highest of them standing at a height of nearly 1000 feet above the present level of the lake. Striking into some of the cañons descending from the Wahsatch Mountains into the Salt Lake Basin, Prof. Geikie found the rocks smoothed, polished, and striated by the glaciers that had come down from the heights and had brought with them great quantities of moraine matter. Mounds of rubbish blocked up the valleys here and there, and some of them he observed to descend to the level of the highest terrace. Hence when the Salt Lake extended far beyond its present area, and was about 1000 feet deeper than now, the glaciers from the Wahsatch Mountains reached its edge and shed their bergs over its waters. Bones of the musk-ox had been found in one of the terraces, showing that an arctic fauna lived in this region during these cold ages.

On his return journey the Professor resumed the examination of the surface deposits of these prairies. Coming out of the Colorado Mountains, he noted, in connection with the gravel formerly observed, great quantities of a peculiar grey clay or *loess* inter-stratified with the gravel, and here and there containing a small terrestrial shell (*Succinia vermeta*). It was a freshwater deposit, one that had been swept by the waters coming down from the mountains over the prairie. It might be regarded as marking one of the phases in the period during which the gravel and sand were being thrown down. Tracing the gravel mounds over an extensive tract, he found that they had been deposited irregularly, as might have been the case from the action of water escaping tumultuously and interruptedly from the melting ends of the ice. The water currents would traverse the plain now in one direction, now in another. The whole prairie, for many leagues east from the mountains, must have been flooded with water derived from the melting ends of the great glaciers.

By these successive floods the gravel and sand were spread out irregularly over the plain, and during the same prolonged period of ablation of the ice there were here and there greater streams or periods of more muddy water, when the fine grey loess was diffused over the flats, as has taken place in the valleys of the Danube and Rhine. No doubt some of the fine detritus may be travelling eastward still, for though the rainfall over much of the prairie country is exceedingly slight, it may suffice to give the fine particles of sand and gravel an intermittent movement to lower levels.

NOTES

WE take the following from the *Times*:—The medals awarded and recommended by the Council of the Royal Society for the present year are: The Copley medal to Prof. Rudolph J. E. Clausius, of Bonn, for his well-known researches upon heat; the Davy medal to Mr. P. E. Lecoq de Boisbaudran for his discovery of gallium; a Royal medal to Mr. William Henry Perkin, F.R.S., for his synthetical and other researches in organic chemistry; and a Royal medal to Prof. Andrew Crombie Ramsay, F.R.S., for his long-continued and successful labours in geology and physical geography. These medals will be presented at the anniversary meeting of the Society, on December 1, when Mr. W. Spottiswoode will deliver his first annual addres as president.

THE following is the list of office-bearers to be proposed at the annual meeting of the Royal Society of Edinburgh, on November 24:—President, the Right Hon. Lord Moncreiff; Vice-presidents, the Right Rev. Bishop Cotterill, Principal Sir Alexander Grant, Bart., David Milne Home, LL.D., Sir C. Wyville Thomson, LL.D., Prof. Douglas Maclagan, M.D., Prof. H. C. Fleeming Jenkin, F.R.S.; General Secretary, Prof. Tait; Secretaries to Ordinary Meetings, Prof. Turner, Prof. Crum Brown; Treasurer, David Smith; Curator of Library and Museum, Alexander Buchan, M.A.; other Members of Council, Prof. Rutherford, Dr. R. M. Ferguson, Rev. W. Lindsay Alexander, D.D., Dr. Thomas A. G. Balfour, J. Y. Buchanan, Rev. Thomas Brown, Robert Gray, Dr. William Robertson, Prof. Campbell Fraser, Prof. Geikie, Rev. Dr. Casenove, David Stevenson, M. Inst. C.E.

A GRAND diploma of honour has been granted by the Jurymen of the Champs Elysées Exhibition to the Signal Corps of the United States for its magnificent set of maps. No other public institution has sent anything to compete with so formidable an opponent.

ABOUT thirty members of the Academy of Sciences have memorialised M. Jules Ferry, the Minister for Public Instruction, in order to obtain a promotion in the Legion d'Honneur on behalf of M. Henry Giffard, the inventor of the injector and the originator of many interesting experiments in aëronautics. M. Giffard was created a Chevalier about eighteen years ago.

PROFESSORS A. WINNECKE (Strassburg) and G. B. Schiaparelli (Milan) have been nominated correspondents of the physico-mathematical class of the Royal Academy of Sciences of Berlin.

THE magnificent series of scientific collections at Dresden have recently been further enlarged by the addition of an ethnographical and anthropological museum. Many of the objects now exhibited in the lecture-hall of the "Zwinger" had accumulated since the year 1857, and the director, in due recognition of the important position now occupied by ethnography and anthropology in the list of natural sciences, has recently made considerable purchases for the opening of the new museum. The director in question is the well-known New Guinea traveller, Dr. A. B. Meyer, under whose able superintendence the Dresden Zoological Museum is also placed.

WE are glad to receive from Mr. E. W. Lewis his "Lectures on the Geology of Leighton Buzzard and its Neighbourhood," which were given to the Working Men's Club of that town. We should like to see lectures of this kind become more and more common; it is a good method of exciting an interest in science and of encouraging the study of local natural history; it is certainly much better than giving a *rechauffé* of scientific text-books.

AT the meeting of the India Council, last week, a final decision was come to regarding the disposal of the India Museum. The Museum will be taken over, as is proper, by the Lord President, and will be administered by the South Kensington authorities; important collections in illustration of the Indian building art of antiquity, and of the economic, mineral, vegetable, and animal productions of India will, therefore, now be from time to time sent to the great centres of the United Kingdom. The botanical part has been intrusted to the authorities at Kew. A grant of 2,000*l*. has been made for the enlargement of the Kew Museum on that account, and a small annual sum will be allowed for contingent expenses and to secure the services of an expert cryptogamist in connection with the collection. In its economic section the India Museum was little more than a very costly duplicate of Kew, which it could never approach in encyclopædic completeness, and it will necessarily be of incalculable benefit to the India Office to keep its economic collections for the future at Kew, where they will be in charge of the first English botanists. In fact, the Indian Secretary will now always have the assurance that the reports on Indian products forwarded by him to the local Governments in India have not only been carefully prepared by his own officers, but are supported by the best scientific advice in this country. The Kew authorities, in continuation of a scheme set on foot by Dr. Forbes Watson, the late Reporter on Products, have undertaken to supply out of their surplus stores samples of Indian articles to any museums in our larger manufacturing and commercial towns which will undertake the cost of suitably exhibiting them to the public. As to the zoological collection, it has always been understood that it would be transferred to the British Museum on the completion by the trustees of their new Natural History Museum at South Kensington. The Buddhistic sculptures will also be taken by the British Museum.

THE *Times* Naples correspondent, writing under date November 8 and 10, states that Vesuvius, which for some time had been capricious in its action, had for a week previously hoisted its red flag. This arises from a small eruptive cone which has sprung up in the centre of the large crater of 1872, and which now rises a few metres above its border. To compare great things with small, the appearance of the summit is that of a small cup in the centre of an immense saucer. The saucer is almost full of lava, which, says the *Osservatorio Vesuviano*, or Prof. Palmieri, has run over the side since October 30, and continues its downward progress on the side of the cone. It is fortunate, says the *Osservatorio*, that on the side on which they are constructing the funicular railway there is a considerable cavity which is not yet filled, so that hopes are entertained that some time will elapse before the lava presents itself in that direction. It may happen, too, adds Palmieri, that an eccentric eruption may occur which will prevent the accumulation of more material. It is thought that a crisis in the history of the mountain is approaching; either there will be a great discharge, such as will terrify the neighbourhood, or, as is more likely, there will be an overflowing of lava, covering the cone with a mantle of fire, and silently inflicting more destruction on property than a grand eruption. Vesuvius has been in an active state now for several years, and Prof. Palmieri has from the first prophesied that the eruption would consist in the overflowing of lava. On the 10th Vesuvius was covered with snow down to its middle, a rare thing so early in the year.

THE juvenile lectures of the Society of Arts will be given this year by Mr. W. H. Preece, on "Wonders of Sound" and "Wonders of Light." The dates for his lectures are December 30 and January 6.

THE French Minister for Commerce has sent to the Academy of Sciences a request to know whether a *diagometer* can be relied upon for ascertaining whether olive oil has been adulterated by common seed oil, and in what proportion. Prof. Palmieri, the director of the Vesuvian Observatory, sent M. Dumas a pamphlet published at the expense of the Chamber of Commerce of Naples nine years ago, showing that the problem had been solved by this apparatus. The principle is the same as the bifilar magnetometer, also invented and designed by Palmieri.

WE have received programmes of the new session of the numerous societies united together under the name of the Cumberland Association for the Advancement of Literature and Science. The programmes of lectures and ordinary meetings are fairly divided between the two fields. The continued prosperity of this provincial association for culture is exceedingly gratifying.

THE Pacific Steam Navigation Company have begun to use the electric light in the illumination of the saloons on board their steamers.

WE are glad to be able to acknowledge the receipt of the Report of the Sheffield meeting of the British Association. This early publication is decidedly a mark of progress.

FOR the first time in its history the Paris Academy of Sciences has regular archives. More than seven hundred cases are filled up with scientific memoirs and documents from the end of the seventeenth century to the present time. Scientific papers left by Réaumur and Ampère are a part of this unexampled collection.

THE bequest of the late Mr. John Miers, F.R.S., to the British Museum, consists of his herbarium of South American plants which he made during his long stay in that country; original drawings and the manuscripts of his published works; and some unpublished manuscripts. Among the more important of his unpublished manuscripts is a list of the native names of the plants. The extent of the herbarium is about 20,000 sheets, on which the specimens are carefully mounted, and as it includes the type specimens figured in Mr. Miers's publications, the acquisition to the Museum is of great value. The cases in which the collection was kept form part of the bequest. It was only last year, when nearly ninety, that Mr. Miers published his "Apocynaceæ of South America," with general remarks on the whole family. The work, which was of 277 quarto pages, was illustrated by 35 plates. The "Contributions to Botany," published in three volumes in 1861, 1869, and 1871, were illustrated by 153 plates, and contained 940 quarto pages of letterpress. All the originals of these are included in the collection sent to the British Museum. There are also a large number of other drawings and sketches of dissections.

ON October 10 a large balloon fell on a farm in the town of Milwaukee, U.S. The air-ship was picked up and temporarily stored in a warehouse. On the 11th an inspection of the canvas was made, to ascertain whether it was the *Pathfinder*, a balloon in which Prof. Wyse had ascended some days previously in company of a gentleman, and had not been heard of since. It was proved that this balloon had been liberated on Thursday, October 7, at six in the evening, at Waukosha in Wisconsin, and had been wandering in the atmosphere. Before being discovered in Milwaukee, it had been seen coming from Lake Michigan in an opposite direction to where Waukosha lies. The body of Prof. Wyse has not been recovered, but the gentleman who had ascended with him was found drowned and naked. It was supposed he had prepared to escape by swimming, and precipitated himself into the water.

THE Manchester Field Naturalists and Archæologists send us an interesting and varied Report for 1877. It contains an account of the numerous excursions made and the papers read at the Society's meetings.

THE several stations of meteorology which have been established in several parts of Paris, according to a vote of the Municipal Council, have been in complete operation for a few months. Startling differences have been occasionally discovered between the readings taken by the several observers at a distance of a very few miles.

THE *éloge* on M. Thiers was pronounced by M. Henry Martin before the French Institute on November 13. M. Marmier returned thanks in the name of the Académie Française. The lecturer made allusion to the studies of M. Thiers in astronomy under the guidance of M. Leverrier, and in chemistry, of M. St. Claire Deville. It was stated that many experiments were made by the late President of the French Republic in the last years of Napoleon III.'s rule. These experiments were conducted in the laboratory of the École Normal Supérieure, rue d'Ulm.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mr. L. H. Ruegg; a Banded Ichneumon (*Herpestes fasciatus*) from West Africa, presented by Mr. H. L. Cocksedge; a Mace's Sea Eagle (*Haliaëtus leucoryphus*) from India, presented by Capt. Butler; a Pomatorhine Skua (*Stercorius pomatorhinus*), British, presented by Mr. F. L. Smith; a Woodcock (*Scolopax rusticola*), British, presented by Mr. J. Pollard; a King Penguin (*Aptenodytes pennanti*) from the Staten Islands, Cape Horn, a Cinereous Vulture (*Vultur monachus*), Europe, a Downy Owl (*Pulsatrix torquata*) from South America, deposited; a Water Rail (*Rallus aquaticus*), British, an Anaconda (*Eunectes murinus*) from South America, purchased.

OUR ASTRONOMICAL COLUMN

THE BIELA COMET METEORS.—Assuming, as some astronomers will probably be inclined to do, that Biela's comet has now lost the cometary form in which it presented itself to us from 1772 to 1852, and that its constitutuent particles, or whatever we may term them, are drawn out into a stream or band, beyond the circumstance of a great aggregation having been encountered by the earth on the evening of November 27, 1872, we are ignorant of the position of any other centre or centres of condensation that may exist, and even of the real extent of that which has been observed, along the comet's track; and hence it is desirable that a watch for the Biela meteors should be maintained during the whole of the last week in the present month. We are not assuming as a consequence of the disruption of Biela's comet before it was generally observed in 1846, that such is the actual condition of its constituent parts; Mr. Pogson's observations of a cometary body at Madras in December, 1872, require that such an assumption should be taken at present *cum grano*, but under any circumstances observations about the time when the earth approaches nearest to the orbit of the comet this year, will possess great interest, and we hope there may be an effective organisation of observers. In 1852, when the comet was last observed, its period of revolution, in the instantaneous ellipse at perihelion, was 2,417½ days; the effect of planetary perturbation thence tended to increase the period, so that in January, 1866, the latest time to which the calculations have been carried, the revolution extended to 2,445 days, according to Michez and Clausen. If this were about the period of the meteoric mass which the earth encountered on November 27, 1872, it is very doubtful if we shall be in proximity to it again during the present century; nevertheless, as above remarked, we do not know its extent along the orbit, and other aggregations may exist. A body moving in the orbit of Biela, and approaching the earth at this date, would be at a distance of about 1·4 from the planet Jupiter in September, 1878, and there might be very sensible effect upon the period of revolution.

A NEW NEBULA.—Dr. Tempel states that on September 19 he found a new nebula which, from his description, appears to be nearly as bright as an average second-class of Sir W. Herschel, and is therefore deserving of attention on the score of possible variability, since in these days we hardly expect to meet with many unknown second-class nebulæ visible in European latitudes. Dr. Tempel mentions that there is a central glimmer as from very minute stars: it is about one minute in diameter, and its position for the beginning of the present year is in R.A. 22h. 41m. 25s., N.P.D. 102° 27'·1: it is very little fainter than the nebula II. 744. He adds that he has often sought for the nebula No. 49 of Auwers, which should be near the new one, but has only found in its assigned position a star of 12m., which has a very faint companion. Auwers 49 is the object observed as a star 11·5m. on October 8, 1855, in one of the Markree zones, and called "nebulous;" position for 1850 in R.A. 22h. 52m. 35s., N.P.D. 101° 19'·9. The late Mr. Edward Cooper had so unfavourable an opinion of the climate in his locality for astronomical purposes (perhaps from long experience of the skies of Italy), that probably he would not have been surprised at the discovery of any number of "nebulous" objects at Markree; but the four volumes of positions of small stars for which astronomers are indebted to him, sufficiently illustrate the good work that may be effected by well-directed energy and skilful arrangement, even in such a climate as we remember to have heard him describe that of Sligo. Pons expressed his fear that the second comet of 1826 would be "drowned in Eridanus," as the sky had been overcast ever since it entered this constellation; on which Mr. Cooper ("Cometic Orbits," p. 152) is tempted to remark that, had Pons "written from the interior of Ireland, there would have been little to fear, for he might have made quite sure of it!"

THE SATELLITES OF MARS.—Both satellites of Mars have been observed with the Washington refractor; the measures of *Deimos* commenced on October 13, clouds interfering on the 10th, when it was first seen, and those of *Phobos* on the 12th. The correction required to the periodic time of *Deimos*, as determined by Prof. Asaph Hall from the observations of 1877, is so small that it will only be certainly ascertained from an exact discussion of the measures at this opposition; the periodic time of *Phobos* requires to be diminished 1·074s., or the corrected period is 7h. 39m. 13·996s.

Phobos and *Deimos* are also under observation with the Ealing reflector.

PHYSICAL NOTES

THE *Scientific American* describes a self-resonant tuning-fork, the invention of the indefatigable Edison. It consists of a tube of thick bell-metal closed at one end, and sawed down longitudinally nearly to the closed end, thus making two "prongs" united to a common base. To tune the prongs into unison with the column of air between them, the tube is put into a lathe and turned thinner and thinner until unison is reached. But how such forks are made of any precise pitch, or how the inclosed air-column contrives to vibrate in spite of the long lateral cuts, our contemporary does not vouchsafe to inform us. There are not many organ-pipes that would resound to their proper note with a saw-cut incised down them front and back.

FOR observation of atmospheric electricity M. Mascart (*Journ. de Phys.*, October) uses a Thomson electrometer connected with a vessel having continuous outflow of water. The deflections of the needle are transmitted every two and a half minutes to a pencil which records them on a sheet of paper. The series of traces forms a curve, not continuous, indeed, but nearly so. This apparatus was put in action at the College of France in the end of February this year, and the curves obtained during the following five months present several interesting features. The potential of the air is shown to be generally positive, with more or less rapid variations. In bad weather the curves become more irregular; rain nearly always produces very great negative deflections. The change of sign appears before the rain comes, and sometimes rain is followed by very high positive indications. There are also some very rare cases of positive rains, and of great negative deflections without apparent rain in the neighbourhood. (This predominance of negative electricity in rain clouds M. Mascart regards as an important point in the question of the origin of atmospheric electricity.) Neglecting accidental variations, one is struck by the fact that the electricity is much more uniform at night and more variable by day. The potential is also considerably higher at night than in the day. The maximum seems to occur about 9 or 10 P.M.; the curve descends slowly towards 6 A.M., then more rapidly; reaches a minimum about 3 P.M., and then rises again in a nearly uniform manner. The indications by the curves are confirmed by numerical tables of monthly averages of eight daily observations at three hours' interval. The results thus obtained are in contradiction with ideas commonly adopted. M. Mascart remarks that the continuous maximum of positive electricity observed at night may be of an exceptional character, owing to the anomalous season; He also suggests the possibility of previous observations having been vitiated through defective insulation.

THE influence of changes of temperature and pressure on double refraction has been recently investigated by Herr Pfaff, of the Erlangen Society of Physics and Medicine, and with (briefly) the following results:—In crystals of the rhombohedric system, when the temperature is raised, double refraction diminishes in quartz, but increases in vesuvianite, beryl, and apatite; it is not changed in Iceland spar (perpendicular to the principal axis), carbonates of iron and of magnesia, tourmaline, mellite, ferrocyanide of potassium, zircon, and cassiterite. In the orthorhombic system it increases in the case of arragonite (perpendicular to the median line), celestine (parallel to P); it diminishes in topaz, celestine, and heavy spar (perpendicular to the median line). In the clinorhombic system it diminishes in adularia (parallel to the median line) and mica; it increases in gypsum (parallel to the primary cleavage), remains constant in anhydrite, topaz, arragonite (inclined to the median line), witherite, carbonate of lead, adularia parallel to M), and the anorthic crystals, albite, oligoclase, labrador, anorthite, axinite, cyanite, and sulphate of copper. Pressure on the whole surface produces the same effect as a lowering of temperature in carbonate of magnesia, Iceland spar, celestine, gypsum, and heavy spar; the others do not present any modification, even those which, like topaz and vesuvianite, are very sensitive to variations of temperature.

PROF. REITLINGER and Dr. Urbanitzky have recently presented to the Vienna Academy the first portion of a memoir "On the Phenomena of Geissler Tubes under External Action," giving in more developed form, an investigation, of which they had already published some results. Various interesting experiments are described, *e.g.*, with reference to the attractions and repulsions of the light columns in Geissler tubes, and a possible joint action of the electrostatic and dynamic states in these, the authors hung a strip of tinfoil (15 ctm. long) from a platinum electrode at the top of a tube, 20 ctm. long, connected with a mercury pump (the second electrode being a straight platinum wire). Before rarefaction commenced the strip flew to the side, immediately the Ruhmkorff was set in action. But on rarefying, this phenomenon became less pronounced, till at 7 mm. the strip hung freely down in the middle. When in this state, it was attracted by a shellac rod rubbed with cloth, and repelled by a glass rod rubbed with amalgam (if the strip was connected with the positive pole, conversely in the other case); but these actions diminished as the rarefaction proceeded, becoming hardly perceptible at 4 mm. with the strip positive, and even at 6 mm. in the other case. A good conductor brought near caused attraction at all degrees of rarefaction in one case; but this, too, disappeared in the other. An experiment showing how the action of static electricity on a conductor is arrested when the latter is made a carrier of dynamic electricity, was made by bringing a rubbed glass or vulcanite rod near the strip, which thereupon went from the vertical to an inclined position. On sending through it the induction current (in either direction) the strip recurred at once to the vertical and remained there.

M. NIAUDET has lately constructed for Prof. Stefan, of Vienna, a Gramme magneto-electric machine, in which the permanent steel magnets are of circular form, instead of the usual elongated horse-shoe shape. The soft iron cheeks which embrace the rotating armature are also of a peculiar form. The new machine is much more compact than those hitherto constructed, and gives very satisfactory results.

A VERY singular theory of electricity and magnetism has recently been put forward by M. Bjerknes, who endeavours to explain the various phenomena upon mechanical principles. If a number of spherical bodies are plunged in an incompressible liquid, in the midst of which they execute isochronous vibrations, they are found to exercise certain forces upon one another. These forces may be either attractive or repulsive, according to the nature of the motions executed. Thus the actions exercised by an electrified particle may be illustrated by a pulsating sphere, that is to say, one which periodically increases in volume. A sphere vibrating to and fro similarly represents a magnetic particle. Unfortunately, however, the theory, to be applicable to electric and magnetic phenomena, would require the forces to act just in opposite directions to that which is found to be the case; for with M. Bjerknes' spheres the like poles attract, while the dissimilar poles repel. Experimentally, the attractions and repulsions thus theoretically deduced have been observed by means of an ingenious apparatus constructed for the inventor in Sweden. The pulsating bodies are a species of elastic capsule suspended from knife-edges by a hollow tube, by means of which the air is forced into and out of the capsule in rapid alternations. The vibrating bodies are little spheres set in motion by delicate levers. The mechanism is in each case driven by a pulley turned by hand. The liquid in which they are immersed is water, and the resultant attractions and repulsions are very clearly demonstrated.

M. GERNEZ has been studying the little-known phenomena of evaporation and distillation under the influence of electrification, discovered by the Abbé Nollet in 1746. The results of M. Gernez's observations have been communicated by him to the Physical Society of Paris, and are of considerable interest. Two concentric tubes communicating with one another above only are filled with a liquid to a common level. Sparks from a Holtz machine are then passed across the intervening air, when it is found that the level rises at the negative and falls at the positive pole. There is, therefore, apparently an actual transport in the direction conventionally agreed upon as the direction of the current. M. Gernez is inclined to attribute this phenomenon to an electrical transport of the liquids along the moistened surfaces of the tubes. Pure alcohol distils over thus at a rate three times as great as that of water, but a mixture of alcohol and water in equal parts at a less rate than pure water. The rapidity of the distillation is increased by the addition of any soluble salt or of a few drops of sulphuric acid or of ammonia solution. No appreciable amount of distillation takes place with bisulphide of carbon, tetrachloride of carbon, or with turpentine. M. Gernez, however, does not think that there is any assignable relation between the conductivity of a liquid and its rate of electro-convective evaporation; nor does he think that there is any necessary connection between this phenomenon and that discovered by Porret of the electric endosmose of liquids across diaphragms of various kinds.

GEOGRAPHICAL NOTES

AT the last meeting of the Russian Geographical Society, in the section of Physical Geography, M. Rylcke communicated the results of his precise measurements on the levels of the Baltic and of the Black Sea. These measurements were begun in 1877, by order of the General Staff, according to the resolutions of the Brussels Congress. Accurate measurements in the ports of the Baltic have proved undoubtedly that the level of the sea at Cronstadt is, by nearly two feet, higher than at Reval, and that its height decreases regularly from north to south, this conclusion being fully supported by Prussian measurements at Memel and at Kiel. For a comparison of the level of the Baltic with that of the Black Sea the necessary computations are not yet advanced enough to yield trustworthy results.

IN his last paper on the Agomes Islands (*Isvestia*, 1879, p. 37) M. Miclucho-Maclay says that here he happened to determine the dimensions of the heads only of fourteen men, and that the so-called "index of the breadth" varied from 69·6 to 81·3; it was thus nearly the same as on the Taui Islands (70·5 to 84·5), where the traveller has done no less than 119 measurements, and does not much differ from what was seen of the Papuans of New Guinea, whose "index" varies from 62·0 to 86·4. According to this wide variation of the "indexes," M. Maclay affirms that we have no right to describe the heads of Melanesians as well as those of the Papuans as dolichocephalic, but rather as mezocephalic; and that the form of the head must not be considered as a proof of a race-distinction between Negritoes and Papuans, as both Melanesians and Papuans display an obvious tendency to brachycephalism, whilst this last was formerly considered as a distinctive feature of the Papuans from the natives of the Philippine Islands. He considers also that within the same races we shall always find both forms of heads, and that a true classification of human races cannot be established on this sole feature; it must be based on a thorough study of the whole of the comparative anatomy. A few measurements on living subjects, however accurate, cannot give the necessary solid bases for a scientific classification.

ACCORDING to a telegram received in Paris from Sierra Leone, two Frenchmen, MM. Zweifel and Moustier, have at length discovered the sources of the River Niger, a feat which has hitherto baffled all explorers. The party appear to have been recently instructed by their employer, M. Verminck, of Marseilles, to explore the Niger for both scientific and commercial purposes; and accordingly, starting from Sierra Leone and following the course of the Kobelle, they reached the foot of the Kong Mountains. By adroit treatment of the hostile tribes at this point, where foreigners had always been refused passage, they were allowed to pass the mountains and explore the three streams which, uniting after a short distance, form the River Niger.

BEFORE concluding his recent explorations in South America, Dr. Crevaux made two attempts to ascend the Içą or Putumayo tributary of the Amazon. Having failed the first time, he ascended the main stream to Tabatinga, on the frontier of Peru and Brazil, and then returned to Para. He there obtained means to enable him to carry out his original intention, and at the second attempt succeeded in ascending the Içą to Cnembe, to the north of Cotopaxi, on the frontier of Bolivia and Ecuador. Starting from this place on May 16, Dr. Crevaux reached the foot of the Andes in eight days. Thence continuing his route towards the north, he arrived at the sources of the Japura after sixteen hours' march. After experiencing great hardships, and hostility on the part of the natives, he reached the Amazon again on July 9, arriving at Para on July 24. He has brought back with him much information interesting alike from a geographical and ethnographical point of view, as well as a collection of plants, which are expected to prove useful as medicines.

IN publishing an interesting letter from its special correspondent with the Russian expedition against the Tekke Turkomans, the *Daily News* states that the "nature of the ground along the course of the Attrek from the Caspian Sea has never been accurately described from personal observation." Without wishing to undervalue this and other letters from the same source, we may be permitted to point out that the ground had been previously examined by a party under General Llomakin, and that Sir Henry Rawlinson, in his paper on the "Road to Merv," read before the Geographical Society on January 27, quoted at length from Russian newspapers a description of this very route by a member of the expedition. A summary of the letters, giving an account of this expedition, which had been addressed to the *Moscow Gazette*, also appeared in NATURE, vol. xix. p. 271.

A LETTER from Herr Hildebrandt, dated Nossibé (Madagascar), states that he has visited Beravi, where the unfortunate traveller, Dr. Chr. Rutenburg, was murdered some time ago. Hildebrandt erected a stone monument on the spot; the body, however, could not be found, in spite of the most assiduous inquiries, the murderers having thrown it into a mountain torrent. Hildebrandt has photographed the spot, and sends a copy to Bremen, accompanied by the last diary and stenographical notes of Rutenburg.

THE Geographical Society of Algiers has nominated for its president M. MacCarthy, an explorer of the Algerian Sahara, who is settled in Algiers, and has been appointed librarian of the National Library of Algiers. This Society has been divided into three sections: Political Geography, Economical Geography, and Physical Geography.

THE Belgian African Society has received letters from Zanzibar, according to which MM. Popelin and Van der Heuvel had arrived at Mpwapwa on August 15 and at Chunyu on September 2. They were to leave the latter place on September 3, and to penetrate into the Ugogo district. At Mpwapwa they met the elephant caravan led by Carter. Each elephant carried about 10 cwt. The march was performed most satisfactorily. In the districts where the tsetse flies abound, the animals were often covered by them without feeling any the worse for it. Only one elephant died through change of nourishment, the whole caravan being fed with what the country offered. M. Dutalis, who suffered from a severe attack of fever, has returned to Europe.

THE Geographical Society of Munich has conferred the title of Honorary Members upon Prof. Nordenskjöld, Dr. Joseph Chavanne (Vienna), and Dr. Emil Holub (Prague). The reception of the latter upon his return to Prague was most enthusiastic. He had been absent for over seven years. The Vienna Geographical Society has elected the following gentlemen as Honorary Members:—Prof. Ujfalvy (Paris), General Kauffmann (Tashkend), Dr. E. Holub (Prague), and Prof. Arendts (Munich). The last-named gentleman has also been nominated Corresponding Member of the Paris Society for commercial geography.

A GENERAL "Geographentag" will be called at Berlin during the summer of 1880. Its special object will be the consideration of plans for the formation of a great German "Gesellschaft für Erdkunde." The idea is not a new one, but projects for the new General Society have already been mooted upon several occasions. At the recent Karl Ritter celebration at Berlin, a "commission" was appointed and charged with the working out of certain preliminaries referring to the subject. The commission is formed of Dr. Nachtigal (Berlin), Prof. Neumayer (Hamburg), Prof. Bruhns (Leipzig), Prof. Rein (Marburg), and Dr. Roth (Dresden)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—In a congregation held on Tuesday, November 18, the amendments to the proposed statute to confer degrees in natural science were taken into consideration. The proposed statute made Greek an optional subject in the natural science curriculum. It appeared from counsel's opinion that the proposed degree would not carry with it the rights and privileges of the master of arts degree. On the latter ground opposition was made to the statute by a considerable portion of those engaged in teaching natural science at Oxford. Prof. Odling had issued a memorandum, extensively signed by residents interested in science, in which he had explained his reasons for opposing the statute. The statute, by completely separating the faculties of arts and natural science, would allow no honour student in one faculty to become an honour student in the other without beginning in the new faculty *ab initio*; and no honour student in the faculty of natural science could fall back, as at present, on the ordinary pass degree. The broader question of lowering the value of natural science degrees by putting them on a different footing from degrees in arts, was not discussed in congregation on Tuesday; but Dr. Magrath's amendment to reject the whole statute except the preamble, was passed by a vote of fifty-four against forty-eight. The whole subject will thus have to be rediscussed on a future occasion.

The examination in the Honour School of Natural Science will commence next Monday, November 24.

CAMBRIDGE.—The Cambridge women students add no unimportant quota to the numbers in residence, numbering something lik 160 or 170 this term. At Girton College there are over fifty students, including about six of the first year who purpose studying natural science. They have a good chemical laboratory, under Miss Herschel's superintendence, also a library which includes many valuable presents of books and apparatus. There are now eleven lecture- and class-rooms, and a good hospital and nurse's room have been built, capable of being entirely detached from the rest of the College. Miss Tomlinson's success in winning an entrance scholarship at the London School of Medicine for Women, and entering for the London Medical Examinations, will doubtless tend to show that a Cambridge course in science is no bad preparation for women as well as men before proceeding to medical degrees.

The Newnham College Association will shortly have two houses of residence facing one another, together with a complete set of lecture-rooms and a chemical laboratory. There are eighty-two students in residence at Cambridge who have come for the lectures to women, besides about twenty who attend the lectures each term, being residents, school-mistresses, &c. Miss Lawrence, who gained marks equivalent to a second-class when informally examined in the last Natural Sciences Tripos, remains in residence, and demonstrates for the lady-students who attend Dr. Michael Foster's and Mr. Balfour's lectures. Mr. Vines's lectures on Vegetable Physiology are open to ladies who obtain special permission.

Mr. Freeman, of St. John's College, has given to the Women's Association a quantity of valuable electrical apparatus which will be used in giving instruction in experimental physics. Mr. R. T. Wright, on leaving Cambridge, resigns his active work for the Association as secretary, and pending the formation of the Newnham College Company, Miss M. G. Kennedy is appointed secretary to the Association for the remaining period of its existence. Nine scholarships have been awarded by the Association on the last higher local and other examinations, and over 700*l*. thus given or lent to students in one year. About 1,000*l*. has been paid to the Association during the year by students attending its lectures. As soon as the memorandum and articles of association of Newnham College are complete, a copy will be kept by Mrs. Bateson at St. John's Lodge, for inspection by any member of the existing Association.

A noteworthy entertainment of the British Medical Association by Cambridge University, town, and county, may be expected next August, when Prof. Humphry will preside. The president's position will be very conspicuous, for he is now, by Mr. Lestourgeon's retirement, senior surgeon and clinical lecturer on surgery to the Cambridge (Addenbrooke's) Hospital and Medical School, as well as professor of anatomy. A public meeting was held on Friday, the 14th, in the Cambridge Guildhall, at 2.30, under the presidency of the Vice-Chancellor (Dr. E. H. Perowne, Master of Corpus Christi College), when Dr. Humphry made a statement of the objects of the Association and the proposed arrangements for the meeting. His son, Mr. A. P. Humphry, one of the Esquire Bedells, is honorary secretary of the Local Executive Committee. Most probably at least a thousand members will attend the meeting. Dr. Michael Foster will deliver the address in Physiology, and Mr. Timothy Holmes that on Surgery. Dr. Paget, Regius Professor of Medicine, will preside over the section of Medicine, he having been president of the Association itself when it last met in Cambridge; and Sir James Paget will be president of the newly constituted section of Pathology. Dr. J. B. Bradbury is to deliver the address in medicine at the meeting; he holds the Linacre Lectureship, delivering lectures on pathology, is medical lecturer of Gonville and Caius College, and one of the physicians to Addenbrooke's Hospital, and took a distinguished position in the Cambridge Natural Sciences Tripos.

Mr. G. B. Atkinson, Trinity Hall, Cambridge, has been appointed secretary of honour examinations.

We are glad to learn that mathematics and geology are now studied by more students who enter the Cambridge Higher Local Examinations. In the examination in mathematics in June, the candidates showed better style and appreciation of mathematical ideas. All the subjects gain favourable reports, and in astronomy one candidate did remarkably well. The work in the differential and integral calculus was good, the introduction of this paper having been successful. In botany there was much guesswork and little evidence of histological work by candidates. One of the candidates, placed first in zoology, sent up admirable work in botany. Some candidates did very well in practical chemistry. The examiner's report on physiology, now first introduced as a separate subject, is on the whole favourable; only one set of papers on physics was sent up. In 1879, Group C (Mathematics) had 60 candidates, of whom 19 failed and 8 obtained a first class; in Group E, 73, of whom 35 failed and 4 obtained a first class.

The Report of the Board of Natural Sciences Studies, which we referred to last week, was rejected by 46 to 26 votes. Prof. Paget and Mr. Bettany issued a fly-sheet complaining that the subjects of examination were now too numerous and extensive; encouraging candidates to an injurious amount of memory-work in attaining "general knowledge and proficiency;" and that there should now be a Biological and a Physical Tripos. Mr. Sedley Taylor and Mr. Vines, as well as Prof. Dewar and Mr. Balfour, object to the advance of human anatomy to so conspicuous a place in the Tripos Dr. Humphry considers the recognition of human anatomy in the Tripos not greater than it deserves. However, he would now prefer a "Medical Tripos."

SCIENTIFIC SERIALS

Journal of Anatomy and Physiology, Normal and Pathological, vol. xiv. part i., October.—Drs. Gibson and Malet, on a pre-sternal fissure, uncovering the base of the heart, pl. 1.—Dr. W. Ostler, case of congenital and progressive hypertrophy of the right upper extremity.—Prof. Flower and Dr. Garson, the scapular index as a race character in man.—Dr. W. Allen, the varieties of the atlas in the human subject and the homologues of its transverse processes, pl. 2.—Prof. Cleland, note on the foregoing.—Dr. Creighton, the infection of the connective tissue in scirrhous cancers of the breast.—Dr. Watson, the homology of the sexual organs, illustrated by comparative anatomy and pathology.—Prof. Bridge, on the pori abdominales of vertebrata.—Prof. Turner, on the pori abdominales in some sharks.—Prof. Turner, a description of a cleft sternum.—Dr. J. Barlow, the physiological action of ozonised air.—Prof. Charles, on the mode of propagation of nervous impulses.—Dr. Cook, on a logwood staining solution.—Dr. Dobson, case of the development of hair on the eyeball of a dog.—Dr. Osler, on Giacomini's method of preserving the brain.—Anatomical notes.

THE recent numbers of the *Scottish Naturalist*, which has now been in existence for nine years, show no falling off from the interest of the earlier ones. In addition to the descriptive papers and lists of localities in the various departments of natural history, we find in the last number a paper on the Gaelic names of plants, one on the effects of the past winter and present summer on hard-wooded plants, and one on the auriferous quartz of Wanlockhead. The list of Scottish insects by experts in the various sections of entomology is still continued in each number. The number for October contains an appreciative notice of the late excellent naturalist, Sir Thomas Moncreiff, Bart., president of the Perthshire Society of Natural Science.

Royal Society of Tasmania, Papers and Proceedings of, for 1877.—Hobart Town, 1878.—Among the more important papers are the following:—F. W. Hutton, on some South Australian Polyzoa (describes several new species from the shores of St. Vincent's Gulf).—Rev. J. E. T. Wood, census, with brief descriptions of the marine shells of Tasmania and the adjacent islands.—Rev. W. W. Spicer, on alien plants.—Rev. J. E. T. Woods, on Australian Siphonaria (describes a new species, *S. zonata*).—M. Allport, on the present stage of the salmon experiment (November 12, 1877).—Baron Ferd. von Mueller, contributions to the phytography of Tasmania, in which he adds a few more plants to his previous enumeration and effects a few changes in nomenclature; there is added a note on *Phyllota* (*Pultenaca*) *diffusa*.—Rev. J. E. T. Woods, on some new Tasmanian marine shells (describes several new species).—The meteorology of Hobart Town, January to December, 1877. In January apricots and Jargonelle pears were ripe, the general apple and pear crop in February. Leaves commenced to fall in March; the chrysanthemums were in flower in April; Lachenalia and Photinia in May; crocuses and *Pyrus japonica* in June; almonds in full bloom in July; trees breaking into leaf in August; horse chestnut in flower in September; mulberry and lime trees in leaf in October; cherries and strawberries ripe in November; currants and gooseberries in December.

Morphologisches Jahrbuch, Band 5, Heft 3.—Dr. G. Born, on the nasal cavity and tear passages in the amniotic vertebrates, pls. 23-24.—L. Graff, on *Geonemertes chalicophora*, a new land Nemertine, pl. 25-27. This new species was found in the earth of a flower-pot in the palm-house at Frankfurt. The larger specimens were 12 mm. in length and $\frac{2}{3}$ mm. in breadth; they are of a milk-white colour. A list of the land nemertines now known is appended, these being the original species of the genus described by Semper, *G. palaensis*, and *Tetrastemma agricola*, of Willemoes-Suhm.—M. v. Davidoff, on the comparative anatomy of the posterior limbs in fishes, pl. 28-31, to which is appended a note by the editor, Prof. Gegenbaur, on the limb question.—Notice of Schneider's "Comparative Anatomy."

Journal of the Russian Chemical and Physical Society.—The last number of this journal contains a paper by Prof. Butleroff, on the present meaning of the chemical theory.—The conclusion of the researches, by M. Lebavin, on the nucleine of milk.—On derivates of the fumaric and maleic acids, by M. Ossipoff.—On cholécamphoric acid, by M. Latchinoff.—On a new alkali derived from quinine, by MM. Wischnegradsky and Prof. Butleroff.—On the theory of dispersion of light, by M. Cheboueff.

SOCIETIES AND ACADEMIES

London

Mathematical Society, November 13.—Mr. C. W. Merrifield, F.R.S., president, in the chair.—The treasurer's and secretaries' reports were read.—The new council was elected, the only changes in which were the substitution of Messrs. Leudesdorf and Lloyd Tanner, in the place of Dr. Spottiswoode, P.R.S., and Prof. H. J. S. Smith, F.R.S., the retiring Members.—The Chairman briefly, but in feeling terms, alluded to the losses the Society had recently sustained by the deaths of such accomplished mathematicians as Prof. Clifford, Sir J. G. Shaw Lefevre, and Prof. J. Clerk Maxwell.—The following communications were made to the Society:—(1) On the binomial equation $x^p - 1 = 0$, trisection and quartisection, Prof. Cayley, F.R.S.—(2) On cubic determinants and other determinants of higher class, and on determinants of alternate numbers, Mr. R. F. Scott.—(3) On a problem of Fibonacci's, Mr. S. Roberts, F.R.S.—(4) Notes on a class of definite integrals, Mr. T. R. Terry. (1) was principally concerned with the presentation in a simplified form of results given in Reuschle's "Tafeln complexer Primzahlen welche aus Wurzeln der Einheit gebildet sind" (4to, Berlin, 1875), and in Jacobi's "Canon Arithmeticus" (4to, Berlin, 1839). (2) was on a branch of determinants which has received but little attention in this country. Mr. Lloyd Tanner communicated a paper on the subject to the Society at its June meeting in the present year. Amongst Continental papers are memoirs by Armenante, Padova, and Garbieri (in the *Giornale di Matematiche*), Dahlander and A. de Gasparis. (3) was an account and extension of work done in the Diophantine Analysis by Fibonacci, and recently by Genocchi. (4) The integrals considered were

$$\int_0^\pi \frac{\cos p x \, d x}{(1 - 2a \cos x + x^2)^n} \text{ and } \int_0^\pi \frac{\sin^2 p x \, d x}{(1 - 2a \cos x + a^2)^{n+p}},$$

where p is a positive integer and n any real quantity, positive or negative, integral or fractional.

Geological Society, November 5.—Henry Clifton Sorby, F.R.S., president, in the chair.—Henry Bruce Armstrong was elected a Fellow of the Society.—The following communications were read:—On the probable temperature of the primordial ocean of our globe, by Robert Mallet, F.R.S. According to the latest hypotheses as to the quantity of water on the globe, its pressure, if evenly distributed, would be equal to a barometric pressure of 204·74 atmospheres. Accordingly water, when first it began to condense on the surface of the globe, would condense at a much higher temperature than the present boiling-point, under ordinary circumstances. The first drops of water formed on the cooling surface of the globe may not impossibly have been at the temperature of molten iron. As the water was precipitated, condensation of the remaining vapour took place at a lower temperature. The primordial atmosphere would be more oblate and less penetrable by solar heat than the present, and the difference of temperature between polar and equatorial regions would be greater; so that, in the later geologic times, ice may have formed in the one, while the other was too hot for animal or vegetable life. Thus, formerly the ocean would be a more powerful disintegrant and solvent of rocks, mineral changes would be more rapid, and meteoric agencies would produce greater effects in a given time.—On the fish-remains found in the cannel coal in the middle coal-measures of the West Riding of Yorkshire, with the description of some new species, by James W. Davis, F.G.S.—On the skull of *Argillornis longipennis*, Owen, by Prof. R. Owen, C.B., F.R.S. In this paper the author described a fragmentary cranium from the London clay of Sheppey, from which it was procured by Mr. W. H. Shrubsole, who also furnished him with the humerus described in a former paper under the name of *Argillornis longipennis*.[1] In the present specimen the lower jaw and the fore-part of the upper jaw are deficient. The author described the characters presented by the specimen in detail, and stated that, like those of the humerus previously described, they seemed to approximate the fossil most nearly to the albatross among existing birds, although, like *Odontopteryx*, it differed from *Diomedea* and also from the cormorant and the totipalmates generally, in the absence of the basirostral external nares and of the supraorbital gland-pits. The present fossil differs from *Odontopteryx* in having the fore-part of the frontal broader and the upper tract of the bill less defined, as also in some other characters; but no comparison of the palatal structure can be made upon the existing specimens. In point of size, taking the albatross as a term of comparison, this skull may well have belonged to a bird with wings of the extent indicated by the humerus already described: and the resemblance of the skull to that of the albatross would also seem to be confirmatory of the specific collocation of the two specimens. The presence of four small pits or perforations on the only part of the alveolar border which appears to be uninjured, leads the author to conjecture that the bird may have been dentigerous.

Physical Society, November 8.—Prof. W. G. Adams in the chair.—The first paper read was on an analogy between the conductivity for heat and the induction balance effect of copper-tin alloys, by W. Chandler Roberts, F.R.S. Mr. Roberts traced a remarkable resemblance between a curve representing the induction balance effect of the copper-tin alloys published by him in June last, and the curve of Calvert and Johnson for the conductivity of heat, and on the other hand he showed that the induction curve does not agree with Matthiessen's curve for the electric conductivity of the same alloys. The author showed that the two alloys which occupy critical points of the curve ($SnCu_3$ and $SnCu_4$) are of much interest. Possibly both are chemical combinations, and the wide difference in the position they occupy probably marks a difference of allotropic state. For the solution of such questions, however, Mr. Roberts considered that we might look with confidence to Prof. Hughes' beautiful instrument, which, he hopes, will also help us to determine whether the relation between conductivity for heat and electricity is really as exact as it has hitherto been supposed to be. As supplementary to this subject Dr. O. J. Lodge stated that he had compared the conductivity of six bars of the tin-copper alloys, as measured by the balance and by the Wheatstone-bridge, and found them to agree very closely. The bridge results confirmed the resemblance traced by Mr. Roberts. Prof. Hughes expressed his opinion that existing tables of conductivity were erroneous. They disagreed among themselves

[1] *Quart. Journ. Geol. Soc.*, vol. xxxiv. p. 124.

and the induction-balance showed that it was difficult to get two pieces of the same metal exactly alike; hence the variation of specific conductivity results.—Prof. Ayrton stated that at a former meeting he had suggested that the electric inertia of the different specimens of metal tested might cause the difference between the results obtained by the Wheatstone Bridge and the induction-balance. Calculation had since led him to the conclusion that the inductive effect is not proportional to the resistance of the metal tested, but to an expression in which the resistance is an exponential. Prof. Hughes replied that as the inductive effect of the metal was destroyed by cutting it so as to interrupt the circuit in it, it was reasonable to suppose that the said effect was due to induced currents circulating in the metal, and therefore was proportional to the conductivity of the metal.—Capt. Armstrong exhibited a standard Daniell cell formed of a porcelain vessel with a porous partition dividing it into two compartments. In one the zinc plate was immersed in a solution of sulphate of zinc, in the other the copper-plate in a solution of sulphate of copper. To use the cell as a standard, it was only necessary to connect the two liquids by a cotton string moistened with water. This arrangement prevented mixing of the liquids, as the string could be withdrawn after use. The resistance was high, but it was a constant standard of electromotive force.—Prof. Guthrie mentioned that Prof. Pirani, of Melbourne, in a letter to him had pointed to the fact that when a dilute acid was being electrolysed, the positive electrode, if made of iron, became incandescent below the surface of the liquid. Prof. Guthrie had found this to be true not only for iron but for other metals, and that it could hardly be due to oxidation, because it took place not only at the cathode or positive electrode, where oxygen was evolved, but also at the anode where hydrogen was evolved. The incandescence appeared to him to be due to resistance. The author exhibited certain experimental results. The positive electrode when immersed in the electrolyte was seen to get red hot and to vibrate rapidly. As the liquid heated the red glow became fainter. The negative electrode, on the other hand, emitted a bright light, accompanied by a noise. The light was tinged with the characteristic colour of the flame of the metal of which it was composed; in the case of a copper electrode, for example, it was greenish. These effects were shown by Prof. Guthrie with iron, copper, and platinum electrodes, in dilute sulphuric and dilute nitric acid. In reply to Prof. Adams, Prof. Guthrie said he had not yet examined the flame by the spectroscope; and in reply to Prof. Foster he stated that the battery power used was fifty Grove's cells. He asked for suggestions as to the cause of the phenomenon.

PARIS

Academy of Sciences, November 10.—M. Daubrée in the chair.—M. de Lesseps stated that a corps for boring operations had been sent out to Panama, and he was going out in a month with a commission of selected engineers of various countries. He applied for a committee to formulate a programme of observations that might be useful to science.—Climatological conditions of the years 1869 to 1879 in Normandy, and their influence on ripening of the crops (first note), by M. Mangon. The observations were made at Saint-Marie-du-Mont (Manche), a few kilometres from the sea. The exceptional character of 1879 in temperature and rainfall is shown by numerical data (the relation to the crops being reserved for another paper).—On a new species of the genus *Anomalurus*, by M. Milne Edwards. The animal was in a collection formed at the Gaboon, by M. Leglaize. It is remarkable for its beauty of colours, and the author calls it *A. erythronotus*. It is like *A. fraseri* in general proportions, but is easily distinguished. The discovery raises to six the number of representatives of *Anomalurus;* all belong to the west of tropical Africa.—On the presence, in surface layers of the ground, of fecundated winter-eggs of phylloxera, by M. Boiteau.—On the results of treatment of phylloxerised vines with sulpho-carbonate of potash, and on the mode of use of this agent, by M. Mouillefert.—The satellites of Mars in 1879, by Mr. Hall.—Determination of the figure of apparent repose of an inextensible cord in motion in space; conditions necessary for its production, by M. Léauté.—On the thermal absorbent and emissive power of flames, and on the temperature of the voltaic arc, by M. Rossetti. For 0·01 m. of any flame traversed by radiation from a flame of the same nature, the coefficients of transparence and of absorption are represented, respectively, by 0·865 and 0·135 m. A thickness of 1 m. renders a flame almost completely athermanous for rays from another like flame. The absolute thermal emissive power of white gas flames (or the intensity of radiation of such flames of indefinite thickness, compared with that of soot at a temperature equal to the mean temperature of the flame), is equal to unity; that of a Bunsen flame 0·3219. A large number of experiments gives about 3900° C. as the maximum temperature of the positive polar carbon extremity, and 3150° for the negative; for the voltaic arc, between these, a temperature of about 4800° (with any intensity of current or thickness of arc).—Researches on the passivity of iron, by M. Varenne. Fuming nitric acid does not act on iron and render it *passive*, so that it is not attacked by dilute nitric acid. The author describes various experiments throwing light on the case. It appears that any agitation in the neighbourhood of the passive metal, whether by a shock or a vibration, or by a current of gas (very weak it may be) as from spongy platinum placed at the bottom of the vessel of dilute acid, in which the passive iron is hung, abolishes the passivity. The gaseous sheath formed on the iron seems to be the obstacle to attack. It is more adherent on a smooth surface, and on a specimen of great molecular condensation than on one rugous and less compact. *In vacuo* the sheath, and with it the passivity, disappear.—On alcoholic fermentation, by M. Cochin. He concludes from experiment that yeast does not produce a soluble alcoholic ferment.—Complementary note on calcination of the *vinasses* (or spent-wash) of beetroot, by M. C. Vincent. A reply to MM. Duvillier and Buisine.—On the organisation and the cellular form in certain kinds of mosses (*Dicranum* and *Dicranella*), by M. Heckel.—On the resistance of sheep of Barbarine race to inoculation with *charbon*, by M. Ollive. He affirms the generality of this character. During the eight years he has lived in Mogador he has never met with any case of the disease.—On the rhythmic excitability of the muscles and their comparison with the heart, by M. Richet. For the heart, as for the muscle of a claw of the cray-fish, contraction (systole) exhausts the muscular element, which then ceases to contract; but it is restored very quickly, and it is during the period of exhaustion (diastole) that the reparation takes place. The cause of rhythm is the same in both heart and muscle—rapid exhaustion and rapid reparation.—Comparison of the action of various curares on the smooth and striated muscles, by M. De Lacerda. They differ in intensity of action on these muscles, not in the nature of the action.—On medullary osseous abscesses, by Dr. Chassargnac.—M. Larrey presented Dr. Bateman's work on Darwinism demonstrated by language, and gave an *aperçu* of it.—M. Chasles presented (from Prince Boncompagni) a photolithographed copy of a long letter from Gauss to Mdlle. Sophie Germain, a student of the École Polytechnique.

THE SACRED BOOKS OF THE EAST

The Sacred Books of the East. Translated by various Oriental Scholars, and Edited by F. Max Müller. Vol. I. *The Upanishads,* Translated by F. Max Müller. Vol. II. *The Sacred Laws of the Aryas,* Translated by Georg Bühler. Vol. III. *The Sacred Books of China,* Translated by James Legge. (Oxford: The Clarendon Press, 1879.)

THE series of volumes, of which the first three have just been issued simultaneously, under the able editorship of Prof. Max Müller, are a very significant sign of our age. Their object is none other than to give to the public the sacred books of the historical religions of the world, translated into English by the best living scholars, without praise or disparagement, and with no reference to theological controversies or the needs of missionary zeal. The translations aim at being exact and faithful representations of the originals, so far as this is possible, and they are published in the interests of science, not of religious dogma. It is intended that the scientific student of religion should possess in them trustworthy materials on which to found his generalisations and build his conclusions. The fact that such a work should appeal to a large public is not so remarkable as the further fact that it has been published at the expense of a university once supposed to be the stronghold of a narrow orthodoxy.

It is difficult to realise that the days are not long past when the very conception of a scientific treatment of religion would have been regarded either with horror or with indifference. The religious world would have none of it; the fashionable world associated science with bones and machinery. The task of translating or of reading the sacred books of other peoples was left to a few zealots bent on destroying the Christianity of modern Europe, or a small band of scholars whose labours were almost unknown beyond the privacy of the study. In many cases, indeed, translation in the true sense of the word was impossible; scientific philology had not yet explained the meaning of half-forgotten Eastern tongues, literary and historical criticism was still seeking its canons, and the wildest notions passed muster as to the antiquity of Oriental books. The mutilated and misunderstood fragments of Hindu or Chinese texts paraded before the reading public were travestied on behalf, now of a traditional orthodoxy, now of an irrational denial of the popular faith. The filthy and absurd rites of later Hinduism were made to subserve the cause of the apologist, while his antagonist retorted with moral excerpts to which a fabulous age was assigned or painted an ideal portrait of Confucius and his doctrines.

Thanks to the application of the scientific method to the study of language, of history, and of society, we can now examine the historical religions of mankind calmly and dispassionately, can estimate their relative influence and importance, can trace their origin and subsequent development. We have learned the great doctrine of historical evolution. The mind of man does not move by fits and starts any more than external nature; it is conditioned by the circumstances surrounding it, and slowly grows to a ripe maturity. The various forms in which the religious emotions of man have clothed themselves, the various dogmas into which they have been crystallised, result from causes which can be discovered by careful research. The words in which they have been expressed lie like fossils in the strata of society revealing to the comparative philologist the ideas that prevailed at the time they were first coined or at the successive periods when their meaning was modified. Doctrine must necessarily develop because the mind of man develops, continually gaining new ideas and new points of view and recasting those of a past generation.

The history of doctrine may be read in the sacred books of a religion and the mode in which they have been interpreted. We see the words of the text gradually becoming fixed and sacred, and then taking upon them strange senses coloured by the beliefs and ideas of a later day. The simple utterances of an Aryan poet came to be regarded as the awful commands of the Almighty, and to constitute an infallible and irresponsible text-book of life and morals, of law and learning.

The relation of a religion, however, to its Bible may be twofold. It may have had an individual founder like the Buddha or Zoroaster, or Mohammed, and then the authority of the founder overrides that of the sacred book which derives its force and sanctity from him; or it may be the slow growth of time and circumstances, moulded, as in the case of Brahmanism, by a powerful priesthood, whose influence and dogmatic system rest entirely on the divine authority with which they have been able to invest their sacred scriptures. In the latter case a far stricter and more uncompromising theory of inspiration is necessary than in the former. To impugn a single jot or tittle of the canon is to overthrow the very foundations of the faith.

It will be a long while before the science of religion can do more than collect its facts and lay down a few broad and more or less provisional generalisations. Only when we know the way in which each of the historical religions of the world has been born and grown up, shall we be able to compare them with one another and with the unorganised religions of barbarous tribes. It has yet to be seen whether the different races of mankind have started with the same stock of religious ideas and followed similar courses of development, or whether, as has sometimes been asserted, each race has its own religion as peculiar and appropriate to itself as the colour of its skin or the character of its hair. If we may argue from the analogy of language the assertion is likely to turn out a false one.

The question of the origin of unrevealed religion cannot, of course, be answered by the study of sacred books. The early struggles of religion to clothe itself in articulate utterance lie too far behind the age of organised faith when a canon first becomes possible. An uncivilised people cannot have a Bible. It may be brought to them by others, but if so, civilisation is brought with it. To determine whether fetishism, or animism or any other "ism" was the primitive form of religion, we must look to other evidences than those presented by sacred books. Sacred books are the records of historical religions only. But it is with these records that the student of religion must begin, rather than with the fragmentary and uncertain relics of older phases of faith.

In his introduction to the first volume, Prof. Max Müller offers some useful words of warning to those who approach the study of these old texts with exaggerated ideas of Eastern wisdom and profundity. "By the side of so much that is fresh, natural, simple, beautiful, and true," there is "much that is not only unmeaning, artificial, and silly, but even hideous and repellent." The extracts culled from them by popular writers, in order to illustrate the exalted character of ancient thought, too frequently stand by the side of other passages which painfully recall the infirmities of human nature. Mankind has worked its way but slowly to its present level of knowledge and enlightenment, and the mixed character of these ancient books may serve to remind us that we, too, have our infirmities and imperfections which will seem as strange to a future generation as those of Eastern sages do to us. Man is the creature of his age, and the best and wisest among us cannot escape from the influences that surround us, and the limitations imposed by the knowledge and prejudices of our own day.

These translations will be useful in dispelling another illusion which the enthusiastic pioneers into the realm of Oriental religion have occasioned. They are as faithful and accurate as the present state of philological science allows, and the reader will, therefore, miss the modern ideas that have too often been read into passages quoted from the sacred books of the East. By changing a word here, and inserting a word there, by assimilating the expressions of the original to the familiar language of our own Scriptures, a false impression of the character of these old books has not unfrequently been produced.

The Upanishads, with which the series of translations opens may be described as the text-books of sacred Hindu philosophy. They preceded the era of the Sûtras, or grammatical treatises on the Veda, the beginning of which may be roughly placed about 600 B.C., and form part of that of the Brâhmanas or Vedic commentaries. They embody the traditional doctrines of the Brahmans regarding the highest objects of human interest and inquiry, and in many cases may be shown to have been incorporated into a Brâhmana. They aim at ascertaining the mystic sense of the Veda, and so lay the foundation of the later Hindu metaphysical systems. At the same time they are not exclusively Brahmanical; on the contrary, they seem composed rather in the interest of the Kshatriya Kings than of the priestly Brahmans. About 150 of them exist, partly in prose, partly in verse, out of which Prof. Max Müller has selected five of the most important to place before the English reader. It must be remembered that, like the Brâhmanas, the Upanishads form part of the inspired Hindu Canon.

The sacred laws of the Hindus, as taught in the schools of Apastamba and Gautama, occupy the second volume of the series. They belong to the Sûtra period of Indian literature, and we have not to read them long to discover the tyrannically Brahman spirit which they breathe. Dr. Bühler considers that the Gautama Dharmasastra is in the main the oldest of existing works on sacred Hindu law. He further places Apastamba at latest in the fourth or fifth century B.C. A translation of the laws taught in the schools of Vâsishtha and Baudhâyana will follow in another volume.

The third volume contains Dr. Legge's translations of the texts of Confucianism, the Shû King, the Shih King, and the Hsiâo King. The Shû King is a collection of historical records, beginning with the reign of Yâo in the twenty-fourth century B.C., and coming down to that of Hsiang B.C. 961. The Shih King or Book of Poetry consists of 305 ancient poems, five of which belong to the time of the Shang dynasty (B.C. 1766–1123), and the rest to that of the dynasty of Châu (B.C. 1123–586). Its philological and literary value is naturally very great. The short treatise known as the Hsiâo King, or classic of filial piety, is regarded by Dr. Legge as containing a Confucian element, but mostly composed in the first century before our era. Astronomical and other reasons on the other hand, dispose him to accept the antiquity claimed by the Shû and the Shih.

Prof. Max Müller may be congratulated on the successful commencement of his great undertaking. The publication of other sacred texts, including the Korân, the works of Lao-tse, and selected portions of the Buddhist and Zoroastrian Scriptures, are expected soon to follow. For obvious reasons, however, the sacred books of ancient Egypt and Babylonia, of which we now possess considerable fragments, have been excluded from the series. The Book of the Dead, the most important part of the Egyptian Canon, will be independently issued before long in a revised text and revised translation, while we must wait for future excavations to complete the mutilated hymns of early Chaldea, a portion only of which is at present in our hands. For many years yet we shall have to be content with collecting and preparing the materials that others will use, with sowing the seed which another generation will harvest. We have, indeed, come to realise that there is a science of religion, but it will necessarily be long before the science has passed out of its firs classificatory stage. A. H. SAYCE

MODERN CHROMATICS

Modern Chromatics, with Applications to Art and Industry. By Ogden N. Rood. International Science Series. (London: C. Kegan Paul and Co., 1879.)

IN Sir Charles Eastlake's preface to his translation of Goethe's "Theory of Colours," he took occasion to pronounce against the accepted theory of Newton (that white light consists of coloured lights compounded together), in the following sentences:—

"It must be admitted that the statements of Goethe contain more useful principles in all that relates to the harmony of colour than any that have been derived from the established doctrine. It is no derogation of the more important truths of the Newtonian theory to say that the views it contains seldom appear in a form calculated for direct application to the arts."

Since the time of Sir Charles Eastlake, however, great strides have been made in the theory of colour. The work of Prof. Rood now before us is the latest contribution to this branch of science; and in dealing with "Modern Chromatics," the author has brought to bear not merely a profound acquaintance with the work of all recent scientific writers on colour-theory, but also an intimate knowledge of the artistic and decorative functions of colour. The reproach laid against the true colour-theory of Newton that it was less fruitful for artistic ends than the false theory of Goethe, is impossible in the face of such modern works as those of Chevreul, Field, Helmholtz, Brücke, and von Bezold. And now Prof. Rood's new work will be welcomed as an addition to the literature of the subject.

The first two chapters are devoted to the general laws of light, and of its dispersion by refraction and by diffraction. Then comes a chapter on the three "constants" of colour, *purity*, *luminosity*, and *hue*, the term luminosity being employed, not as artists sometimes employ it to describe a particular "effect" of light and shade in a picture, but as the equivalent of the measurable intensity or brightness of the light. The author avoids the term "intensity" in this sense, that it may not be confounded with the term "saturation," a quality of colour which depends upon both purity and luminosity, and which is also sometimes erroneously spoken of as the "intensity" of a colour. The four following sections deal with the production of colour by interference and polarisation, by turbid media, by fluorescence and phosphorescence, and by absorption. The last of these chapters is very carefully written, and contains spectroscopic diagrams of a number of absorbing media. Their bearing upon the all-important question of the tint transmitted by two coloured media jointly is clearly explained. The remaining chapters are devoted to Young's Theory, Mixture of Colours, Complementary Colours, Colour Systems, &c. A concluding chapter deals with Painting and Decoration.

Following von Bezold, Prof. Rood rejects the term "indigo" introduced by Newton into the classification of the spectrum colours, and describes the colours between green and violet as *blue-green*, *cyan-blue*, *blue*, and *violet-blue*. The spectrum line F stands between "cyan-blue" and "blue," while "violet-blue" begins about half-way between F and G, and ends a little beyond the latter line. This classification differs slightly from that of Listing.

A detailed account is given of Maxwell's Theory of Colours, of the experiments by which he arrived at his results, and of the colour-chart devised by him. It is unfortunate, however, that the author has divided his excellent remarks on this head, giving part in an appendix to Chapter VIII., part in another appendix to Chapter XIV., and the elementary explanation of the method of balancing the colours upon p. 219 of the text. Apart from this awkward arrangement the matter is admirably put; and is the best exposition of Maxwell's theory in the language. Indeed it is singular that most English text-books ignore Maxwell's work in this department. In the English edition of Deschanel's "Natural Philosophy," which is almost the only one which touches the matter at all, the brief paragraph in which the theory is dealt with lacks the perspicacity that mostly distinguishes that well-known work.

There are one or two sentences in the work which cannot command our assent; and should be revised when another edition is called for. Thus, on p. 86, we are told that Becquerel and other earlier experimenters succeeded in obtaining fleeting photographs of the colours of the spectrum, but that "the colours thus obtained are produced merely by the *interference* of light." And again, "In blue eyes there is no real blue colouring matter *at all*" (p. 58). On p. 94 the author claims as his own an experiment described originally in this country by T. Rose, the inventor of the kalotrope. A reference is given on p. 82 to the darkening of tint of water when heated, due to increased absorption: but the author makes no reference whatever to the important observations of Gladstone, Hartley, and Ackroyd on the similar changes which take place in almost all coloured bodies when heated; nor to the significant observation of the last-named experimenter, that with increasing temperature the absorption appears to increase most in the blue end of the spectrum in the case of those solid bodies of fixed composition which expand with a rise of temperature, while it increases most at the red end for those few bodies such as iodide of silver which contract with a rise of temperature. Hering's theory of colours deserves a more extended notice than the very short note given in the final appendix. A brief account is given on p. 83 of a simple means devised by Simmler for observing the red rays which are abundantly reflected by green leaves: a thick plate of blue cobalt glass in conjunction with a plate of yellow glass serving to cut off all rays except the red and the blue-green. The writer of this notice independently described some few years ago a similar device, in which by taking a solution of permanganate of potash in a glass tank of a convenient size, the blue, green, and yellow rays were similarly absorbed, allowing only red and violet bands to pass, thus constituting, like Simmler's double plate, an erythroscope.

The portions of Prof. Rood's book which bear upon artists' work are numerous, and his observations are of importance. There is, for example, a careful discussion of the change of visible tint suffered by coloured surfaces under diminished illumination; and a parallel discussion of the results obtained by mixing pigments with a proportion of black. A list is given of those pigments which are liable to change or fade by exposure. The reason why oil colours do not materially change their tint on drying is carefully argued; and the *rationale* of Pettenkofer's "regeneration" process for picture-restoring is given. Chapter IX. sums up the indisputable evidence for regarding red, blue (or violet), and *green*, and not red, blue, and *yellow*, as the three fundamental colours, and later on is discussed the reason why a greater luminosity is obtained in mixing two colours optically, or by laying them side by side in minute touches, than is obtained by laying them over one another or by mixing them on the palette; and the author adds no less truly than concisely: "every mixture of pigments on the painter's palette is *a stride toward blackness*."

We can commend the volume to the notice of all who study colour, whether from an æsthetic or a scientific point of view. SILVANUS P. THOMPSON

OUR BOOK SHELF

Zeitschrift für das chemische Grossgewerbe. Kurzer Bericht über die Fortschritte der chemischen Grossindustrie. In Vierteljahres-heften, iii. Jahrgang. Unter Mitwirkung angesehener Technologen und Techniker. Herausgegeben von Jul. Post. (Berlin: Verlag von Robert Oppenheim, 1879.)

THIS volume is the third issue of an Annual Report of Chemical Technology in Europe and America, published in quarterly parts, the contents of each part being arranged under the following heads :—

1. Generalities and Statistics, Description of Apparatus and Machinery, Heat-production.
2. Dry Distillation of Heating and Lighting Materials, Sulphide of Carbon, Petroleum, Coal-gas, Wood-tar, Asphalte, &c.
3. Sulphur, Acids, Alkalis, Aluminium Salts, Borates, Chromates.
4. Oils and Fats, Resins, Glycerin, Volatile Oils, Lubricating Materials.
5. Sugar, Starch, Fermentation, Wine, Beer, Spirits, Vinegar.
6. Food, Meat and its Preparations, Milk and Dairy Produce, Flour and Baking.
7. Dye-stuffs, Dyeing and Calico-printing.
8. Tanning.
9. Matches and Explosives.
10. Glass, Earthenware, Cement, Plaster.
11. Metallurgy—Iron, Copper, Tin, Lead, Bismuth, Antimony, Nickel, Mercury, Silver, Gold, &c.
12. Smaller Industries—Oxalic Acid, Cellulose, Salicylic Acid, Tartaric Acid, Chloral Hydrate, Mineral Waters, Chloride of Zinc.

Detailed criticism of the immense amount of matter contained in the 900 pages of the volume is, of course, impossible. Suffice it to say that the whole has been compiled with great care; every available source of information appears to have been thoroughly ransacked; and the necessarily condensed descriptions of the several processes and products are supplemented by copious references to original papers. Lists of chemical patents taken out in Great Britain, America, France, Belgium, and Austro-Hungary, are also given at the end of each quarterly part, the whole extending to forty closely-printed pages.

In the possession of such a report of chemical industry as the one now under consideration, and of the admirable *Jahresbericht* of Dr. Wagner, the manufacturers of Germany are certainly fortunate; and when we consider the vast extent and importance of chemical manufactures in England and America, it is matter of surprise and regret that no similar work exists in the English language. Projects for such a work have, indeed, been started in this country, but their execution appears to be a problem for the future.

Southern Stellar Objects for Small Telescopes, between the Equator and 55° South Declination, with Observations made in the Punjab. By J. E. Gore, M.R.I.A., A.I.C.E., &c. (Lodiana, 1877.)

THIS small work is divided into two sections. The first contains objects arranged according to the constellations, and chiefly selected from Sir John Herschel's Cape volume, which are within the scope of telescopes of very ordinary capacity, including double stars, clusters and nebulæ, with special reference to stars which may prove to be variable. The second section contains the more original work of the author, who was provided with telescopes 3 and 3·9 inches aperture, in the Punjab, and wholly relates to southern stars possibly variable, some new and noteworthy cases being adduced.

Mr. Gore appears to have made a useful comparison of Harding's "Atlas" with the sky, so far as relates to stars found in it, which do not occur in the great catalogue from the "Histoire Céleste" of Lalande, or are underlined in the "Atlas," and it is in such cases that he has met with the most decided evidence of variability. Amongst them we may note L. 1028, a star twenty minutes due north of L. 8951, one in R.A. about 4h. 58m. for 1880, N.P.D. 111° 14′, apparently variable from 6m. to 9m.; L. 19,662 from 4·5m. to 7m.; L. 23,228; Oeltzen 17,670 (No. 31 in Mr. Gore's list), observed three times by Argelander, and estimated 5, 7, and 5·6, which is 6m. in Harding, but not in Lalande or Heis; No. 37, or Oeltzen 20363, called "a fine ruby star" by Sir John Herschel, and 6½, and found to be only 8½ or 9m., and fiery red with a 3-inch refractor in July, 1875, and L. 43,239. Generally, the objects mentioned in the author's second section will deserve further examination.

There is frequent reference to the magnitudes assigned in Proctor's "Atlas," by the side of those given by such original authorities as Lacaille, Heis, or even Harding; this is a mistake, and is more calculated to mislead than to assist a judgment on the question of variability. The author of this Atlas distinctly states in his preface that he has followed the magnitudes of the British Association Catalogue except for stars in Sir John Herschel's list, which is a comparatively small one; the work is more of a popular description, and so far as we know may be useful to amateurs, but it is idle to quote the indications of this Atlas with those of Argelander or Heis, whose magnitudes are the results of actual comparison with the heavens. Probably after his clear reference to the source whence his magnitudes have been derived, no one will have been more surprised to find his work quoted as an authority in a question of change of brightness of a star than Mr. Proctor himself. We should hardly have referred to this point, were it not that others have made the same mistake as Mr. Gore.

There are many misprints in this small volume, which should be avoided in another edition.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

A New Nebula

ON November 14, the Rev. T. W. Webb discovered a small nebula, or nebulous star, in Cygnus. It is apparently identical with D.M. + 41, No. 4004, 8·5m.

1880 = 21h. 2m. 31s. + 41° 45′·3.

At Dunecht Observatory the object was seen, on November 22 and 23, to be approximately monochromatic, seen through passing clouds; about 5″ diameter. LINDSAY

Dunecht Observatory, November 24

Does Sargassum Vegetate in the Open Sea?

THE reply of Dr. Wild in NATURE, vol. xx. p. 578 to my query, does not satisfy me, for he partly cites old reports, that are, as I showed, mostly suspicious of being a mixture of the prevalent opinion since Columbus and observed facts.

If it has been stated formerly that pelagic varieties (?) multiply only by simple growth and subdivision, and a wide area covered with sea-weeds corresponding to the Sargasso Sea occurring in the North Pacific, I believe that is only a compilation. I crossed the Pacific Sargasso Sea (as it is printed on the charts) in December, 1874, from 140° W. long., 35° N. lat., to 174° W. long., 29° N. lat., and observed no Sargassum at all! But it is possible that the quantity differs in different years. I ask, therefore—and beg forpersonal observations only—has any one seen a difference in the quantity or density of floating Sargassum in different years, and in what degree or quantity has (1) brownish or olive-coloured, and (2) yellowish pale Sargassum been seen in several years?

A flowering branch with buds of any garden plant, if cut and put into water, does not wither suddenly, but sometimes opens continuous to the buds, and may even sprout, but never for a long time; but we never call such cut flowering branches put into a water-glass water plants. I take Sargassum to be analogical, and it should not be allowed to consider the dying broken Sargassum or Fucus, that swing in the open sea, as pelagic in habit, or as a living variety of the open sea.

If it has been stated that the last branches of floating Sargassum are paler, more delicate, and more active in their vitality; I believe that to be no real observation, but only a supposition, for the more delicate and more branched ends become certainly pale at first, and with the diminution of chlorophyll can never increase their vitality. Does any one know in what time the olive-coloured broken Sargassum gets pale, and if pale Sargassum does really sprout to some extent, which I doubt, how long it continues to sprout? and further, after what time do the dead round air-vesicles of Sargassum break off? I should wish these questions cleared up by personal observations.

Remarkable Prediction of Cold

IN NATURE, vol. xxi. p. 48, in the Meteorological Notes, it is stated, on the authority of Mr. Glaisher, that the present unusually cold weather set in on October 27, 1878. You perhaps are not aware that this was predicted almost to the day by Prof. Piazzi Smyth in NATURE, vol. v. p. 317. In an article on Heat Waves he gives the dates of these phenomena as follows:—Years 1834·8, 1846·4, 1857·8, 1868·8, and 1880·0; the heat wave of 1880 to be preceded by a cold wave commencing 1878·8, which is, I need scarcely say, the end of October, 1878.

Dulwich, November 17 B. G. JENKINS

The Lizard

LAST August, while superintending the burning of some dry bush in my pasture, I was surprised to see a ground lizard (*Lacerta agilis*) run up to the flames and stop on a bed of hot ashes. My little son who was with me endeavoured to turn it aside with a stick, but on his trying to do so, it darted into the fire and was soon consumed. This I thought at the time accidental, but later in the day we returned to the same spot, and in a few minutes a larger lizard of the same species deliberately ran up to the burning bush; it paused on the warm ashes wagging its tail to and fro, apparently enjoying the heat, when all of a sudden it darted into the flames, and like the first one was instantly a willing holocaust. I turned to the Negro, who was burning the bush, for explanation, but like most of his race he accepted the fact as a matter of course, remarking "lizard seem to love fire." My ideas went back to the legends of the salamander. The story of the French consul at Rhodes (M. Pothonier), who one day found his cook in a terrible fright thinking the "devil was in the fire," and when he looked into the bright flames, saw there a little animal with open mouth and palpitating throat, and on trying to secure it with the tongs, it ran into a heap of hot ashes. He secured it and gave it to Buffon, who found it to be a small lizard, whose feet and a portion of the body were half roasted. M. Pothonier first thought it was incombustible, having remained in the fire three minutes, but imagined that it might have been brought in with the fuel. Nicander, Dioscorides and Pliny, all allude to the fire-proof qualities of the "salamandra." Aristotle speaks of the salamandra's power of extinguishing fire with the copious secretion of saliva which it has the power of ejecting into the flames. As far as my own observation goes all lizards have the power of ejecting saliva. The Negroes have a dread of the croaking lizard's (*Gecko*) "spitting" at them. I do not believe that any Jamaica lizard has *poisonous* saliva, but that the saliva is deleterious, I am quite sure. That cats get "fits" from eating lizards is a well accepted fact, their *hair* falls out, and they become sick and droop, confirming the belief in the depilatory properties of the salamander's saliva. As Martial puts it (Lib. ii. Ep. lxi.):—

> "Desine jam, Lalage, tristes ornare capillos,
> Tangat et insanum nulla puella caput.
> Hoc salamandra notet, vel sæva novacula nudet,
> Ut digna speculo fiat imago tuo."

Before closing these jottings, I should like to correct an error in a recent work on Natural History, in which it is stated that "the *Iguana is extinct in Jamaica.*" This is *not* the case. They are still to be found in numbers on the Cashew trees in the lowlands, especially St. Catherine's. I once had a long fight in trying to pull a large one out of a hole in a tree, by the tail. He won the battle "by the skin of his tail."

Monattrie, St. Andrew, Jamaica, W.I., October 14 JASPER CARGILL

The "Hexameter," Πᾶσα δόσις ἀγαθή . . . κ.τ.λ.

IT is surely no argument against Prof. Clerk Maxwell's notion, that in the epistle (James i. 17) the enclitic particle τε is omitted. Read, of course,

Πᾶσα δόσις τ' ἀγαθὴ καὶ πᾶν δώρημα τέλειον,

and the verse is perfect. The practice of omitting a word (or part of a word) necessary to the scansion of a verse is all too common with prosists quoting poetry. I give one example from an English writer. Robert Greene, the earliest to allude to Shakespeare, in his "Groatsworth of Wit bought with a Million of Repentance" (1692), quotes, just as if they were prose, six lines from a contemporary poet; and in so doing omits two whole words, and part of another! He writes, as prose, omitting all that I here give in italics—

> "*Then* onely Tyrants should possesse the earth,
> *Who* striving to exceede in Tyranny,
> Sh*ould* each to other be a slaughter-man;
> *Un*till the mightiest outliving all,
> One stroke were left for Death, that in one age
> Man's life should end."

I am pleased to learn from the obituary notice in NATURE of that great man, that Clerk Maxwell's thoughts during his illness reverted to Shakespeare; but had he less profitably thought of Greene's assault on Shakespeare, and had it struck him that the foregoing must be in heroic verse, what would be thought of the critic who should object to this, that the first, second, and fourth of these so-called verses are, by one syllable each, too short?

Athenæum Club, November 22 C. M. INGLEBY

IT cannot be supposed that our translators meant to compose a verse when they wrote the line which Longfellow transfers bodily into his "Evangeline":—

"Husbands, love your wives, and be not bitter against them."

So the metrical cadence here may be quite accidental. Still I cannot think that the defect of quantity in the final syllable of δόσις is fatal to the idea that it may be a line from an early Christian doxology: especially when we suppose it written in Alexandrian or Hellenistic Greek. The arsis, or natural stress of the voice, would cover up the defect, especially in chanting; and it would scarcely be a defect at all to non-classical ears. The process which rapidly from the Christian era substituted stress or accent, as we now understand it, for quantity, seems to have been greatly accelerated by the hymns of the Church. In any case every trace of such quotations is of great interest to every student of the New Testament. HENRY CECIL

Bregner, Bournemouth, November 22

Unconscious Cerebration

I HAVE delayed noticing a communication, headed Unconscious Impressions, by Mr. C. J. Monro, in NATURE, vol. xx. p. 426. This refers to what Dr. Carpenter calls Unconscious Cerebration, but which when I discovered it likewise, I called Unconscious Thought.

With Mr. Monro's conclusion that an unconscious impression is stronger than a conscious one, his statement does not impress me, nor is it supported by my own experience.

My attention had been recalled to the subject by observing children, and in their actions it appears to me we may find the beginning of the process of unconscious cerebration. So far it appears that conscious cerebration precedes and lays the foundation for the unconscious process. When a baby is practising, as for instance in handling an object, its attention is closely given in the early stages and in its various experiments, and it is only after a time that the performance becomes purely mechanical.

The same is to be noted of young animals.

Hence I conclude that as various practices become habitual, and, as some style them, instinctive, conscious cerebration ceases to be employed. Thus is formed the habit of only regarding some objects consciously, and necessarily that of regarding others without cerebration. Thus I treat unconscious cerebrations as becoming habitual. HYDE CLARKE

Mr. Thomas Bolton's Natural History Discoveries

I ONLY became aware on Saturday evening last, the 15th inst., of the paragraph kindly inserted by Prof. E. Ray Lankester, F.R.S., as editor, in the *Quarterly Journal of Microscopical Science* for October, in reference to my studio and agency for the supply of microscopic organisms. Of course I have to thank him most sincerely for calling the attention of naturalists to my efforts, and so strongly calling on them to support me, but he has given me credit in some directions which is due to other naturalists to whom I am under considerable obligations. I wish to correct this view at once by writing to your periodical in preference to waiting till the next number of the *Quarterly* can appear. Prof. Lankester's language may lead those who have not seen other reports to put down the actual first finding of several organisms new to the British fauna to me, whereas several of them were first picked up by others.

The *Leptodora* was found at Olton during a visit made by a party of the Birmingham Natural History and Microscopical Society on July 26. Whilst the president, Mr. Graham, the curators, Messrs. Levick and Lloyd, some other members, and myself, were searching the pool from a boat, Mr. Levick's unusually sharp eyes first called the attention of the others to some lively organism in his bottle, which he at first thought to be a larva, and Mr. Graham was, I believe, the first to suggest that it was probably a larval form of an Entomostracan. After this they were collected in large numbers with the net. As soon as possible I asked my friend Mr. Forrest to make a drawing, which I had printed, and drew up a short account of it for my subscribers, describing it as a larval form of one of the Entomostraca; but before I had finished writing this I found one carrying four large eggs in the second segment of the body, which fact I added to my description, and which I pointed out would lead to the supposition that it was no larva, but a mature animal. I sent the specimens out on August 1, and the earliest notice I had from my subscribers was from Sir John Lubbock, F.R.S., who wrote by return to say he was much interested in the curious crustacean which he believed to be new to this country, and on August 6 Prof. Lankester wrote to say the crustacean I had sent was the *Leptodora hyalina*. In looking over the water in which we had taken the Leptodora, I found another Entomostracan which was new to me, and I called Mr. Forrest's attention to it, and gave him some specimens which he took home and studied, and finding no trace of them in Baird's "Entomostraca," he made a drawing of it and drew up a description of it for the *Midland Naturalist* of September, under the name of *Daphnia bairdii*. With permission of the editor I distributed copies of this plate and description, with living specimens, to my subscribers on August 8, and on the 13th Prof. Lankester wrote me to say "the beautiful *Daphnia bairdii* of Mr. Forrest is the already described *Hyalodaphnia kahlbergensis* of Schödler" (see Mr. Forrest's further remarks, *Mid. Nat.*, November, page 281). In looking over Prof. Lankester's remarks, I was surprised to see his account of the new Protozoa, which reminded me that on April 30 he had written to me saying that the Amœbæ gathering was only interesting, and asking me to send him a good lot more, as he thought he had found something new, but I could only send him a small tube more, as this, together with the large Amœbæ to which he refers, came from a small beaker aquarium in the study of my friend Mr. Levick.

I must apologise for having taken up so much of your space, but in fairness to Mr. Levick and Mr. Forrest, I could not well let the report pass without comment, giving them full credit of first finding the objects; but at the same time I cannot help thinking that the discoveries (if ever published) would have been much longer before they had been brought before the scientific world, had it not been for the distribution of the specimens through my agency. As it is, however, my wish not to take more credit than is due, I shall always be glad to point out the first finders of organisms which may be entrusted to me for distribution, and which may *afterwards* turn out to be of any special interest.

In furtherance of Prof. Lankester's kind appeal to naturalists for the pecuniary support of my agency, I must really ask them to act upon it, as, so far, my studio is not sufficiently remunerative to induce me to persevere with it much longer, as my receipts for the last year have barely covered my office rent, collecting, and individual expenses. THOMAS BOLTON

17, Ann Street, Birmingham, November 19

Intellect in Brutes

THE following is a curious instance of discrimination, which I have observed in my bullfinch. He is in the habit of coming out of his cage in my room in the morning. In this room there is a mirror with a marble slab before it, and also a very cleverly-executed water-colour drawing of a hen-bullfinch, life-size. The first thing which my bullfinch does on leaving his cage is to fly to the picture (perching on a vase just below it), and pipe his tune in the most insinuating manner, accompanied with much bowing to the portrait of the hen-bullfinch. After having duly paid his addresses to it, he generally spends some time on the marble slab in front of the looking-glass, but without showing the slightest emotion at the sight of his own reflection, or worthying it with a song. Whether this perfect coolness is due to the fact of the reflection being that of a cock-bird, or whether (since he shows no desire to fight the reflected image) he is perfectly well aware that he only sees himself, it is difficult to say.

SOPHIE FRANKLAND

"Asia Minor" in the "Encyclopædia Britannica"

IN the article on "Asia Minor" in the new edition of the "Encyclopædia Britannica," in speaking of Tchihatcheff's "Asie Mineure," the writer says: "But those [vols.] which should have contained the geology and the archæology have never been published." As this may mislead some of your readers it may be worth recording the fact that the part on geology was published in 1867-69; and the palæontological division in 1866-69. J. B. B.

Oxford

ON THE SOLUBILITY OF SOLIDS IN GASES[1]

THIS investigation was undertaken in the hope that, by an examination of the conditions of liquid matter up to the "critical" point, sufficient knowledge might be gained to enable us to determine under what particular conditions liquids are dynamically comparable, in order that the microrheometrical method[2] (which the Royal Society has done one of us the honour of publishing in the *Philosophical Transactions*) might be applied to determine their molecular mass and energy relations. It seemed that as the laws relating to gases and liquids merge at what was called by Baron Cagniard de la Tour[3] "l'état particulier," and by Dr. Andrews[4] the "critical point," an examination of matter up to the limit of the liquid state would be likely to yield us much information. The time we have to devote to scientific work being very limited, we found that it was quite impossible to make much advance by using the apparatus devised by Dr. Andrews, as the time required to change from one liquid to another was more than we had at our disposal. We therefore devised a new apparatus, which will be described in a more lengthy communication, but which, we may state, can be opened, the liquid changed, and again closed for a new experiment, in about one minute.

The question as to the state of matter immediately beyond the critical point being considered by Dr. Andrews to be at that time incapable of receiving an answer, we imagined that some insight might be gained into its condition by dissolving in the liquid some solid substance whose fusing point was much above the critical point of the liquid, and noticing whether, on the latter passing its critical point and assuming the gaseous condition, the solid was precipitated or remained in solution. We found that the solid was not deposited but remained in solution, or rather in diffusion, in the atmosphere of vapour, even when the temperature was raised 130° above the critical point, and the gas was considerably expanded. When the side of a tube containing a strong gaseous solution of a solid is approached by a red hot iron, the part next the source of heat becomes coated with a crystalline deposit which slowly redissolves on allowing the local disturbance of temperature to disappear. Rarefaction seems to be the cause of this deposition, because if

[4] "Bakerian Lecture," *Phil. Trans. Roy. Soc.*, 1869, p. 588.

the temperature be raised equally and the volume retained at its original value, no deposition takes place. Those experiments have been done with such solvents as alcohol (ethyl and methyl), ether, carbon disulphide and tetrachloride, paraffins, and olefines, and such solids as sulphur, chlorides, bromides, and iodides of the metals, and organic substances such as chlorophyll and the aniline dyes. Some solutions show curious reactions at the critical point. Thus ethyl alcohol, or ether, deposits ferric chloride from solution just below the critical point, but re-dissolves it in the gas, when it has been raised 8° or 10° above that temperature.

It appeared to us to be of some importance to examine the spectroscopic appearances of solutions of solids when their liquid menstrua were passing to the gaseous state, but as all the substances we have yet been able to obtain in the two states give banded spectra with nebulous edges, we are only able to state that the substance does not show any appreciable change at the critical point of its solvent. Such was the case with anhydrous chloride of cobalt in absolute alcohol. It was suggested to us by Prof. Stokes that the substance obtained by the decomposition of the green colouring matter of leaves by acids, and which yields a very fine absorption spectrum, might be useful for our purpose. We have prepared the substance according to the careful directions so kindly furnished us by Prof. Stokes, and find that it shows the phenomenon in a marked manner, whether dissolved in alcohol or ether. The compound is easily decomposed by heat under ordinary circumstances, and yet can be dissolved in gaseous menstrua, and raised to a temperature of 350° without suffering any decomposition, showing the same absorption spectrum at that elevated temperature as at 15°.

We considered that it would be most interesting to examine by this method a body such as sodium, which, besides being an element, yields in the gaseous state sharp absorption lines. An opportunity seemed to be afforded by the blue solution of sodium in liquefied ammonia, described by Gore,[1] but we found that, on raising the ammonia above its critical point, the sodium combined with some constituent of the gas, forming a white solid, and yielding a permanent gas, probably hydrogen.

There seems, in some cases, to be a slight shifting of the absorption bands towards the red, as the temperature rises, but we have as yet been able to make no accurate measurements.

When the solid is precipitated by suddenly reducing the pressure, it is crystalline, and may be brought down as a "snow" in the gas, or on the glass as a "frost," but it is always easily redissolved by the gas on increasing the pressure. These phenomena are seen to the best advantage by a solution of potassic iodide in absolute alcohol.

We have, then, the phenomenon of a solid with no measurable gaseous pressure, dissolving in a gas, and not being affected by the passage of its menstruum through the critical point to the liquid state, showing it to be a true case of gaseous solution of a solid.

Private Laboratory, Sword Street, Glasgow

ON PHOTOGRAPHING THE SPECTRA OF THE STARS AND PLANETS [2]

FOR many years it has seemed probable that great interest would be attached to photographs of the spectra of the heavenly bodies, because they offer to us conditions of temperature and pressure that cannot be attained by any means known at present on the earth. The especial point of interest is connected with considerations regarding the probable non-elementary nature of the so-called elementary bodies. There has long been a suspicion in the minds of scientific men that one or more truly elementary bodies would be found from which those substances which have not as yet been decomposed are formed. The recent publications of Lockyer have attracted particular attention to this topic.

The most promising laboratory processes for accomplishing the dissociation of our present elements depend upon the action of heat, especially when accompanied by electrical influences, and upon relief of pressure. But the temperature we can employ is far below that found in the stars, which is comparable only with the heat of our sun, and when in addition the application of heat is restricted by the narrow range of circumstances under which we can also reduce the pressure, complete success seems to be impracticable in the laboratory.

But in the stars, nebulæ, and comets, there is a multitude of experiments all ready performed for us with a variety of conditions of just the kind we need. It remains for us to observe and interpret these results, and this is the direction I have sought to pursue.

There is but one mode of investigation that can add materially to the knowledge astronomy has given us of the heavenly bodies—that is the spectroscopic. This in its turn is capable of a subdivision into two methods, one by the eye, the other by photography. Each of these has its special advantages and each its defects. The eye sees most easily the middle regions of the spectrum, and can appreciate exceedingly faint spectra; by the aid of micrometers it can map with precision the position of the Fraunhofer lines, and by estimation it can with tolerable accuracy approximate to the relative strength, breadth, and character of these lines. The character of the spectrum lines is, however, of great value for the purposes we are now speaking of, and the greatest precision is needed. Photography, on the other hand, as applied to faint spectra, deals mainly with the more refrangible region, and cannot at present be employed in stellar work below the line F. Fortunately there is no break in the spectrum between the place where the eye leaves off and photography begins, and hence the two methods lend one another mutual assistance. The photograph, when suitably accommodated with a standard reference spectrum from some known source, gives valuable indications as to the positions and all the peculiarities of the lines.

But the application of photography to the taking of stellar spectra is surrounded by obstacles. These are partly due to the small quantity of light to be dealt with, and partly to the fact that it is necessary to overcome the motion of the earth and other causes, such as atmospheric refraction, which seem to make a star change its place continually. The exposures of the sensitive plate require to be sometimes for two hours, even with a large telescope; and if during that time the image of the star at the focus of the telescope has changed place $\frac{1}{350}$ of an inch, the light no longer falls on the slit of the spectroscope. The changes of the earth's atmosphere in regard to photographic transparency, as well as by fog, also offer impediments and promote the chances of failure. There is often a yellow condition of the air, which may increase the length of exposure required forty times or more.

It will from what has been said above, be readily perceived that a research such as this consumes a great deal of time; in fact, these experiments and the preparations for them have extended over more than twelve years. A large telescope is required, and for many reasons the reflector at first seems most suitable. Recently, however, I have found that the refractor has also some special advantages.

In 1866 I had already constructed a silvered glass reflector of $15\frac{1}{2}$ inches aperture, which was commenced in 1858, and had taken with it many hundreds of photographs of the moon. But as the mounting had been

[1] *Proc. Roy. Soc.*, vol. xxi. p. 145.
[2] Read before the National Academy of Sciences, October 28, by Henry Draper, M.D.

contrived for lunar photography and to avoid the moon's motion in declination, the instrument was not suitable for the spectroscopic work contemplated. A reflector of 28 inches aperture was therefore commenced in 1866, and in 1871 it was ready for use.

On May 29, 1872, my first photograph of the spectrum of a star was taken, the spectrum of Vega being photographed by the aid of a quartz prism. At this time I did not happen to know that Dr. Huggins, who is so distinguished for his thorough and accurate researches on the visible portion of the spectra of the heavenly bodies, had already made some attempts in this direction, as is shown by the following paragraph from the *Transactions* of the Royal Society for 1864:—"On the 27th of February, 1863, and on the 3rd of March of the same year, when the spectrum of Sirius was caused to fall upon a sensitive collodion surface, an intense spectrum of the more refrangible part was obtained. From want of accurate adjustment of the focus, or from the motion of the star not being exactly compensated by the clock movement, or from atmospheric tremors, the spectrum, though tolerably defined at the edges, presented no indications of lines. Our other investigations have hitherto prevented us from continuing these experiments farther, but we have not abandoned our intention of pursuing them."

During August, 1872, I took several photographs of the spectrum of Vega, and these showed four strong lines at the more refrangible end of the spectrum, the least refrangible being near G. On pursuing the subject and seeking to ascertain what substances gave rise to these lines, it became obvious that a photographic study of this part of the spectrum for the metals and non-metals was necessary to interpret the results. This, of course, opened out a large field for experiment, requiring many years for its study, and hence, as several physicists were engaging in the study of the spectra of the metals, I concluded to discontinue the experiments commenced in 1870 on the spectra of the metals and to confine the investigation mainly to the non-metals. The initial step was, however, to obtain a fine photograph of the normal solar spectrum, so that the wave-lengths of the lines up to O [wave-length 3440] might be determined with precision.

In the spring of 1873 I published a paper on the diffraction spectrum of the sun, illustrated by a photograph embracing the region from wave-length 4350, near G, to 3440, near O, and in the fall of the same year took photographs of the spectra of several non-metals, notably nitrogen, carbon, and oxygen. The experiments were interrupted, in the spring of 1874, by going to Washington to superintend the photographic preparations for the United States observations on the transit of Venus.

Since that time my experiments have been divided into two parts, an astronomical portion occupying principally the summer season, and a laboratory portion during the rest of the year. The former consisted of photographs and observations on the spectra of the stars, planets, and sun; the latter of photographic work on the spectra of the elements, and particularly the non-metals, and has led to the discovery of oxygen in the sun.

In 1876 Dr. Huggins published a note in the *Proceedings* of the Royal Society, accompanied by a woodcut of the spectrum of Vega, with a comparison solar spectrum. Seven lines were observed in the spectrum of Vega. In the summer and autumn of 1876 I made several photographs of the spectra of Vega, α Aquilæ, and Venus, and sent a note concerning them to the *American Journal*.

Since that time Dr. Huggins has pursued the subject actively in spite of the London atmosphere, and has attained very fine results, which I had the pleasure of seeing at his observatory last spring. These he is preparing to publish shortly. In my observatory photographs have been taken of the spectrum of Vega, Arcturus, Capella, α Aquilæ, Jupiter, Mars, Venus, the moon, &c. Recently the plan has been to have a comparison solar spectrum on every plate, derived either from the diffused light of our atmosphere or from the moon or from Jupiter. In this way no difficulty in determining the wave-lengths of the lines is encountered, and the changes produced by our atmosphere are eliminated. The telescope and spectroscope are now in good working order, but to secure the requisite degree of precision of movement it has been necessary to make seven different driving-clocks before a satisfactory one was attained.

It has been remarked that on account of the faintness of the light of stellar spectra, prolonged exposures of the sensitive plate are required. In former times, when the dry processes of photography were much less sensitive than the best wet plates, the exposure was limited by the length of time the plate could be left in the camera without being stained by drying. But now, since the gelatino-bromide process has been introduced, this obstacle has been removed and a sensitive plate is sometimes exposed two hours to the spectrum of a star and then almost an hour to Jupiter for the comparison spectrum. The best, and most sensitive, gelatine plates I have used are those made by Wratten and Wainwright, of London; Dr. Huggins was good enough to call my attention to them.

It is not worth while to describe the various forms of spectroscope that have been employed in the last ten years; quartz, Iceland spar, hollow prisms and flint glass have been the materials, and they have been sometimes direct vision and sometimes on the usual angular plan. Gratings on glass and speculum metal given to me by Mr. Rutherford have been tried. The length of spectroscope has been sometimes 28 feet and sometimes not as many inches.

The especial spectroscope for stellar work that is now on the telescope is intended to satisfy the following conditions: (1) to get the greatest practicable dispersion with the least width of spectrum that will permit the lines to be seen; (2) to use the entire beam of light collected by the 28-inch reflector or 12-inch achromatic without loss by diaphragms; (3) to permit the slit to be easily seen so that the star may be adjusted on it; (4) to avoid flexure or other causes that might change the position of the spectrum on the sensitive plate in pointing the telescope first on one and then on another object; (5) to admit of observing the spectrum on the sensitive plate at any time during an exposure without risk of shifting or disarrangement. The dispersion is produced by two heavy flint prisms which are devoid of yellow colour; the telescopes are about 6 inches in focal length, and the slit has a movable plate in front of it, enabling the operator to uncover either the upper or the lower portion at will.

During the past summer this spectroscope has been used with the Clark refractor of 12 inches aperture, partly because the 28-inch reflector has been kept unsilvered since it was used in taking photographs of the transit of Mercury, on account of its employment in certain experiments on the sun. Moreover, there is an advantage possessed by the refractor for this work which does not appear at first sight. Naturally one supposes that a reflector which brings all the rays from the star, no matter what their refrangibility, to a focus in one plane, would be best, because when the slit is put in that plane it is equally illuminated by rays of all refrangibilities, and the spectrum will be parallel-sided in its whole length. On the other hand a refractor is not achromatic, for the violet end of the spectrum comes to a focus either inside or outside of the plane of the rays in the middle of the spectrum, and in observing the spectrum it is not parallel-sided. This peculiarity was used by Mr. Rutherford to enable him to correct a telescope lens for the ultra-violet rays. It is easy, therefore, with a refractor, so to adjust the position of the slit that you may have a spectrum tolerably wide at F and G, and which gradually diminishes in width towards H, and finally becomes linear at M. Now as the effect of atmospheric absorption on the spectrum increases as you pass from G toward H and above H, by diminishing the width of the spectrum you can in some measure neutralise the effect, and at one exposure obtain a photograph of nearly uniform intensity from end to end, though it is of variable width. If it were not for this it would be necessary to have the spectrum over-exposed at G in order to be visible above H, or else to resort to an elaborate diaphraghming which is difficult.

It is my intention next season to return to the use of the 28-inch reflector, because it collects nearly five times as much light as the 12-inch does, after making allowance for the secondary mirror. Of course in a large reflector the difficulties of flexure and instability of the optical axis are much increased, and keeping a star on the slit will be troublesome, especially as the magnifying power on the image is about 50.

As to the results obtained, it has already been mentioned that the spectra of several stars and planets have been photographed. The subject of planetary spectra will be reserved for a future communication. A preliminary examination at once shows that these stellar spectra are divisible into two groups: (1) those closely resembling the solar spectrum, and (2) those in which there are relatively but few lines, and those of great breadth and intensity. The photographs of the spectra of Arcturus and Capella are so similar to the solar spectrum, that I have not up to the present detected any material differences. But, on the other hand, the spectra of Vega and α Aquilæ are totally different, and it is not easy without prolonged study and the assistance of laboratory experiments to interpret the results, and even then it will be necessary to speak with diffidence. I have not as yet obtained any stellar spectrum photographs belonging to the third and fourth groups of stellar spectra as described by Secchi. These, if obtainable, will aid materially in discussing the whole subject, but unless a star passes near the zenith it is hard to make a fair study of its spectrum by photography, because atmospheric absorption in the ultra-violet region increases rapidly as the altitude decreases. In the case of the sun I have found that at sunset the exposure necessary to photograph the spectrum above H, is often 200 times as long as at mid-day.

In the case of the spectrum of Vega, when examined by the eye, the lines C, F, near G and *h*, are readily visible, but lines such as D and *b* are relatively faint. It is clear, then, that hydrogen exists to a large extent in the atmosphere of that star. But on examining the photograph of its spectrum it is evident that other lines just as conspicuous as the hydrogen lines, are present. One of these corresponds in position and character to H_1, and seems to coincide with a calcium line. It appears to me, however, that the evidence of this coincidence is not complete.

In attempting to reason from these photographs as the matter now stands, it is necessary to try at every step farther experiments in order to find out whether the facts agree with the hypothesis, and it is this very condition of affairs that gives hopes of results valuable in their bearing on terrestrial chemistry and physics. In the photographs of the spectrum of Vega there are eleven lines, only two of which are certainly accounted for, two more may be calcium, the remaining seven, though bearing a most suspicious resemblance to the hydrogen lines in their general characters, are as yet not identified. It would be worth while to subject hydrogen to a more intense incandescence than any yet attained, to see whether in photographs of its spectrum under those circumstances any trace of these lines, which extend to wave-length 3700, could be found.

It is to be hoped that before long we may be able to investigate photographically the spectra of the gaseous nebulæ, for in them the most elementary condition of matter and the simplest spectra are doubtless found.

THE FUNCTION OF CHLOROPHYLL

THE Report of the Berlin Academy for July last contains a remarkable paper by Prof. Pringsheim on this subject. In pursuing his researches upon chlorophyll, he had found that positive results could only be obtained by employing *intense* light, and in this paper he gives some account of the conclusions at which he has been enabled to arrive by the use of this method.

By means of a heliostat and a strong lens, the object to be observed under the microscope is brightly and constantly illuminated; the effects of this illumination, which are striking, are produced in a few (3-6) minutes. Assuming that the object contains chlorophyll-corpuscles, the first visible effect is the rapid disappearance of the green colour, so that the object appears as if it had been lying for some days in alcohol, the corpuscles retaining however their form and consistence. Changes now gradually become apparent in the protoplasmic cell-contents; the circulation of the protoplasm, where it exists, is arrested; the bridles of protoplasm rupture, and the nucleus is displaced; the ectoplasm contracts, becomes permeable to colouring-matters, and the turgidity of the cell disappears; the cell presents, in fact, all the symptoms of death.

It seems natural to suggest that these effects may be due, to some extent at least, to the action of the high temperature to which the cell is exposed under these conditions. Prof. Pringsheim, anticipating this criticism, is careful to point out that they are produced by all the different parts of the visible spectrum. They are quite evident when the light has previously passed through a solution of iodine in carbon disulphide, but they are more distinct when the light has passed through an ammoniacal solution of cupric oxide; the light to which the object is exposed consisting, in the former case, of red rays, in the latter, of blue and violet. Moreover, if the solution of iodine be so concentrated that only the rays of a greater wave-length than 0·00061 m.m. can pass, these effects are not produced although about eighty per cent. of the heat is transmitted; on the other hand, if the ammoniacal solution of cupric oxide be so concentrated that the whole of the rays of low refrangibility to a wave-length of 0·00051 m.m. are absorbed, the effects are rapidly and vividly produced, although the amount of heat which passes is comparatively small. From these facts he concludes that the phenomena in question are the results not of the action of heat, but of that of light.

This important point being settled, he proceeds to determine in what manner this action of the intense light is affected by the atmosphere in which the object exists. As the result of a variety of experiments he finds that these effects are only produced when the atmosphere contains oxygen.

These are very briefly the facts which Prof. Pringsheim has ascertained by this method; we will at once pass to the consideration of the conclusions which he draws from them. He concludes, in the first place, that the decomposition (oxidation) of chlorophyll in the living plant is a process of combustion which is influenced and promoted by the action of light, and which stands in no relation to the decomposition of carbonic acid by the plant. Since the green colour of the chlorophyll-corpuscles which have become blanched is not subsequently restored, even though the cell continue to live, it appears that this oxidation of the chlorophyll is not a normal physiological occurrence, but that it is purely pathological. Prof. Pringsheim was unable to find any substance in the cells which might be regarded as the product of the oxidation of the chlorophyll, neither could he detect any increase of the fat or starch in the blanched cell, nor the formation of grape-sugar or dextrin: he therefore concludes that the products of the oxidation of the chlorophyll are given off in the gaseous form. In the second place he concludes that the changes produced in the protoplasmic cell-contents are the direct effects of the photochemical action of light. That they are not due to the presence of the products of the decomposed chlorophyll is shown by the fact that they may be observed equally well in cells which do not contain chlorophyll, such as the stinging-hairs of the nettle, &c. This being the case, he infers that they too are produced by a process of combustion. The final conclusion to which he comes is that chlorophyll exercises a protective influence over the protoplasmic cell-contents by absorbing the actinic rays of the spectrum, thus diminishing the combustion (respiration) going on in the cell; that it is in fact the regulator of the respiration.

In another series of experiments Prof. Pringsheim endeavours to determine what are the substances which become oxidised in the process of respiration. He finds in all chlorophyll-containing cells, a substance which can be best extracted by immersing the parts—leaves for instance—in dilute hydrochloric acid for several hours. This substance, to which he gives the name of hypochlorin or hypochromyl, is of an oily nature; it is probably a hydrocarbon which consists only of carbon and of hydrogen, or one which contains oxygen also in its molecule, but in smaller proportion than the carbohydrates; it is soluble in alcohol, ether, turpentine, and benzol, but insoluble in water and in solutions of neutral salts; it occurs in long, red-brown, crystalline needles which soon harden after extraction, into an imperfectly crystalline mass of resinous or waxy consistence. It is readily oxidisable, as is shown by the fact that it disappears from the cell on exposure to intense light in an atmosphere containing oxygen, even sooner than the chlorophyll. Prof. Pringsheim is of opinion that this substance is the first product of the assimilation of the chlorophyll-corpuscle, and that starch and oil are subsequently formed from it by oxidation.

Applying these views to the life of the cell under ordinary conditions, the changes going on in the cell when exposed in the air to sunlight would be somewhat as follows: the general protoplasm would undergo some amount of oxidation, but not so much as to materially diminish its quantity or affect its properties; in the chlorophyll-corpuscles, oxidation would be either entirely arrested in consequence of the absorption of the actinic rays by the green colouring-matter, or at least so much diminished that the synthesis of the elements of water and carbonic acid to form hypochlorin could take place.

Since this paper is stated to be a merely provisional account of these very interesting experiments, it is hardly fair to submit it to a detailed criticism: it will be better to wait until the publication of the more complete account which Prof. Pringsheim promises in an early number of his *Jahrbücher*. All that will be attempted at present is to indicate some of the principal difficulties which beset the acceptance of these new views. For instance, exception may be taken to the view that chlorophyll, when exposed to intense light is oxidised into gaseous bodies. It is well known that an alcoholic solution of chlorophyll, when exposed to sunlight in the presence of air, becomes oxidised and assumes a pale yellow colour; it may be that this also takes place in the chlorophyll-corpuscles, the yellow colour being hardly distinguishable on account of the smallness of the quantity which is present. Again, it will doubtless have occurred to every reader of this paper that hypochlorin may be nothing more than the wax which has long been known to exist in considerable quantity in chlorophyll-corpuscles. But the main difficulty has reference to the protective functions which Prof. Pringsheim ascribes to chlorophyll. Admitting that the changes described above as occurring in the protoplasmic cell-contents are really the results of excessive oxidation consequent upon exposure to the intense light, it is evident that they are effected less quickly than the oxidation of the chlorophyll itself; that is to say that, *ceteris paribus*, the chlorophyll is more readily oxidised than the protoplasm. This being the case, it is not easy to understand how the former can efficiently protect the latter from the oxidising influence of light and regulate its respiration. This difficulty might perhaps be met by the suggestion that fresh supplies of chlorophyll are continually being formed, but we have no knowledge yet at present of any such continual formation of chlorophyll; on the contrary, it is a well-established fact that when once the chlorophyll of a corpuscle is oxidised, it does not regain its green colour.

It might perhaps be possible to obtain some further knowledge on this subject by observing the effects produced in cells by the action of strong light falling upon them, in some cases, directly, in others, after having passed through a solution of chlorophyll which would be renewed from time to time if necessary. If it were found, that, in the latter case, the cells remained uninjured whereas in the former they soon died, some important evidence in favour of Prof. Pringsheim's views would be obtained. It might then be possible to extend these experiments and to bring about the formation of starch from carbonic acid and water in the cells of fungi, and even of animals, for Mr. Geddes' interesting observations on planarians show that animal as well as vegetable protoplasm is capable of effecting this synthesis.

SYDNEY H. VINES

THE CAMBRIDGE NATURAL SCIENCES TRIPOS

WOULD science suffer by the division of the second part of the tripos into a non-biological and a biological division which might be taken in successive weeks with separate examiners?

Let us make sure that in future geologists know well their chemistry and physics, and insist on all biologists knowing how to work their microscope well. Perhaps some geologists will shrink from a division of subjects; and consider that every geologist should know palæontology well. But the study of fossil plants and animals is surely a part of systematic botany and zoology; in fact, geology and palæontology would gain by being separated, so far as the one is physical, stratigraphical, petrological, and mineralogical, or the other truly biological. The knowledge of fossils as characterising a "formation" is not a biological subject; a man may recognise fossils well enough for geological purposes who knows little of zoology properly so called. Biology suffers greatly from the want of palæontologists as distinct from physical geologists and petrologists. How many men are there who would agree that biology ("the study of things living or that have lived") is very difficult to separate from physical and non-biological subjects for examinational purposes? Let us acknowledge that it is more necessary that, at the commencement of his scientific career, a man should be known and recognised as a well-educated biologist than as a vegetable anatomist, or a palæontologist, or an embryologist. Every man seeking biological honours may find sufficiently little chemistry and physics in the first part of the natural sciences tripos not to daunt him, if he is capable of research. Surely it is better to secure a man's general physico-chemical knowledge if he is to be a geological surveyor of the first rank, and also train him in elementary biology, than to encourage too early specialisation.

My proposal is that in the second part of the natural sciences tripos four or more examiners should be specially chosen to set and approve the biological questions, and four or more, the physico-chemical and geological questions; that the latter should have a separate class-list and days of examination, with four written papers of three rows each, and a practical examination; and that the biological examination should have four papers and be in other respects similarly conducted, letting no special marks of distinction be given. Few first-rate candidates would desire to take both these examinations, and if they desire further distinction in particular subjects, original work in research or authorship, is surely the best test; and the University might subsequently give to competent men degrees in science which now it unfairly cannot give; the degree of Doctor of Science should be given to men qualified to be University Readers or Professors in Science.

Mr. Hillhouse, of Trinity, the Assistant Curator of the Cambridge Herbarium, and one of the editors of the *Cambridge Review*, in an article last week, admits that which many promoters of learning might think a sign of unrest and indecision, rather than of real growth, namely, that the regulations issued by the Board of Natural Sciences Studies must be very mutable, and continually need revision. As to the argument for human anatomy as such receiving a prominent place in a tripos, Mr. Hillhouse says it rests on the fallacy that men are likely to study a subject with more interest if it is made a subject of a tripos, than if it is included in the M.B. But, his experience is, the man who will not work for his M.B. will surely not work for his tripos; if anything, he will work better for M.B. than tripos.

The University of London, having for a long time required all candidates for the degree of B.Sc. to pass in elementary mathematics, physics, geology, palæontology, and the other biological sciences, as well as logic, has now reverted to the wiser plan of examining at its 1st B.Sc. in elementary mathematics, physics, inorganic chemistry, and elementary biology, and at the degree examination (for B.Sc.), giving the degree for passing in three out of nine divisions of sciences, so that a biological student may, if he chooses, enter for a very clearly-defined examination in botany, zoology, and physiology. The Cambridge man will then soon prefer the B.Sc. Lond., with the subsequent possibility of a doctorship in science, given for thorough attainment in the special subject of his life-study and teaching, unless biology receives fair play at Cambridge. Why is it that Martin, Hartog, Marshall, and Vines have taken their D.Sc. (Lond.), to mention biologists only? It is surely not that they are devoted to examinations, but that Cambridge was not yet able to give them the distinction in their chosen subjects which they were entitled to demand. Biology, worthy of the name, is still to a very considerable extent proscribed or suspected in Cambridge. In a future age how strange a survival of prejudice this will seem. G. T. Bettany

THE PLANETS OF THE SEASON

Saturn

We recently called the attention of our astronomical readers to that noble planet, the captain of our celestial guard, those three that keep the mid-watch of the night in an imposing order that may not return for ages; at distances nearly equal, and in a line not widely deviating from a great circle of the sphere. Saturn, the next in position, may now be the subject of a cursory notice.

The aspect of this most interesting of the planets is at the present time singularly elegant and attractive. The relief, however, is delicate, and the details not conspicuous; but though the presentation may be less adapted for a close scrutiny than that of either the full opening or the evanescent phasis of the ring, its examination will not fail to reward the careful observer.

Schröter had a true insight into the pervading character of the universe when he described it as uniform in plan, with an endless variety in detail. Such is evidently the case with the planetary system. We find everywhere arrangements in part closely parallel or even identical with those most familiar to us, in part so rapidly divergent that the connecting analogies are strained, and thin away, as it were, till the bond of union can be traced no longer. Saturn is a complete instance of this. The dependence on the great central ruler, the spherical form, the polar flattening, the rotation on an inclined axis, the accompaniment of an atmosphere—all correspond with our own; while the differences, not only in magnitude, but in density and the force of gravity, are so great that we cannot even guess at the component materials. We endeavoured lately to point out how limited is our knowledge of Jupiter, though in various ways favourably circumstanced for observation; but on Saturn, with the exception of his change of seasons, we should find ourselves still greater strangers; and the terrestrial analogies that aided us so little there would here be of still less service. Every difficulty is magnified by the vast increase of distance and defalcation of light; we can only record what we see, and much of that is neither familiar nor intelligible.

It is easy, however, to perceive a strong general resemblance between these two great globes, not only in gigantic dimensions, want of density, and velocity of rotation, but in various atmospheric characteristics, such as parallelism of direction (sometimes, according to Herschel I., not quite equatorial on Saturn), contrasted colouring, and the occasional formation of bright and obscure patches. And yet in one main feature there is a very marked dissimilarity—the position of their axes. In this one point Saturn, after a decided interruption in the series, reverts to the type of the earth and Mars. And it is scarcely conceivable that the presence or absence of a change of seasons should not be strongly felt in its effects. One result, however, which might on a superficial view have been expected, is absent from Saturn. There is no luminous deposit around the poles, which, on the contrary, are often more dusky than the equatorial regions, and this alone would infer a different atmospheric constitution from our own, even if we left out of sight the consideration that such might well be expected when the subjacent materials are as light as cork, and the whole globe would float high out of water. But for this curious deviation from regular sequence—a kind of deviation so remarkable and so significant in the planetary system—we should have remarked as complete an analogy between Jupiter and Saturn as that which is believed to obtain between the Earth and Mars.

The changes, however, in the atmosphere of Saturn are not usually so conspicuous as those on Jupiter; nor is this to be wondered at, when we consider its inferior brilliancy at a distance measured by hundreds of millions of miles. The equatorial zone is usually represented as of prominent and unvaried brightness, and the dusky belts differ much in depth and arrangement at different times. Luminous and dark patches, though not common, are far from being unknown. The white equatorial spot, resolving itself ultimately into a streak, which was observed by Hall in 1876, though not, as has been asserted, an unprecedented, was a very remarkable instance of the former class, as one perceived by Herschel I., ninety-six years before, had been of the latter. This dusky spot was situated near the limb, where on Jupiter it would presumably have been invisible; yet much could not be inferred from this solitary observation, nor from that of Chacornac on the transit of the largest satellite, which showed a limb more luminous than the centre of the disk. Everything of this kind should be noted, but nothing pressed into the service of a foregone theory.

The flattening of the sphere at the equator, as well as the poles, announced by Herschel I. as the result of many observations in 1805, has never been very satisfactorily explained. It might have been discarded as an illusion resulting from the crossing of the outlines of the globe and rings, had it not been confirmed by repeated measurement at the time. It is considered to have been subsequently disproved by a repetition of that process in other hands; but it does not appear that the latter measures were taken at a time when the alleged deception existed. An experiment might be tried of placing at a distance from the eye (or better, the telescope, to insure perfectly similar conditions) a transparency copied from Herschel's figure, but with an elliptical, instead of "square-shouldered," outline; but even if, under any varied illumination, the deception should recur, his measures would still have to be accounted for, which do not seem to have been affected by any imperfection in his micrometer.

Part of Saturn's ring as observed by Trouvelot with the 26-inch Washington refractor.

But however this apparent anomaly may be disposed of, we are brought face to face, in the ring-system, with phenomena unexampled, as far as our sight can reach, though there may be thousands of them, and of still stranger things in the depths of infinity. The minor peculiarities of this complex arrangement are at present not readily traceable in so foreshortened a projection, and some of them would require instruments of great light and power; but the gauzy portion of the slowly-opening ring is already within the reach of moderate apertures. On many accounts these marvellous features deserve an increasing degree of scrutiny as the opportunities for it are becoming more and more favourable; and we may yet gain a further insight into their structure. Still we must not expect too much. Even should the bright rings be, according to the prevalent opinion, a closely-packed mass of satellites, we can hardly suppose it to be "resolvable" with any future increase of optical power. Theory, indeed, pronounces against a solid or even fluid composition; but the confident application of theory may possibly prove hazardous where materials wholly unknown may be dominated by polar forces of unexplored intensity. It may, indeed, be still an open question whether the aspect of the dusky ring, especially as projected across the ball, can be reconciled with the idea of a thin and scattered stream of satellites, an idea that perhaps would never have occurred to any actual observer, and that seems only a theoretical consequence of the supposed constitution of the other rings. Many questions, in fact, remain open, in this system of wonders; whether its general dimensions, or the proportions of its several parts, are unchangeable; whether minor divisions can always, or ever, be established; whether the gauze ring is distinctly separated from its neighbour; whether its colour is invariable; whether a similar material glazes over, so to speak, the great division of the two bright rings; whether any plausible explanation can ever be attempted of the extraordinary outlines of the shadow of the globe upon the outer ring, consistent with a thinness edgeways almost invisible. There may well be "more things" here "than are dreamt of in our philosophy." And in respect of the general idea of possible changes, it is but fair to bear in mind that our knowledge of this planet is confined to a relatively short period, as compared with his annual revolution. Only some seven Saturnian summers and as many winters have been exercising their influence on that peculiarly delicate and complicated system since the first employment of telescopic investigation—far less time since the commencement of minute scrutiny. And in addition to this the excentricity of the orbit is sufficient to vary the amount of solar radiation at different periods of his year, much more than is the case with our own globe.

It should not be forgotten, too, that the rotation of the ring has hitherto been deduced from theory alone, and ought, if possible, to be determined by observation; though where Herschel I. has failed, and Bond has not succeeded, there may not be a very bright prospect for subsequent observers.

The satellites are interesting in many respects; among others they afford a curious instance of the diversity of detail with unity of idea already alluded to. In our own case the attendant bears so large a proportion to its primary that Earth and Moon have been compared to a double planet. Next, in Mars, we find a ratio of the most opposite description. In Jupiter an intermediate proportion exists between the primary and secondaries, while the latter do not differ in magnitude very widely among themselves. In Saturn we have an extension and combination of the previous systems, not only in number but in character; extreme minuteness in several being found in juxtaposition with considerable bulk in one of the attendants. The striking irregularity of their sequence in point of magnitude is a fresh exemplification of the deviation from uniformity already referred to as so generally, and indeed almost universally, observable in the solar system. It may be noted among the retinue of Jupiter, where the largest is not the outermost of the satellites; but it is still more observable in the more complicated arrangement of the satellites of Saturn. The smallest in a general sense range nearest to the primary, yet the largest is not the most distant; and next in position to him comes the most minute of all. On the same principle it is highly unlikely that the regular progression 1, 2, 4, 8 should express the real number of the satellites attending respectively on the Earth, Mars, Jupiter, and Saturn. More, probably, own the control of the latter, and may be reserved as a triumph for Mr. Common's magnificent 37-inch mirror which the spirited possessor fully deserves.

The well-known fact that the difficulty in detecting objects of this nature diminishes as they become more familiar, is well exemplified in these minute points. Enceladus, once considered as suitable only for great apertures, has been several times seen by Franks with a 5-inch object-glass; my less acute vision with 9½ inches of a silvered mirror distinguished it in 1878, not readily, indeed, but quite certainly, in the absence of the primary from the field.

The variable light of the outermost, Japetus, in different parts of his orbit, has long been known, and might have been readily explained by a synchronism of rotation and revolution, but for superinduced irregularities similar to those of the satellites of Jupiter, and probably depending upon a similar cause. Schröter detected differences of brightness in some of the others, on opposite sides of the planet; but the subject deserves a fuller investigation.

T. W. WEBB

NOTES

WE record with deep regret the death of John Allan Broun, F.R.S., on Saturday last, at the age of sixty-two years. Mr. Broun was many years in India, as Director of the Observatory of the Maharajah of Travancore, and has been resident in London for the last six years. We hope next week to give details of Mr. Broun's life and the valuable services he has rendered to meteorology.

WE regret to learn that Prof. A. H. Sayce is compelled to spend the winter in Egypt on account of his health. We trust his sojourn on so congenial a soil will quite re-establish him.

A MARBLE medallion of Father Secchi has been placed in front of the Stilvio Observatory, 2,543 metres above the level of the sea. The observatory owes its establishment to him.

THE Swedish Academy of Sciences has appointed Dr. B. V. Wittrock, the celebrated algologist, to be keeper of the botanical department of the Swedish State Museum, in succession to Prof. N. J. Andersson, who has retired in consequence of the bad state of his health.

THE works for creating an astronomical observatory on the top of Etna were progressing favourably, but have been arrested for some months owing to the state of the weather. The central iron cupola and the telescope would have been placed this year if the operation had not been prevented by the large quantity of snow which fell prematurely on the mountain. This establishment is unrivalled for its position under an admirable sky, and will be placed on an immense natural platform situated at an altitude of 3,000 metres above the sea. The central crater has an elevation of 350 metres, and the observatory has been built at its very foot. An hotel is also being built, where twenty persons can find board during fine weather.

THE Municipal Council of Lyons, after a protracted discussion, has voted a credit for raising a statue to Ampère, who was, with Arago, the inventor of the electro-magnet. Ampère was a Catholic, and the son of a magistrate who had been beheaded at Lyons after the great revolution of 1793. The elder Ampère had written the charge against Challier the *Montagnard*, whose death caused the breaking out of civil war and the shedding of the blood which deluged Lyons during so many months.

THE death is announced of the eminent physicist, Friedrich von Ewald. He died at St. Petersburg on October 16 last, at the age of sixty-six years. He was for many years instructor to the Czarewitch.

FRIENDS and admirers of the late Herr Theodor Heuglin, the well-known African traveller, have erected a monument to his memory in the Prager Cemetery, at Stuttgart; it consists of a large erratic block from Upper Suabia, adorned with the medallion portrait of the deceased. Prof. Kopff, of Baden Baden, was the sculptor of the medallion. The monument was unveiled a few days ago.

THE death is announced of Mr. Serjeant Cox, on Monday, in his seventieth year. Mr. Cox was known as the author of several works in physiological psychology, written mainly from a spiritualistic point of view.

AT Hamburg, the resolution has been passed to erect a new Natural History Museum, for which the sum of 1,000,000 marks (50,000*l.*) will be expended. It appears that through the great marine trade of the city, its rich natural history collections are rapidly increasing year by year. Up to the present not one half of these collections could be properly exhibited to the public for want of space. All this will be changed when the new building is completed.

A CATALOGUE of scientific serials, from 1633 to 1876, has been recently prepared by Mr. Samuel H. Scudder, assistant-librarian at Harvard College Library, and under the auspices of that library, which has met the expense of publication, with the expectation that the demand for the volume will refund the outlay, and with the promise that, if so far remunerated, this shall be the beginning of a series of "works such as may be properly undertaken by a public library, and do not offer inducement for commercial speculation." The catalogue embraces the transactions and bulletins or proceedings of learned societies in the natural, physical, and mathematical sciences of all countries, as well as independent journals. It is the result of a large amount of painstaking labour and should prove an invaluable companion to those engaged in research, or otherwise interested in the progress of science.

FEW local natural history societies can show a better record of work done than the Torrey Botanical Club, the *Bulletin* of which is published monthly or bi-monthly. In addition to records of localities and descriptive articles of local and geographical interest, the pages of this publication not unfrequently contain contributions of sterling value on important points of morphology and physiology. Articles of this character in the numbers which have recently reached us are "Notes on the Relative Age and Dimensions of a Number of Different Trees," by N. L. Britton, and "A Few Notes on the Abnormal Absence of Colour in Plants," by A. Hollick.

IT is intended to erect a statue at Hanover in memory of the late eminent technologist, Karmarsch.

THE recent Hungarian earthquakes were coupled with phenomena of a most remarkable nature. The large island in the Danube near Old Moldowa was completely cleft in two by one of the shocks. From the chasm thus formed a gigantic column of water shot forth partly flooding the island. On October 18 the giant fountain suddenly ceased to flow, but numerous funnel-shaped craters had formed from which black sand and clay were ejected. Near Weisskirchen the old ruins of the Castle of Golubacz have fallen in completely, and in the vicinity several caves were rendered inaccessible. These caves were the breeding places of the dreaded Kolumbacs mosquitos, and if this insect is thus exterminated the earthquake may, with all the damage it did, have yet been of some use. Another smart shock was felt at Temesvar on Friday morning last. A violent earthquake is reported from Iceland. It occurred on September 24 last and is ascribed to volcanic eruptions in the Krisuvik mountains, a locality where eruptions have not been known within the memory of the present generation.

RUDOLF FALB has written from San Francisco to German friends to inform them that a monument in Bolivia much more ancient than the times of the Incas has given him a clue to the origin and development of speech and writing. He is apparently inclined to recur to the Semitic hypothesis.

AT the opening meeting, last week, of the Society of Arts the following prizes were awarded:—The Gold Medal, offered for the best means of saving life at sea, to Messrs. J. and A. W.

Birt, "for the collection of buoyant articles sent in by them;" the Society's Silver Medal, to Mr. Herbert Singer, for his "Essay on the Art of the Silversmith;" to Mr. F. Toplis and to Mr. Joseph Lucas, for their papers containing "Suggestions as to the best Means of dividing England and Wales into Districts for the Supply of Pure Water;" to Mr. Alfred Haviland, M.R.C.S., for his paper on "The Distribution of Disease popularly considered;" to Mr. John Hollway, for his paper on "A New Application of a Process of Rapid Oxidation, by which Sulphides are utilised as Fuel;" to Mr. Conrad W. Cooke, for his paper on "Edison's Loud-Speaking Telephone;" to Mr. Thomas Wardle, for his paper on "The Wild Silks of India, principally Tusser;" to Dr. William Wallace, F.R.S.E., for his paper on "Gas Illumination."

THE second part of vol. xxiv. of the "Mémoires de la Soc. de Physique et l'Histoire Naturelle de la Genève" has just appeared. It contains:—Report of the President to December 31, 1878, by Prof. E. Wartmann; Researches on the Fecundation and the Commencement of Henogeny among Various Animals, by M. Hermann Fol; On the Genus Hemimerus, Wolk., apparently furnishing a new order in the class of Hexapods, by M. H. de Saussure; Description of a New Species of Trygonid belonging to the genus Pteroplatea, by M. Godefroi Lunel; Comparative Anatomy of the Leaves in some families of Dicotyledons, by M. Casimir de Candolle.

IN reference to an article in the *Globe* on Sapphires in Siam, Mr. Bryce-Weight writes to that paper that through one of the Siamese princes in England he has learned that there are several sapphire mines in Siam, on the sea coast, with thousands of people at work, valuable gems having been found and sold at a good profit.

IN the beginning of October there was discovered, at about a kilometre from Guisseny, under a mass of rocks, a cavern fifteen metres long by four broad. This cave has two openings, one towards and about four metres above the sea, the other towards the land. The cavern was found throughout its length covered with a bed of ashes and charcoal about two centimetres thick. Underneath this was found a sort of dry stone masonry, then human bones, remains of cinerary urns, evidently of "Celtic" origin, and a considerable quantity of bones of mammals. Among the latter are some which do not appear to belong to contemporary fauna. Finally, a stone hammer and a sharp, polished axe of porphyry appear to show that this cavern is a sepulchral grotto of prehistoric times.

A SECOND enlarged edition is announced by Mayer, of Cologne and Leipzig, of Sonnenschmidt's "Kosmologie," the history and development of the universe on the basis of the most recent scientific researches.

THE *Journal of Applied Science* draws attention to the substitution of paper for wood in Germany in the manufacture of lead-pencils. It is steeped in an adhesive liquid and rolled round the core of lead to the required thickness. After drying, it is coloured to resemble an ordinary cedar pencil. The pencils sell in London to retailers at about 3*s*. a gross.

AT the first meeting of the Statistical Society, on the 18th inst., the President, Mr. Brassey, presented the Howard Medal and 20*l*. to Miss Beatrice A. Jourdan, as the writer of the best essay "On the Improvements that have taken place in the Education of Children and Young Persons during the Eighteenth and Nineteenth Centuries." The President announced as the subject of the essay of next year, "The Oriental Plague, in its Social, Economical, Political, and International Relations."

THE long pending telephone litigation in the United States has at last been settled by a compromise which leaves Prof. Bell master of the field. The National Bell Telephone Company have bought up the conflicting rights, and acquired all the telephonic inventions of Elisha Gray, of Mr. Edison, and of Mr. G. M. Phelps. The Western Union Telegraph Company, however, is to be licensed to convey telephonic messages, while the right to establish telephone exchange systems is to remain exclusively with the Bell Company. The shares of the National Bell Telephone Company are now quoted at 700 per cent.

THE multiplication of the correct time by electricity, as inaugurated by Leverrier, is now organised at Paris, on an immense scale, by the Municipal Council. A length of 15,000 metres of tubes is placed alongside the Boulevards and the principal streets, where a large number of dials will mark the time during day and night. Private clocks will be kept to time on payment of a small fee.

A COMPETITIVE experiment took place on September 19 in the green-room of the Grand Opera of Paris, on the respective illuminating power of Jablochkoff candles and Werdermann lights. The Werdermann light was found most steady, and the Jablochkoff most powerful. The experiments will be continued next week before the public, and a final resolution will be taken afterwards. The President of the Republic and the Minister of Fine Arts are represented.

ON November 11 a stream of falling stars was observed, at nine o'clock, at Chatelherault, when the sky was exceptionally clear.

A COURSE of six evening lectures on Photography will be given at the Sorbonne every Thursday evening by M. Davanne, President of the Photographic Society of Paris, with experiments. These lectures are organised by the Scientific Association of France, presided over by M. Milne Edwards. The ordinary evening lectures will begin only in January.

THE second French Atlantic cable has been successfully laid down from Brest to the American shores, through the Scilly Islands and Newfoundland. Congratulatory messages have been exchanged between the Presidents of both Republics.

PHOTOGRAPHERS, professional and amateur, will, we believe, derive much assistance from the "Photographic Printer's Assistant," by Mr. W. Heighway, just published by Richardson and Best. The directions given are such as have been found successful in actual practice.

M. CHARCOT, the chief physician of Salpetrière, opened, three years ago, a course of lectures on nervous affections, annexed to his clinic. The number of persons asking for admission has been so considerable that the administration of Public Assistance has built an amphitheatre with 500 seats in the hospital. The lectures, which are delivered every Sunday, were begun on November 16, before a full house. The amphitheatre was fitted up with an Alliance Magneto-electric machine, worked by the steam-engine of the washing-house. In each lecture a number of patients are introduced on the platform illustrating the theories of the lecturer, and many photographs are projected on the screen by electricity. In the lecture of November 23 the lecturer projected two engravings reproduced from Montgeron, an author of the beginning of the eighteenth century, who advocated the genuineness of miracles executed on the grave-stone of Diacre Paris. One of these represented a young lady who had been declared by the doctors of the age to be incurable of club-foot, and the other engraving the same person after having been cured in a trance. These two figures were engraved and published by Montgeron as exhibiting a case of supernatural agency. M. Charcot proved they were analogous to several of the cases which had been presented to his audience and could be cured by the same process.

Dr. Richardson asks us to say that in his article on Fleuss's New System of Diving in last number, p. 63, col. 2, 25th line from bottom, "fully seven minutes" should be "forty-seven minutes."

The additions to the Zoological Society's Gardens during the past week include a Yellow Baboon (*Cynocephalus babouin*) from West Africa, presented by Mr. Cecil B. Hankey; a Collared Peccary (*Dicotyles tajaçu*) from South America, two Domestic Sheep (*Ovis aries*), presented by Mr. H. Sandbach; a Little Grebe (*Podiceps minor*), British, presented by Mr. A. F. Buxton; a South American Rat Snake (*Spilotes variabilis*) from South America, presented by Mr. Thomas Harrod; two Geoffroy's Cats (*Felis geoffroii*) from Paraguay, two Barbary Falcons (*Falco barbarus*) from North Africa, a Red-throated Diver (*Colymbus septentrionalis*), British; a Common Curlew (*Numenius arquata*), European, deposited; two Common Tiskins (*Chrysomitris spinus*), a Reed Bunting (*Emberiza schœnichus*), a Pied Wagtail (*Motacilla yarrelli*), British, purchased; a Gaimard's Rat Kangaroo (*Hypsiprymnus gaimardi*), two Smooth Snakes (*Coronella lævis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

The "Uranometria Argentina."—The publication of this great and meritorious work is just announced, though, so far as we know, the complete volume has not yet reached Europe. The system of observations upon which it is based was designed and commenced by Dr. B. A. Gould, the distinguished director of the Argentine Observatory, immediately after his arrival at Cordoba in September, 1870, on accepting the superintendence of the new establishment, and while awaiting the completion of the observatory buildings and the arrival of telescopes which had been ordered in Europe, but delayed by the outbreak of the Franco-German war, and the work upon it has been continued with more or less attention to the present year. It was intended to represent in a series of charts and accompanying catalogue the sky from the south pole as far as 10° north of the equator, as it appears to the naked eye, showing all stars down to a round magnitude fixed at 7·0, with their characteristics of duplicity, variability, and colour, and the milky-way in all its ramifications and gradations of brightness. The actual observations were assigned to the four assistants, Messrs. Rock, Davis, Hathaway, and Thome, who had proceeded to Cordoba from the United States, the first three returning home at the expiration of three years, when the Uranometry was already finished as to its general details. Mr. Thome subsequently reviewed the entire work twice, and with the result that Dr. Gould considers it improbable that any star so bright as 7·0, on a scale which it has been desired to extend accurately from Argelander's, will have escaped insertion, while notwithstanding the great degree of nicety implied, he thinks the magnitudes are essentially correct to the nearest tenth. During the first two years the work was continued on all cloudless nights, both summer and winter, at an average of six hours' work each night. The total number of stars of which the magnitudes have been assigned is 10,649, and the total estimates of magnitudes 44,510, or more than four for each star.

With the view to having a uniform basis for estimates of magnitude throughout the whole heavens, Argelander's magnitudes for a region lying from 5° to 15° north of the equator, having the same meridian altitude at Bonn and Cordoba, were collected by classes, and "the stars of each class then assorted and shaded into the adjoining ones until a scale of tenths was formed." . . . "The scale as finally adopted resulted from the accordant estimates of all four assistants for each tenth up to 7·0." A "Type-belt Catalogue" of 722 stars was formed in this way, intended, as we have intimated, to serve as a standard for all future determinations of magnitude, in whatever part of the heavens. All the stars occurring in the "Uranometria" have been observed for accurate position at least four times with the meridian circle, and a general catalogue will appear in due course.

The charts are thirteen in number, and an index-chart is added showing at once the whole extent of the Uranometry. The printing was effected by the photolithographic process, as the most accurate and least expensive. Photographic negatives of the manuscript charts were taken, thus permitting their exact transfer to the stones. The chief trouble experienced in the printing was to give the star-dots the proper blackness, and yet to keep the milky-way within reasonable shade.

In a special chapter, Dr. Gould collects all variable and suspected variable stars, with particulars, thus providing interesting work for those amateurs who can command the southern heavens, and work from which much may be learned.

From a discussion of the general distribution of the stars throughout the sky, Dr. Gould is led to conclude that "there is in the sky a girdle of bright stars, the medial line of which differs but little from a circle inclined to the Galactic circle by a little less than 20°. The grouping of the fixed stars brighter than 4·1 is more symmetric relatively to that medial line than to the Galactic circle, and the abundance of bright stars in any region of the sky is greater as its distance therefrom is less. The known tendency to aggregation of faint stars towards the milky-way is according to a ratio which increases rapidly as their magnitudes decrease, and the law of which is such that the corresponding aggregation would be scarcely, if at all, perceptible for the bright stars." These facts, Dr. Gould continues, indicate the existence of a small cluster, within which our own system is excentrically situated, but which is itself not far removed from the mean plane of the Galaxy; this cluster he considers to be of a flattened shape, somewhat bifid, and consisting of rather more than 400 stars, of an average magnitude of 3·6 or 3·7, but comprising stars from the first to the seventh.

We have abridged these particulars from an interesting article on the "Uranometria Argentina," in the Buenos Ayres *Standard*.

It is impossible to avoid expressing admiration for the scientific spirit and enlightenment of the Government of the Argentine Republic in providing means for the execution of this important work, the first astronomical contribution from their National Observatory, but, we believe, to be followed by others, for which materials are completing, and which, it cannot be doubted, under the superintendence of Dr. Gould, will collectively secure for the Observatory of Cordoba a high position in the history of astronomical establishments, and, in connection with other enterprises of which we hear from time to time, for the comparatively small nation by which it is supported, the respect and good wishes of the scientific world.

The "Lick Observatory," California.—From San Francisco we receive details of recent progress towards carrying out the intentions of the will of the late James Lick, who died October 1, 1877, bequeathing the sum of 700,000 dollars to trustees for the purpose of purchasing land and erecting upon it "a powerful telescope, superior to and more powerful than any telescope ever yet made," with an observatory and other appurtenances, to be conveyed eventually to "the Regents of the University of California." The first site considered was at Lake Tahoe, but it was soon rejected; Mount St. Helena, at the intersection of Napa, Sanoma, and Lake counties, was then visited; it is upwards of 4,300 feet high, and was known to have atmospherical conditions favourable for astronomical purposes. Mr. Lick spent one night upon its summit. Among other points visited was Mount Hamilton, the elevation of which is still greater, and Mr. Lick finding that its advantages, so far as known, were equal to those of the former mountain, finally determined upon Mount Hamilton as the site of his proposed observatory; it is something less than fourteen miles east by south, from San José in Santa Clara county. A road to the summit twenty miles long was commenced in 1875, and finished in December, 1876, at the expense of Mr. Lick, and surroundings to the extent of more than 1,500 acres were secured to form the observatory property. The site was thus, contrary to what has been generally stated, decided upon before Mr. Lick's decease, and Prof. Newcomb had been asked to test the capabilities of the station, to obtain a guide as to the size and character of the instrument or instruments to be provided; Prof. Newcomb was too much engaged upon his official duties to undertake this work in 1877, and recommended application to be made to Mr. S. W. Burnham, of Chicago, who arranged last April to visit Mount Hamilton, with his own 6-inch Alvan Clark refractor; he arrived in the middle of August, and after spending thirty-two nights upon the mountain, up to September 27, all of which except five were extremely favourable, he appears to have agreed in opinion with Prof. Newcomb, who was able to visit Mount Hamilton early in October, that it is "the finest observing location in the United States." With regard to the size of the great telescope to be mounted there, much will probably depend upon the success attending the construction of the 30-inch refractor, which Alvan Clark and Sons have engaged to furnish for the Imperial Observatory at Pulkowa, but the trustees purpose to secure a 12-inch to be used in the observation of the next transit of Venus, and to remain one of the permanent fixtures of the Observatory.

San José is in about 121° 50′ west of Greenwich, and 37° 16′ N. Of Mount Hamilton it is stated that, "although practically out of the coast range fog-belt, an occasional gale blows the mist across the Santa Clara Valley from two points—Monterey Bay and the Sand-hill Gap just south of the city. On extraordinary occasions this fog reaches the crest of Mount Hamilton, but ordinarily the sky is cloudless all summer." The trustees have their work well in hand, though there remains much to be done before the whole design of the munificent founder of the observatory can be realised. It is intended that a meridian-circle, an instrument necessarily requiring considerable time in its construction, and other accessories, shall be provided in addition to the great telescope and the smaller equatorial. If we are not mistaken, Mr. Burnham has added a number of new double-stars to our lists, from his tentative work with the 6-inch refractor on Mount Hamilton.

GEOGRAPHICAL NOTES

A RUSSIAN journal announces the early departure of a scientific expedition, under the direction of Lieut. Onatsevitch, to make hydrographic investigations in the Sea of Japan and the Sea of Okkotsk. One of M. Onatsevitch's assistants, Ensign Heller, has already gone to Vladivostock in the cruiser *Asie*, taking with him numerous instruments with which the hydrographic department has equipped the expedition. M. Lanevsky Volk and four other naval officers will accompany M. Onatsevitch by way of Siberia. The object of this expedition is to fill lacunæ in the works of Babkine, Bolchew, Staritsky, Yelagnine, and others. It will have to explore, especially from the hydrographic point of view, the mouths of rivers which fall into the Sea of Japan, from the southern frontier of Russia to the Bay of Castries. It will make geodetic observations in the southwest part of Peter the Great Bay and at the mouth of the Amour. Lastly, it will study the water-courses, and the east and south parts of the Isle of Sakhaline, the district of La Perouse, &c.

AT the meeting of the Geographical Society on Monday evening the secretary read a paper by Capt. A. H. Markham on the Arctic campaign of 1879 in the Barents Sea. The title of the paper, however, is somewhat of a misnomer, as the narrative was chiefly confined to the proceedings of the *Isbjörn*, to which we have already referred. Some few details were also furnished as to the trip of the second Dutch expedition in the *Willem Barents*. Among the various matters of interest dealt with, perhaps one of the most interesting was the description of a large glacier on one part of the coast of Novaya Zemlya. This glacier Capt. Markham ascended, and walked along it for some two or three miles into the interior; he found numerous fissures in it, at the bottom of which ran rivulets, and some of which were so deep and wide that they could not be crossed except by making a long *détour*. During the trip a considerable amount of information was gained in regard to the movements of the ice in the Barents Sea, and the best season for future attempts at exploration, especially in the direction of Franz Joseph Land; it was made quite clear, however, that a larger vessel and the aid of steam are absolutely necessary to secure really useful results.

WITH reference to the discovery of the sources of the Niger, it is stated that MM. Zweifel and Moustier traversed the Hokko and Limbah countries, which, covered with forests on Winwood Reade's visit ten years ago, was now found very little wooded, the demand for the oily almonds of the palm tree having induced the natives to plant oil palms in the place of forests. A Koranks mission told the explorers that the Niger passed between Mount Lomat and another mountain, and that its three sources, the junction of which formed a small lake, were two days' march from the latter. After many dangers and privations, the travellers found the main source near the village of Koulaks, on the frontier of Koranks, Kissi, and Kono, its native name being the Tembi. The travellers could not enter the Sangara country on the right bank of the river; but they are confident that the Tembi is the longest of the three streams mentioned by the Koranks, and consequently the origin of the Joliba or Upper Niger.

M. DE LESSEPS is to leave in a few days for Central America, in order to survey the concession granted by the Columbian Government for a sum of 750,000 francs, which was paid a few months since. The surveying within a certain time is an obligation which, not being complied with, would render the concession void. The promoter of the new canal took leave of the Geographical Society of Paris on November 21.

A DISCUSSION has been raised before the Geographical Society of Paris by the alleged discovery of the source of the Niger by two Frenchmen, commercial travellers, as referred to last week.

THE Freie Deutsche Hochstift at Frankfurt has received further news from Dr. Gerhard Rohlfs and his travelling companion Dr. Stecker, according to which the two travellers were already on a steamer sailing for Malta. Herr Rohlfs is said to be so exhausted that he intends to abstain from any further African exploring expeditions. Amongst the objects which the travellers were robbed of are all their diaries, notes, and scientific instruments, besides the rich collection of presents sent by the Emperor of Germany to the Sultan of Wadai.

NO. 10 of Band xxii. of the *Mittheilungen* of the Vienna Geographical Society, contains papers on the Ethnological Conditions of South Russia at their chief epochs, from the earliest times to the first appearance of the Sclavs, by Dr. Jar. Vlach; the Mississippi and its Basin, by Dr. Hesse-Wartegg; the district of Shushu, in Transcaucasia, by Carla Serena. Among the notes is a valuable statistical and geographical account of the Vilayet of Trebizond, from an Austrian Consular Report. As a supplement to the *Mittheilungen* is announced a *Zeitschrift für wissenschaftliche Geographie*, edited by Julius Iwan Kettler, assisted by a staff of eminent German geographers. This journal will embrace all departments of mathematical, physical, commercial, ethnological, descriptive, and historical geography; and promises to prove one of the most valuable geographical journals published. It will be issued every two months.

CAPT. HOWGATE has published a neat little volume on the cruise of the *Florence* in the preliminary Arctic Expedition of 1877-8. He gives many interesting notes made during the wintering in Cumberland Gulf, both of the country and people. The scientific results have been published separately, and these we shall notice in detail.

THE *Cape Argus* announces the starting in October of an African Expedition from the Cape, under, and at the expense of, two young Englishmen, Messrs. Beaver and Bagot. They have only two bullock waggons and a few blacks, but their ambitious programme is to make a "General and Astronomical" survey of the whole region between the Zambesi and the Albert and Victoria Nyanzas. This region is ignorantly described in the *Argus* as being almost totally unexplored. The two light-hearted young Englishmen allow themselves four years to accomplish their gigantic undertaking. We shall watch their progress with curiosity. They are stated to have had an interview with the Geographical Society before leaving; the officials of the Society, we believe, are not able to recall the incident.

IN a letter to M. Sibiriakoff, Prof. Nordenskjöld expresses his intention of undertaking another voyage to the northern coast of Asia as soon as circumstances permit. "After my return," he says, "I think of spending a year on preparing an account of the voyage of the *Vega*, and it is my desire then to continue the exploration of the Icy Ocean along the coast of Siberia, making the River Lena the point of departure, and the New Siberian Isles the basis of operations. For the object I have proposed to myself—namely, the rendering of the northern part of Asia completely accessible to commercial shipping—the prosecution of these researches is of paramount importance."

A TELEGRAM to the *Moscow News*, dated Katt Koorgan, November 14, gives the latest intelligence received from the Russian scientific expedition appointed to explore the Oxus or Amu Darya, and report on the best route for a great Central Asian railway. On October 19 the members met the Khan of Khiva, who said he would give orders in due time for the demolition of the dams at Bant and Shamurat. The eldest men among the Yomouds and Tschenderen pledged themselves to procure labourers for the purpose of cleaning out the bed of the Usboi between Sary Kamysch and the Caspian Sea.

THE death is announced of the Dutch lieutenant, Koolemans Beynen, who accompanied Sir Allen Young in his two *Pandora* voyages, and last year was second in command of the Dutch

Arctic expedition in the *Willem Barents*. He edited for the Hakluyt Society an account of the three voyages of William Barents. A daily contemporary confounded Lieut. Beynen with the well-known Arctic explorer, Lieut. Payer, who, we are glad to say, is alive and as well as ever.

RECENT advices from Japan state that the port of Gensan in Corea has been opened to Japanese traders. The Japanese, however, appear to have been more anxious to obtain the opening of Nikawa, a more important place, and about nineteen miles from the capital, Hányang (Seoul). The Coreans refused to concede this point, probably on account of a sacred character attaching to the road which separates the two.

BIOLOGICAL NOTES

OOSPORES OF "VOLVOX MINOR."—Dr. Kirchner, in the recent part of Cohn's "Beiträge zur Biologie der Pflanzen," describes the germination of the oospores, and in this supplements the important contribution made by Cohn himself to our knowledge of this interesting plant in the first volume of the same work. The first appearance of germination was in February. The contents of the oospores during a rapid swelling out of the endospore, made their appearance through the ruptured exospore, and soon presented a sphere-shaped body, which then divided into two portions, these being perpendicular to one another. The newly-formed cells so separate from one another that they hang together by their ends. These ends form the one pole of the later-to-be-developed ball-like colony; the other pole is afterwards closed in, when the maximum of the cells is attained. Each oospore thus gives rise through cell division, followed by the characteristic cell displacement, to a new volvox colony. The fact of *V. minor* being diœcious was given as a character to distinguish it from *V. globator*, but this, according to the author, does not hold true; both colonies seem to pass through a purely female stage and afterwards through a male stage, each colony being bi-sexual.

CEDAR OF LEBANON IN CYPRUS.—Sir Samuel Baker, in his late residence in this island, has been fortunate in bringing to light the existence of this tree, or a variety of it, according to Sir J. D. Hooker. It seems the monks of Trooditissa Monastery assured the former that the "chittim-wood" of Scripture, a kind of pine, grew in the mountains near Krysokus. Trusty messengers having been despatched in search thereof, they brought back specimens of a cedar, with dense foliage and a superior quality of wood. Sir J. Hooker, to whom the specimens were forwarded, after a careful examination, finds that this tree differs from the true cedar of Lebanon in having shorter leaves and smaller female cones, with other slight differentiations. He names it, therefore, *Cedrus libani*, var. *brevifolia*, a short botanical account of which, along with Sir Samuel's letter, be laid before the Linnean Society at their last meeting. In his letter Sir S. Baker further hints that a variety of cypress some thirty feet high and seven feet girth, with a cedar-coloured wood, and powerfully aromatic scent of sandal-wood, in his opinion, is the celebrated "chittim-wood." He asks: "Why should Solomon have sent for cedar, which is so common in Asia Minor?" Another hard-wooded cypress, of twenty feet high, yields an intensely hard wood resembling *Lignum vitæ*.

NEW GENUS OF MYRIAPOD.—In the October number of the *American Naturalist* Mr. J. A. Ryder describes and figures a new genus allied to the little myriapod described some years since by Sir John Lubbock as Pauropus. This new American form is found in moist situations under sticks and decaying vegetable matter. It is called *Eurypauropus spinosus*, receiving its generic name in reference to its great relative width. The body is composed of six segments, possibly of seven. The head is partly free, the surface of the head and other segments is covered with small tubercles or spines. Two pairs of legs are attached to each of the second, third, fourth, and fifth segments, which, with a single pair on the first segment, makes nine pair in all. The legs are completely concealed in life by the lateral expansions of the body segments. The oral region seems to be very similar to that in Pauropus. There is no evidence of tracheal openings. Eyes seem to be absent. The antennæ are five-jointed, inserted close together at the front of the head, and are branched. The outer branch bears two of the many-jointed filaments, between the bases of which arises a pedicel surmounted by an ovoid semi-transparent body with linear sepal-like processes clasping it much as in *Pauropus pedunculatus*. The length is one-twentieth of an inch, and the habitat Fairmount Park, Eastern Penna.

ZOSTERA MARINA.—A. Engler, in a recent number of the *Botanische Zeitung* (October 10), has published some interesting observations on the fertilisation and growth of the sea grass growing at Kiel. He pronounces Hofmeister's observations on the fertilisation of Zostera as incorrect, but corroborates those of Clavaud (published in the *Botanische Zeitung* for August). At first it is true that the thread-like stigma lies on the neighbouring anther lobes, mostly those of two different anthers; next the style elevates itself, and so the stigma comes out of the narrow slit in the sheath, and receives the pollen given out by some of the older spadices. After fertilisation, the thread-like stigmas disappear, and at the same moment will be found clusters of as yet unopened anthers around the stigmaless gynœcia, these now having fertilised ovules. This was probably the stage observed by Hofmeister when he described the fertilisation as taking place inside the unopened inflorescence. Certainly the anther-lobes are not at this stage always emptied of their contents, and certainly when this emptying takes place the gynœcia are often beyond the power of being fertilised. The conditions of the buds in Zostera also specially engaged Engler's attention, because the sympodial bud system appeared similar to that in many of Araceæ. The main shoot which roots in the mud develops out of the angle of the nodal scale like lower leaves, which, however, soon die off, sterile buds, and then after the formation of four to six internodes in the ground, grows upwards, now developing leaves often a metre long, but never in the same year is the inflorescence observed. The sterile sprouts are found to the right and to the left of the main shoot; the upper internodes of this latter elongate and erect themselves, but now in the angles of the lower leaves are only fertile buds developed, which lie alternately right and left of the main axis. The first fertile bud is generally quite free, and carries three to four club-shaped bodies sympodially arranged as described by Eichler. The following fertile buds grow for a great while along with the main axis, the axis of growth thus presenting a flattened cone-shaped form with two furrows superimposed on a cylindrical axis. As to the inflorescence, Engler suggests that it is not impossible, but that the Gynœcia and Andrœcia may each represent separate flowers so arranged that male and female flowers of the s mplest type should stand opposite to one another. This, though opposed to the views of Ascherson and Eichler, seems to have some support from the fact that in the case of Spathicarpa ("Flora Brasiliensis," pl. 51), one of the Araceæ, this position of the male and female flowers occurs; only in this case, there can be no doubt of the fact, as there seems of necessity to be in Zostera, for the Andrœcia and Gynœcia are in Spathicarpa formed of several sexual leaves.

THE ONTOGENY AND PHYLOGENY OF THE CTENOPHORA.—Prof. Haeckel, in a recent number of *Cosmos* (vol. iii. Part 5, August, 1879), describes a new form which he calls *Ctenaria ctenophora*, as a connecting-link between the Ctenophora and the Medusæ. This species is figured, but fuller details are promised in the author's "System of the Medusæ," which, illustrated with forty plates, is nearly ready for publication. The new form is placed as a craspedote in the order of the Anthomedusæ, and in the family of the Cladonemidæ. Accompanying a brief description, there is an interesting paragraph on the "Ontogeny and Phylogeny of the Ctenophores." It would seem highly probable that the Ctenophores are descended from the Cladonemidæ, and that their still earlier ancestors were Hydrozoa allied to Tubularia. Among the newer adaptations, by means of which the Medusæ form of the younger Ctenophore originated, the most important is undoubtedly the change in the method of locomotion. The Medusæ swim in a spasmodic manner by irregularly contracting their umbrellæ, and then driving the water out of the cavity. The easy gliding, swimming movement of the Ctenophoræ is brought about by the vibrations of the little oar-blades which cross over the surface of the eight radial ciliated combs. While this newer form of motion took the place of the former, a number of other changes were immediately brought about according to the laws regulating the correlation of organs. The more important morphological relations were nevertheless, through the conservative power of inheritance, preserved. This interesting form possesses the eight ad-radial thread-cell channels as in Ectopleura, the trichter as in Eleutheria, the oral formation as in Cytæis, the canal-formation as in Cladonema, and the tentacles and tentacular pockets as in Gemmaria; transitory between two classes, it furnishes a new convincing proof of the verity of the doctrines of development.

ARSENIC IN ANIMALS.—Prof. Ludwig has recently (*Wiener Akad. Anz.*) inquired into the distribution of arsenic in the animal organism after ingestion of arsenious acid. The objects he examined were the organs of suicides who had poisoned themselves with arsenic, and of dogs which were poisoned, some acutely, some chronically, witb arsenic. In all experiments it was found that the arsenic accumulated most in the liver, and that in acute poisoning the kidneys also contained abundant arsenic, whereas in the bones and in the brain there was little of the poison. In case of chronic poisoning with arsenic, where death did not ensue, the poison was found to remain (after ingestion was stopped) longest in the liver, being much sooner excreted from the other organs. The results of this investigation are in direct opposition to those obtained by Scolosuboff, who always found most arsenic in the brain.

DIOPTRICS OF THE EYE.—In the investigation of the dioptric properties of the crystalline lens of the eye, physiologists have hitherto accepted an index of refraction of the lens determined for only one condition of accommodation. It seemed desirable to Herr Matthiessen to attain greater accuracy by ascertaining the dioptric properties of the lens in different states of accommodation, the structure of the lens as now known being fully considered. The subject is discussed at length by him in *Pflüger's Archiv* (xix. p. 480). In tabular form he presents a comparison of the positions of the dioptric cardinal points for the human eye and for the eyes of several lower animals, corresponding to different states of accommodation, infinite distance 160 mm. and 100 mm. A comprehensive list of works on the dioptrics of the lens and the eye generally is added to Herr Matthiessen's paper.

EXPERIMENTAL DETERMINATION OF THE VELOCITY OF LIGHT[1]

LET S, Fig 1, be a slit through which light passes, falling on R, a mirror free to rotate about an axis at right angles to the plane of the paper; L, a lens of great focal length, upon which the light falls, which is reflected from R. Let M be a plane mirror, whose surface is perpendicular to the line R M, passing through the centres of R, L, and M, respectively. If L be so placed that an image of S is formed on the surface of M, then, this image acting as the object, its image will be formed at S, and will coincide point for point with S.

If, now, R be turned about the axis, so long as the light falls on the lens, an image of the slit will still be formed on the surface of the mirror, though on a different part, and as long as the returning light falls on the lens, an image of this image will be formed at S, notwithstanding the change of position of the first image at M. This result, namely, the production of a stationary image of an image in motion, is absolutely necessary in this method of experiment. It was first accomplished by Foucault, and in a manner differing apparently but little from the foregoing.

In this case, L, Fig. 2, served simply to form the image of S, at M; and M, the returning mirror, was spherical, the centre coinciding with the axis of R. The lens, L, was placed as near as possible to R. The light forming the return image lasts, in this case, while the first image is sweeping over the face of the mirror, M. Hence the greater the distance, R M, the larger must be the mirror, in order that the same quantity of light may be preserved, and its dimensions would soon become inordinate. The difficulty was partly met by Foucault, by using five concave reflectors instead of one; but even then the greatest distance he found it practicable to use was only twenty meters.

Returning to Fig. 1, suppose that R is in the principal focus of the lens, L; then if the plane mirror, M, have the same diameter as the lens, the first or moving image will remain upon M as long as the axis of the pencil of light remains on the lens, and *this will be the case no matter what the distance may be.*

When the rotation of the mirror, R, becomes sufficiently rapid, then the flashes of light which produce the second or stationary image become blended, so that the image appears to be continuous. But now it no longer coincides with the slit, but is deflected in the direction of the rotation, and through twice the angular distance described by the mirror, during the time required for light to travel twice the distance between the mirrors. The displacement is measured by its arc, or, rather, by its tangent. To make this as large as possible, the distance between the mirrors, the radius, or distance from the revolving mirror to the slit, and the speed of rotation should be made as great as possible.

The second condition conflicts with the first, for the "radius" is the difference between the distances of principal focus and the conjugate focus for the distant mirror. The greater the "distance," therefore, the smaller will be the "radius." There

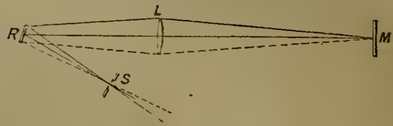

FIG. 1.

are two ways of solving the difficulty: first, by using a lens of great focal length, and, secondly, by placing the revolving mirror within the principal focus of the lens. Both means were employed. The focal length of the lens was 150 feet, and the mirror was placed about fifteen feet within the principal focus. A limit is soon reached, however, for the quantity of light received diminishes very rapidly as the revolving mirror approaches the lens.

The chief objection urged in reference to the experiments made by Foucault is that the deflection was too small to be measured with the required degree of accuracy. This de-

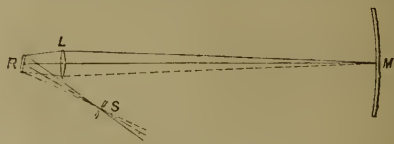

FIG. 2.

flection was but a fraction of a millimeter, and when it is added that the image is always more or less indistinct on account of atmospheric disturbances, as well as imperfections of lenses and mirrors, it may well be questioned whether the results could be relied upon within less than one per cent.

In the following experiments the distance between the mirrors was nearly 2,000 feet. The radius was about thirty feet, and the speed of the mirror was about 256 revolutions per second. The deflection exceeded 133 millimetres, being about 200 times that obtained by Foucault. If it were necessary it could be

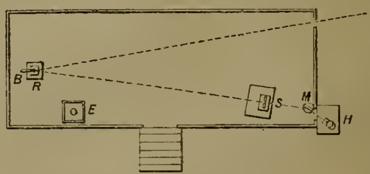

FIG. 3.

still further increased. This deflection was measured within three or four hundredths of a millimeter in each observation; and it is safe to say that the result, so far as it is affected by this measurement, is correct to within one ten-thousandth part.

The site selected for the experiments was a clear, almost level stretch along the north sea-wall of the Naval Academy. A frame building was erected at the western end of the line, a plan of which is represented in Fig. 3.

The building was forty-five feet long and fourteen feet wide, and raised so that the line of light was about eleven feet above

[1] By Albert A. Michelson, Master, U.S. Navy Read before the American Association.

the ground. A heliostat at H reflected the sun's rays through the slit at S to the revolving mirror, R, thence through a hole in the shutter, through the lens, and to the distant mirror. The interior of the building was painted black. In a room underneath the part, R, was the apparatus which supplied the air for turning the mirror.

The heliostat was kindly furnished by Dr. Woodward, of the Army Medical Museum, and was a modification of Foucault's

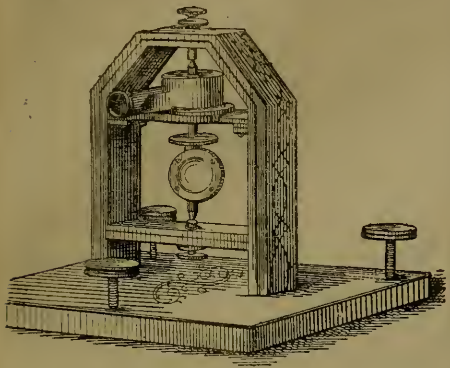

FIG. 4.

form, designed by Keith. It was found to be easy of adjustment and quite accurate.

The light was reflected from the heliostat to a plane mirror, M, Fig. 3, so that the former need not be disturbed after being once adjusted.

The revolving mirror was made by Fauth & Co., of Washington. It consists of a cast-iron frame, Fig. 4, resting on three levelling

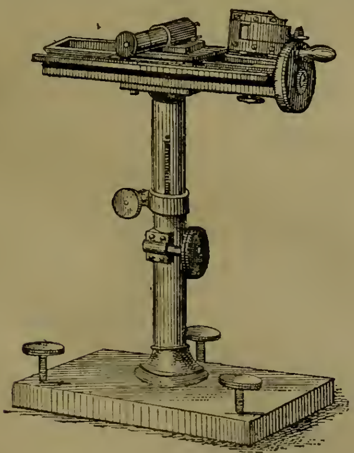

FIG 5.

screws, one of which was connected by cords to the table at S, Fig. 3, so that the mirror could be inclined forward or backward while making the observations. Two binding screws, terminating in hardened steel conical sockets, hold the revolving part. This consists of a steel axle, the pivots being hardened, expanding into a ring, which holds the mirror. The latter was a disc of plane glass, made by Alvan Clark, about one and a quarter inch in diameter and 0·2 inch thick. It was silvered on one side, the reflection taking place from the silvered side. A species of turbine wheel is held on the axle by friction. This wheel has six openings for the escape of air. The air entering on one side acquires a rotary motion in the box, carrying the wheel with it, and this motion is assisted by the reaction of the air in escaping. The disc above the mirror serves the purpose of bringing the centre of gravity in the axis of rotation. This was done, following Foucault's plan, by allowing the pivots to rest on two inclined planes of glass, allowing the arrangement to come to rest, and filing away the lowest part of the disc; then trying again, and so on, till it would rest in indifferent equilibrium. The part corresponding to the disc in Foucault's apparatus was furnished with three vertical screws, by moving which the axis of figure was brought into coincidence with the axis of rotation. This adjustment was very troublesome, and in this apparatus was found unnecessary. When the adjustment is perfect the apparatus revolves without giving any sound, and when this is attained the motion is regular and the speed great. A slight deviation causes a sound, due to the rattling of the pivots in the sockets, the speed is very much diminished, and the pivots commence to wear. In Foucault's apparatus oil was furnished to the pivots, through small holes running through the screws, by pressure of a column of mercury. In this apparatus it was found sufficient, at high speed, to touch the pivots occasionally with a drop of oil.

The quantity of air entering could be regulated by a valve,

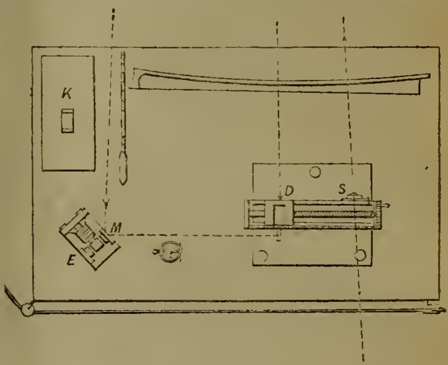

FIG. 6

to which was attached a cord leading to the table. The revolving mirror was mounted on a brick pier.

The apparatus for measuring the deflection was made by Grunow, of New York.

It consists of a screw, with divided circle, Fig. 5. To the frame is attached an adjustable slit. On the screw travels a carriage which supports the eyepiece, which consists of an achromatic lens, having in its focus at the end of the tube a single vertical silk fibre.

Next the eye is a piece of plane glass, inclined at an angle of 45°. In measuring the deflection, the eyepiece is moved till the cross hair bisects the slit (with which it is nearly in the same plane), and the reading of the scale and divided circle gives the position. This is made once for all, unless the slit be altered in width or position. Then the eyepiece is moved till the cross hair bisects the deflected image of the slit; the reading of scale and circle are again taken, and the difference in readings gives the deflection. The screw has no lost motion, so that readings may be taken with the screw turned in either direction. This apparatus is mounted on a standard with rack and pinion, and the base furnished with levelling screws.

To regulate and measure the speed of rotation, a tuning-fork, bearing on one prong a steel mirror, was employed. This was kept in vibration by a current of electricity from five gravity cells. The fork was so placed that the light from the revolving mirror was reflected to the piece of plane glass in the eyepiece, thence reflected into the eye. When fork and revolving mirror are both at rest, the eye sees an image of the revolving mirror.

When the fork vibrates, this image is drawn out into a band of light. When the mirror commences to revolve, this band breaks up into a number of moving images of the mirror; and when, finally, the mirror makes as many turns as the fork makes vibrations, these images are reduced to one which is stationary. This is also the case when the number of turns is a sub-multiple. When it is a multiple, or a simple ratio, the only difference is that there will be more than one image.

Hence, to make the mirror execute a given number of turns, all that is necessary is to pull the cord attached to the valve, to the right or left, till the images of the revolving mirror come to rest.

The electric fork made about 128 vibrations per second. No dependence was placed upon this rate, however, but at each set of observations it is compared with a standard Ut_3 fork, the temperature being noted at the same time. In making the comparison the beats were counted for 60 seconds.

It is interesting to note that the electric fork, as long as it remained untouched and at the same temperature, did not change its rate more than 0·01 or 0·02 vibration per second.

Fig. 6 represents the table at which the observer sits. The light from the heliostat passes through the slit at S, goes to the revolving mirror, etc., and on its return forms an image of the slit at D, which is observed through the eyepiece. E represents the electric fork, bearing the steel mirror, M; K, the standard fork on its resonator.

The lens was made by Alvan Clark. It was 8 inches in diameter, focal length 150 feet, not achromatic. It was mounted in a wooden frame, placed on a support moving on a slide about 16 feet long, placed about 80 feet from the building. As the diameter of the lens was so small in comparison with its focal length, its want of achromatism was inappreciable. For the same reason the effect of "parallax" was too small to be noticed.

The stationary mirror was one of those used in taking photographs of the transit of Venus. It was about 7 inches in diameter, mounted in a brass frame capable of adjustment in a vertical and a horizontal plane by screw motion. Being prismatic, it had to be silvered on the front surface. To facilitate adjustment, a small telescope furnished with cross hairs was attached to the mirror by a universal joint. The heavy frame was mounted on a brick pier, and the whole surrounded by a wooden case, to protect it from the sun.

The adjustment was effected as follows:—

A theodolite was placed at about 100 feet in front of the mirror, and the latter was moved about, till the observer at the theodolite saw the image of his glass reflected in the centre of the mirror. Then the telescope attached to the mirror was pointed at a mark on a piece of cardboard attached to the theodolite. Thus, the axis of the telescope was placed at right angles to the surface of the mirror. The theodolite was then moved to 1,000 feet, and, if found necessary, the adjustment repeated. Then the mirror was moved till its telescope pointed at the hole in the shutter of the building. The adjustment was completed by moving the mirror by signals, till the observer, looking through the hole in the shutter through a good spyglass, saw the image of the glass reflected centrally in the mirror.

Notwithstanding the wooden case about the pier the mirror would change its position between morning and evening, so that the last adjustment had to be repeated before every series of experiments.

(*To be continued.*)

ON THE MOUNTAINS OF THE NORTHERN AND WESTERN FRONTIER OF INDIA[1]

THERE are certain moot questions relating to the mountains of the north-west frontier of India upon which it appears desirable to elicit the opinion of geographers. On this occasion I propose to discuss the western limits of the Himalaya; the northern and southern limits of the Hindu Kush; the parallelism and lateral communications of the ranges between the Hindu Kush and the Aralo-Caspian plain and of other parts of the north-west frontier; and the limits of the Iranian group of highlands, at its junction with the Tibeto-Himalayan and Pamir groups. Finally the proper route of a railway to India between Mesopotamia and the Indus is indicated along a remarkable line of elevated valleys parallel to the coast.

[1] Paper read at the Sheffield meeting of the British Association by Trelawney W. Saunders.

The Himalaya ranges form a part of the great girdle of mountains which continuously encircle the central portion of the Asiatic Continent, and include the Chinese colonial dependencies of Ili, Mongolia, Kokonor, and Tibet.

This vast mountain girdle is naturally grouped into four parts corresponding with the outlets of its exterior drainage according to their connection with the Arctic, Pacific, and Indian Oceans, and the Aralo-Caspian Seas respectively. These four divisions of the great mountain girdle have been named from their chief features, (1) the Tibeto-Himalayan, (2) the Yunling, (3) the Altaic, and (4) the Pamir systems. The interlacing or overlapping of these systems at their junctions is not always easy to make out, and presents occasional difficulties like other systems of classification, no matter what the subject may be.

The question of the western termination of the Himalaya relates to two divisions of the great girdle, namely, The Tibeto-Himalayan and the Pamir, to which must be added another group lying outside those two, but impinging on them at its north-east corner. This group is formed by the Iranian highlands, a compact quadrilateral mass bounded by the lowlands of the Indus, the Arabian Sea and the Persian Gulf, the lowland of the Tigris and Euphrates, and the Aralo-Caspian plain. The only questions which can well arise with regard to the boundaries of the Iranian mountain system, relate to its north-west and north-east angles, where it unites with the Tauric system on the one hand and the Himalaya and Pamir on the other. It is with the latter only that we propose to deal now.

My Tibeto-Himalayan system was introduced in 1870 in "A Sketch of the Mountains and River Basins of India in two Maps, with Explanatory Memoirs." It was further developed in the *Geographical Magazine*, for July, 1877; and I am indebted to the distinguished chairman of this section for an appreciative account of it in two editions of his "Memoirs of the Indian Surveys in 1871 and 1877." It resolves the leading features of the vast mass of which it treats into four great chains with their outer slopes and intermediate valleys or plateaus. I am obliged to allude briefly to this bygone work, for the purpose of forming a logical basis for the argument which follows.

The northern and southern Himalaya are two of these great chains. The Karakorum-Gangri and the Kuenlun are the other two. The Southern Himalaya rises from the great plain of India, and its culminating summit is distinguished by an extraordinary chain of snowy peaks throughout the whole extent which is claimed for it. The catenary and close succession of these snowy peaks cannot be denied, for they have been fixed in position and altitude by the indubitable observations of the great Trigonometrical Survey of India. Nor can the existence be disputed of the line of valleys which forms the northern base of this snowy range and distinctly separates it from the Northern Himalaya.

Yet an antiquated theory conceived before the existence of this snowy range was demonstrable, is still held to be possibly tenable by the authors of the recently published manual of the Geology of India, although they do not condescend to any reason for their conclusion.

Now this is not merely a matter of dispute between geologists and geographers, but it is one of the greatest practical importance with reference particularly to the potent question of lateral communications about which much has been said lately in reference to the Iranian system in Afghanistan. In the successive valleys following one after the other in the same line, each of which I have specifically named in the *Geographical Magazine*, there is indisputable evidence of the separation of the two ranges, and of that lateral communication which is an ordinary feature of mountain systems, rather than otherwise.

The Northern Himalaya has its southern base in these valleys, while its northern base is found in the extended trough along which flows the upper courses of the great rivers Indus, Sutlej, and Sanpu.

It is usually said that the Himalaya extends up to the gorge of the Indus on the west and to the gorge of the Sanpu on the east, and this is the extent assigned to the Himalaya by the authors of the "Manual of the Geology of India." But this restriction falls short of the limits which we have already assigned to the Tibeto-Himalayan system, on the basis of the natural oceanic watersheds. It also falls short of the extension attributed to the Himalaya on the west by observers and geographers of celebrity; and we shall endeavour to prove that it falls short, on the west at least, of the plain and simple application of the same conditions as those on which the Himalaya is allowed to extend up to the gorge of the Indus.

The valley of the Upper Indus running from south-east to north-west, at the northern base of the Northern Himalaya, and between the Northern Himalaya and the Karakorum Mountains, is carried forward in the same direction by the valley of the Gilgit river up to Vassin, and thence over a relatively low water-parting into the upper valley of the Kunar river. Near the confluence of the Indus with the Gilgit, the Indus makes a rectangular bend on entering the gorge through which it intersects both ranges of the Himalaya to enter the plain of Peshawur. But the range of the Northern Himalaya which, it is allowed, dominates the left bank of the Indus as far as the gorge, does not cease there, but is continued across the Indus in the same direction as before, and proceeding westward forms the southern barrier of the Gilgit, Yassin, and Chitral valleys, until it meets the Hindu Kush on the west of the Kunar river. The separation of the Hindu Kush from the Himalaya will be discussed further on. The valleys of Gilgit, Yassin and Chitral, in which the base of the Northern Himalaya is found, are indeed a prolongation of the great trough which forms its northern base throughout. At the extremity of the Himalaya the Kunar river drives a passage through a gorge which remains unexplored, although it is probably not less accessible than the gorge of the Indus with which we have only recently been made acquainted.

Having now traced the Northern Himalaya up to the Hindu Kusb, the continuation of the Southern Himalaya west of the gorge of the Indus remains to be made out. It is defined by a series of peaks fixed by the Trigonometrical Surveyors in a line from that gorge up to the southern end of the Kunar gorge. Beyond the Kunar, the line of peaks bulges southward and bends again northward following the base formed by the Kunar, the Kabul and the Panjshir valleys, till it meets the Hindu Kush. Like the rest of the peaks of the Southern Himalaya, the peaks west of the Indus form the culminating summits of the southern slope which ascends in unbroken continuity along the whole extent of the Indian lowland, from the eastern extremity of the valley of Assam to the plain of Peshawur, and the line of the Kabul river. Lieut. Wood, the explorer of the Oxus, who as surveyor accompanied Sir Alexander Burnes' famous mission to Kabul, remarks that "the Himalaya, as is well known, bounds Hindustan on the north, and after crossing the river Indus, extends westward to the valley of Panjshir." The Trigonometrical surveyors have since defined the exact position of the great peaks which mark the culminating summit of the range along its whole extent. At the present time, we have still to await the exploration of the high ground between the northern and southern ranges west of the Indus. There is little doubt that it will be found to correspond with the rest of the interval between the ranges throughout their extended course.

We may now turn to the Hindu Kush. The ends of the axis of the Hindu Kush are well defined as that axis is the water-parting between the basins of the Indus and the Oxus. Its southern base is to be sought in the same line of watercourses which define the northern base of the Northern Himalaya with the addition westward of the Ghorband valley. The known parts of this line include the Ghorband and Panjshir valleys, and the Upper Kunar in Chitral. It remains for future exploration in Kafiristan to trace out a line of lateral valleys serving to connect the Panjshir with the Upper Kunar, in order to complete the line of contact and division between the Hindu Kush and the Northern Himalaya.

The northern base of the Hindu Kush may be traced from Bamian along the Surkhab to its junction with the Anderab valley, from the head of which, I have little doubt, a line of lateral valleys will be found connecting Anderab with Kuran, Zebak, the Panja, and the Sarbad-wakhan or southernmost head of the Oxus

The division between the Hindu Kush and the Himalaya is, so far as it goes, likewise the division between the Tibeto-Himalayan system and that of the Pamir. To complete the division of the latter systems we must find a line of watercourses from the Kunar river up to the Tagh Dumbash Mountain, which marks the common termination of the Karakorum and the Hindu Kush; and from the Tagh Dumbash Mountain the dividing line of the two systems must be carried down to the plain of Yarkand by an afiluent of the Yarkand river.

The Pamir group of mountains has the southern base of the Hindu Kush for a part of its southern limit. Its western base is in the plain of Gobi between the Yarkand and Kashgar rivers. Its northern base is in the plain of Kokand or Ferghana, watered by the Syr Daria or Jaxartes of the ancients. The western base strikes southward along the foot of the mountains; crosses the Zarafshan river and passes Bokhara; after which the group bends round to the eastward and finds its southern base along the right bank of the Oxus, up to its outlet from the mountains; then it follows the mountains crossed by the Lataband Pass, to the Akserai or Surkhab river, which it ascends to Bamian and Ghorband, where the continuation of the southern base of the Pamir group is found in the southern base of the Hindu Kush, as already mentioned.

We have heretofore defined the indisputable limits of the great quadrilateral Iranian group, and while the recollection of the limit of the Pamir along the course of the Surkhab or Akserai to Bamian and Ghorband, is fresh upon us, we will at once point to the same line as defining the separation and the contact of the Iranian and Pamir groups. From Ghorband by the line of the Kabul river to the Indus, is also traced, the separation and the contact of the Iranian with the Himalayan group. We cannot see that a more distinct or better limitation can be suggested for these important items of geographical nomenclature.

The principal ranges in the Pamir group are now fairly made out by British and Russian observers. The most easterly range is that of the Western Kuenlun, which rises in the plain of the Gobi above the cities of Yarkand and Kashgar, and culminates in snowy peaks, of which Togarmah is 25,500 feet in height above the sea, and Tash-balik is 22,500 feet. Westward of the Kuenlun range is the water-parting between the basins of Lake Lob and of the Oxus, a range which is in continuation with the Karakorum and Hindu Kusb, and the meeting of the three is at Tagh Dumbash. This range was long since pointed out by that grand geographer Baron Humboldt, and was identified by him with the Bolor of Oriental writers. An attempt has been made by a mistaken Russian geologist and some of his followers, and also by a critic distinguished for another reason, to do away with this well established and distinctive name; but such a feature parting two famous river basins and connecting other great ranges cannot go unnamed; and we contend that the name rendered classical by the labours of Alexander Humboldt, ought to be maintained. This Bolor range is separated from the Kuenlun by a series of valleys with streams that descend to the Gobi, including the Kizilyart Plain in the northern part, while in the southern part the repetition of the name Tagharmah is probably connected with the ancient Toghari, or Tochari. The Bolor range also forms the eastern limit of the Pamir or Roof of the World, a lofty plateau rich in summer pastures, drained by the Oxus and its affluents, and bounded on the west by another great range named Khoja Mohammed.

If we compare this part of the Pamir system with the western Himalaya, a certain similarity will be observed. Thus the Upper Oxus between the Khoja Mohammed and Bolor ranges, flows at an altitude similar to that of the Upper Indus, between the Northern Himalaya and the Karakorum ranges, or about 10,000 feet. West of the Khoja Mohammed range, is the range crossed by the Lataband pass, the latter separating the lowland of Kunduz from the elevated valley of Lower Badakshan, just as the southern Himalaya separates the elevated valley of Kashmir, from the lowland of the Punjab.

Lieut. Wood represented the Khoja Mohammed range as extending from the great bend of the Oxus to the Kokcha or river of Badakshan, and beyond that river in a south-westerly direction, that is, nearly parallel with the Hindu Kush. We shall consider its further extension presently. Similarly the Lataband range must be regarded as extending all along the Aralo Caspian plain from Kunduz to the Caspian Sea, and along the south of that sea to the Armenian plateau. Like the southern Himalaya it has its outer base in the great plain, but the inner base, has so far only been made out at intervals, and is an object that well deserves observation with reference to the existence of natural facilities for lateral communication along the side of the highland.

In pursuing this interesting subject we have to point to two well determined parallel lines already set out forming respectively the great waterparting and the base in the plains. The waterparting in question is formed in continuation of Karakorum westward, (1) by Hindu Kush, between the Oxus and Indus basins; (2) by Koh-i-Baba between the Oxus and Helmund basins; (3) by Siah Koh between the Murghab and Helmund. We will not pursue the culminating line further at present. A succession or chain of lateral valleys follows we believe both sides of this summit. On the north side we follow the Upper

Oxus as far as it flows parallel with the Hindu Kush; then cross over the pass of Ishkashm to the Upper Kokcha from which in all probability the Anderab valley is accessible, and also Bamian. From Bamian Capt. Conolly passed to the upper waters of the river of Balkh and thence into the valley of Hari Rud, which expands westward to the meridian of Herat.

Between the meridian of Herat and Kabul, at least three lines of lateral communication are partially delineated. These are the parallel valleys of the Hari Rud, of the Murghab, and of the route traversed by Vambery, and the Russian officer Grodekov. Indeed it can be still further demonstrated that practical lateral communication exists throughout the whole length of the Iranian and Himalayan systems, and probably offers greater facilities of transit than the transverse routes.

On this point a few words appear to be called for, by the statements of a recent writer, a member of parliament, and formerly an Indian Governor of great distinction, who has denied the existence of lateral communication along and within the Sul'man Mountains which form the easternmost part of the Iranian system and extend nearly from the Kabul River to the sea.

So far from lateral communication being wanting in this locality, which is now of much importance on account of its being brought by treaty within the scope of British administration—so far from the lateral communication being deficient and much less altogether absent—it constitutes as in the other mountains which we have discussed, a characteristic and marked feature of them. Indeed the outermost slope or scarp of the eastern Suliman has been delineated like a rising series of parallel gutters, terraces, or troughs, in the beautiful maps of the Derajat prepared by the surveyors under the guidance of Major-General Sir Henry Thuillier, who for so long a time filled the office of Surveyor-General of India, and whose presence here is such an advantage to the section.

In the heart of the mountains two lines of lateral communication can be already traced, even with our present very scanty information. Both are on the east of the waterparting of the Helmund and Indus basins, which is formed by the western range of the Suliman. One skirts the very summits of the range and is formed at its northern limit by the uppermost valleys of the Kurram, west of the Peiwar Kotul. It is watered by a stream which descends from near the Shutargarden Pass to the Kurram, where it meets another branch of the Kurram coming from the Mangal country on the south-western limits of the Kurram basin. From thence there is a communication with the district of Furmul which was known to the Turki Emperor, geographer, and conqueror of India—the famous Baber. Furmul lies at the head of the Dawar valley and river, which descends from it straightway to the Indus, but has never yet been wholly traversed by Europeans. Furmul is occupied by the Karoti tribe of the famous Povindah merchants, unless the Waziri have driven them out.

From Furmul this lateral line passes on to the Dwa Gummul another haunt of the Karoti people, who, as Povindahs and periodical visitors and traders to India, should have a clear interest in being friendly with us. From the Dwa Gummul we pass on to a southern headwater of the Gummul, and so on to the head of the Zhob valley, which is connected with the Thal-Chotiali route to Peshin.

There is another very important lateral line, a part of which was made known to Lieut. Broadfoot of the Royal Engineers as far back as 1842, by a native name, signifying "the road of the Waziri," a dominant tribe in those parts. This also connects the Kurram valley with the Dawar and Gummul valleys; and it is prolonged from Gummul up to the Chotiali route, by the great Zhob valley, which has at least been distinctly seen from both ends, in a direction nearly meridianal. We all know the great road which has been traversed by British troops between Kabul, Ghazni, Kandahar, and Kelat, and eastward of this, on the western side of the western Suliman range, a route has been traversed from Zurmul to lake Abistada, and from the lake to Kelat, British troops have marched over the Toba highland.

So much by way of proof of abundant lateral communication along the mountains west of the Indus.

One word more relating to the lateral communication through the hills and valleys of the south slope of the great Iranian highland. For it relates to the construction in the near future of a railway to India. From sheer ignorance some have proposed to carry such a line along the coast in a deadly climate with the atmosphere of a permanent hot bath. But the true route is found in one of those elongated lateral valleys which at a considerable elevation above the sea and in a better climate than that of the lowland on the coast, stretch all along from the Pubb river on the borders of India to Mesopotamia. Among these is the line of the Kej valley and a succession of others leading to Shiraz, from whence there is little doubt that a practical line may be found up to Bagdad.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Professorship of Experimental Physics has been formally continued by the Senate, and there is now no doubt that if Lord Rayleigh is willing to undertake this onerous office, he will be elected Professor. A memorial requesting him to be a candidate signed by almost every elector in a very short time seems like a command. It shows that there is no fear, and every hope for a beneficial result to education following. Lord Rayleigh's knowledge of the working of the University and the Scientific Commission will give him a most commanding position. It is a clear "call" from the University when such men as Adams, Besant, Cayley, Dewar, Ferrers, Frost, Garnett, J. W. Glaisher, Hughes, Liveing, R. K. Miller, Peile, Pendlebury, Routh, Salvin, Skeat, Stoke, James Stuart, Todhunter, Venn, James Ward, W. Aldis Wright and others unanimously record their view that it would tend greatly to the advance of physical science and to the advantage of the University that Lord Rayleigh should occupy the chair of Experimental Physics at Cambridge.

Messrs. C. W. Moule (Corpus) and S. H. Vines (Christ's) have been appointed members of the Botanic Garden Syndicate till November 20, 1882; Drs. Power and Phear have been appointed on the Museum and Lecture Rooms Syndicate; Mr. Henry Sedgwick and Mr. V. H. Stanton are again on the Local Examinations Syndicate; Messrs. W. D. Niven and G. H. Darwin are appointed on the Observatory Sydicate; Messrs. Bradshaw, Bensly and Peile, and Dr. Hart and Mr. Aldis Wright are on the University Press Syndicate; the two latter are special elections in view of the publication of the Revised Translation of the Bible; P. T. Main and F. M. Balfour on the State Medicine Syndicate.

Mr. S. H. Vines is also appointed on the Natural Science Studies; and Dr. Paget has been elected on the Council of the Senate, as a Professor, in Prof. Maxwell's place, for one year, and by only one vote over Prof. Stuart. Dr. Paget has on previous occasions been unwilling to come forward for such an onerous post, and would hardly now have done so, but for the short term of office required, and the importance of the medical and natural science rearrangements at Cambridge demanding his aid if the University showed its confidence in him.

An amended schedule for 2nd M.B. Camb. to come into operation in June, 1880, as far as regards comparative anatomy differs from that at present in force in introducing *excretory* and *reproductive* organs, as being required to be known in addition to the other principal systems: the tapeworms parasitic in man, cockroach, fresh-water mussel, whiting, and rabbit are introduced, while the spider and the cockchafer, oyster, perch, and rat disappear. In the specification as to the vertebrate skeleton, the cod displaces the perch, the dog replaces the rat. These changes all seem to be in the direction of providing larger and more conspicuous and accessible specimens to be studied, or those more necessary for a medical student.

SCIENTIFIC SERIALS

Journal of Botany, September, October, and November.—The last three numbers of this journal are mainly occupied with articles on descriptive and systematic botany, extracts, and reviews, with the exception of two, to which special attention may be called.—In the September number Mr. S. Le M. Moore has a "preliminary notice" on mimicry of seeds and fruits, and the functions of seminal appendages. He points out the number of seeds or fruits that bear a striking resemblance to coleopterous or other insects, by means of which he believes they may often escape from their seminivorous enemies by being passed over as insects, or, being picked up and thrown away by insectivorous birds, may thus become disseminated. He adduces striking instances of this mimicry in Polygalaceæ, Leguminosæ, Umbelliferæ, and especially Euphorbiaceæ, in which the carunculus of the seed closely resembles the head of the insect, and the raphal line the line between the closed clytra, the seed being often besides symmetrically striped or spotted. The main object of the fleshy carunculus has been generally assumed to be the supplying of food to the young embryo; but this, Mr. Moore believes, is not confirmed by actual experiment. It also no doubt serves to attract seminivorous birds, through whose body the seed passes to be prepared for germination.—In the November number Mr. S. H. Vines has an article on alternation of generations in Thallophytes, the main object of which, however, is to show that it does not exist, except in a very few cases. This is indeed in accordance with the general view of botanists. Mr. Vines still holds to his view that alternation of generations occurs in Characeæ; though why he now returns to the very doubtful position which he had previously abandoned, that the Characeæ are Thallophytes, is not explained.

Nuovo Giornale Botanico Italiano, October.—Sig. Borzì continues his series of papers on the morphology and biology of the Phycochromaceæ, the present portion being devoted to the structure and classification of the Scytonemaceæ, which he makes to consist of seven genera, viz., Coleodesmium, Bzi.; Tolypothrix, Ktz.; Hilsea, Kirchn.; Scytonema, Ktz.; Stigonema, Ag.; Capsosira, Ktz.; and Hapalosiphon, Näg. The various modes of increase he defines to be (1) by pseudoramuli, or portions of filaments which deviate from the ordinary direction, heterocysts being sometimes interposed between these and the filament from which they spring; (2) by spontaneous fraction of the filaments, the different portions remaining united in a bundle within a common gelatinous envelope, where they increase independently; (3) by hormogonia, or fragments which become detached from the filament, and which move slowly in the water in a rectilinear direction, light exercising no influence on the movement; (4) by spores, or isolated cells capable of resisting cold and excessive drought. In the same number A. Bertolini describes a new disease of the cherry-laurel, caused by a parasitic fungus, to which he gives the name *Oidium passerinii*, and which attacks the fruit. It makes its appearance in the form of irregular white spots, composed of filaments which invest the epicarp of the fruit, and from which rises a delicate down. The former is the mycelium of the fungus, the latter consists of the ovoid conidia arranged in moniliform filaments.

THE *Revue Internationale des Sciences* (September) contains the following among other papers:—The plant and man in their reciprocal relations, by Dr. Ernest Hallier.—On the geology of the Japanese Archipelago, by M. G. Maget.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 20.—"On Definite Integrals involving Elliptic Functions." By J. W. L. Glaisher, F.R.S.

"Values of the Theta and Zeta Functions for certain Values of the Argument." By J. W. L. Glaisher, F.R.S.

"On Certain Definite Integrals." No. 5. By W. H. L. Russell, F.R.S.

"On the Action of Nuclei in Producing the Sudden Solidification of Supersaturated Solutions of Glauber's Salt." By Charles Tomlinson, F.R.S.

"The Geometric Mean, in Vital and Social Statistics." By Francis Galton, F.R.S., and Donald McAlister, B.A., B.Sc., Fellow of St. John's College, Cambridge.

"On the Normal Paraffins. Part III." By C. Schorlemmer. F.R.S., Professor of Organic Chemistry in Owens College, Manchester.

Zoological Society, November 18.—Prof. Flower, F.R.S., president, in the chair.—An extract was read from a letter addressed to the Secretary by Mr. H. O. Forbes, on the subject of the distribution of the badger-headed Mydaus in Java.—The Secretary read an extract from a letter received from Dr. A. B. Meyer, in which the habitat of *Cervus alfredi* was stated to be Samao and Leyte Islands, of the Philippine group.—Mr. Edward R. Alston exhibited some mammals collected by Mr. Wardlaw Ramsay, 67th Regiment, including examples of some species new to the faunas of Burma and Afghanistan.—Mr. Alston also exhibited one of the typical skulls of *Tapirus dowi* (Gill), which had been entrusted to him by the authorities of the U.S. National Museum. He remarked that the young tapir from Corinto, Nicaragua, which was formerly alive in the Society's Gardens, was really an example of *T. dowi*, and not, as had been hitherto supposed, of *T. bairdi*.—Prof. Flower exhibited and made remarks upon the skull of a White Whale (*Delphinopterus leucas*), recently obtained in Sutherlandshire.—The Secretary exhibited on behalf of Mr. Rowland Ward, the head of a chamois, with two pairs of horns.—Communications were read from Mr. L. Taczanowski, C.M.Z.S., containing descriptions of a new *Synallaxis*, from Peru, which he proposed to name *Synallaxis fruticola*; and of a new *Myiarchus*, from the same country, proposed to be called *M. cephalotes*.—A third communication received from Mr. Taczanowski contained a notice of some birds of interest recently received from Turkestan.—A communication was read from Captain Shelley, containing an account of a collection of birds made in the Comoro Islands, received from Dr. Kirk, H.B.M. Consul-General at Zanzibar. The collection contained 186 specimens. A *Zosterops* which appeared to be new was named *Z. kirkii*, in acknowledgment of the assistance rendered to ornithology by Dr. Kirk.—A second paper by Captain Shelley, gave the description of two new species of African birds.—Lieut.-Col. H. H. Godwin-Austen, F.Z.S., read a description of the female of *Lophophorus sclateri*, Jerdon, from Eastern Assam.—A communication was read from Dr. Goodacre, F.Z.S., on the question of the identity of the common and Chinese geese.—A communication was read from the Rev. O. P. Cambridge, C.M.Z.S., on some new and rare spiders from New Zealand; with characters of four new genera.—A communication was read on some African species of Lepidoptera, belonging to the sub-family, Nymphalinæ, by Mr. W. L. Distant. In this paper several instances of great variation were given, and some corrections made in the nomenclature. A new genus, five new species, and the male of *Halma lucasi*, Down, were also described.—Mr. R. G. Wardlaw Ramsay read the description of a new oriole, from N. E. Borneo, which he proposed to call *Oriolus consobrinus*.

Royal Microscopical Society, November 12.—Dr. Beale, F.R.S., in the chair.—Ten new Fellows were elected and eleven proposed for election at the next meeting. Prof. Weismann and others were elected Hon. Fellows.—A paper by Mr. H. E. Forrest, on the anatomy of *Leptodora hyalina*, was read; also papers by Mr. J. Fullagar, on a supposed new species of freshwater *Freia*; by Col. Woodward, on amplifiers and the use of chloride of cadmium and glycerine as a fluid for homogeneous immersion, and by Mr. J. Mayall, jun., on his immersion stage illuminator, which was exhibited to the meeting. Among the objects exhibited were anomalous forms of *Acinetæ*, by Mr. Badcock, an improved micratome, by Mr. Ward; various algæ and infusoriæ, by Mr. Bolton, a new compressorium, by Mr. Graham, and Zeiss's travelling-microscope, by Mr. Crisp.

Anthropological Institute, November 11.—E. B. Tylor, F.R.S., president, in the chair.—The following new Members were announced:—A. Tylor, F.G.S., Baron von Hugel, Capt. R. C. Temple, and G. W. Bloxam, F.L.S.—Mr. E. W. Brabrook, secretary to the Anthropometric Committee, exhibited two albums of photographs collected by that body.—A report on the Bheel tribes of the Vindhyon Range was read by Col. Kincaird, fully describing the manners, customs, and superstitions of these little-known people, from experience derived during many years' residence amongst them. The Bheels are very dirty in their habits: their principal diseases are enlarged spleen and small-pox.—A paper was read by Mr. A. H. Keane on the relations of the Indo-Chinese and inter-oceanic races and languages, to show that Further India is occupied by two types, the fair and tbe yellow (Caucasian and Mongolian), the former speaking polysyllabic-untoned, the latter monosyllabic toned, languages; that both of these types, intermingled with the Papuan or dark races, constitute the whole of the population of Malaysia; that the Caucasian alone appears in the Eastern Pacific as the "*Sawaiori*," or "large brown Polynesian race." The absence of the monosyllabic languages from the oceanic area was accounted for, the expression "Malayo-Polynesian" shown to be misguiding, and the Malay type itself was considered to be, not fundamental, but essentially mixed—the result of fusion in the Eastern Archipelago of the fair and yellow elements.—Mr. S. E. Peal exhibited a fine collection of ethnological drawings made in Assam.

VIENNA

Imperial Academy of Sciences, October 9.—The vice-president made reference to the deaths of Dr. Fenzl, of Vienna, and Dr. v. Brandt, of St. Petersburg.—The following among other papers were read:—Earthquakes in Canea on the night of August 9-10, by Herr Miksche.—On the decline of water in springs, rivers, and streams with simultaneous rise of high-water in cultivated lands, by Herr v. Wex.—Reply to Prof. Heer (with regard to the task of phyto-palæontology), by Prof. von Ettingshausen.—Further investigation of spark-waves, by Prof. Mach and Herr Simonides.—On rational plane curves of the third and fourth order, by Herr Ameseder.—On the development of back-vessels and specially of the muscular system in Chironomus and some other insects, by Herr Jaworowski.—Determination of altitude of the pole at the Observatory of the Technical High School in Vienna, by Dr. Tinter.—Studies on a plane conic section of rotation, whose parameters are of the same size, by Herr Rotter.—Discovery of two comets by Herr Palisa and Herr Hertwig.—On combinations from animal tar. II. Non-basic constituents, by Dr. Weidel and Herr Ciamician.—On the phenomena in Geissler tubes under external action (first part), by Prof. Reitlinger and Urbanitzky.—On a species of configurations in the plane and in space, by Herr Kantor.

Paris

Academy of Sciences, November 17.—M. Daubrée in the chair.—The following papers were read:—Meridian observations of small planets at the Greenwich and Paris Observatories during the third quarter of 1879; communicated by M. Mouchez.—On the temperature of decomposition of vapours, by M. Sainte-Claire Deville. He supports M. Berthelot's views in opposition to M. Wurtz. The quantity of heat liberated by formation of a compound substance has no known relation with its temperature of decomposition.—Observations on M. Cochin's note on alcoholic fermentation, by M. Berthelot.—Observation of the ultra-violet limit of the solar spectrum at different altitudes, by M. Cornu. Fifty-two *clichés* were obtained at three stations: Riffelberg (2,570 m. alt.), Rigi (1,650 m.), and Viège (660 m.) The extreme ultra-violet limits were, severally, λ 293·2, 294·8, and 295·4; the difference between Riffel and Viège (1,910 m.) being thus only 2·2 units (or millionths of a millimetre), or about 1 unit for 900 metres' altitude, a small amount of variation.—Explosion of carbonic acid in a coal-mine, by M. Delesse. This occurred in a coal-pit at Rocheville (Gard), where there is much carbonic acid (no fire-damp). Two men at 345 m. depth heard two successive detonations (without flame), had their lamps blown out, became faint, and were just able to throw themselves into the cage, when they were pulled up. Three others, at 246 m. depth, perished. It is the first time the CO_2 has been so compressed and condensed in the coal as to cause explosion. Some seventy-six tons of coal were disengaged; and the CO_2 liberated is estimated at a maximum of 4,546 cubic metres. It is thought that a new stratified mass of iron pyrites being very strongly oxidised and decomposed, the resulting sulphuric acid dissolving in subterranean water reaches the triassic limestone, and so produces CO_2, which diffuses through the fissures of the coal. M. Dumas supported this view.—Second note on the effects and mode of action of antiseptics; effects on pus, by MM. Gosselin and Bergeron. Rightly used camphorised brandy, carbolic acid ($\frac{1}{50}$) and alcohol at 86° are, in the same degree, moderators of inflammation and preventives of septicæmia.—Climatological conditions of the years 1869-1879 in Normandy, and their influence on ripening of the crops (continued), by M. Mangon. In the north-west of La Manche, the low temperature of the end of 1878, of the first six months, and especially of July, 1879, and the abnormal rains of February and June, retarded the harvest about twenty-two days for corn, twenty for barley and beans, and ten to twelve for buckwheat. By noting the sum of degrees of temperature in each year since sowing, we may, with aid of the tables here given, calculate very exactly a month or six weeks in advance the time of harvest for the crops named.—On the true number of fundamental co-variants of a system of two cubics, by Prof. Sylvester.—Critical reflections on the experiments concerning human heat, by M. Hirn.—M. de Lesseps presented communications relating to a railway from Algeria to Senegal and Soudan, Belgian expeditions in Central Africa, and the public laws applicable to international rivers.—Atmospheric polarisation and the influence of terrestrial magnetism on the atmosphere, by M. Becquerel. He proves that a variable divergence exists between the plane of the sun (meaning thereby a plane passing through the observer's eye, the point looked at, and the centre of the sun) and the plane of polarisation of the atmosphere at any point, and thinks the influence of the earth's magnetism appears in rotating the plane of polarisation.—On a class of functions analogous to the Eulerian functions studied by M. Heine, by M. Appell.—New principle of meteorology furnished by an examination of earthquakes, by M. Delauney. Earthquakes seem to pass through a maximum when Jupiter and Saturn are about the mean longitudes of 265° and 135°. A recrudescence of earthquakes in winter the author attributes to streams of cosmic meteors, and the influence of Jupiter and Saturn in the positions stated to their passage through such streams.—Remarks on M. Boiteau's paper about winter eggs of phylloxera in surface-layers of the ground, by M. Balbiani.—On the causes of reinvasion of phylloxerised vineyards, by M. de Lafitte.—A telegram from General Ibanez announced completion of the geodetic connection of Spain with Algeria (November 16).—Observations of a satellite of Mars (Deimos) at Paris Observatory, by M. Bigourdan.—On doubly-periodic functions with singular essential points, by M. Picard.—Spots and protuberances observed with a spectroscope of great dispersion, by M. Thollon. The displacements and alterations of lines in observations of spots are specially striking. They are always in the same direction, and seem to indicate a motion from periphery to centre. A brilliant protuberance observed with narrow slit, illuminated vividly portions of the line C, which presented numerous solutions of continuity. The prodigious velocity of 25 km. per second indicated by the line, and lasting some time, suggests doubt as to the reality of the supposed cause.—The problem of the Euripus, by M. Forel. He traces the action of seiches as well as of soli-lunar tides in the currents of these straits.—On chlorophyll, by M. Gautier. He describes how he obtained chlorophyll pure and crystallised in 1877. He regards it as closely related to bilirubin, in aptitudes, reactions, and elementary constitution, and consequently to hematine.—Viviparity of *Helix studeriana* (Ferussac), by M. Vignier.—On the relative distribution of mean temperatures and pressures in January and July, by M. Teisserenc de Bort.—M. Le Bon gave some results of measurement of crania of eminent men in the Museum of Natural History. The high average figure of 1,732 cc. (capacity) was got from twenty-six skulls.—M. De Coiney described a meteor observed by day at Jevah (Dordogne).

THURSDAY, DECEMBER 4, 1879

YALE COLLEGE AND AMERICAN PALÆONTOLOGY

ALTHOUGH notices have from time to time appeared in European scientific journals of the scientific expeditions sent out from Yale College to the Western Territories of the United States, probably only those palæontologists and geologists who have crossed the Atlantic and have had an opportunity of seeing all that is yet visible of the vast amount of material collected at New Haven can adequately realise the enormous additions which have been and are being there daily made to our knowledge of extinct vertebrate life. Thanks to the generous liberality of the late Mr. George Peabody, who has endowed centres of scientific progress in various parts of America, Yale College has been supplied with an admirable Museum of Natural History and with a fund for its maintenance. By his deed of gift the donor provided that after one portion of the money had been employed in erecting the museum, a certain sum ($20,000) should be set apart and invested until it should reach at least five times its original amount, when it might be employed for further building; while the interest of a further sum of $30,000 should be devoted to the maintenance and extension of the collections, in the proportion of three-sevenths to zoology, three-sevenths to geology, and one-seventh to mineralogy.

The wise intentions of the founder have been most faithfully and successfully carried out by his trustees. The building now erected, though forming only one wing of the magnificent pile which they will ultimately complete, is already amply filled with the collections of the several departments. The rooms open to the public are well-lighted, and the cases are carefully arranged and easy of consultation. But by far the larger part of the collections is still stored in the cellars, awaiting the growth of the premises. Unfortunately, however, the boxes are accumulating in these lower regions at a rate which one fears must be greater than that of the building fund.

The mineralogical cabinet has been entirely rearranged and displayed by Mr. E. S. Dana, who, with Prof. Brush, is amply sustaining the old mineralogical renown of New Haven.

The unique feature, however, in the Peabody Museum, is the vast collection of vertebrate fossils from the Western Territories, made by the enthusiastic labours of Prof. O. C. Marsh. Only a small portion of this enormous series has yet been placed in cases for public inspection. But the Professor, with infinite courtesy and patience, conducted the writer of these lines through the stores from cellar to roof, brought under his notice examples of the more interesting and important of the "finds," and furnished him with notes of the collection and permission to use them, of which he now gladly avails himself.

After having spent several years in bringing together, from the Cretaceous and Tertiary strata of the Atlantic coast, a very considerable mass of material, the Professor came to the conclusion that this field was essentially exhausted, and that it was to the unexplored territory beyond the Missouri River, that the palæontologist must now look for additional facts to help him to an intelligent comprehension of the progress of vertebrate life in the past. This conclusion having been confirmed by his own observations during a short trip to the Rocky Mountains in 1868, he, in 1870, organised the first of the Yale Scientific Expeditions. After spending five months in the field the party returned well laden with fossil treasures from the Cretaceous and Tertiary formations. The success of this experiment having been so marked the four succeeding years witnessed the departure of as many expeditions, all of which were likewise successful. The results may be briefly summed up in the statement that, altogether, within six years, these expeditions under Prof. Marsh brought to light more than four hundred species of vertebrate fossils new to science, of which only about two-thirds have as yet been described. At the time when these explorations began, the West was almost wholly unknown, and the investigators were exposed to great hardships and to no little danger from hostile Indians. It is to be hoped that Prof. Marsh may be induced to write down and publish a narrative of his life and adventures in the wild west in search of fossils. The samples which in friendly talk he communicated to the present writer were so entertaining, that the book could not fail to prove most interesting, and would no doubt help on the cause of palæontology in America.

Among the numerous extinct animals discovered during the progress of these explorations are many groups which differ widely from any forms of life previously known. Prominent among these, and extremely interesting from their bearing on questions of evolution, are the toothed birds of the Cretaceous formation, the *Odontornithes*, all the known specimens of which are in the Yale Museum. These constitute a new sub-class, and have been divided into two well-marked orders: the *Odontolcæ*, which have the teeth implanted in grooves, and the *Odontolormæ*, with the teeth in distinct sockets. The *Odontolcæ* were large swimming birds, somewhat resembling the Divers of the present day, but with rudimentary wings, of no possible use to their possessor. The vertebræ were as in modern birds. The typical genus is *Hesperornis*, and at least three species are known. The second order includes small birds, very different in appearance and characters from the preceding group, with large and powerful wings, and biconcave vertebræ. Two genera and several species are known, which belong to this order. The type genus is *Ichthyornis*. All the toothed birds known at present come from the upper Cretaceous of Kansas, and more than one hundred individuals are represented in the Museum. A memoir on this group, with forty quarto plates, by Prof. Marsh, is now in the press.

In the same formation this active explorer discovered the first American Pterodactyls, or flying reptiles. These animals are extremely interesting, not only on account of their enormous size—for some of them have a spread of wings of nearly twenty-five feet—but more especially from the fact that they were destitute of teeth; in this respect resembling modern birds. They represent a new order, *Pteranodontia*, named from the type genus, *Pteranodon*, of which several species are now known. Numerous anatomical points of much importance will, no doubt, be brought to light by a close study of this remarkable aberrant group, and the ample material now in the museum, representing more than six hundred individuals, will render their elucidation comparatively easy.

With the toothed birds and the Pterodactyls, have been found great numbers of Mosasauroids, a group of reptiles, which, during Cretaceous times, attained an enormous development both as to numbers and the variety of forms by which it was represented. Several new families, including a number of new genera and many species, here appeared, and flourished abundantly. The *Tylosauridæ* were very large, some of them being more than sixty feet in length, whle the *Edestosauridæ* were much smaller. The very abundant material secured, representing not less than twelve hundred individuals belonging to this order, has enabled Prof. Marsh to settle many doubtful points with regard to the structure of these reptiles, and to determine that they possessed hind paddles, and were covered with dermal scutes.

The Cretaceous formations of the West likewise have yielded numerous turtles and other reptiles, and many fishes, some of them of great interest, and very full series of specimens of all of these, representing not less than five thousand individuals, are at present in the Yale College Museum. The fame of these discoveries has led other explorers into the same field. A most formidable rival in enthusiasm and energy is Prof. E. D. Cope, who has filled the houses at Philadelphia with bones from the West, who has published some valuable memoirs upon them, and to whose work attention will be directed on another occasion.

Besides the discoveries made by Prof. Marsh and his parties in the Cretaceous of the West, the old Eocene lake-basins between the Rocky Mountains and the Wahsatch Range were, during the summer of 1870, explored with most interesting results, their age being then fully determined and announced. Many remarkable forms of life, most of them very different from anything previously known, have been disinterred. Of all of these, perhaps none are more extraordinary than the gigantic *Dinocerata*, a new order recently established by Prof. Marsh. These animals nearly equalled the elephant in size, but with shorter limbs. The skull was furnished with two or more pairs of horn cores, and with enormous canine tusks similar to those of the walrus, while the brain was proportionally smaller than in any other land mammal. Three genera and several species are known. These great creatures seem to have lived in considerable numbers about the borders of the old Eocene lakes, and their remains are found quite abundantly, buried in the dirt that once formed the muddy bottom. Remains of more than two hundred different individuals are now in the Peabody Museum, and a volume descriptive of them by their discoverer is now in course of preparation.

Another new order of mammals, made known by the same untiring anatomist from these same deposits, is that of the *Tillodontia*. These animals are in many respects very remarkable, and notably in presenting characters which seem to indicate affinities with several widely different groups. Thus the skull, feet, and vertebræ resemble those of some carnivores; the anterior incisors forcibly remind one of the corresponding teeth in the rodents; the lower molars are of the Paleotherium ungulate type. Two families of this order are known: the *Tillotheridæ*, in which only the incisors, and the *Stylinodontidæ*, in which all the teeth grow from persistent pulps. The largest specimens of this order were about the size of a tapir.

From these Eocene deposits, too, were obtained the first remains of fossil *Quadrumana* known from the New World. These early primates, according to their discoverer, seem to have relationships both with the lemurs of the Old World, and with the South American monkeys. Two families have been discovered: the *Lemuravidæ*, named from the principal genus, *Lemuravus*, which have forty-four teeth, and the *Limnotheridæ*, which have not more than forty. The large number of genera and species by which this group is represented in these Eocene deposits, show that, even at this early period, the American primates had reached a high degree of development, and enjoyed, up to that time at least, very favourable conditions for their existence. They are all, however, low generalised forms, the characters of their teeth and other portions of the skeleton bearing considerable resemblance to the corresponding parts in the ungulates and carnivores. Besides the groups already mentioned, the same Eocene lake-basins yielded the remains of marsupials and bats (neither of which had before been found fossil in America), together with many species of birds, serpents, lizards, and fishes.

Since the original account of American fossil horses given by Leidy, the Eocene strata of New Mexico and Wyoming have yielded two very important ungulates, which have helped to complete the history of the descent of the horse, so well worked out by Prof. Marsh. These relics carry back the ancestry of this familiar quadruped to the oldest Tertiary time. The earliest form, *Eohippus*, was about the size of a fox, had forty-four teeth, the molars having short crowns, and being quite different in form from the premolars. There were four well-developed toes, a rudiment of another on the forefoot, and three toes behind. The structure of the feet and of the teeth in *Eohippus* indicates, beyond question, that the direct ancestral line to the modern horse had already separated from the Perissodactyls. The second of these ungulates, *Orohippus*, is from the Wyoming Eocene, and is evidently next to *Eohippus*, which it now replaces in the line of descent. In size it about equalled its predecessor, but the rudimentary digit of the forefoot has disappeared, and the last premolar has gone over to the molar series. Another Eocene equine, discovered in Utah, is *Epihippus*.

The discoveries made by the Yale expeditions in the "Miocene" and Pliocene formations of the Rocky Mountains and the Pacific coast were scarcely less numerous and interesting. From these deposits were obtained the large series of specimens which served to complete the genealogical line of the horse from the four-footed Orohippus of the Eocene to the large *Equus fraternus* of the later Pliocene, which does not differ, appreciably, from the horse of to-day. From the "Lower Miocene" comes *Mesohippus*, which is about the size of a sheep, and has three usable toes of nearly equal size, and a long splint or rudiment of another, corresponding to the second digit of a five-toed foot. *Miohippus*, a somewhat later form, bears a close resemblance to *Mesohippus*, but the side toes are smaller, and the splint is very short. In *Protohippus*, from the lower Pliocene, there is a considerable increase in size, the splint has disappeared, and the two side toes have become so small that they no longer reach the ground, but are merely dew claws, like those of the deer or ox. *Pliohippus*, which is found in a still higher horizon of the Pliocene, is as large as a donkey, has lost the dew claws, but has the splints much longer than the same bones in the modern equines. Finally, at the top of the Pliocene comes a true *Equus*, which completes the line. Besides the forms mentioned, there are many intermediate ones, which show that the transition has taken place in the order indicated. Many additional characters of the skull, brain, and teeth, add weight to, and confirm, the evidence furnished by the feet.

Among the other treasures of the Museum are bones of mammals allied to the modern rhinoceros, which occur abundantly in strata, said to be of Miocene age, both in Oregon and the Rocky Mountain region. These remains furnish material for tracing the descent of these creatures from the upper Eocene to the close of the Pliocene, when they appear to have become extinct. A strange group of ungulates, found in the so-called Lower Miocene of the plains, were the huge *Brontotheridæ*, which appear to have been allied to the *Dinocerata*, and also to *Rhinoceros*. In size they equalled the *Dinocerata*, and, like them, had an elevated pair of horn cores on the maxillary bones. An immense quantity of the remains of these animals, representing several genera and over two hundred individuals, has been collected, and is now in the Museum.

Until within a year or two, no Tertiary edentates were known from America, although their remains were found in abundance in the superficial post-Tertiary deposits. Recently, however, the Museum has received, from the "Lower Miocene" of Oregon, the remains of two species belonging to this group and to the genus *Moropus*. These are of large size, and were, essentially, huge sloths. From the Pliocene deposits of Idaho and California, and from the same formations east of the Rocky Mountains, other large species have been discovered belonging to the genera *Moropus* and *Morotherium*. Many other groups of mammals, including primates, carnivores, suillines, camels, &c., have been collected in these formations, which also yield numerous birds, reptiles, and fishes.

Although observations had been made by previous investigators, on the size of the brain in Tertiary mammals, Prof. Marsh was the first to institute any systematic inquiry into the laws which governed and the causes which acted upon, brain-growth in these ancient animals. Some of his conclusions, based on specimens now in the Museum, have been already given to the world, but they may be fittingly cited here: (1) All Tertiary Mammals had small brains; (2) there was a gradual increase in the size of the brain during Tertiary time; (3) this increase was mainly confined to the cerebral hemispheres, or higher portion of the brain; (4) in some groups the convolutions of the brain have gradually become more complicated; (5) in some the cerebellum and olfactory lobes have even diminished in size.

Some of the additional conclusions already reached in regard to American Tertiary mammals, so far as they are now known, are stated as follows:—(1) All the *Ungulata* from Eocene and Miocene deposits had upper and lower incisors; (2) all Eocene and Miocene mammals had separate scaphoid and lunar bones; (3) all mammals from these formations had separate metapodial bones.

Although the Cretaceous and Tertiary fossils make up a large part of the geological collections of the Peabody Museum, the other formations are well represented in its store-rooms. This is especially true of the recently discovered Jurassic beds of the Rocky Mountains, which have yielded, since the summer of 1877, a great number of interesting forms. The parties that have been collecting for Prof. Marsh have been more than usually successful, and a study of the strange animals, many of them new to science, which have been sent to the Museum, has resulted in several discoveries of great interest. These Jurassic fossils are chiefly dinosaurs, crocodiles, turtles, and fishes. The first of these are extremely abundant, and the horizon from which they come has been named by Prof. Marsh, from one of the genera there discovered, the Atlantosaurus Beds. These dinosaurs varied widely in size and structure, for while some of them, *e.g.*, *Nanosaurus*, were no larger than a cat, others were, by far, the largest land animals of which we have any knowledge. Among the discovered remains of *Atlantosaurus immanis* is a femur over six feet in length. A comparison of this specimen with the same bone in living reptiles indicates that *Atlantosaurus*, if similar in proportions to the crocodiles, would have been more than one hundred feet in length. The anatomical points cleared up by the discovery of the bones of the feet in these dinosaurs are of great importance and interest. From these same Atlantosaurus Beds come the strange *Stegosauria*, recently described by Prof. Marsh; a new order of reptiles whose affinities are, as yet, but imperfectly understood, but which appear to have most relationship with the dinosaurs. The Atlantosaurus Beds have furnished, moreover, the only Jurassic mammals yet found in America. These remains, apparently all marsupial, belong, so far as known, to four genera and eight species, which Prof. Marsh has described. He has also recently made known, from the marine Jurassic beds of the Rocky Mountains, a peculiar group of reptiles (*Sauranodontidæ*) allied to *Ichthyosaurus*, but without teeth.

An enumeration of the fossil treasures of New Haven would, however, fail to do justice to this marvellous collection if it made no mention of the almost incredible state of preservation of the fossils. A European student is lucky if he finds a tooth or a jaw; most fortunate should he stumble upon a cranium; the envy of the whole tribe of collectors should he disinter a whole skeleton. But even when most successful he meets with the bones often in a fragmentary, or badly preserved condition, or imbedded in so tough a matrix that they cannot be adequately cleared for study without almost certain detriment. The vast regions open to American research in the West, however, are the very paradise of palæontologists. Almost as fresh as if the animals had only recently died, the bones protrude sometimes in great numbers from the edges of the escarpments. When the first explorers went into these tracts they found the skulls grinning at them from the faces of the bare dry verdureless cliffs of the "bad lands." The diligence of Professors Marsh, Cope, and their parties has no doubt cleared away a good many of the prominent objects. But the number still to be exhumed must be enormous.

Entire skeletons with almost every bone in place show how tranquilly and thoroughly the remains of the early Tertiary vertebrates were entombed in the mud of the lakes on whose shores and waters they lived.

CHRONOLOGICAL HISTORY OF PLANTS

Chronological History of Plants: Man's Record of his own Existence illustrated through their Names, Uses, and Companionship. By Charles Pickering, M.D. (Boston: Little, Brown, and Co.; London: Trübner and Co., 1879.)

THIS is an extraordinary book, difficult alike to characterise and to review. It is a monument of enormous labour and erudition, but it is not easy to discover the plan upon which it is compiled, and it certainly does not fulfil the promise of its title. A "chronological history of plants" would be an interesting and valuable work, if understood to mean a history of the ages and countries in which particular plants have been introduced from abroad, or those of home growth first adapted to the use of man. This, indeed, is the work which Dr. Pickering seems to have contemplated; it is not, however, the work which he has accomplished.

Neither the historian, the philologist, nor the botanist will be satisfied with the huge volume now presented to them. Dates are given with a show of minute accuracy which the materials for ascertaining them unfortunately do not justify. Thus, to go no further than the second page, we find the mysterious paragraph, "Second generation, September 1st, 4234, among living men." As similar entries occur on the following page, with the names of Enoch, Irad, and other descendants of Cain attached to them, I suppose the paragraph must be interpreted to mean that the second generation of living men first saw light on the 1st of September, B.C. 4234. How Dr. Pickering knew this I cannot imagine. If we turn over a few leaves we find the dates of the early Egyptian kings set down with equal minuteness, and, it must be added, with an equally small show of reason. Dr. Pickering even knows the exact dates of the antediluvian monarchs of Babylonia, though he has forgotten the right name of the town of Pantibibla, from which several of them were said to have come. His knowledge of the heroic age of Greece is equally precise. Thus he tells us that in 1290 B.C. Jasus was "succeeded by Crotopus, son of Agenor, and now ninth King of Argos;" and then follows some interesting information about the Pelasgians and their wanderings.

Dr. Pickering's philology is not less remarkable than his chronology. He shocks the Hebrew scholar by calling *tzôn* ("sheep") *tzan*, of which, by the way, he says that it was "regarded even by Dicæarchus as probably the first animal domesticated"—a statement likely to be disputed by those who have occupied themselves with the history of the domestication of animals. Under the year 1720 B.C., he remarks that "the northern language from which certain Greek words were taken probably at this time in existence"—a statement which will be new to most philologists and Greek scholars. Naturally he has never heard of the explanation of the word *foxglove*, which makes it a popular corruption of *folk's-gleed*, or "row of bells."

But it is the botanist who has most reason to complain of Dr. Pickering's work. Instead of a "chronological history of plants," he finds the names and notices of various specimens of the vegetable world catalogued in the most arbitrary way under dates which have little or no connection with the age in which they were first known or used by man. So far as the earlier half of the book is concerned, the notices might in most instances have been as well entered on another page as that on which they are actually found. Why, for instance, should the *Artemisia absinthium* or the *Iris sambucina* be described under the date 1734 B.C., and what possible connection can there be between 1203 B.C and the *Phragmites communis?* The only relation that can generally be traced between the dates and the plants recorded under them is little better than a pun. Because the almond or *luz*, which Dr. Pickering calls *lwz*, is mentioned in Genesis xxx. 37, it is recorded under the year 1506 B.C., the year in which Joseph was "born to Jacob and Rachel;" because a brick from the small pyramid of Dashur was discovered to contain the straw of the jointed charlock and field-pea, an account of these plants is given under the year 2079 B.C., the assumed date of the building of the pyramid; and the mention of "Pelasgus establishing himself as king in Arcadia" in 1354 B.C. calls up a description of the *Quercus esculus*. As a set-off against this learned trifling, a vast quantity of matter is introduced which has nothing to do with plants and their history. Thus it would be quite intelligible if the author had given a list of those Egyptian hieroglyphics which represent plants, but the long, though imperfect, catalogue of hieroglyphic characters of all kinds which he actually has given, though fitted for a treatise on Egyptian grammar, is certainly out of place in a history of the vegetable world.

There is only one explanation that can be offered for the character of this extraordinary volume. Dr. Pickering was an able and learned scholar, trained in scientific methods and capable, as is proved by his "Races of Man," of producing good scientific work. But his "Chronological History of Plants" has been published since his death, and has consequently not had the benefit of his own compilation and revision. It consists simply of the notes he collected during a long course of voluminous reading, arranged, not upon any scientific plan, but under the convenient headings of his common-place book. The student may possibly construct a chronological history of plants out of them, but such a history does not exist at present. The volume is a mine of materials which, thanks to a careful index, can be easily used, though considerable caution is required in doing so. As it stands, however, it is hardly better than a mass of undigested and ill-arranged facts, mixed up with dates and statements calculated to send a shudder through the sensitive frame of the critical historian. Posthumous works are not unfrequently the most cruel injury that can be inflicted by friends upon the memory of the dead, and it is hardly likely that Dr. Pickering would have relished the appearance of his elaborate notes in precisely their present form.

A. H. SAYCE

CHALLIS'S "PRACTICAL ASTRONOMY"

Lectures on Practical Astronomy and Astronomical Instruments. By the Rev. James Challis, M.A., F.R.S., &c. (Cambridge: Deighton, Bell, and Co.; London: George Bell and Sons, 1879.)

AS LONG since as the year 1843 the Plumian Professor of Astronomy and Experimental Philosophy in the University of Cambridge commenced a course of lectures upon practical astronomy and the use of astronomical instruments, the proximity of an observatory provided with instruments of first-rate quality appearing to him to give facilities for acquiring a knowledge of the practical branch of the science which ought to be taken advantage of. The syllabus of these lectures has been utilised as the groundwork of the present volume, but the progress of astronomy has necessitated the introduction of various modifications in the original plan and contents.

By far the larger portion of the volume is devoted to the description and use of instruments found in the larger fixed observatories, the illustrations being usually applicable to instruments in the Cambridge Observatory, and the work being therefore more especially adapted to the use of students in that university, who have frequent access to the observatory. Notwithstanding this circumstance, however, the treatise will be found to convey much information on practical matters and details, which is not of so limited an application.

The fixed instruments which are treated of at length are the transit instrument, the mural-circle, the transit-circle, incorporating in its employment the purposes of the two former instruments and the equatorial. The transit-circle may now be said to have wholly superseded the mural-circle and transit-instrument in most of the principal observatories, but the explanations of them given by Prof. Challis being applicable to the reduction of meridional observations generally, are also applicable in great measure to the transit-circle. The latest observations with a mural-circle which we remember to have seen were made at the Naval Observatory, Washington, and the instrument still figures in the last description of that establishment. Prof. Challis enters fully into such details as the mechanical adjustments of a transit instrument and the correction of errors by calculation, the construction and application of the collimating eye-piece, the azimuth-error obtained by astronomical observations, and correction for error of level, also upon a method of correcting the errors of a transit-instrument for deviation of the pivots from a cylindrical form, a defect which, if we are not mistaken, considerably exercised not only Prof. Challis, but his successor Prof. Adams, as exemplified in the Cambridge instrument. The computation of apparent and mean right ascensions follows, with reference to recent corrections of the more important astronomical constants entering into such work. Similarly the author describes the method of observing with the mural-circle, and the calculation of the mean polar distances of stars and the geocentric polar distances of the sun, moon, and planets with numerical examples. The equatorials of the Cambridge Observatory and their appliances are particularly described, and the adjustments of this form of astronomical instrument and the method of deducing the right ascension and polar distance of a celestial object from the observations. Reference is also made to the "counterpoise mounting" of an equatorial, and the arrangements, advantages, and disadvantages of this form of mounting.

Other fixed instruments of which some account is given are the altitude and azimuth instrument, with special reference to that at the Royal Observatory, Greenwich, the zenith sector, Airy's reflex zenith tube, and the transit in the prime vertical. There are also articles upon transportable instruments, as the theodolite and sextant, on the chronographical method of registering transit-observations, the different methods of determining terrestrial longitudes, the solar parallax, and miscellaneous additional subjects of less importance.

The volume, as we have already stated, and, indeed, as is hinted by Prof. Challis, may appear to be more especially adapted to students in the university who desire an acquaintance with the principles of astronomical practice, and in his preface the author urges the advantages of giving attention to a subject of this kind, "as a mental exercise of much educational value, inasmuch as it is altogether unlike any process of reasoning by abstract symbols, and may serve as a corrective to the effect of too exclusive an attention to reasoning of that kind." But there are few works of its nature in English astronomical literature, a circumstance which is likely to secure for it a wider circle of readers.

The volume has been published at the expense of the Syndics of the University Press.

OUR BOOK SHELF

The Carboniferous Limestone and Cefn-y-Fedw Sandstone of the Country between Llanymynech and Minera, North Wales. By George H. Morton, F.G.S., F.R.G.S.I., Honorary Secretary of the Liverpool Geological Society. (London: David Bogue, 1879.)

IN this excellent monograph, which is now reprinted from the *Proceedings* of the Geological Society of Liverpool, Mr. Morton has brought together a vast amount of valuable information concerning the lower carboniferous rocks, as displayed in a district where they have been but little studied. The splendid escarpment of the Eglwyseg rocks, near Llangollen affords a series of magnificent sections, the interpretation of which, however, requires considerable patience, care, and caution on the part of the field geologist. Mr. Morton shows that the succession of the lower carboniferous rocks in North Wales presents marked points of difference from that which is observed either in Yorkshire or Derbyshire. He divides these lower carboniferous rocks into two groups—the carboniferous limestone below and the Cefn-y-Fedw sandstone above; and in the correlation of these he adopts the views originally put forward by Prof. A. H. Green, and since supported by Mr. D. C. Davies, namely, that the conglomerate and sandstone strata overlying the carboniferous limestone represent not only the millstone grit, but also the Yoredale rocks of Prof. Phillips and the Geological Survey.

Mr. Morton shows that the carboniferous limestone of this district attains a thickness of 1,200 feet, and he gives detailed descriptions of the several members of which it is made up, with lists of the fossils obtained from each. The overlying arenaceous formation is 723 feet thick, and consists of alternations of sandstone conglomerate and shale; these beds contain marine shells, with some plant-remains. The sections which are given in this monograph enable us to trace the numerous and rapid changes which these carboniferous strata undergo within comparatively limited areas. The manner in which the several members of the series overlap one another, as has already been pointed out by Mr. Davies, is also admirably illustrated in this work of Mr. Morton's.

Perhaps no part of this excellent memoir will prove of more general interest to geologists than Mr. Morton's account of the numerous faults which traverse the district; the positions and effects of these being illustrated by a map and several sections. The isolated patch of carboniferous rocks faulted down among the Silurian strata near Corwen is also more fully described than by any previous author. Besides the numerous woodcuts and lithographic plates, the work is illustrated by three admirable photographs by Mr. W. H. Wilson. We heartily recommend this exhaustive monograph to the attention of our readers, as a model of the kind of work which may be advantageously undertaken by the members of local scientific associations. J. W. J.

Magnetism. The High School Series. (London: T. Murby, 1879.)

THE anonymous author of this little work of sixty-eight pages has produced a very readable and in many ways admirable primer of Magnetism for boys and girls. Clearly written, well illustrated, and dealing with such matters of experiment as boys and girls can verify for themselves, it will be sure to command popularity. The experiment on p. 22, which suggests the form of the curve of magnetic intensity along a bar-magnet by the length of the chain of nails which can be hung on at equidistant points, thus building up visible ordinates on the abscissæ is new to us, and as neat as novel. One cannot help wondering, however, why the author has assumed that "high-school" pupils must have mathematics and even arithmetic kept almost entirely out of sight. Why the separate chapters are entitled as "Lectures" is not very evident. The "Lecture," for example, on "Diamagnetism"—the ninth of the ten—is just thirty-seven lines long, and takes just two minutes to read aloud!

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

To Astronomers

I HAVE the honour to inclose to you a copy of a circular which I have lately sent out from my observatory to upwards of 200 observatories, public and private, scattered over the face of the globe. I have long felt that it was highly desirable that some means should be found whereby the discoveries in astronomy should be made public in a rapid and systematic manner, more especially in this country, where I am proud to say we number so many among all classes who take an intelligent and earnest interest in this the highest of the studies of nature. After much thought as to the best means of carrying out the plan, I determined, it may be presumptuously, to endeavour to do the work myself, and to that end I issued the circular to all directors of observatories whose addresses I could lay my hands upon. Should I have the fortune to receive favourable replies from abroad, I hope to make the matter successful. Now as to the distribution of the news in the British Islands: I am making a list of those who apply to me for the circulars and I will endeavour to post these within 24 hours of receiving the notice myself. I have made arrangements with the telegraph officials, that any telegram addressed (as below) shall be sent out at whatever hour it may arrive: I have further set up a small printing press in my observatory from which to pull the circulars, as I feel sure that this is the most convenient method and the least liable to error.

In conclusion I may add that should any devise a better means for doing this work, I will at once place my experience at their disposal and do all I can to assist them. LINDSAY

Haigh Hall, Wigan,
November 29

"The Observatory, Dun Echt, Aberdeen,
"November 1, 1879.

"SIR,—I am very anxious to form some system whereby information of astronomical interest may be rapidly and widely disseminated among English observers; and I would beg to ask for your assistance in carrying out my plan.

"In the event of your discovering a comet, new star, or other object of immediate interest, I would ask you to send me a telegram announcing the discovery and giving such details as are usual.

"I have purposely omitted to mention minor planet discoveries, inasmuch as this branch is already admirably carried out by the Berlin Observatory.

"For convenience, the telegram should be in the form recommended by the Vienna Academy in the 75th vol. of the *Astr. Nachr.*, No. 1785, page 142, as follows:—'Comet (new star, &c.,) Discoverer, Date, Local Mean Time of Observation (in hours and minutes), Place of Discovery, Right Ascension *in Arc* (degrees and minutes), North Polar Distance (degrees and minutes), Daily Motion in R.A. and N.P.D. (minutes of arc) plus or minus, Description, Diameter of Comet, &c. (in minutes of arc).

"Thus a telegram would run:—

"'Comet Winnecke 5 April. 1445 Strassburg 33157 07508 Motion 0 minus 60.'

"This would read:—

"'Comet discovered by Winnecke, 5th of April, 14 hours 45 minutes Mean Time Strassburg, R.A. 331° 57′, N.P.D. 75° 8′. Daily Motion, stationary R.A., minus 60′ in Polar Distance.'

"Noughts should be put in where are no significant figures, so as to make three figures for degrees, and two for minutes (five in all), in R.A. and in N.P.D., similarly four in the Local Time.

"Telegrams, &c., should be addressed—

"'*Observatory, Dun Echt, Aberdeen.*'

"I will engage to distribute the notices of discovery within 24 hours of receiving the telegram, by means of a circular, sent out by first post from my Observatory, to all those who would be likely to make useful observations, and who will also favour me with their addresses.

"At present, it is only by accident that private observers hear of the discovery of Comets, &c., and it is obviously greatly to the advantage of astronomy that early and reliable information should be spread over the British Islands, without having to wait for its publication in some of our scientific journals.

"I should feel much gratified if I may feel assured of your valuable co-operation in this matter.

"Believe me, yours very faithfully,
"LINDSAY,
"Pres. Roy. Ast. Soc."

The Cresswell Cave Exploration, 1876

IT seems to me proper to notice the statements made by Mr. Heath in a pamphlet on the bone-caves of the Cresswell Crags, published in August last, and since more broadly put in the Manchester press, calling in question the results of the exploration carried on by the Committee in 1876.[1]

It is insinuated that the engraved bone now in the British Museum, discovered by the Rev. J. M. Mello, and the tooth of Machairodus, discovered by myself, are not *bonâ fide* discoveries in the caves of the Cresswell Crags, but were placed there by some one, not specified, and were derived from some other locality, which also is not specified. With regard to the engraved bone, it is only necessary to say that Mr. Heath was not in the Robin Hood Cave when Mr. Mello's discovery was made, while

[1] Committee:—President: Sir John Lubbock, Bart., F.R.S., M.P. Secretary: Prof. Boyd Dawkins, M.A., F.R.S. Treasurer: Fredk. Longden, Esq. Members: Prof. Busk, F.R.S.; Prof. Prestwich, F.R.S.; John Evans, Esq., F.R.S.; A. W. Franks, Esq., F.R.S.; the Rev. J. Magens Mello, M.A., F.G.S.; Rooke Pennington, Esq., LL.B., F.G.S; William Bragge, Esq., F.G.S.; R. D. Darbishire, Esq., B.A., F.G.S. The work is under the direction of the Rev. J. M. Mello, Prof. Boyd Dawkins and Mr. Heath, F.R.H.S, being superintendents. The Report will be prepared for the Geological Society of London by the Rev. J. M. Mello and Prof. Boyd Dawkins.

it so happens that I was present, and can testify to the accuracy of Mr. Mello's statement. With regard to the tooth of Machairodus, which I discovered and afterwards showed to Mr. Heath, it is asserted that it was without adherent matrix, and without the moisture which it would possess had it been imbedded in the cave for ages. These assertions are disproved by the facts that the tooth unfortunately split in pieces in process of drying, and that the matrix of red earth, only partially removed when it was repaired and gelatinised in the Owens College Museum, is still to be seen in the pulp cavity.

In the exploration of the caves, in 1876, the discoverer, Mr. Mello, was director, while I undertook to name and classify the remains, and we drew up a report published in the *Quart. Geol. Soc. Journ.*, 1877, p. 475. Mr. Heath and myself acted as superintendents of the work, under the direction of Mr. Mello.

It was Mr. Heath's duty as superintendent to hand over to the director the notes on which the above assertions are based, as well as any other notes relating to the work entrusted to him. He did not do so. If he had any fault to find, it was his duty to lay it before the committee, and in the interest of truth to make his statement when the report was read at the meeting of the Geological Society, at which he was present. He did neither of these things. Nor when he had many opportunities of saying what he liked at the meeting of the British Association at Sheffield, after my paper before the Geological Section, and our addresses at Cresswell, did he say one word, although he was present at both. The pamphlet in question was to us the first intimation that he differed with us as to the facts.

In conclusion it only remains for me to add that Mr. Heath was *not* a member of the Exploration Committee, that he was merely a subordinate to Mr. Mello, and that, on his own showing, he kept back for nearly three years notes considered by him to be valuable, which he was in honour bound to communicate at once to the director for the information of the committee—notes which were as much the property of the committee as the fossil remains discovered in the caves at their expense. I am instructed that the only notes which he gave to the director were certain measurements of the inside of the Robin Hood Cave, which it was found necessary to have done over again.

W. BOYD DAWKINS,

"The Society for the Encouragement of Literature and Science"

THE attention of the Council of the Geological Society has been called to the prospectus of a "Society for the Encouragement of Literature and Science," in which the letters "F.G.S." are appended to the name of one of the vice-presidents and to that of the "Secretary-in-Chief." I have been directed by the Council to make it generally known that neither of these gentlemen is a Fellow of the Geological Society, as would naturally be inferred from their use of these letters, and I shall feel greatly obliged by your insertion of this note in your columns.

Geological Society, Burlington House, November 27 — W. S. DALLAS, Assist. Sec. Geol. Soc.

THE attention of the Council of the Linnean Society of London has been called to a paper or prospectus of a "Society for the Encouragement of Literature and Science," whereof W. Sarjeant-Rodway is stated to be "Secretary-in-Chief," and wherein the names Lewis Biden, A. Ware, and Joseph Blackburn Leslie each appear followed by the letters F.L.S., which letters are those appointed to indicate "Fellow of the Linnean Society"—a chartered society. Its attention has also been called to another paper apparently put forth by a "Conchological Society of London," wherein the name W. Serjeant-Rodway appears as "Secretary and Founder," with the addition of the letters F.L.S. (Lond.).

As no one of these four gentlemen is a Fellow of the Linnean Society, the Council of the same Society has requested me to make the fact known, and I shall therefore be much obliged if you will be so kind as to give insertion to this letter in NATURE.

Linnean Society, Burlington House, Piccadilly, W., November 27 — ST. GEORGE MIVART, Zool. Sec. Lin. Soc.

Does Sargassum Vegetate in the Open Sea?

IF the correspondent in NATURE, vol. xxi. p. 80, under the above title, would again refer to my communication in vol. xx. p. 578, which I much regret he finds so unsatisfactory, he will see that the several statements and quotations it contains are exclusively based upon "personal" observations made by myself and by the naturalists on board the *Challenger* during our cruise in the North Atlantic in the year 1873. In replying to his inquiries in vol. xx. p. 552, I was only anxious to supply him with what I considered to be the latest and the most reliable information available on the subject, and which hardly deserves to be qualified as "old reports" and as "a mixture of the prevalent opinion since Columbus and observed facts."

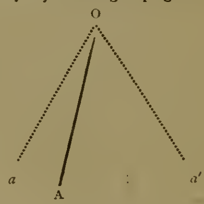
The term *Sargasso Sea* has been extended by geographers, and not incorrectly so, to all oceanic areas where large aggregations of sea-weed are met with, and it does not necessarily imply the presence of Sargassum, *i.e.*, *Sargassum bacciferum* in these regions, since the original Spanish word *Sargazo* (in Portuguese *Sargaço*) simply means "sea-weed." I am, therefore, not surprised that the correspondent should not have found any gulf-weed while crossing the Pacific Sargasso Sea.

Nor can the obscurity in which so many details connected with the gulf-weed are still involved be fairly ascribed to want of observation on the part of the few naturalists who have had the opportunity of studying this interesting alga *in situ*, that is to say, in the middle of the North Atlantic, but rather to the great difficulty, if not impossibility, of ascertaining the life-history of a specimen accidentally found floating on the surface of the ocean. For this reason I fear that some time may elapse before the numerous questions put by the correspondent in vol. xxi. pp. 80–81 can be satisfactorily answered. A botanist stationed for several seasons at Bermudas, or on one of the Bahama Islands, might probably succeed in throwing some light upon the successive stages in the growth and decay of *Sargassum bacciferum*.

J. J. WILD

The Paces of the Horse

I VENTURE to offer the following illustration of the effect produced on the eye by a horse galloping.



I take a pencil, O A, and oscillate it rapidly between the positions O *a* and O *a′*. The impression produced on my eye is an indistinct fan-shaped figure, *a* O *a′*, bounded by two rather distinct images of the pencil in its extreme positions O *a* and O *a′*. The indistinctness of the fan-shaped figure is caused by the rapid change of position of the pencil, which is reduced to a minimum at O *a* and O *a′*, where the pencil swings up to, and returns back from, its extreme positions, passing over the same ground twice in successive instants of time, and thus seeming to pause in the immediate neighbourhood of those positions. An artist representing this effect would draw the indistinct fan-shaped figure; and the two rather distinct images of the pencil at O *a* and O *a′*.

The relative motion of the legs of a horse galloping may be looked upon as that of rapidly oscillating pendulums with this very important addition; that besides their pendulum-like oscillations, they go through rapid *internal* changes of form, owing to the bending, or doubling up, of the legs at the knees, hocks, and fetlocks, at every stride. The rapidity of these internal changes is reduced to a minimum when the leg is in its extreme *outstretched* position. Again, it is in this same position that the rapidity of change of position owing to the pendulum-like oscillation is also at a minimum. The two minimums are, as it were, *coincident*, and, as a consequence, every leg as it reaches its outstretched position, seems for an instant to pause, leaving a rather distinct impression on the eye. The other legs on successively reaching their respective outstretched positions produce corresponding impressions on the eye. It is a fact that the legs do not reach these positions *simultaneously*; they reach them *successively*, but the image produced by one leg in its outstretched position has not time to be obliterated before the images of the other legs are produced in their corresponding outstretched positions. Therefore they appear to us to be all simultaneously in those outstretched positions, and it is thus that the artist should represent them. It is his duty to represent things as they *appear*, rather than as they actually *are*, at a given instant of time.

The fan-shaped form noticed in the case of the oscillating pencil becomes exceedingly indistinct, if it does not disappear altogether, in the case of the galloping horse's legs. This is owing to the rapid internal changes of form of the legs.

Your correspondent, Sir W. G. Simpson, Bart., states in his excellent letter produced in NATURE, vol. xxi. p. 55, that a galloping horse might be represented with all its legs gathered under it. I venture to disagree with him for this reason: the two "minimums" to which I have referred in a former part of this letter are *not* coincident when the legs are in their extreme position gathered under the body, and therefore no such distinct image of them in that position is produced. The "minimums" are only coincident in the other extreme, viz., the outstretched, position.

The artistic representation of a horse's paces other than galloping, as also that of other objects in motion, can be determined by similar reasoning. V. B. BARRINGTON-KENNETT

15, Hyde Park Gardens, W., November 26

Force and Momentum

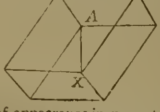
IT is commonly said that change of momentum is evidence that force has acted or is acting on the mass, and that the rate at which the momentum is changing is the measure of the force. Thus, in his lecture on "Force," Prof. Tait says: "Force is the rate of change of momentum" (NATURE, vol. xiv. p. 462). This is not true if the mass be variable. Suppose a sphere of ice moving with constant velocity in a straight line through hot space. The mass, and therefore the momentum, is changing at every instant by the evaporation of the ice. The evaporation being supposed uniform over the entire surface, any force impressed on the sphere by the mutual repulsion between it and a particle of vapour thrown off at a point, p, is balanced by an equal force at the other end of the diameter through p. Hence, the resultant of all these forces is nothing. Here, then, we have change of momentum of the sphere, although no force acts on it. In like manner the change of momentum of a rocket and of a locomotive engine is partly due to change of mass. Does it not hence appear that change of *velocity* is the proper evidence of the action of force? When a variable mass, m, is in motion, the proper measure of the force acting on m at any given instant in any given direction is—not the rate of change of momentum, but—the product of the value of the mass at that instant, and the value of the rate of change of the velocity at that instant and in that direction, *i.e.*, the measure of the force is not $\frac{d(mv)}{dt}$, but $m\frac{dv}{dt}$.

E. G.

[There is no such thing in nature as a "variable mass"; and our correspondent's difficulty arises from his omitting to take account of the momentum of each of the parts (however small) into which a mass may be divided. In most good works on dynamics he will find the motion of a rocket, or of a descending rain-drop (which gathers mass as it falls), accurately treated on the assumption that the momentum produced per unit of time is the measure of the force acting.—ED.]

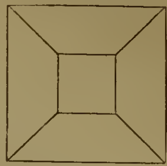
Change in Apparent Position of Geometrical Figures

THE perplexing illusion to which Mr. Bellamy refers (NATURE, vol. xx. p. 362) has long been known, and various explanations have been given of it by physicists. Sir Chas. Wheatstone, in 1838, showed clearly that it is a mental operation, while combating the idea of Prof. Necker, of Geneva, who attri-



buted the alteration of appearance in geometrical figures, not to a mental operation, but to an involuntary change in the adjustment of the eye for obtaining distinct vision. Necker's experiment is substantially the same as that described by Mr. Bellamy. The solid angles at A and X being alternately looked at, sometimes one and sometimes the other appears the nearer, the entire figure at the same time changing in unison; and as Wheatstone points out, "the change of figure frequently occurs while the eye continues to look at the same angle."

In the following experiment it is seen more clearly still that the operation is a mental one, because there is neither movement of recti, oblique, nor ciliary muscles. Two concentric squares have their corners joined by straight lines. The lesser square



will appear in a plane anterior, or posterior to the larger, according as we regard the figure as the representation of a truncated pyramid, or as the representation of a room with its sides all sloping away to the distant square wall. Here no eye muscles are concerned; the image on the retina remains unaltered, and the only operation is a mental one, a turning to the results of past experience. WM. ACKROYD

Mutual Attraction of Spectral Lines

I DO not know that it has been remarked that a line in the diffraction-spectrum (whether bright or dark) must be shifted from its normal position in case another line falls very near it. Neighbouring lines must be attracted if both are bright or both dark, and repelled if one is bright and the other dark. The reason is that the lines are only maxima or minima of light, and the differential coefficient of the sum does not vanish at the same points as the differential coefficients of the separate terms. The shifting will be the greatest in the case of a faint line near a very intense one. I have succeeded in this way in shifting the positions of lines by measurable amounts (1″ to 2″).

Baltimore, Md., November 14 C. S. PEIRCE

EXPLORATION OF TIMOR

IT will be perhaps of some interest to the readers of NATURE to hear that Mr. Riedel, the Dutch resident on Timor (Timor Kupang), who formerly lived on Celebes, and collected a great deal on this island for European museums, and who is known by his various writings on different scientific questions concerning the East, has just returned from a twenty-five days' journey through Central Timor from 123° 30′—125° E.L., as he wrote to me in a letter dated October 6. No European has made such a journey through Timor before, and it has been very troublesome. But the country is, Mr. Riedel remarks, a splendid one, and very suitable for coffee and cinchona cultivation. The traveller did not see any Negritos, who, according to the assertion of M. Hamy, live in the interior of Timor, nor did he hear anything of a Casuary which was reported from there recently. Mr. Riedel collected many geographical notes, and sketched a map of the parts which he visited. A small collection of plants was forwarded to me by Mr. Riedel, and I have sent them to Kew, as Prof. Oliver formerly had the kindness to determine several botanical collections of Mr. Riedel's from Celebes. Dresden, November 29,
Royal Zool. Museum

LAND SHELLS OF THE AUSTRAL ISLANDS

THE small island of *Rurutu* (Oheatora of Capt. Cook) is about 320 miles south-south-west of Tahiti; it is eight miles in length, and has an elevation of 1,500 feet, over 100 feet consisting of old coral reefs which have been upheaved to that altitude. Mr. Charles de Gage, a resident and experienced naturalist, has collected a number of land-shells, which have been studied by Mr. Andrew Garrett, and described in the *Proc.* Acad. Nat. Sci. Philadelphia. One of the most interesting species is *Partula hyalina* (Broderip), found abundantly in three groups of islands. In Tubuai, 100 miles east of Rurutu, it is abundant, and the Austral group appears to be its metropolis. It is found, though sparingly, in nearly every valley in Tahiti. It was also obtained by Mr. Garrett at Mangaia, one of the Cook's, or Hervey Islands, 400 miles *west* of Rurutu. The variation in examples from the three groups is remarkably slight. It is a strictly arboreal species, and has a uniform white colour.

Another species, *Stenogyra juncea*, Gould (sp.), is found very widely through Polynesia, in all groups north of the equator, and south of all islands from the Marquesas and Paumotus, to the Viti group, and probably ranging further west; they are found under loose stones, beneath decayed wood, among dead leaves, &c., and range from near the sea-shore to 2,000 feet above the sea. Another well-known genus, *Succinea*, is now recorded from Rurutu, slightly differing from a Tahitian species, *S. pudorina* (Gould).

Chondrella (Pease) is remarkable for having no tentacles; during locomotion the animal is nearly or quite concealed by the shell, which is carried diagonally. In creeping, only the extreme tip of the muzzle is seen from above, while the eyes are plainly visible through the transparent shell. The extreme interest of the fauna of oceanic islands becomes continually more evident.

DISTINGUISHING LIGHTS FOR LIGHT-HOUSES

SIR WILLIAM THOMSON writes a long letter on this subject to the *Times* of Tuesday, the letter being the result of a most interesting experimental cruise of ten days on board Her Majesty's ship *Northampton*, in the English Channel, from which he has recently returned, having had many good opportunities of observing the lights on the south coast of England. This has revivified his conviction of need for a threefold reform in our lighthouse system, which he has been urging and re-urging since 1872 with hitherto but partial success:—A great quickening of nearly all revolving lights; the application of a group of dot-dash eclipses to every fixed light; and the abolition of colour as a distinction of lighthouse lights, except for showing dangers and channels and ports by red and white and green sectors. Of about 120 revolving lights on the English, Scottish, and Irish coasts, there are in all eighteen in which the periods are ten seconds or less and the times of extinction seven seconds or less. In these quick revolving lights the place of the light is not practically lost in the short intervals of darkness; the eye sweeping deliberately along the horizon, with or without the aid of a binocular, to "pick up the light," passes over less than the breadth of its own field of view in the period of the light, and thus picks it up almost as surely and quickly as if it were a fixed light. And so in respect to compass bearings, whether taken roughly and quickly by inspection or more accurately by azimuth compass, the bearing of the ten-second or quicker revolving lights is taken almost as easily and accurately as if the light were continuous. Sir William contrasts this with the case of the ordinary minute-period revolving light, or even the half-minute period to which some formerly slower lights have been quickened. He shows how difficult it is to pick up these slow lights, and his own experience proves that a fixed light like the Eddystone is much more valuable than the slowly revolving Start.

The Wolf light he found most irregular in its periods, the successive periods of light varying from nineteen to forty seconds, and of darkness from nineteen to thirty-four. These irregularities are apt to lead to most serious mistakes, as Sir William shows.

"Except in one unimportant case—the Dungeness Low Light, which flashes every five seconds—all the revolving lights of the English Channel are too slow, and it would be an unspeakable improvement if, with that exception, every one of them had its speed sextupled. There is no mechanical difficulty in the way of doing this. Generally the same mechanism would suffice with a mere change of adjustment of the governor; but the lightkeeper would have to wind up the weight oftener or longer.

"Revolving lights are, however, but a small minority of all the lighthouses of the world. Of the 623 lights of the British and Irish coasts, just 110 are revolving lights, and the remaining 513 are fixed, and there is a crying want of distinction for fixed lights. The distinction by colour alone ought to be prohibited for all lighthouse lights, on account of its liability to confusion with ships' and steamers' side-lights. Southsea Castle, with its red and green port and starboard side lights, seems as if actually planned to lure on to destruction an unsuspecting enemy carefully approaching the coast with Thomas Gray's happy rule well impressed on his mind:—

> " 'Green to green, and red to red,
> Perfect safety, go ahead.'

He does so, and is wrecked on Southsea beach.

"My proposal for supplying the want is to distinguish every fixed light by a rapid group of two or three dot-dash eclipses, the shorter, or dot, of about half a second duration, and the dash three times as long as the dot, with intervals of light of about half a second between the eclipses of the group, and of five or six seconds between the groups, so that in no case should the period be more than ten or twelve seconds. This proposal has been carried into effect with perfect success in Holywood Bank Light, Belfast Lough, now the leading light for ships entering the Lough, but which until 1874 was inclosed in a red glass lantern and was only visible five miles, and was constantly liable to be mistaken for a sailing vessel's port side light entering or leaving the harbour of Belfast, or the crowded anchorage of Whitehouse Roads. In 1874 the red glass was removed, and the light was marked by dot, dot, dash (— — ———, or letter U), repeated every ten or twelve seconds, and has been so ever since. It is now recognised with absolute certainty practically as soon as seen in ordinary weather from the mouth of the Lough, ten miles off, and has proved most serviceable as leading light for ships bound for Belfast or entering the Lough.

"It is much to be desired that the dot-dash system should be seriously considered by the lighthouse authorities of our islands. Hitherto, when attention has been called to it, it has been dismissed with a pleasantry, 'Winking lights won't do,' or else something utterly different has been gravely considered and justly condemned. It is satisfactory now to know that the Deputy-Master of the Trinity Board, Sir Richard Collinson, K.C.B., has, after its character was correctly put before him by the recent Select Committee of the House of Commons on Electric Lighting, given it his approval in the concluding answers of his evidence."

The *Times*, in commenting on Sir William Thomson's letter, speaks of the subject as one of great national importance, Sir William speaking with the twofold authority of a distinguished man of science and of a practical yachtsman. The *Times* endorses emphatically all Sir William's recommendations, and insists especially on doing away with colour as a distinctive feature of lights.

"If," the *Times* concludes, "the recommendations of Sir William Thomson should eventually lead to a reform of this importance and magnitude, he will be a benefactor to humanity; but even without this his advice cannot fail to commend itself to navigators. It bears one of the most distinctive marks of genius—simplicity; and now that it has been brought fairly under the notice of the public, we may confidently hope that in the future, whatever may have been the case in the past, it will not have to contend against that love for 'the thing which has been' which in all periods of history has afforded a distinguishing characteristic of the average official intelligence. In a nation of sailors and yachtsmen a suggestion for the improvement of lighthouses and for the greater safety of shipping ought to be certain of speedy and complete consideration upon its merits alone."

THE TURKOMANS

AT the meeting of the Anthropological Institute on November 23, there was read a short but suggestive paper on these wayward children of the desert, contributed by Prof. Arminius Vambéry. The learned writer, who has perhaps as great a personal knowledge of Eastern nations as any man living, regarded the Turkomans as on the whole the purest and most representative branch of the widespread Tûrki family and described their outward features as quite distinct from the Mongolian. His account was somewhat vague, but the inference evidently was that they belonged in his opinion ethnically to the Caucasian rather than to the Mongolian group. Nor did he attribute this to the gradual absorption of Iranian elements, but, on the contrary, stated that intermarriages with Persian women were much less frequent than is usually supposed, and that the Turkomans are now what they always have been, men of medium stature, like the Kirghizes and unlike the Usbegs and Osmanlis, amongst whom tall individuals are far from rare, with straight or but very slightly oblique ("almond-shaped") eyes, handsome regular features and fair complexion. He further stated that the Turkoman language was also one of the very purest Tûrki tongues still spoken, so much so, that an ordinary Seljukian Turk of Asia Minor would have less difficulty in conversing with a Tekke or Yomut Turkoman than with his nearer neighbours the Turki nomads of Azarbijan and other parts of Persia. In fact, such is the purity of their speech, that the Rev. James Bassett, of the American Mission at Tehrân, is now putting through the press in London his translation of St. Matthew's Gospel in the Jagatai Tûrki for the special use of the Tekke Turkomans. Jagatai, it need scarcely be remarked, is one of the most cultivated of all the Tartar tongues and is still current in Bokhara, Khiva, Ferghana, and parts of Kashgaria. In it are written the Emperor Baber's memoirs, and being less affected by Arabic and Persian elements than the Osmanli of Constantinople, it may be taken as, on the whole, the most representative of Tûrki idioms. On the other hand, the Tûrki belongs undoubtedly to the same great linguistic connection as the Mongolian, both being recognised by modern philologists as collateral, though independent, members of the so-called Finno-Tataric or Ural-Altaic family of languages. Hence Vambéry's description of the physical characteristics of the Turkoman race places them in a sufficiently anomalous position from the anthropological point of view, in so far as they would seem to belong ethnically to the Caucasian, but linguistically to the Mongol stock. Such anomalies are, no doubt, common enough, and instances abound of peoples having changed their language and adopted that of the races by whom they may have been subdued or otherwise influenced. But in the present case the difficulty cannot be got over in this way, nor is it pretended that the Turkomans have adopted a Mongolian form of speech, or indeed that they ever spoke any other language than Tûrki. But Tûrki and Mongolian being offshoots of the same organic tongue, it follows that both races must have had a common origin, and that the Turkomans have since become differentiated from the ethnical, while retaining the linguistic connection. Now this is entirely at variance with the commonly-accepted doctrine that physical traits are always more persistent than speech, in other words that, assuming absolute isolation, the process of linguistic will always be more rapid than that of racial evolution.

In the abstract this is no doubt true enough, but practically there is no such thing as absolute isolation in the present stage of the world's history. Least of all can it be predicated of the Turkomans, who are intruders from the east or north-east in their present habitat, who must have absorbed far more Iranian blood than Vambéry is inclined to admit, and who, instead of being the purest representatives of the Turki race, seem really to be a mongrel people, the outcome of fusion of Mongolian and Caucasian elements in Hyrcania, Bactriana, and the Lower Oxus basin. It must be remembered that the whole of this region, as far north at least as the 40th parallel, formed an integral part of the ancient Persian Empire, and the presence of numerous Iranian communities still speaking Persian dialects both in the lowlands and highlands of Turkestan (Tajiks and Galchas) sufficiently proves that this region was fairly occupied by peoples of Iranian stock, if, indeed, it was not their primitive home, before the arrival of the Turki race driven still westwards by the Mongolians of the Gobi. When the Persian power was finally broken by the Arabs, Turki hordes easily took permanent possession of the Atrek and Murghab Valleys, as well as of the Lower Oxus; but in so doing they gradually absorbed as much Iranian blood as to have in course of time become largely assimilated to the Caucasian type. The same fate overtook their Seljukian brethren in Asia Minor and the Balkan peninsula, all of whom have everywhere become largely Aryanised, and have thus collectively contributed to produce the impression, shared by Vambéry with many ethnologists, that the Tûrki and Mongol types were originally distinct. They themseves have always rightly looked on each other as brethren, and although no importance can be attached to the tradition of a legendary Tûrk, son of Japhet, whence both sprang through the twin brothers Tatar and Mongol, it nevertheless points, like so many other national myths, at a fundamental truth.

Nor are the Mongolian traits so far effaced from the Turkoman race as Vambéry would have us suppose. In "Clouds in the East" Valentine Baker, an equally careful observer, describes them as "muscular, heavy-limbed men, with large hands, rather flat, broad faces, and small eyes, thus showing much of the Tatar type" (p. 212). He even expresses his surprise that it should still be so distinctly marked, "as they constantly capture Persian girls, who become their wives, and so must bring a strong infusion of Persian blood into the race" (*ib.*).

The genuine Tûrki type, however, is still best exhibited in the Kazaks, or, as they are more frequently called, the Kirghizes and Kara-Kirghizes of the West Siberian steppes and Pamir table-land. These Kirghizes speak a pure Tûrki dialect, and because of their distinctly Mongolian features—square, flat face, high cheek bones, oblique eyes, large mouth, &c.—they are supposed to be Mongolised Tatars by those who hold the two types to be originally distinct. But the supposition is entirely gratuitous, and although they may have been to some extent affected by Mongolian elements during the incessant migrations of the Central and Eastern Asiatic nations, there is nothing in their appearance to imply any profound modification of their outward features, while their Tûrki speech militates against the assumption. They resemble the Mongolians because both were originally one, and because in their present homes between Kulja and the Ural Mountains they came in contact with no foreign elements by which the race could be seriously affected. In the Kirghizes we therefore recognise a living proof of the primordial identity of Turk and Mongol.

The transition between the Kirghizes and Turkomans is formed by the Kipchaks of Khokand and other parts of Eastern Turkestan, who, though often classed with the

Mongolian Buryats,[1] are of the genuine Tûrki stock, and speak a pure Tûrki language, though rude and marked by some distinct features.

Touching the numbers and strength of the Turkoman tribes proper, opinions vary considerably. While Behm and Wagner reckon them at no more than 450,000, Vambéry still adheres to the number of one million given in his "Travels in Central Asia," adding that further research may tend to increase, but certainly not to diminish that figure. This estimate is partly borne out by Gen. Obrutcheff,[2] who makes them amount in 1874 altogether to about 930,000, exclusive of the "Eski-Turk" and other scattered members of the family in Asia Minor, North Syria, the Euphrates Valley, and Persia.

In view of recent and pending political events, the subjoined list of the Turkoman tribes with their localities and approximate numbers may be acceptable:—

Tribe.	Population.	Locality.
Tekke: Akhal	300,000 (Akhal and Merv)	N. slopes Kuren-dagh and on Tejend River (Lower Heri-rûd).
Tekke: Merv		Merv Oasis.
Goklan	55,000	Upper Atrek, Gurgan, and Simbur, and in Mazanderan.
Yomut: Atabai	135,000 (Atabai and Jaffarbai)	S.E. Coast Caspian, eastwards to Kizil-Arvat, and on Lower Oxus below Khiva.
Yomut: Jaffarbai ...		
Ersari	300,000	Left bank Oxus, about Char-jui; hence called "Lebâb" or "River" Turkomans.
Al-Ili	15,000	Between Oxus and Afghan frontier.
Chaudor	30,000 ?	Ust Urt plateau, east from N. end Caspian.
Salor	20,000	About the Murghâb between Merv and Herat.
Sarik	40,000	Merv Oasis.
Sakar	10,000	About Sarakhs.
Essen-Ili	115,000	South from the Chaudor.
Amr-Ili.........	15,000	About Middle Oxus.
Ui and Aimak	7,500	N. frontier Hazarajat.
Kara Dashli...	7,500	N. frontier Hazarajat.
Kozanli.........	20,000	Kozen Dagh (Taurus).
Pekmeshli...	30,000 (Pekmeshli to Rehanli)	Euphrates Valley and N. Syria.
Genkani ...		
Kecheli......		
Bejeli		
Rehanli......		
	1,100,000	

The discrepancy between this estimate and that of Obrutcheff is due to the fact that in the above list are included the Turkoman nomads of Asiatic Turkey, besides a large branch of the Goklans, some 8,000 families, now settled in Mazanderan.

A. H. KEANE

DISCOVERY OF A GASEOUS NEBULA

THE Rev. T. W. Webb writes as follows to the *Times* on the subject of Lord Lindsay's letter in NATURE last week:—

On the night of November 14, while sweeping in the constellation Cygnus with a low power on my 9·38 inch silvered speculum by With, I perceived an object resembling, but not quite identical with, a bluish 9 magnitude star. The use of higher magnifiers at once detected the existence of an ill-defined bright disk, subtending about 4″, and surrounded perhaps with a slight amount of glow. It has since been identified at other observatories as No. 4,004 in Argelander, + 41, the place for 1880 being R.A., 21h. 2m. 31s.; D., + 41° 45′·3. Through the kindness of Dr. Copeland, by whom it has been carefully examined under the greatest instrumental advantages at Lord Lindsay's observatory at Dunecht, North Britain, I am enabled to add the following interesting particulars. It is not circular, and has a sharp nucleus near the north-preceding edge, with a faint effusion of light in the opposite direction. Three very measurable bright lines were found in a powerful spectroscope, of which the positions, as given by two sets of measures, were respectively 500·1, 495·7, 487·0, and 500·1, 495·6, 486·0. When these values are compared with those deduced by D'Arrest from the results of several observers of known objects of this nature—500·4, 495·7, 486·1—there can be no remaining doubt that the object in question is of the very interesting and mysterious class termed planetary, or, more correctly, gaseous nebulæ. Dr. Copeland assigns 8, 5, and 1, as the approximate intensities of these lines, reckoning from the least refrangible direction. It can occasion no surprise that its true characters should have escaped the piercing and practised gaze of Argelander, as it would require a much larger instrument than that which he employed to give any intimation of its nature.

[1] "Le nom de Bouroute leur est absolument inconnu" (Ch. de Ujfalvy in *Bul. de la Soc. de Géographie* for June, 1878.

A NEW PLANETARIUM

SIGNOR N. PERINI, of Garrick Chambers, Garrick Street, has invented a planetarium, which, so far as we are aware is in all respects superior to, more *vraisemblable* than, any apparatus of the kind hitherto attempted. The structure, for such it really is, consists first of a hemispherical dome, fourteen feet in diameter at the base and the same in height, resting on twelve columns. Getting underneath the dome, one sees the vault overhead coloured so as to represent the starry sky, with the milky way and the constellations in their proper places. Suspended from the top by a narrow hollow rod is an opal globe lit up by gas or electricity to represent the sun, and around this, at their proper proportional distances, are suspended by almost invisible wires, the planets from Mercury to Uranus. By a slight turn of a key Signor Perini sets the solar system in motion, when the sun revolves on its axis, and all the planets in their proper *elliptical* orbits and at their proper axial inclination, and with proportionate velocity. Saturn has his rings and the other planets their moons; the earth, about the size of a walnut, by a mechanism peculiar to itself, revolves on its axis at a rate accurately proportioned, the same mechanism causing the moon, a small pearl, to revolve round the earth in its own proper orbit. Round the base of the dome the various signs of the zodiac are indicated, and the paths of the planets are shown by ellipses traced around the vault. The spectator is supposed to be standing somewhere underneath the solar system, and the general effect is very striking. To us it seems the most effective method hitherto devised to convey to old or young a realistic conception of the arrangement and motions of the planets. During the working of the mechanism not a sound is heard, though above the dome, and concealed from view is an elaborate arrangement of machinery. This machinery is of the nature of clockwork, with, however, a special feature by means of which the elliptical motions of the planets are effected. Inside the earth is a watchwork arrangement, which could easily be adapted to the other planets were it not for the expense. When wound the machinery can be kept going continuously for upwards of five hours; it can be stopped at any moment. The invention has, we believe, cost Signor Perini seven years' unremitting work and seven hundred pounds expenditure. We believe that the work has all been done at night and during early morning hours, as the inventor has to give his daytime to his profession of teacher. Signor Perini informs us that he could without difficulty make his planetarium as large as the Albert Hall and small enough to become a school apparatus for teaching. He showed us a table, like a small writing-table, between the tops of which he had arranged his machinery on a small scale to give motion to a tellurium which he fits on to the table. Of course the invention, as indeed Signor Perini admits, may be capable of improvements in detail, but as it stands it seems to us a triumph of ingenuity and determined perseverance, for which its inventor deserves the highest credit.

A MICROSCOPIC SERENADE[1]

O COME, my love, and seek with me
A realm by grosser eye unseen,
Where fairer forms will welcome thee,
And dainty creatures hail thee queen.
In silent pools the tube I'll ply,
Where green conferva-threads lie curled,
And proudly bring to thy bright eye
The trophies of the protist world.

We'll rouse the stentor from his lair,
And gaze into the cyclops' eye;
In chara and nitella hair
The protoplasmic stream descry,
Forever weaving to and fro
With faint molecular melody;
And curious rotifers I'll show,
And graceful vorticellidæ.

Where melicertæ ply their craft
We'll watch the playful water-bear,
And no envenomed hydra's shaft
Shall mar our peaceful pleasure there;
But while we whisper love's sweet tale
We'll trace, with sympathetic art,
Within the embryonic snail
The growing rudimental heart.

Where rolls the volvox sphere of green,
And plastids move in Brownian dance,—
If, wandering 'mid that gentle scene,
Two fond amœbæ shall perchance

[1] From *Scribner's Monthly Magazine* for November.

Be changed to one beneath our sight
By process of biocrasis,
We'll recognise, with rare delight,
A type of our prospective bliss.

O dearer thou by far to me
In thy sweet maidenly estate
Than any seventy-fifth could be,
Of aperture however great!
Come, go with me, and we will stray
Through realm by grosser eye unseen,
Where protophytes shall homage pay,
And protozoa hail thee queen.

JACOB F. HENRICI

JOHN ALLAN BROUN

IT is only a few weeks ago that it became our painful duty to record the untimely death of a distinguished mathematical and experimental physicist, and we have now to mourn the loss of one equally distinguished in observational inquiry. John Allan Broun was born at Dumfries, where his father had, we believe, a normal school especially intended for young men about to enter the navy. Upon the death of his father, Mr. Broun, then about twenty years of age, went to the University of Edinburgh, and speedily became a successful student in more than one branch of knowledge. But his strongest attachment was always to physical science, and the late James D. Forbes, who was at that time Professor of Natural Philosophy at Edinburgh, considered Mr. Broun as one of his very best pupils. A friendship was thus formed which lasted through life.

About 1842 the scientific world began to perceive the necessity of conducting cosmical inquiries, and Sir Thomas McDougal Brisbane, in the most generous manner, agreed to establish and maintain a magnetical observatory at his residence at Makerstoun. Prof. Forbes had thus the opportunity of recommending his pupil, Mr. Broun, to Sir Thomas, who gave him the directorship of his observatory. In this capacity he continued to reside at Makerstoun for some years, where the delight of pursuing an occupation congenial to his tastes was enhanced by the great pleasure he derived from the society of Sir Thomas Brisbane, and of his amiable family, and their loss one after another was a very severe trial to him. It was no slight task to superintend an institution such as this in a branch of science then comparatively new, and Mr. Broun laboured so hard at his duties that he began to have palpitation of the heart, caused, probably, by his constant night watches. In consequence of this he obtained as his assistant Mr. John Welsh, who became one of his warmest friends, and who afterwards, as Director of the Kew Observatory, won for himself a high reputation in the course of a life that was, unhappily, very short.

Mr. Broun left Makerstoun in 1850 and went to Paris, where he formed the acquaintance of the lady who was afterwards his wife, Isaline Vallouy, the daughter of a clergyman in the Canton du Vaud, and belonging to an old Protestant family of Dauphiné (du val Louise) who had fled from France at the Revolution. This lady is now left to mourn his loss. From this marriage he had three sons and two daughters. Of his sons one is an architect, one has just left this country to enter upon his duties as civil servant in the North-West Provinces of India, while another, in preparation for the Indian forest department, is finishing his studies at Nancy. In 1851, through the influence of his friend, Col. Sykes, Mr. Broun was appointed director of the Trevandrum Observatory, an institution supported by His Highness the Rajah of Travancore, and he left this country for India in the same year. Of the scientific value of his work in India we will speak later on; but we may remark that it was attended with many difficulties. He wished amongst other things to have observations at different heights, and the great difficulties which the carrying out of this plan required have been more or less recorded in his various reports. We say more or less, for it may be questioned whether his reports, so admirable in every other respect, do full justice to himself and to those difficulties which he successfully overcame. Mr. Broun, we believe, advanced on his own responsibility the funds necessary for this experiment, but he was afterwards reimbursed. A deafness which never left him began in one of his excursions on the hills with these objects in view. He had been observing all day in the hot sun—in the evening he took a bath and got a chill from the hill breeze after it. He came back to Europe in 1866 in the hope that medical treatment might remove his deafness, returning to India for three years more.

After having finally left India he resided first in Lausanne in Switzerland, and then in Stuttgart in Germany, where his whole time was devoted to the preparation of the first volume of the results of the Trevandrum observations. This cost him an immense amount of labour without rest or recreation of any kind, except perhaps an hour or two devoted in the evening to music with his family. He was a skilled violinist, and was particularly fond of Beethoven's music. In London, where he resided for the last six years of his life, he gave his whole time and energy to the prosecution of the work he had in hand, so much so that even in taking a walk the subject would always be present to his thoughts. Two years ago his health began to give way, and he left London for the New Forest, a change which seemed for a time to be of service to his health. But again, after another year, he found that continued work was affecting his brain, and during a stay at Lynton (Devonshire) he had in 1878 a kind of nervous attack, which was the beginning of his last illness. He never altogether rallied after this attack, and was much distressed last winter at being obliged to cease from all work, but he bore this trial with much meekness and gentleness of manner to all around him.

Being rather worse in the spring, he made up his mind to go to Switzerland in search of strength, and after a few weeks of much weakness spent at Bex, he began to rally and to enjoy the walks in that beautiful neighbourhood. From there he went to Finhaut, Chamouny, and Tête Noire, and greatly enjoyed his daily excursions in the mountain paths and over the hills; indeed he used to say that they made him feel quite young again. At first after his return to London he complained of his head, but he seemed stronger again just before his death, and worked a few hours daily. He had begun an article for NATURE, and assured his family that he did not overfatigue himself. On the 22nd of last month he died suddenly. He took up the newspaper in the morning to glance at it near the fire. He had not done so for five minutes when he said, "I think I am going to faint." Medical aid was at once procured, but he had a kind of suffocation for two or three minutes, and all was over.

In reviewing the life and labours of John Allan Broun it is impossible to fence off that portion of his character which relates to science, and discuss it without reference to the other parts of his nature. To do so would be to throw away the key of the very chamber which we wish to enter.

He was a man of the most scrupulous integrity, of the most sensitive conscience. But this extreme scrupulosity did not prevent him from appearing in the most amiable character to his fellow men; for he was at the same time a man of the most delicate social instincts, and eminently qualified to shine in society; a very warm friend and a very good companion. If any one suffered from his scrupulous nature it was himself, or, to speak more properly, it was that portion of his surroundings which goes by the name of "material interests." It is of course a mistake to suppose that the highest interests of any man can ever suffer from his being honest.

He was a devoted adherent to the Free Church of Scotland, and at a time when subscription to certain formulæ was insisted on from the professors at the Scottish Universities, his conscientious scruples stood in the way of his obtaining any appointment of this nature. Had it not been for these he might, no doubt, have had the chair of Practical Astronomy at Edinburgh, or that of Natural Philosophy at St. Andrews.

And here we may be permitted to quote a few sentences from a letter written by Prof. Forbes to Sir James Graham (then Home Secretary) urging the claims of Mr. Broun to the former of these posts. After describing the scientific qualifications requisite for an astronomer, he goes on to say:—"But beyond all these may be reckoned a conscientious zeal in the discharge of a duty, often irksome, generally solitary, without which the observatory establishment is not only useless but injurious. In these respects I can cordially recommend Mr. Broun to the favourable notice of Government from more than six years' intimate acquaintance with him. . . . He was subsequently selected by Sir Thomas Brisbane to direct the noble magnetical and astronomical observatory, erected and maintained by his liberality at his seat near Kelso. . . . You are aware how much labour and ingenuity have been expended in devising magnetic instruments and experiments. You must be aware of the skill and patience required to conduct such experiments, of a kind almost new, and with instruments whose actions and errors are almost untried. Now from frequent examination of Mr. Broun's methods, I think I am justified in saying that not one of the magnetical observatories under the direction of Her Majesty's Government has been more vigorously managed than that of Sir T. Brisbane, conducted by Mr. Broun, and probably none with more intelligence and ingenuity."

We cannot help feeling that during the latter years of his life, while he resided in London, Mr. Broun might have received a somewhat larger measure than was accorded him of generous and sympathetic treatment from those specially interested in the progress of observational inquiry. Possessed of no considerable amount of private means, he was living upon a small pension which he had from the Rajah of Travancore, and which has now expired with him. He had been led to believe that one of his labours after leaving India would be to superintend the reduction of his observations. But the publication of these reductions was discontinued after the first volume of results appeared, and, in consequence, a large mass of valuable observations made at considerable cost is now lying absolutely useless.

Surely the course of action which will establish and maintain an observatory, and then decline to make public the records is only comparable in folly with that of a man who begins to build a house which he is not able to finish.

It was a source of great sorrow to Mr. Broun that he was thus prevented from completing what he might justly consider to be the work of his life, and he then endeavoured to procure some employment by which, while advancing his favourite science, he might likewise add to his somewhat slender resources. About that time the meteorological office of this country was in process of reconstruction and he had thoughts of offering his services as one of the meteorological council. It was clear however that his deafness would be considered by those in power as a fatal disqualification for such an appointment, and in consequence he did not press his claims. It certainly seems a great pity that a national institution of this nature so liberally endowed by government should have allowed a man like John Allan Broun to die in their midst without attempting to avail themselves in some becoming and honourable manner of those large stores of information peculiarly suited to their purpose which he alone of all men living possessed, and which he was particularly anxious to communicate to others.

About this time too, Sir E. Sabine resigned his office of magnetical superintendent, and it might naturally have been supposed that Mr. Broun was the very man to succeed him. The office was, however, discontinued. He now made application to the Government Fund of the Royal Society for a sum of money to enable him to improve and complete the reduction of the Colonial magnetic observations. But the immediate and apparent responsibility from quarter to quarter of the possessor of such grants, was peculiarly fatal to a man like Broun. The work seemed to go on growing the more he examined it, and he was never satisfied without going still more deeply into the subject than he had already gone.

Then his health began to give way, and the thought that he had received money for which he had rendered no equivalent hastened still more the progress of his malady.

At last the end came, and we can now hope no longer to complete his labours as he would have himself completed them had he been spared to us but a little longer.

It has been said of an eminent experimentalist that great as were his successes, his failures must have cost him even more thought. If this be true in experimental research, it is peculiarly true in observational inquiry where every idea in order to be tested entails a laborious investigation. Mr. Broun, whose mind was very fertile, must have often spent great labour apparently to no purpose, but on the other hand his successes were very marked, and he did not hesitate to consider a new fact as abundant compensation for a large amount of failure. We cannot attempt to give here an exhaustive catalogue of his various labours. But we may allude to the volumes embracing the results of the Makerstoun observations as pre-eminent for the skill employed in the development of new methods. These volumes alone must have cost him an immense amount of thought.

In 1861 he communicated to the Royal Society of Edinburgh, two papers of marked value. In one of these the errors and corrections of the bifilar magnetometer were discussed, including the determination of its temperature coefficient, which Mr. Broun showed might be found in a more correct method than that hitherto adopted.

The second of these papers was on the horizontal force of the earth's magnetism, for which he established the annual laws from a discussion of observations taken at various places. He likewise discovered that the variations of this element from day to day are nearly the same over all the world.

For these discoveries he was awarded the Keith Medal of the Royal Society of Edinburgh. We have already alluded to the great labour he spent upon the first volume of the "Results of the Trevandrum Observations." In this volume conclusions of the greatest scientific interest are deduced, and Mr. Broun has been able to give in a complete form the laws which regulate the solar-diurnal variation of magnetic declination near the equator. But his researches regarding the lunar-diurnal variation of this element form perhaps the most original and interesting part of the volume. He has claims to be considered as an independent discoverer of this variation, and he has certainly increased our knowledge of its laws more than any other magnetician. We may mention his observation that the lunar action was reversed at sunrise and that it was much greater during the day than during the night, whether the moon was above or below the horizon, as particularly noteworthy and likely to throw much light on the theory of the subject. We have already alluded to Mr. Broun's discovery of the similarity, all the world over, of the changes from day to day of the earth's horizontal force. Certain of these changes he found to be due to the moon, while others had a period of twenty-six days. These last he attributed to solar action, and in discussing the subject he found that the greater magnetic disturbances were apparently due to actions proceeding from particular meridians of the sun. This is a subject of very great importance, and its exact meaning has yet to be discovered.

Mr. Broun was no less eminent as a meterologist than as a magnetician. His observations regarding the barometer are of the greatest importance. In this branch of inquiry he has shown the apparent simultaneity of the changes of mean barometric pressure over a great part of the globe, and he has likewise discovered a period of twenty-six days. He was the first to commence those systematic observations of clouds at various altitudes that are now so extensively made, and in a paper read not long since before the Royal Society of London, of which body he was an old member, he pointed out certain relations between atmospheric motions and the directions of the lines of equal barometric pressure. For his various researches, he obtained in 1878, just one year before his death, the Royal Medal of that Society.

These are only a few of the many labours of one whose loss, so deeply felt by all his friends, may be regarded as a calamity by the cultivators of meteorology and magnetism, branches of knowledge in which he was second to none who has yet appeared.

BALFOUR STEWART

NOTES

DR. WARREN DE LA RUE, F.R.S., has just sent to the Chemical Society Research Fund a third donation of 100*l.*, the whole amount to be devoted to a single research.

IN the person of Lady Sabine, who died at Ashley Place on the 28th ult., at the age of seventy-two years, a woman of most remarkable clearness of intellect and of power of memory has passed away. In 1827 she married Sir Edward (then Captain) Sabine, and for more than fifty years her main occupation and her chief enjoyment was to assist him in his investigations, especially in terrestrial magnetism. None but her most intimate friends can know how much of the laborious calculations in the "Contributions" were really effected by her, while she translated Humboldt's "Cosmos" and "Ansichten der Natur," besides numerous smaller papers. One of their oldest friends has truly said, "I deeply sympathise with Sir Edward; the death of his wife has rendered the number of beautiful lives in the world one less."

THE following are the probable arrangements for the Friday evening meetings before Easter, 1880, at the Royal Institution:— January 16, Prof. Dewar, F.R.S.; January 23, Dr. W. B. Carpenter, C.B., F.R.S., "Sea and Land in Relation to Geological Time;" January 30, John Marshall, F.R.S., "Proportions of the Human Figure;" February 6, William Huggins, D.C.L., F.R.S.; February 13, W. H. Preece, C.E., "Wheatstone's Telegraphic Achievements;" February 20, Rev. H. R. Haweis, "Old Violins;" February 27, Frederick J. Bramwell, F.R.S.; March 5, H. N. Moseley, F.R.S., "Deep-Sea Dredging and Life in the Deep Sea;" March 12, C. William Siemens, D.C.L., F.R.S.; March 19, Prof. Tyndall, D.C.L., F.R.S. The following are the lecture arrangements before Easter:—Christmas Lectures (adapted to a juvenile auditory): Prof. Tyndall, D.C.L., F.R.S., six lectures on "Water and Air," on December 27 (Saturday), 30, 1879, January 1, 3, 6, 8, 1880; Prof. Edward A. Schäfer, F.R.S., ten lectures on "The Physiology of Muscle," on Tuesdays, January 13 to March 16; H. Heathcote Statham, two lectures on "Modern Architecture since the Renaissance," on Thursdays, January 15 and 22; Prof. Dewar, F.R.S., eight lectures on "Recent Chemical Progress," on Thursdays, January 29 to March 18; Prof. T. Rupert Jones, F.R.S., three lectures on "Coal," on Saturdays, January 17, 24, 31; Ernst Pauer, three lectures on "Handel, Sebastian Bach, and Joseph Haydn" (with musical illustrations), on Saturdays, February 7, 14, 21; four lectures on "History of Literature," on Saturdays, February 28, March 6, 13, 20.

At the request of the Government of the Cape Colony and the trustees of the South African Library at Cape Town, Sir Bartle Frere has desired Prof. Max Müller and Prof. Sayce to select a qualified successor to the late Dr. Bleek, to continue his labours as colonial philologist and as custodian of the valuable library presented to the colony by Sir George Grey. The salary will be 500*l*. a year, of which 300*l*. will be contributed by the Government, and 200*l*. by the committee of the South African Public Library. Applications and testimonials only may be sent to Prof. Max Müller, Oxford.

The lectures in connection with the Brown Institution will be delivered by Mr. W. S. Greenfield at the University of London on December 17, 18, 19, 22, and 23 at 5.30 P.M. The subject will be "Recent Investigations on the Pathology of Infective and Contagious Diseases."

The French Minister of Public Instruction has appointed a section of the Commission of Historical Monuments for the purpose of establishing an official record of all megalithic constructions and erratic blocks discovered in France and Algiers.

The grants voted by the Legislative Assembly of France for 1880 have been sent to the Senate, and according to every probability will be voted without any material alteration. The sum of 59 millions of francs was voted for public instruction, 2½ millions more than were asked for by the Government. In 1870 the grants for educational purposes were 26 millions and in 1851 only 16 millions. Among the items in the grants are the following:—The grant for the National Institute is 707,762 fr., for the Academy of Medicine 75,000 fr., the College of France 466,000 fr., the Museum of Natural History 835,000 fr., for astronomical and meteorological observatories 835,000 fr., for the National Library 674,000 fr., for the National Library and Museum of Algiers 296,000 fr., travelling expenses for explorers 200,000 fr., École des Hautes Études (conducting experiments, &c., &c.) 300,000 fr.

The Edinburgh Liberals, who have had a week of almost uninterrupted oratory from their idol, Mr. Gladstone, have been impressing science into their service, in order that Mr. Gladstone's voice might reach a much larger audience than any single hall in Edinburgh could hold. On Saturday he addressed an audience in the largest hall in Edinburgh, the Corn Exchange; but as this could not anything like hold the multitude that wanted to hear him, it was connected by telephone with another hall at some distance. We shall let the *Daily News* correspondent describe the result of the arrangement:—"The audience distinctly heard the cheering and singing of the meeting in the Corn Exchange, and also the strains of the band. Lord Roseberry's voice was also recognised, and it was gathered that he was saying pleasant things about Mr. Gladstone. Next came a burst of cheering, the sound of which was suddenly stopped, and a long interval of silence followed, varied from time to time by the murmur of distant cheers. Then as suddenly as silence had fallen, there came the sound of Mr. Gladstone's voice, and he was followed pretty well through 'some remarks on corn averages and the condition of India.' All this, which greatly mystified the telephonic audience, is capable of easy explanation. Observers of Mr. Gladstone's manner in the House of Commons will remember what an important part the right hon. gentleman's hat plays in his great speeches. He invariably places it on the table, a little to one side of him, and on the top of it he places his notes, which he rapidly shuffles and re-arranges as the oration progresses. This afternoon, bringing his hat to the table in his accustomed manner, he unconsciously planted it right in front of the cylinder of the telephone which had been fixed on the table, thus, of course, cutting off the means of communication. As the speech proceeded, he began the re-arrangement of the papers and the movement of the hat, which latter he finally drew away from the telephone, and then became audible in another building a quarter of a mile off, 'some remarks on corn averages, and the condition of India.'" It is a pity Mr. Gladstone had not been put up to the arrangement; we are quite sure, had he known, he would not have adopted so "obstructive" a line of action with his hatful of papers.

A new light company has started a public subscription in Paris for 80,000*l*. The inventor proposes to dispense with magneto-electric machines, by resorting to Bunsen elements of special construction, and to dispense with regulators by incandescent light. An immense number of prospectuses have been circulated amongst the peasantry, and the funds are collecting with an amazing rapidity.

Scribner's Monthly, one of the best monthlies anywhere, has an interesting illustrated article in the December number on the Johns Hopkins University.

A competition having been opened for erecting a memorial of the siege of Paris on the Rond Pont of Courbevoie, M. Bartholdi, the author of the gigantic statue representing the French-America alliance, has executed a model representing a balloon with a sailor aëronaut and the beseiged city receiving messages from a carrier-pigeon. The *ensemble* is grand and picturesque. It has raised the enthusiasm of Paris aëronauts, who are to make a public demonstration in support of M. Bartholdi's schemes.

The *Colonies* of November 22 contains a long and valuable list of works on Commercial Botany, drawn up by Messrs. G. J. Symons and P. L. Simmonds.

The new part of Mr. Bentham and Sir Jos. Hooker's "Genera Plantarum" will be published in January, and will complete the Dicotyledonæ. Only one other part, the Monocotyledonæ, will remain to be published.

On November 21 M. Mariette-Bey read, before the Academy of Inscriptions of Paris, a long report on the new excavations which are to be executed in Egypt. This address having been delivered in a solemn meeting of the Academy, it is certain that the illustrious Egyptologist will obtain a grant from the French Government.

The *Kölnische Zeitung* says that a rack railway, of the Righi type, will be erected on the Drachenfels, one of the seven hills situated on the left bank of the Rhine. The survey of the intended line is proceeding with activity.

The Kane Geyser, or spouting water-well, has lately attracted much attention from the sight-seeing public. Some exact data regarding it are furnished in a recent notice by Mr. Ashburner (*Amer. Jo. of Sci. and Arts*, November). The well is situated in the valley of Wilson's Run, near the Philadelphia and Erie railway-line, and four miles south-east from Kane. It was drilled in the spring of 1878 to a depth of 2,000 feet, but, as no petroleum was found in paying quantities, the casing was drawn and the hole abandoned. In drilling, fresh-water veins were met with down to 364 feet, which was the limit of the casing. At 1,415 feet a very heavy "gas-vein" was struck, and this gas was allowed free escape while the drilling was continued to 2,000 feet. When the well was abandoned, the fresh water flowed in, and the conflict between the water and gas commenced. The water flows into the well on top of the gas till the pressure of the confined gas becomes greater than the weight of the superincumbent water, when an expulsion takes place, and a column of water and gas is thrown up to a great height. This occurs at present at regular intervals of thirteen minutes, and the spouting continues for one and a half minutes. The column, according to measurement, varied in height from 108 to 138 feet. The gas of the mixture can be readily ignited. After nightfall the spectacle is grand. The antagonistic elements of fire and water are so promiscuously blended that each seems to be fighting for the mastery. At one moment the flame is almost entirely extinguished, only to burst forth at the next instant with increased energy and greater brilliancy. During sunshine the spray forms an artificial rainbow, and in winter the columns become incased in huge transparent ice-chimneys.

WE have received the numbers for October and November of the *Natural History Journal* "conducted by the Societies in Friends' Schools." This journal continues to sustain its reputation, and several papers in these numbers are highly creditable.

THE *Colonies and India* states that a new store of guano has lately been discovered in a series of caves about 100 miles east of Cape Town. It is described as being a light-brown powdery mass, in which a number of solid nodules occur. An analysis shows that it contains 68 per cent. of ammonia compounds, 16 per cent. of phosphates, and 2 per cent. of nitrogen. In the same caves are considerable quantities of salts, forming a crystalline mass, and containing 33 per cent. of phosphoric acid, 11 per cent. of sulphuric acid, 15 per cent. of nitric acid, 19 per cent. of potash, and 7 per cent. of ammonia.

CONSUL CALVERT, reporting on the trade and commerce of Alexandria for 1878, thus refers to the new fodder plant, the Téosinté (*Euchlæna luxurians*), which has attracted so much attention lately in tropical countries. During the last three or four years experiments have been made at Cairo and attended with complete success, and it is expected that it will eventually prove to be a great acquisition to Egyptian agriculture. The plant attains the height of from thirteen to sixteen feet, and so rapid is its growth that in an experiment made in July at Cairo the plant after having been mown down grew one foot in four days. On analysis the plant is found to contain much saccharine matter, and to be much more nourishing for animals than the native clover or *verseem* (*Trifolium alexandrinum*).

UNDER the title of "Notes on the Flora of Surrey," a list of plants known to occur in the five adjoining counties, but not really known in Surrey, has been published by Mr. A. Bennett, of 107, High Street, Croydon, who has issued the list "as a first step towards a proposed supplement to the flora of the county, and with the wish that those botanists who may be able to help will kindly do so, either in confirming by specimens any doubtful plants reported for the county, or by giving the localities where they may be gathered, so that search may be made next season." Mr. Bennett's list is a useful one, though the botanical nomenclature has been very carelessly corrected, if indeed corrected at all.

MR. CHARLES GILBERT, of Bedford Street, has published "Tables of Metric Measures and their English Equivalents," by G. M. Barns, for use by engineers, architects, contractors, and others.

WE some time ago announced the death of the librarian of the "Leopoldino-Karolinische" Academy for Natural Sciences, Dr. Behn, of Dresden. The statutes of the Academy prescribe that the library must be at the librarian's place of residence. Consequently the whole library, consisting of some 40,000 volumes, has been transferred to Halle, where Dr. H. Knoblauch is the new librarian.

IN a lecture delivered at Bristol by Mr. Lant Carpenter, he spoke of his recent visit to the United States, and remarked that amongst the various improvements and things which were being tried there, one that struck him as much as anything was the extraordinary development within the last two or three years of the application of electricity to the purposes of practical life. He gave several remarkable examples of the way in which the system is applied in the United States for the protection of safes, vaults, and other valuable property, alarms being rung in a central office whenever a forcible entrance was attempted in any one of, say, 500 vaults, the alarm indicating which one. In many cities and towns in the States, he said, there were district telegraphs established. From a central office wires ran to every private house in the district which wished to be connected, and by this means you could communicate with the central office, and by a prearranged set of signals on a bell, the inmates of the house could call a cab, a policeman, a messenger, or a doctor, by simply pulling a handle. The lecturer, in speaking of the practical application of electricity to a system of fire alarms, explained the general system pursued in all large towns in the United States, and spoke of the extraordinary rapidity with which fire-engines are turned out ready for use on receipt of the electric signal. Six or eight seconds was the usual time. Electric signal boxes were fixed in the streets, and any person, on becoming aware of a fire, could turn a handle and communicate at once with the central stations, where the officials would know from which box the signal came. An automatic system was at work in New York, where 500 shops, stores, and warehouses were protected by an apparatus which sounded an alarm in a central office whenever the temperature of any place rose above a given point. Mr. Carpenter stated that in all large towns in the United States of America there was a system of telephone exchanges established. It was a system by which a large number of persons had these telephones in their houses, the wires of which all converged in a central office, and by such an arrangement any one of the subscribers to the exchange could talk to any other person who was also a subscriber through the central office. The wire from each house ended in the central offices, and by simple arrangements any one wire could be readily joined to any other, thus putting two people into communication. The lecturer gave instances of this arrangement, explaining that so perfectly were these telephones constructed that a person's voice could be readily and easily recognised. The lecturer proceeded to comment upon their recent extraordinary and rapid development in every large town in the United States. The subscribers to these exchanges were numbered by thousands, and their uses and advantages were many. Not only were they now connecting different parts of one town by means of these exchanges, but steps were being actively taken to connect towns together by similar means. In conclusion, the lecturer urged that if science, practically applied, was to form so large a portion of our daily life, was not that a very strong argument for so arranging our educational work that every child should be instructed in the rudiments of science? Dr. W. B. Carpenter, having been invited to address the meeting, said he felt convinced that in the next generation the telephone would become almost as generally used as the telegraph was now, though he did not mean to say the latter would be superseded.

AN interesting Roman structure has recently been discovered at Regensburg (Ratisbon). It consists of a subterranean aqueduct of some 10 metres in length, 1½ metres in height, and 60 centimetres in breadth, built of colossal blocks of stone.

THE additions to the Zoological Society's Gardens during the past week include a Common Wood Owl (*Syrnium aluco*), European, presented by Mr. W. J. Smith; a Turquoisine Parrakeet (*Euphema pulchella*) from New South Wales, presented by Mr. A. Battescombe; a Macaque Monkey (*Macacus cynomolgus*) from India, a Barbary Falcon (*Falco barbarus*) from North Africa, deposited; a Reeves's Muntjac (*Cervulus reevesi*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

A SEVENTH STAR OF THE ORION-TRAPEZIUM.—In addition to the well-known fifth and sixth stars in the trapezium of Orion, the former detected by Struve with the Dorpat refractor on November 11, 1826, and the latter by Sir John Herschel with Sir James South's large refractor at Kensington, on February 13, 1830, the elder Bond, soon after the mounting of the Harvard instrument, perceived, roughly in the direction of the sixth star, a fainter and more distant one, which is No. 24 of his memoir on the nebula published in 1848. M. O. Struve, with the telescope of similar dimensions at Pulkowa, could not see this star, a circumstance which might be attributable either to variability, or to the difference of altitude of the object at Pulkowa and at Harvard College. It was repeatedly observed by G. P. Bond, and is No. 636 of his catalogue printed in *Annals* of the Astronomical Observatory of Harvard College, vol. v., where its magnitude is estimated to be 13·3 on Argelander's scale. The Pulkowa measures gave for the sixth star position 128°·8, distance 3″·73 at the epoch 1858·78; from the Harvard differences of right ascension and declination we find, for the seventh star, position 136°, distance 12″·1. In Bond's later notes the following references to this star, amongst others, occur:—1863, January 19 and 23, difficult; January 30, easy, though faint; February 14, not difficult, though requiring attention and effort. 1864, February 3, under fine definition, though easily seen, probably fainter than in the previous year; February 29, readily seen and possibly brighter. Referring to the notes in 1850 and 1851, it is remarked that the star is "often mentioned in these earlier observations; as *certainly* seen on the dates 1850, February 7, March 2, March 5, March 11; it is not mentioned March 10, and was not seen March 12; not mentioned 1850, December 27, but seen again 1851, February 3." It was observed on several occasions in 1859 and 1860. On January 28, 1861, seen by glimpses, and on February 13 easily. On January 31, 1862, not seen. Some of these observations might appear to point to variability, but others seem to afford "another and quite different explanation of the phenomena." If we are not mistaken, this seventh star has been recently caught up with the Ealing reflector; but there are other telescopes in this country which should be competent to cope with it, and the star may deserve some attention.

LUNAR ECLIPSES.—In the small eclipse of the moon (magnitude 0·17) which will occur on the 28th of the present month, the first contact with the shadow takes place at Greenwich at 3h. 37m. P.M., and the last contact at 5h. 15m.; the moon rises at 3h. 46m. Of the eight lunar eclipses occurring within the following five years, only one, that of October 4, 1884, will be wholly visible in this country. The circumstances of these eclipses may be thus very briefly indicated:—

1880, June 22.—Invisible, the middle at 1h. 50m. P.M.
Dec. 16.—Total; beginning of total phase at 2h. 54m. P.M., the moon rising at 3h. 46m.
1881, June 12.—Invisible, the middle at 6h. 54m. A.M.
Dec. 5.—Nearly total (0·97); first contact with the shadow at 3h. 28m. P.M., the moon rising at 3h. 50m.
1883, April 22.—Invisible, the middle at 11h. 39m. A.M.
Oct. 16.—First contact with shadow at 5h. 59m. A.M., the moon setting at 6h. 25m.
1884, April 10.—Invisible, the middle near noon.
Oct. 4.—Total, visible throughout, the middle soon after 10 P.M.

PARALLAX OF A SMALL STAR.—Dr. Geelmuyden, of the Observatory at Christiania, by a series of observations extending over more than twelve months, finds "a notable parallax" for the ninth magnitude star, No. 11677 in Oeltzen's Catalogue from Argelander's northern zones. This star has a proper motion of 3″·04 in the direction 274°. The parallax appears to amount to about 0″·25, but the result is considered far from definitive. The position of this star is in R.A. 11h. 13m. 49s., N.P.D. 23° 30′ 2 for 1880.

NEW NEBULÆ IN ERIDANUS.—M. Block has detected at Odessa two nebulæ in this constellation, which are not found in Sir John Herschel's General Catalogue, the first in R.A. 3h. 28m. 9s., N.P.D. 116° 16′·5, the second in R.A. 3h. 33m. 48s. N.P.D. 116° 43′·7 for 1880. The former is pretty bright, and five minutes in diameter, the latter "considerably bright," with strong central condensation, and readily observed even with the moon above the horizon. The repeated discovery of uncatalogued nebulæ in these days becomes of much interest in connection with the question of variability.

PHYSICAL NOTES

PROF. STEINHAUSER, of Vienna, has recently pointed out that there exists a determinate relation between the size and relative position of the two views of a stereoscopic picture, the lenses of the camera with which it is taken, and the optical arrangements of the stereoscope in which it is to be viewed. If these relations are observed rightly, the effect of relief will be much more perfectly attained for all parts of the picture than if they are neglected. The eye-pieces of the stereoscope above the plane of the photographic pictures ought to be made as nearly as may be equal to the focal length of the objective of the photographer's camera, and this again should be about equal to the mean distance of easy vision, or, from ten to twelve inches. Herr Steinhauser, after developing the theory of the instrument in relation to this point, throws out three very definite and simple suggestions for the photographers. Firstly, that all stereoscopic pictures should be taken with lenses of equal focal length, say 15 centimetres; secondly, that all should be made of equal breadth, or about 75 millimetres; thirdly, that the distances between the centres of the objective-lenses should always be kept constant.

THE *passivity* of iron when employed as the positive pole of a nitric acid battery, or as positive electrode of a voltameter cell containing nitric acid, has recently been studied by M. Louis Varenne, who concludes that the passive state is due to a film of nitric peroxide which collects upon the surface of the iron and protects it from further chemical action. M. Varenne states that this film is apparent when the surface of the iron is examined under the microscope. He finds that the passive state ceases if a stream of carbonic dioxide or of hydrogen is passed through the liquid, and that solution proceeds apace. He also finds that nitric peroxide gas is evolved from the passive iron when it is placed *in vacuo*.

ANOTHER new instrument may shortly be expected from the *atelier* of Dr. König, which will probably settle for ever the dispute between himself and Mr. A. J. Ellis as to the correctness of his tuning-forks of normal pitch. It will indicate a variation of one vibration in ten thousand from the assigned pitch.

M. PELLAT finds that Latimer Clark's standard cell is not entirely free from variations in its electromotive force. He has found two similar cells may differ from one another by a quantity equal to the $\frac{1}{100}$th part of the electromotive force of a Daniell's cell. M. Pellat employs an electrometer to measure the residual difference of potential when the two cells are connected up in opposition to one another, and believes that by this means his observations are free from possible errors due to polarisation when the galvanometer method of comparison is adopted.

HERR EDLUND has drawn attention to an electrical experiment that has not hitherto been thoroughly explained. Let an open metal tube or cylinder, capable of rotation about its axis, be placed over a magnet of double its own length, so that its lower end is opposite the middle of the magnet, while its upper end is opposite the magnet pole. Then let a current of electricity of sufficient strength be passed from one end of the tube to the other. The tube is found to rotate with a velocity which is independent of the resistance of the metal of which it is composed and of its thickness. Longitudinal slits cut in the tube do not affect its rotation. There is therefore here a complete conversion of electromotive force into ponderomotive force. W. Weber inferred that the resistance of the movable conductor to the passage of the current is the medium of this transfer of the energy, and argued that the first tendency is to rotate the current in the conductor, but that as this could not be done without moving electricity through the substance of the conductor, and therefore against its resistance, the principle of least heat requires that the energy should be transferred in an indefinitely short time to the conductor itself, which therefore rotates. Herr Edlund, however, sees in the experiment a confirmation of his "unitary" theory of electricity.

SIGNOR GUIDI, an Italian engineer, has suggested the employment of electricity in the preparation of steel in the following manner:—A dynamo-electric machine driven by steam or water power is caused to electrolyse water; the oxygen and hydrogen gases thus furnished are to be employed in smelting the carboniferous ore of iron, which is reduced by the hydrogen at the high temperature of the flame, thus producing at one operation either steel or pure malleable iron at will. Signor Guidi states, however, that to turn out two tons daily would require the constant employment of a 120 horse-power engine.

GEOGRAPHICAL NOTES

THE Lisbon correspondent of the *Daily News* telegraphs that Ivens and Capello have arrived ill at Loanda, after two years' exploration. They are suffering from fever and other complaints induced by privation, and were almost without clothes. According to government instructions, they have completed a general map of Loanda. They explored the rivers Quango and Quanza, and the territories bordering on their basins. They could not descend the Quango to its confluence with the Zaire on account of the resistance of the hostile tribes. Capello appears quite old, and hardly recognisable. Ivens is better, though ill. Both are thorough scientific men. They bring important notes extending over 32 degrees, plans of the territories and the roads, and meteorological, magnetic, and geographical observations made with the excellent instruments they carried. They were well received by the chief of the Motiango territory, from which the German explorer, Schultz, was excluded; but the chief would not allow any white man to pass east at the peril of his life. They visited the highlands of Bihé, and explored several rivers to their sources. Nearly all their followers deserted them. They were received with great enthusiasm on their arrival at Loanda, and will go to Mossamedes to recruit, prepare their plans, and write out their observations. The period of their return to Lisbon is uncertain.

AT a late meeting of the Russian Geographical Society some details were communicated as to the expedition exploring North-Western Mongolia under M. Potanin. In a letter the traveller describes his route during July and August, which first led from Tsoosilan to the River Kharkiri, and thence to the Lake of Khirghisnor, layers of coal being found on the way. The banks of that lake being barren, the explorers halted near Lake Baganor, only six versts distant from the other sheet of water. Khirghisnor is a great deal larger than Lake Kharaous, and the Mongols asserted the existence of only two such immense reservoirs in the country—namely, the Oobsa and the Kirghisnor. From the latter the expedition marched south, with intent to strike the point where the waters of Lakes Kharaous and Durganor fall into Dzabchin. On August 4 the travellers came to the salt lake Dzerennor, and not till the 9th did they reach the banks of the River Tachteteli, that being the name applied to the mingled volumes of the large lakes flowing into the Dzabchin. Marching round the southern part of Lake Kharaous, the explorers then arrived at the town of Kobda on September 1, with rich scientific collections of all kinds. M. Potanin intended again making for Oolangol, thence proceeding to Oolookem.

THE committee of the Dutch Arctic Expedition have made known their determination to fit out, for the third time, their little sailing schooner *Willem Barents*. The cost of the new expedition is estimated at a little over 1,000*l*.

AFTER the presidential address and the paper on Sumatra read at the first meeting of the session, the new number of the Geographical Society's periodical gives us some notes on the Cocos or Keeling Islands, from the pen of Mr. H. O. Forbes, who went out to the East in October of last year for the purpose of investigating the fauna and flora of certain districts in the Malay Archipelago. While in Java, before commencing this work, he availed himself of an opportunity of paying a visit to these far-away islands, in order to ascertain what changes had occurred since the visit of H.M.S. *Beagle* in 1836; these are shown on the map accompanying his paper. Next we find a note on the boundary line between Chili and Bolivia, illustrated by a map, which explains to some extent the existing disturbances in South America. The geographical notes furnish an account of the progress being made towards Lake Tanganyika by Dr. Mullen's successors, the late Mr. Frank Oates's researches in Matabeleland, and Major Biddulph's tour in Chitral and Yassin. There is also some information of interest respecting Transcaucasia.

A CONTRACT has been concluded by the Molala Shipbuilding ompany, Sweden, to construct a steamer of Molala Bessemer teel, of 100-horse power, to trade between China and Siberia.

FROM the Abstract Report of the Indian Surveys for 1877-8 we see that a large amount of work was done during the season by the various departments, all now united under one organisation. Some interesting and important details are given of various trans-frontier explorations.

THE October *Bulletin* of the Paris Geographical Society begins with a long and valuable paper by M. Wiener on the Dead City of Gran-Chimu and the city of Cuzco. The paper is accompanied by large and careful plans of the two cities, and we believe is a valuable contribution to a puzzling problem. Admiral Fleuriot de Langle has a paper on African migrations, and M. Jules Girard on the subsidence of the surface of the Low Countries. M. Hamy gives an interesting *compte rendu* of M. G. Retzius's recent work on Finnish Ethnology.

THE ROYAL SOCIETY

THE anniversary meeting of the Royal Society was held on December 1, and a somewhat long address was read by the President Mr. Spottiswoode. After referring to some of the losses by death which the Society had sustained, he passed on to business which has occupied the attention of the Council during the current year.

Two important contributions to the Society's funds are announced. First, an unconditional bequest of 1,000*l*. by the late Mr. Sidney Ellis, of Leicester; and secondly, a legacy by the late Sir Walter Trevelyan, "the interest of which is to be applied to the promotion of scientific research."

The Royal Society, as is well known, possesses a rather extensive gallery of portraits, almost exclusively of Fellows of the Society, but among them also a fine painting of Lord Chancellor Bacon. Many of these portraits, however, have, through the lapse of time, begun to show signs of decay. Acting under the advice of Mr. F. W. Burton, F.S.A., Director of the National Gallery, the Council has entrusted the pictures which seemed most to require attention to the care of Mr. Dyer, of Orchard Street, who is now engaged upon them. Some of the portraits require lining, and others cleaning, or partial restoration. As will be seen from those which have been returned to their places, the work appears to have been done in a satisfactory manner. The present appearance of the pictures has been much improved, and it is hoped that these interesting portraits of those who have gone before us may now be passed on in an unimpaired condition to future generations.

Among other acquisitions 973 portraits of Fellows of the Royal Society, formed by the late J. P. Gassiot, Esq., F.R.S., have been bought during the past year. The collection consists mainly of engravings, many of which are of great artistic merit, and in excellent condition.

During the past year a small but perhaps not unimportant change in the mode of dealing with the papers to be read at the weekly meetings has been made. This consists first, in deciding a week earlier than heretofore, what papers should be advertised for reading: and secondly, in reading each week as many as practicable of those in hand, so as to leave as few as possible to stand over. The weekly journals are now able to announce to the public the papers which will be read at the Royal Society (as has in fact long been the case with other Societies) during the next week. But the main object of this arrangement has been early publication; that is to say, publication both in its technical sense of reading before the Society, and in its more widely accepted sense of appearance in the Society's Proceedings. When this was first proposed, it was feared there would soon arrive a period of scientific famine, and that occasions might occur when the Society would meet with no papers before it. Whether this would be so great a calamity as was at first imagined is still an open question, for such has been the scientific fertility of the season, that the threatened catastrophe has never yet actually occurred.

"But so far from suffering by a deficiency of matter we have more often found our difficulties in the number of papers to be read in a single evening. And on such occasions the Secretaries have been good enough to take especial pains to make themselves masters of the contents of the papers, and to communicate in a few words to the meeting the substance of each. It is, I believe, not too much to say that the 'reading' of papers carried out in this way has been the most agreeable and instructive, and has been particularly provocative of intelligent and pertinent discussion. . . . .

"There is a possible alteration in our arrangements which has often appeared to me to be worthy of consideration, and which from conversations with some of our Fellows appears to meet with sufficient support to justify my bringing it before this our anniversary. I refer to the hour at which our weekly meetings are held. Hitherto, in accordance with the usage of scientific societies in London, we have met in the evening. But changes in the habits of society, and the increasing distances from Burlington House at which many of our Fellows reside, seem to render a large weekly attendance difficult. On this account it appears to me desirable to inquire whether an afternoon hour might not better suit the convenience of our members. In that case, I should suggest 5.0 P.M.; and as our meetings seldom extend to two hours in duration, it would generally be practicable for Fellows to reach home by about seven o'clock. . . .

"These changes, if adopted, would require the alteration of the Statute relating to the hour of meeting. But if the suggestion were adopted before the end of the year, there would still remain nearly half the Session of our Society after complying with the necessary formalities. . . .

"It has often been suggested," we read, "that our weekly meetings might be rendered more interesting if the communications were more often accompanied by experiments, or by other modes of optical illustration. The Council has hitherto met these requirements by supplying, from time to time, such appliances as appeared necessary. But that important element, the electric light, and batteries on a large scale, have generally been avoided, on account of the inconveniences attending them. It has, however, been thought that authors would be much encouraged to illustrate their communications experimentally if the main appliances were known to be always ready to hand. . . .

"Again, the mode of lighting our meeting-room by means of sunlights has proved inconvenient to many of our Fellows, on account of its heat and glare; and it is considered undesirable to adopt ordinary gas-burners in its stead for fear of injury to the pictures. We are, however, no longer driven to this alternative, as we may now look to the electric light as a possible mode of illumination.

"These considerations have led me to make an offer, as I now do, to the Society, of a gas-engine of eight horse-power, which, in the opinion of those best qualified to judge, will be amply sufficient both for experimental illustration and for illumination. And I have much pleasure in adding that, on hearing of this offer, our Fellow, Mr. Siemens, immediately expressed his wish to add a dynamo-machine, or rather a pair of such machines, of improved construction (one for alternate, the other for direct currents), the principle of which he had already contemplated bringing before the Society. The other requisites, such as an optical lamp and a few instruments of frequent use, will doubtless soon follow. But, in proposing thus to promote experimental illustration of papers read before the Society, I think it right to add that I do not contemplate, nor do I think it desirable, that the Society should in any sense establish a laboratory; all that is here intended is, that the main appliances for illustration should be found ready to hand here, while the special apparatus would be furnished by the authors themselves."

With regard to the government grant and fund, it is in the opinion of the President desirable that the minds, not only of the Council, but also of the Fellows generally should during the present year be turned to the question, whether it is advisable, in the interests of science, that the fund should be maintained: and if so, whether in its present or any altered form?

In May last the Secretary of State for India asked the advice of the Royal Society on the question of deputing to this country Major J. Herschel on the subject of pendulum observations. The subject is one in which the Royal Society has on more than one occasion taken an active interest; and a reply, prepared by Prof. Stokes was sent. Major Herschel is on his way to England, to carry out the proposed work.

The Publications of the Society. — The Catalogue of Scientific Papers.—The second volume of the supplementary decade, viz., 1863–73, has been brought to a close, and copies are now in the hands of the Fellows and the public. It exceeds in bulk any of the earlier volumes of the work, and extends to 1,310 pages. In this supplement, 343 additional scientific serials have been catalogued, making the total of such serials now comprised in the whole no less than 1,938. The donation list for this volume has been the same as that for former volumes, with the addition of a few societies and institutions sanctioned by the Treasury at the recommendation of the Council. The Fellows have the right to purchase the supplement at the same reduced price per volume as the original work. The Council has authorised the preparation of titles for another decade; and some progress has already been made in the work.

An extra volume of the *Philosophical Transactions* (vol. 168) has been issued, in which the observations made by the naturalists who accompanied the Transit of Venus Expeditions to Kerguelen's Land and Rodriguez, and descriptions of their collections by persons specially acquainted with the several subjects are brought together. The volume is divided into four sections, viz., the Botany and Zoology of each of the two islands respectively.

In estimating the affinities of the flora and fauna of Rodriguez, the authors were under great difficulties owing to our imperfect knowledge of the plants and animals of the other Mascarene Islands. But almost all their observations point strongly to the conclusion that the present animals and plants are the remains of a once more extensive flora and fauna which has been gradually broken up by geological and climatic changes, and which more recently has been greatly interfered with by the agency of man.

The papers presented to the Society, and read at the evening meetings, are stated to have been more numerous than in any previous year of its existence, and have during the last twelve months reached a total of 118. Some of them appear to have excited unusual interest among the Fellows and their friends; for, on more than one occasion the meeting-room was filled to an almost unprecedented degree.

The President took the opportunity of expressing his own impressions of a few which fall, more or less, within his own range of study, first of all referring to the assiduity and success with which Mr. Crookes has continued his labours.

The work of the Institution of Telegraph Engineers, the Iron and Steel Institute and other similar associations was then referred to.

The justification for the award of the medals for the present year was thus stated:—

The Copley Metal has been awarded to Rudolph Julius Emmanuel Clausius, Foreign Member of the Royal Society, for his investigations in the Mechanical Theory of Heat.

The mechanical theory of heat as at present understood and taught has been so essentially a matter of growth, that it would be difficult to assign to each investigator the precise part which he has taken in its establishment. It will, however, be admitted by all, that the researches of Clausius rank high among those which have mainly contributed to its development. These researches extend over a period of thirty years, and embrace important applications of the theory not only to the steam-engine, but to the sciences of electricity and magnetism.

Even to enumerate those who have contributed to one branch of the subject, viz., the kinetic theory of gases, would be beyond my present purpose and powers; but as Clausius himself states, both Daniel and John Bernoulli[1] wrote on the subject. And, even, to go back to earlier times, Lucretius[2] threw out the idea; while Gassendi, and our own Boyle, appear to have entertained it. Within our own recollection, Joule, Meyer, Kroning, Clerk Maxwell, and others have made invaluable contributions to this branch, as well as to the general subject of the mechanical theory of heat. But however great the value of these contributions, it may safely be stated that the name of Clausius will always be associated with the development of earlier ideas into a real scientific theory.

A Royal Medal has been awarded to W. H. Perkin, F.R.S. Mr. William Perkin has been, during more than twenty years, one of the most industrious and successful investigators of Organic Chemistry.

Mr. Perkin is the originator of one of the most important branches of chemical industry, that of the manufacture of dyes from coal-tar derivatives.

Forty-three years ago the production of a violet-blue colour by the addition of chloride of lime to oil obtained from coal-tar was first noticed, and this having afterwards been ascertained to be due to the existence of the organic base known as aniline, the production of the coloration was for many years used as a very delicate test for that substance. The violet colour in question, which was soon afterwards also produced by other oxidising agents, appeared, however, to be quite fugitive, and the possibility of fixing and obtaining in a state of purity the aniline product which gave rise to it, appears not to have occurred to

1 In the 10th section of his "Hydrodynamics."
2 "De rerum Naturâ," lib. ii. 111—140.

chemists until Mr. Perkin successfully grappled with the subject in 1856, and produced the beautiful colouring matter known as aniline violet, or mauve, the production of which, on a large scale, by Mr. Perkin, laid the foundation of the coal-tar colour industry.

His more recent researches on anthracene derivatives, especially on artificial alizarine, the colouring matter identical with that obtained from madder, rank among the most important work, and some of them have greatly contributed to the successful manufacture of alizarine in this country, whereby we have been rendered independent of the importation of madder.

Among the very numerous researches of purely scientific interest which Mr. Perkin has published, a series on the hydrides of salicyl and their derivatives, may be specially referred to; but among the most prominent of his admirable investigations are those resulting in the synthesis of coumarin, the odoriferous principle of the tonquin bean and the sweet scented woodruff, and of its homologues.

The artificial production of glycocol and of tartaric acid by Mr. Perkin conjointly with Mr. Duppa, afford other admirable examples of synthetical research, which excited very great interest among chemists at the time of their publication.

It is seldom that an investigator of organic chemistry has extended his researches over so wide a range as is the case with Mr. Perkin, and his work has always commanded the admiration of chemists for its accuracy and completeness, and for the originality of its conception.

A Royal Medal has been awarded to A. C. Ramsay, F.R.S. Prof. Ramsay has been for a period of nearly forty years connected with the Geological Survey of Great Britain, and during by far the greater part of that time either as Director or Director-General of the Survey. During this long period, in addition to his official labours in advancing our knowledge of the geology of this country, he has published works on the "Geology of Arran," "The Geology of North Wales," "The Old Glaciers of North Wales and Switzerland," and "The Physical Geology and Geography of Great Britain," now in its fifth edition. His papers in the *Quarterly Journal* of the Geological Society, and elsewhere, are numerous and important, especially those on theoretical questions in physical geology, such for instance, as "The Glacial Origin of Lake Basins," "The Freshwater Formation of the Older Red Rocks," and "The History of the Valley of the Rhine, and other Valleys of Erosion." There are, indeed, among living geologists few who can claim to have done more to extend our knowledge in the important fields of geology and physical geography.

The Davy Medal has been awarded to P. E. Lecoq de Boisbaudran. The discovery of the metal gallium is remarkable for having filled a gap which had been previously pointed out in the series of known elements. Mendelejeff had already shown that a metal might probably exist, intermediate in its properties between aluminium and indium, before Boisbaudran's laborious spectroscopic and chemical investigation of numerous varieties of blende led him to the discovery and isolation of such a metal.

The separation of the minute traces of gallium compounds from blende is an operation presenting unusual difficulty, owing to the circumstance that compounds of gallium are carried down by various precipitates from solutions which are incapable by themselves of depositing those compounds.

EXPERIMENTAL DETERMINATION OF THE VELOCITY OF LIGHT[1]

II.

FIG. 7 represents a plan of the lower floor of the building. E is a three horse power Lovegrove engine and boiler, resting on a stone foundation; B, a small Roots' blower; G, an automatic regulator. From this the air goes to a delivery pipe up through the floor to the turbine. The engine made about four turns per second, and the blower about fifteen. At this speed the pressure of the air was about half a pound per square inch.

The regulator, Fig. 8, consists of a strong bellows, supporting a weight of 370 pounds, partly counterpoised by 80 pounds, in order to keep the bellows from sagging. When the pressure of the air from the blower exceeds the weight, the bellows commences to rise, and in so doing closes the valve, V.

This arrangement was found in practice to be insufficient, and the following addition was made: a valve was placed at P, and the pipe was tapped a little farther on, and a rubber tube led to a water gauge, Fig. 9. The column of water in the smaller tube is depressed, and when it reaches the horizontal part of the tube, the slightest variation of pressure sends the column from one end to the other. This is checked by an assistant at the valve, so that the column of water is kept at nearly the same point, and the pressure thus rendered very nearly constant. The result was satisfactory, though not in the degree anticipated. It was possible to keep the mirror at a constant speed for three or four seconds at a time, and this was sufficient for an observation. Still it would have been more convenient to have kept it so for a longer time. The test of uniformity was, however, very sensitive, as a change of speed of 0·02 of a revolution per second could be detected.

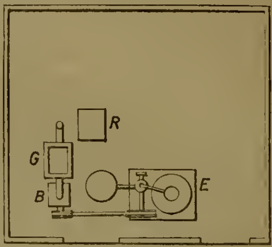

FIG. 7.

It was found that the only time during the day when the atmosphere was sufficiently quiet to get a distinct image was during the hour after sunrise or during the hour before sunset. At other times the image was "boiling," so as not to be recognisable. In one experiment the electric light was used at night, but the image was no more distinct than at sunset, and the light was unsteady.

The method followed in experiment was as follows:—The fire was started half an hour before, and by the time everything was ready the gauge would show 40 or 50 lbs. of steam. The mirror was adjusted by signals as before described. The heliostat was placed and adjusted. The revolving mirror was adjusted by being moved about till the light returned to it from the distant mirror. The axis of the revolving mirror was also inclined to

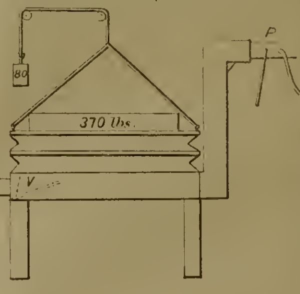

FIG. 8.

FIG. 9.

the right or the left, so that the direct reflection of light from the slit fell above or below the eyepiece, as otherwise this light would overpower that from the reflection from the distant mirror, &c., which forms the image to be observed. This inclination of the axis of rotation introduces a small error, which is duly allowed for in the calculations.

The distance between the front face of the mirror and the cross hair of the eyepiece was then measured, by stretching from one to the other a steel tape, making the drop of the catenary about an inch—when the error on account of the curve, and that due to the stretching of the tape, just counterbalanced each other.

The position of the slit, if not determined before, was then

[1] By Albert A. Michelson, Master, U.S. Navy. Read before the American Association. Continued from p. 56.

found as before described. The electric fork was then started, the temperature noted, and the beats between it and the standard fork counted for 60 seconds. This was repeated two or three times before every set of observations.

The eyepiece of the micrometer was then set approximately, and the revolving mirror started. If the image did not appear, the mirror was inclined forward or backward till it came in sight.

The cord connected with the valve was pulled right or left, till the images of the revolving mirror, represented by the two round spots to the left of the cross hair, came to rest. Then the screw was turned till the cross hair bisected the deflected image of the slit. This was repeated till ten observations were taken, when the mirror was stopped, temperature noted, and beats counted. This was called a set of observations. Usually five such sets were taken morning and evening.

The steel tape used was one of Chesterman's, 100 feet long. It was carefully compared with the copy of the standard yard made by Wurdemann, by a comparator. The result showed that the error of the tape was 0·006 foot. The true length was 100·006 feet.

The micrometer was also compared with the standard yard and the standard meter, the first giving for the value of one scale division,

division,	0·99650 mm.
and the second,	0·99642 ,,
Mean	0·99646 mm.

One turn of the screw was found equal to 1·0009 divisions. Hence the value of one turn was 0·99655 millimeter.

The distance between the pier for the revolving mirror and the stationary mirror was measured by means of the steel tape. Square lead weights were placed along the line, and measurements taken from one to the other, the tape resting on the ground and stretched by a force of 10 pounds. The measurements, five in all, were all made at about 62° F. The results are:—

	1985·13
	1985·17
	1984·93
	1985·09
	1985·09

	1985·08
True distance	1986·23

The rate of vibration of the standard fork armed with a tip of copper foil was found by allowing it to trace its record on the lampblacked cylinder of a Schultz's chronoscope. The time was given either by a sidereal break-circuit chronometer or by a mean time clock. In the former case the break circuit worked a relay which interrupted the current from three Grove cells. In the latter, the circuit was broken by the pendulum. The spark from the secondary coil of a Ruhmkorff was delivered from a wire near the tip of the fork. The rate of the chronometer, the record of which was kept at the Observatory, was very regular. It was found, from observations of transits of stars during the week, to be + 1·3 seconds per day, which is the same as the recorded rate.

The correction for temperature was found by Prof. Mayer to be + 0·012 v.s. for a diminution of 1° F.

My own result was + 0·0125 v.s.

Adopted + 0·012.

The following is the table of results:—

	256·069
	256·089
	256·077
	256·012
	256·087
	256·074
	256·061
	256·100
	256·084
	256·066
Mean	256·072

In one of these observations I counted the beats between this fork and another, first while the former was tracing its record, and then when it was free and in position as for use. The difference, if any, was less than 0·01 v.s.

As the result obtained depends directly on the rate of vibration of the fork, I was not willing to trust entirely to my own work, and asked Prof. Mayer to make a determination.

He kindly offered to make it together with myself. Accordingly, I went to the Hoboken Institute, and a series of ten determinations were made under the following conditions:—

The fork was wedged into a wooden support, and the tip allowed to rest on lampblacked paper wound about a metal cylinder, which was turned by hand. Break-circuit clock was used, the rate of which was ascertained by comparison with the Western Union time-ball. The spark from the Ruhmkorff passed from the tip of metal attached to the fork, piercing the paper. Size of the spark was regulated by resistances.

Table of results was as follows:—

	256·072
	256·126
	256·091
	256·108
	256·068
	256·090
	256·112
	256·124
	256·080
	256·070
Mean	256·094

The effect of scrape was sought for again, and found to be 0·003 v.s.

The effect of the support, however, was greater, both combined being − 0·026 v.s.

Making this correction, the result becomes:—

	256·068
Former result ...	256·072
Mean	256·070 vibrations per second, at 65° F.

The formulæ employed in the calculations are:—

$$(1) \quad \dots \quad \dots \quad \dots \tan\phi = \frac{d_1}{r}$$

$$(2) \quad \dots \quad \dots \quad \dots \quad V = \frac{2592000'' \times D \times n}{\phi''}.$$

Where ϕ = angle of deflection.
d_1 = displacement, or $r.\tan\phi$.
r = radius of measurement.
D = twice the distance between mirrors.
n = number of revolutions per second.
α = inclination of plane of rotation.
V = velocity.

D and r are expressed in feet, and d_1 in millimetres.

Substituting for d_1 its value,

$$d \times 0{\cdot}99655 \times \sec\alpha,$$

where d_1 is the displacement in turns of screw, and $\log \sec\alpha = 0{\cdot}00008$, we have, reducing to kilometres:—

$$(3) \quad \dots \quad \dots \quad \tan\phi = c_1 \frac{d}{r} \qquad \log c_1 = 0{\cdot}51457$$

$$(4) \quad \dots \quad \dots \quad \dots \quad V = c\,\frac{n}{\phi} \qquad \log c = 0{\cdot}49670$$

In the calculations the effect of temperature on the screw, scale, and tape used in finding ρ was neglected. It can be applied to the final result for the mean temperature, which was 75·6° F.

Correction for tan ϕ is − 0·000003 × 13·1 = − 0·0004.

Correction for V is + 12 kilometres.

The direction of rotation was right-handed. To eliminate any possible error on this account, the mirror in eight of the later observations was inverted, thus making the rotation left-handed, and the deflection measured to the left. The results were the same as before, within the limits of error.

To eliminate errors due to a regular variation in speed during every revolution, if any such could exist, the position of the frame was changed in several experiments. The results were the same as before.

To test the question as to whether the vortex of air about the mirror had any effect on the deflection, the speed was lowered to 192, 128, 96, and 64 turns per second. If the vortex had any effect, it should have decreased with the lower speed, but no such effect could be detected.

Finally, to test if there were any bias in making the observations, the readings in several sets were taken by another, and the results written down without divulging them. The separate readings, as will be shown in the following specimen, were as consistent as when made by myself, and the final results agree with those of other observations:—

Data for Working out Observations

Ut_3 fork makes 256·070 vibr. per sec. at 65° F.

D = 3,972·46 feet.

tan α = tangent of inclination of plane of rotation = 0·02.

c_1 = log = 0·51457.

c = log = 0·49670.

d = deflection as read from micrometer.

r = radius.

ϕ = angle of deflection.

n = number of revolutions per second.

V = velocity of light in kilometres.

B = number of beats per second between electric Ut_3 fork and standard Ut_3 fork. Electric fork makes $\frac{1}{2}$(256·07 + B + cor.) vibr. per second, and n is a multiple submultiple or simple ratio of this.

Cor. = correction for temperature of standard,
= − 0·012 v.s. per degree F.

Mean result[1]	299,728
Cor. for temp.	+12
Vel. of light in air	299,740
Cor. for vacuum	+88

Vel. of light *in vacuo* = 299,828 kilometres per second.

SCIENTIFIC SERIALS

American Journal of Science and Arts, November.—Mr. Stockwell, who has been systematically examining the physical theory of the moon's motion, here calls attention to a secular inequality in that motion, produced by the oblateness of the earth. For attracted points out of the plane of the equator, and not beyond the parallels of 35° 16′ (which is the moon's case), the attraction of the earth is less than it would be if the latter were spherical. The author says he has found several inequalities in the moon's motion, not recognised by existing theories, and of even greater practical importance than the foregoing.—The diamagnetic constants of bismuth and calc-spar in absolute measure have been determined by Prof. Rowland and Mr. Jacques. In their paper the former develops mathematical expressions for the various coefficients of magnetisation, while the latter describes the experimental method adopted: first, exploration of the field, and then noting the time of swing of little suspended bars of the substances in it. The constants for bismuth are

$$\left\{\begin{array}{l} k_1 = -\ ·000000012554 \\ k_2 = -\ ·000000014324 \end{array}\right\};$$

for calc-spar,

$$\left\{\begin{array}{l} k_1 = -\ ·000000037930 \\ k_2 = -\ ·000000040330 \end{array}\right\}.$$

—Mr. Gibbs's elaborate paper on vapour-densities is here concluded. The relation between temperature, pressure, and volume for the vapours of peroxide of nitrogen, formic acid, acetic acid, and perchloride of phosphorus, differs widely from that expressed by the usual laws, and the hypothesis of a compound nature of the vapour is probable. Mr. Gibbs had proposed equations to express the relations between temperature, pressure, or volume, and quantities of the components in such a "gas mixture of convertible components." In his paper he reviews all known experimental determinations of the vapour densities, and finds fair agreement with formula.—We note also accounts of Mr. Michelson's recent experimental determination of the velocity of light; of the remarkable Kane Geyser well (arising from a conflict between gas and water in a petroleum region), and of Mr. Edison's resonant tuning-fork.—Besides Prof. Marsh's recent address, there are further notes by him of new Jurassic mammals from the Rocky Mountains, showing a resemblance to known types of the Purbeck in England.

The American Naturalist, vol. xiii. No. 11, November, contains:—B. B. Redding, How our ancestors in the Stone Age made their implements; Isaac C. Martindale, Colorado plants; C. G. Siewers, Mould as an insect destroyer; W. N. Lockington, Notes on Pacific Coast fishes and fisheries; William Trelease, On the fertilisation of our native species of Clitoria and Centrosema; Recent Literature; General Notes; Scientific News; Proceedings of Scientific Societies.

Annalen der Physik und Chemie, No. 10.—A useful paper by Herr Fromme, in this number, treats of the electromotive force of the Grove, Bunsen, and Daniell batteries, as related to concentration of the liquids. The force of a Grove, whenever this cell is traversed by a very weak current, decreases continuously with concentration of nitric acid and approximately in proportion. That of the Bunsen, under like conditions, is, for the higher concentrations, about equal to that of the Grove, but from a concentration C = 55 greater, because it remains constant, while the decrease in the Grove goes on. The force of the Grove increases with increased concentration of the sulphuric acid to a maximum between C = 25, and C = 35, and thereafter decreases at a more rapid rate.—Herr Kundt and Herr Röntgen have succeeded in proving electromagnetic rotation of the plane of polarisation in several of the less easily condensed gases; and quantitative results for air, hydrogen, oxygen, carbonic oxide, and marsh gas, are here given. The rotation is in direction of the positive current (as with water and sulphide of carbon), and its amount is approximately proportional to the density. It is estimated that 253 km. air in the north-south direction would give a rotation of 1°. The author's apparatus (including a means of compression to about 250 atm.) is described.—Prof. Lommel contributes two papers; in one of them, on Newton's dust rings, he seeks to show the adequacy of the diffraction-theory to explain the phenomena, as against the diffusion theory (interference of diffusely reflected light); in the other paper, on Stokes's law, he controverts M. Lamansky's experimental support of the general validity of this law, which he (Prof. Lommel) had before impugned, as inapplicable to a certain "critical region" in which the fluorescence and absorption-spectra overlap.—Herr Wüllner describes a five-band spectrum of oxygen obtained both from the positive and the negative light in spectral tubes, to which was admitted oxygen produced by electrolysis. When the charge of gas was allowed to stand a quarter to half an hour, the spectrum was changed into that of carbon.—Herr Narr endeavours further to show that the loss of electricity by an insulated body in a gas cannot alone be explained by rise of temperature of the gas, or conduction through the insulating supports, or the presence of particles of foreign substances, as dust, water, or mercury vapour. Nor is there, apparently, a special conductivity of the gas in the ordinary sense.—The changes of density produced in steel by hardening and annealing, are indicated by Herr Fromme.—Herr Riecke has a mathematical paper on the doctrine of the poles of a bar-magnet; and Herr Gerland shows historical reason for believing that the caloric engine was conceived by Leibnitz in 1706, and that Papin is alone the inventor of the centrifugal pump.

[1] In the original a table of observations appears which we are obliged to omit for want of space, while we give the result of the same.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 27.—"A Memoir on the Single and Double Theta-Functions," by A. Cayley, F.R.S., Sadlerian Professor of Pure Mathematics in the University of Cambridge.

Chemical Society, November 20.—Dr. Gilbert in the chair.—The Chairman announced that a ballot for the election of Fellows would take place at the next meeting, December 4.—The following papers were read:—A chemical study of vegetable albinism, Part II. Respiration and transpiration of albino foliage, by Mr. Church. White foliage does not possess the power even in sunshine of decomposing the carbonic acid in the air. Experiments were made with leaves of the maple, holly, ivy, and Alocasia; 1,000 sq. ctm. of the leaves of the Alocasia evolved in two hours, 15·06 and 38·96 parts of carbonic acid per 10,000; 1,000 sq. ctm. of green leaves 1·14 parts. White holly sprays placed in water, gained in two hours five times as much in weight as green leaves, but when no water was supplied, the green lost about twenty times as much as the white.—Contributions to the history of putrefaction, Part I., by Mr. C. T. Kingzett. The author has examined dilute solutions of albumen, beef, and fish as to their oxygen-absorbing power in different stages of putrefaction, by titrating with permanganate. He finds that such substances require less oxygen as the putrefactive process proceeds; he also discusses the bearing of his results on the permanganate method of estimating the organic matter in potable waters.—Notes on manganese dioxide, by C. R. A. Wright and A. E. Menke. The authors have made an exhaustive study of the various methods for preparing manganese dioxide; in most cases the product contains potash and is deficient in oxygen; the methods which yielded the purest manganese dioxide were, heating manganese nitrate to 160° C., mixing a hot solution of a manganese salt with an excess of permanganate, or in the cold with the addition of zinc sulphate or ferric chloride. The volumetric processes of Kessler and Pattinson gave good results; the authors suggest some convenient modifications of these methods; they have verified the statements of Gorgeu, Guyard, and Pickering, but have disproved those of Morawski and Stingl.—On the reaction between sodium thiosulphate and iodine; estimation of manganese oxides and potassium dichromate, by S. Pickering. The author has carefully worked out the influence of dilution, excess of potassium iodide, heat, and other conditions, on the results obtained by Bunsen's volumetric method of estimating manganese oxide. He suggests a simplified method of procedure and compares results obtained by the two processes.

Linnean Society, November 28.—Prof. Allman, president, in the chair.—Messrs. Winslow, Jones, and Wm. Wickham were elected Fellows.—Sir J. D. Hooker exhibited a specimen and read a paper on the discovery of a variety of the cedar of Lebanon on the mountains of Cyprus (see *Science Notes*).—The president also laid on the table examples of a cone-bearing *Cedrus deodora*, grown by Mrs. C. St. Clair at Parkstone, Dorset.—Mr. E. M. Holmes exhibited and made remarks on a series of rare British lichens, Hepaticæ, and freshwater algæ. He noted that the so-called *Echinella articulata* which now chokes the filter beds of the reservoir at Bradgate, Leicester, was in reality an undescribed form, but bearing resemblances to Zooglœa.' Mr. Holmes likewise exhibited, and for the first time in England, the leaves, flowers and portion of the trunk of the tree (*Andira araroba*) yielding the so-called Goa powder. This vegetable secretion appears to destroy and replace the woody tissue of the heart-wood. The source of the powder was long enveloped in mystery, but from its containing chrysophanic acid it was believed to be the product of a fungus. Recently it has been found that the cane grows in Bahia, is sent to Lisbon, thence exported to the Portuguese colonies in the East where it is used as a specific for ringworm.—Mr. T. Christy showed two aboriginal Australian skulls with occipital thickening (forwarded by Dr. Bancroft), and supposed to have been induced by the blows of knobkerries.—Mr. Marshall Ward read a contribution to our knowledge of the embryo sac of phanerograms. In this paper, stages in the development of the ovule in *Butomus umbellatus*, *Alisma plantago*, *Anemone japonica* and other forms have been carefully observed and delineated from microscopic section. The views of Strasburger, Vesque and Warming are severally compared and reviewed, the author holding intermediate opinions. Mr. Ward advances the following:—The ovule so far as its nucleus is concerned arises as a group of cells which divide and become arranged in groups of sister cells symmetrically related to the shape of the whole organ. One cell group leads in growth and fulfilling a special purpose, becomes the embryo sac. Further feeble division of this latter produces a watery cell with two nuclei. Each nucleus again produces four nuclei by bipartite division followed by grouping, and a nucleus from the top group moves towards the middle sap cavity. Each group of four cells is a prothallus, and the cell producing this a macrospore. The two most successful macrospores behave similarly to those of some vascular cryptograms, and finally germinate, producing a ruddy prothallus of four naked nuclei. The egg-cell is an oösphere, all that is left of the lower part of the rudimentary archegonium, its upper part probably being represented by the two "synergidæ" which are to be looked upon as having acquired a secondary function from being merely protective and guiding neck-cells of an archegonium.—Mr. Alfred Haddon read a paper on the extinct land tortoises of Mauritius and Rodriguez. Examination of a large store of material obtained by Mr. Edward Newton, corroborates the two Mauritian species *Testudo triserrata* and *T. inepta* described by Dr. Günther; but it adds no fresh example to that apparently unsatisfactory species *T. leptocnemis*. Of remains from the Island of Rodriguez the species *T. Vosmæri* can alone be distinguished. The free coracoid of *T. inepta* is now for the first time recorded, while that of *T. Vosmæri* is wonderfully irregular in character. Great variation in the ankylosis of the coracoid with the shoulder girdle pertains in this extensive series in the Cambridge Museum.—The secretary read in abstract a communication by Mr. Edward J. Miers, viz.: On a small collection of crustacea made by Mr. Edward Whymper, chiefly in the N. Greenland Seas, with an appendix on additional species collected by the late British Arctic Expedition.

Entomological Society, November 5.—H. W. Bates, F.L.S., F.Z.S., vice-president, in the chair.—Mr. T. R. Billups, of Peckham, was elected an Ordinary Member of the Society.—Mr. W. C. Boyd exhibited a remarkable variety of *Aspilates citraria*, a specimen of *Cidaria testata* in which the hind wings were apparently absent, and a Noctua resembling *Hadena dentina*, but differing from that species in the form of the body. Mr. McLachlan read some remarks he had received from Prof. Forel relative to the sculptured stones on the shores of Lake Leman. Three principal types of markings were described, the first of which was ascribed to the agency of *Tinodes*.—Prof. Westwood exhibited a series of drawings illustrating the economy and transformations of several species of trichopterous and other neuropterous insects, also drawings of some undescribed species of exotic heteropterous-hemiptera contained in the Hopeian collection; he likewise drew attention to a modification of the professorship which had been proposed by the Oxford Commissioners, whereby the science of entomology would probably be neglected, and which would to a certain extent render nugatory the intentions of the founder of the professorship and donor of the collections. Prof. Westwood also referred to the affinity of the genus *Polyctenes*.—Mr. J. Jenner Weir exhibited some ants, apparently a species of *Atta*, which he had found in large quantities at Pisa, and which were peculiar in having collected around their nests, large quantities of small empty shells of *Helix caputata* and *H. virgata*; Mr. Weir also exhibited a specimen of an *Orgyia*, stated on the authority of Mr. Gates to have emerged from the larval skin, without passing through the pupal state.—Mr. W. L. Distant communicated a note relative to some Indian hemiptera which he had received from India through Mr. F. Moore for examination, with the names of the plants on which they were found.—The Secretary read a note and exhibited a photograph which he had received from Dr. Fritz Müller.—The following papers were also communicated:—"List of the Hemiptera collected on the Amazons by Prof. Trail," Pt. 1, by Dr. F. Buchanan White.—"Descriptions of new Genera and Species of Tenebrionidæ from Madagascar," by Mr. F. Bates;—and "Descriptions of new Coleoptera from East Africa and Madagascar," by Mr. C. O. Waterhouse.—Mr. Butler communicated a paper on the natural affinities of the lepidoptera hitherto referred to the genus *Acronycta* of authors.—From an examination, chiefly of the larval characters, the author proposed to distribute the British species of the genus among the Arctiidæ, Liparidæ, Notodontidæ, and Noctuites.

Meteorological Society, November 19.—Mr. C. Greaves, F.G.S., president, in the chair.—The following gentlemen were elected Fellows:—Capt. C. K. Brooke, Rev. E. Carr, M.A., Capt. R. A. Edwin, R.N., W. B. Fawcett, C. J. Harland, J. Lucas, F.G.S., H. Mellish, G. B. Nichols, the Earl of Northesk, Dr. J. Robb, T. H. Walker, and C. L. Wragge, F.R.G.S.—The reports on the phenological observations for 1879 were read, the Botanical being by the Rev. T. A. Preston, M.A., F.M.S., the Entomological by the Rev. C. H. Griffith, B.D., F.M.S., and the Ornithological by J. Cordeaux. With the exception of a few days in the earlier parts of February and of March, the whole of the year 1879 has been characterised by a temperature almost invariably below the mean, accompanied with much wet and little or no sun; the effect on vegetation has been consequently very great. Foliage has, as a rule, been excessively luxuriant and dark, "forming the most remarkable feature of the year;" but rarely has fruit been able to ripen, and the second shoots have frequently been weak and unhealthy. Flowering has invariably been very late, as much as a month in some districts, the hay harvest often not completed till nearly the end of August, some still in "cock" in the Moorland district of Staffordshire, as late as September 30; and the corn harvest not only extremely late, but the corn in very poor condition, not properly ripened. With regard to insects the two most notable occurrences of this most dismal season have been the swarms of *Pyrameis cardui* and *Plusia gamma*; both these species have been wonderfully numerous, especially the latter, which has absolutely swarmed. The great severity of the past winter caused an almost unprecedented mortality amongst birds, great numbers of various species succumbing to the cold. This mortality was perhaps most apparent amongst the Turdidæ and the starlings. Spring brought little or no improvement, birds nested much beyond their average time, and in a vast number of instances the first eggs have been addled and destroyed by cold rains and an abnormally low and continuous temperature. The scarcity of young partridges is probably unprecedented, on some manors not a young bird is to be found, and it will take several good nesting seasons to bring up the stock of their old numbers.—A paper on the meteorology of Zanzibar, by Dr. John Robb, was also read. The average annual rainfall is rather more than 61 inches, or only about double the average yearly fall in England; and the average number of rainy days is 120. The greater rains fall in March, April, and May, the lesser rains are from mid-October to the end of the year. The driest month is September, with an average rainfall of 1·86 inch; no month is rainless. The mean temperature of five years is 80°·6, and the average yearly range, from highest maximum to lowest minimum, is 17°·3. The hottest months of the year are February and March, with a mean temperature of 83°·1 and 83°·4 respectively; the cool months are July and August, averaging 77°·5 and 77°·7. This gives a small amplitude of the yearly fluctuation, rather less than 6°, and to this limited range of temperature is largely due the debilitating nature of the climate of Zanzibar, particularly as affecting the nervous system. The heat is constant and moist, and even gentle exercise is usually attended with excessive perspiration.

PARIS

Academy of Sciences, November 24.—M. Daubrée in the chair.—The following papers were read:—On the heat of formation of ammonia, by M. Berthelot. He was led to doubt previous data. The action of chlorine on ammonia cannot rightly be used (as it has been) for the purpose, nor that of hypobromites, though preferable. M. Berthelot resorted to direct combustion of ammoniac gas by means of free oxygen. He arrives at + 21·0 and + 12·2 cal. for the heat of formation of dissolved and gaseous ammonia respectively. Between + 12·2 and + 26·7 (the number previously adopted) there is + 14·5 difference (the largest experimental error hitherto made in thermochemistry).—On crystallised chlorophyll, by M. Trécul. A claim of priority; he described crystals of chlorophyll in 1865.—Geodetic junction of Algeria with Spain; international operation executed under the direction of Gen. Ibañez and M. Perrier, by M. Perrier. Science has now a meridian arc of 27°, the largest that has been measured on the earth and projected astronomically on the sky. M. Perrier gives interesting details of the work, which included transport of steam-engines and Gramme machines, &c., to four mountain tops, Mulahacen and Tetica in Spain, Filhaoussen and M'Sabiha between Oran and the frontier of Morocco. Military guards were required, and the parties watched for signals from August 20 till September 9, without success. The observations, commenced on the latter date, terminated October 19.—Experimental researches on a new property of the nervous system, by M. Brown-Sequard. Certain parts of the nervous system, when under irritation, cause suddenly, or nearly so, a notable increase of the motor or sensitive properties of other parts of the system. Thus transverse section of a lateral half of the base of the brain increases the motor properties of the parts of this centre before the section, while the opposite is produced on the opposite side; the same with section of the sciatic nerve, or a lateral half of the dorsal or lumbar cord.—Researches on nitrification, by MM. Schlœsing and Muntz. They appear to have isolated the organism which effects the oxidation of nitrogen, *the nitric ferment*. The corpuscles are abundant, very small, and slightly elongated. The ferment is killed infallibly by a temperature of 100°, and 90° seems to stop its action. Deprivation of oxygen and desiccation are unfavourable to it. In media rich in organic matters, mucor is its chief enemy. It is not found normally in air; mould is its most favourable medium.—Observations on the egg-laying of winged phylloxeras in Languedoc, by M. Mayet.—On quadratic forms, by M. Poincaré.—Determination of curves and surfaces satisfying the conditions of double contact, by M. Zeuthen.—Specific heat of solutions of hydrochloric acid, by M. Hammerl. He tabulates his results, and modifies M. Marignac's formula so as to make it applicable to concentrated solutions.—On a new mode of separation of nickel, and of cobalt, by M. Dirvell. This consists in mixing with a solution containing cobalt and nickel, a (cold) saturated solution of salt of phosphorus, mixed with a solution of bicarbonate of ammonia, no longer giving any ammoniacal odour.—Constitution of dibromised ethylene, by M. Demole.—New method of analysing with precision the potashes of commerce, by MM. Corenwinder and Contamine. This method (very rapid and exact) relieves the operator of the necessity of first separating the sulphuric acid, phosphoric acid, and silica, which form with soda insoluble combinations in alcohol.—On the alterations of the epidermis, in affections of the skin, or of mucous membranes, which tend to the formation of vesicles, pustules, or pseudo-membranous productions, by M. Leloir.—Observations on the salivary glands of the Echidna, by M. Viallanes. The parotid glands, so constant in mammalia, have in this case escaped the attention of Cuvier and Owen, and the latter denies their existence in Echidna; but the author found them well developed. Instead of being in front of the auditory canal they are far behind it, at the level of the middle of the neck. On either side there are two sub-maxillary glands, one deep, the other superficial, and the latter seems also to have escaped attention.—M. Chasles presented, from Prince Boncompagni, a portion of "Researches on the Manuscripts of Pierre le Fermat followed by unpublished Fragments of Bachet, and of Malebranche."—M. Larrey presented a Portuguese work by M. Ennes, "The Medical Life of Nations."

THURSDAY, DECEMBER 11, 1879

CAMBRIDGE UNIVERSITY

THE draft of the proposed Statutes just issued by the Commissioners, will, if we mistake not, mark an era in the history of one, at all events, of our Universities. It indicates a large and wise view on the part of the Commissioners, and though it will scarcely place Cambridge on a level, so far as teaching power goes, with a second-rate German University, it will go far to remedy the present state of things, and on it a superstructure may in time be laid in true harmony with the wants of the time.

What the Commissioners have really had to do is to convert an assemblage of "Hauts Lycées" into a living University, and, of course, this had to be done, if it were done at all, at the expense of the Colleges. This has long been foreseen, and the way in which it has been approached leaves nothing to be desired, so far as the manner goes; if a minimum only had not been fixed many might have said that the proposal hardly went far enough. The Commissioners evidently have faith. It will be best to give in the first instance an analysis in the words of the Statutes as far as possible.

In order to obtain contributions from Colleges for university purposes, it is ruled that the Colleges shall pay to the University in every year, out of their revenues, a sum determined according to the following quota, viz.:—

For every 1,000*l.* levied,—

Peterhouse	23
Clare	47
Pembroke	47
Gonville and Caius	62
Trinity Hall	33
Corpus Christi	43
King's	126
Queens'	19
St. Catharine's	19
Jesus	57
Christ's	57
St. John's	169
Magdalene	7
Trinity	229
Emmanuel	33
Sidney Sussex	25
Downing	4

This quota, which must have cost somebody a vast amount of trouble, enables any one to judge of the effect of the scheme on any College. Thus, assuming that Peterhouse pays its non-Resident Fellows 230*l.* a year, the sacrifice of two of these will alone be required to enable that College to do its share towards providing 20,000*l.* annually for University purposes.

We mention this because we are sure to hear of the Colleges being crippled, and it is clear that only wooden legs are threatened.

The quota is subject to revision at any time not less than five years after the approval of the Statute by the Queen in Council, and again after intervals of not less than ten years from that or any subsequent revision, the revision at such times being made, on the requisition of any one or more Colleges, by the Chancellor of the University with assistants.

The sum to be contributed by the Colleges in any year from January 1 next after the approval of the Statute by

the Queen in Council to the end of the year 1882 is not to be less than 8,000*l.* nor more than 10,000*l.*; in each of the years 1883, 1884, 1885, and 1886 not less than 12,000*l.* nor more than 15,000*l.*; in each of the years 1887, 1888, 1889, and 1890, not less than 16,000*l.* nor more than 20,000*l.*; in each of the years 1891, 1892, 1893, and 1894, not less than 20,000*l.* nor more than 25,000*l.*; and in every subsequent year not less than 25,000*l.*

The Colleges will not be required to contribute in any year a greater sum than 25,000*l.* without the consent of a majority of votes at a meeting of Representatives of the Colleges called for the purpose of considering the question.

This money contribution, however, is not the only one. Taking advantage of a system which has, it may be said, been suggested by the best of the Colleges themselves, it is ruled that there shall be in every College one or more Fellowships assigned to Professorships, such Fellowships to be called Professorial Fellowships.

The Professor admitted into any Professorship to which a Fellowship is thus assigned shall thereby *ipso facto* vacate any Fellowship he may hold at any College; and he shall have the same privileges, dividend, and emoluments as any other Fellow of the College to which the Professorship is attached. A Professor admitted into any Professorship to which a Fellowship is assigned by this Statute shall *ipso facto* vacate any Mastership he may hold at a College other than that to which the Professorial Fellowship attached to the Professorship is assigned; and if the Professor be admitted to the Mastership of any College other than that to which the Professorship is attached, he shall vacate his Professorship.

If upon the vacancy of any Professorial Fellowship the College declines to elect as Fellow the Professor to whose office the Fellowship is assigned, the Fellowship will remain vacant, its dividend being paid to the University.

A Professor retiring from office after holding it for not less than twenty years, shall be deemed thereafter an Honorary Fellow of the College, enjoying such privileges and advantages as the College may from time to time determine.

The first vacancy in the Fellowships of a College after the election of a Professor to whose office a Fellowship at that College is assigned, is to be appropriated to the Professorship.

The next section of the new Statutes deals with the Financial Board of the rehabilitated University. We need not refer to this here, except to say that the scheme seems wisely drawn and that the Colleges are to be well represented on it.

We next come to the Boards of Studies.

Eleven such Boards are to be constituted for all important departments of study recognised in the University, and are to consist of the Professors hereinafter assigned to such boards severally, together with such Readers, University Lecturers, Examiners, and other persons as may be chosen from time to time by the Senate.

The Boards to be first appointed are for—

Divinity.	Medicine.
Law.	Classics.
Language.	History.
Mathematics.	Moral Science.
Physics and Chemistry.	Music.
Natural Science.	

But with great wisdom, and here it is to be added that the Commissioners have introduced as much elasticity as possible, the University is to have power to vary the number and designation of these Special Boards from time to time on the recommendation of the General Board of Studies, provided that the whole number of such Boards shall never be less than eight.

The Professors assigned to the said eleven Boards are as follows:—

Divinity	Regius. Lady Margaret's. Hulsean. Norrisian. Ely.
Law	Regius. Downing. Whewell.
Medicine	Regius. Downing. Anatomy. Pathology.
Classics	Regius of Greek. Latin.
Language	Regius of Hebrew. Arabic. Sanskrit. Anglo-Saxon.
Mathematics	Lucasian. Plumian. Lowndean. Sadlerian.
Physics and Chemistry	Jacksonian. Chemistry. Mechanism. Cavendish of Physics. Astronomy and Astronomical Physics.
Natural Science	Woodwardian. Botany. Mineralogy. Zoology and Comparative Anatomy. Physiology.
History	Modern History. Disney. Thirlwall. Dixie.
Moral Science	Knightbridge. Political Economy. Mental Philosophy and Logic.
Music	Music.

Power is again given to the University to vary the assignment of Professors to the several Special Boards on the recommendation of the General Board of Studies.

Each Special Board is to consult together from time to time on all matters relating to the studies and examinations of the University in its department, and in consultation with the Professors, Readers, and University Lecturers connected with its department, frame a scheme of lectures in every year; taking care to provide that the subjects of the said lectures be determined with regard to the general objects of every particular Professorship, so as to distribute the several branches of learning in the best manner.

These Special Boards are to be controlled by a General Board of Studies, consisting of the Vice-Chancellor, one member of every Special Board of Studies elected by that Board, and eight members of the Senate.

The duty of the General Board is to consult together on all matters relating to the studies and examinations of the University, including the maintenance and improvement of existing institutions, and the establishment and maintenance of new institutions.

Among the functions of the General Board are the superintendence of laboratory work and the subordination when necessary of the Readers and University Lecturers to the professors.

Those who know Cambridge at present will have seen in the foregoing lists some new Professorships. As a matter of fact six new Professorships are to be established in the University for the following subjects, viz.:—

Physiology.
Pathology.
Mental Philosophy and Logic.
Astronomical Physics.
History, Thirlwall.
Ecclesiastical History, Dixie.

The Professors in these subjects are to be appointed before the end of the year 1882.

Here again the Commissioners show a wise discretion in ruling that the University shall have power to establish from time to time Professorships for other departments of learning or science. The Professorships so established may either be limited to a definite term of years or to the tenure of office of one Professor only; and if not so limited, they may be suspended or discontinued on the occurrence of any vacancy.

The stipends of the Professors, it is suggested, should be raised from their present level to correspond with the following scheme:—

Professors.

	£		£
Regius of Law	600	Experimental Physics	750
Whewell	500	Mechanism	400
Regius of Medicine	400	Astronomical Physics	500
Anatomy	300	Woodwardian	500
Pathology	600	Botany	300
Greek	750	Mineralogy	300
Latin	750	Zoology and Comparative Anatomy	600
Arabic	500	Physiology	600
Sanskrit	500	Modern History	400
Anglo-Saxon	500	Thirlwall.	
Lucasian	750	Dixie.	
Plumian	750	Knightbridge	400
Lowndean	600	Political Economy	300
Sadlerian	600	Mental Philosophy and Logic	400
Jacksonian	600	Music	200
Chemistry	750		

It must not be forgotten that the above sums are exclusive of the dividend on the Fellowship which is held by each Professor; and, further, the University is given power to vary the stipends from time to time, *provided that no such variation shall affect the interest of a Professor without his consent, or diminish the aggregate amount of payment to the whole body of Professors.* That is to say, the scheme is perfectly elastic, only the Commissioners do not intend to have it improved into effeteness.

The actual increase to the Professoriate, it will have been seen, is small; the ultimate increase to the teaching power of the University is, however, great. This is accomplished by the appointment, in connection with the departments of study for which Special Boards of Studies are appointed, of a body of teachers called Readers.

The number of Readers to be appointed is twenty-nine, distributed as follows:—

Divinity	2
Law	3
Medicine	2
Classics	4
Language	4
Mathematics	6
Physics and Chemistry	4
Natural Science	2
History	1
Moral Science	2

Of these not less than fourteen are to be appointed before the end of the year 1882, and the rest before the end of the year 1886.

The University may vary the connection of the Readers with the several Special Boards of Studies, and increase their number, upon the recommendation of the General Board of Studies.

The stipend of a Reader is 400*l.* a year, subject to variation by grace of the Senate upon the recommendation of the General Board of Studies, but no such variation shall affect the interest of a Reader without his consent, *or diminish the aggregate amount of payments to the whole body of Readers.*

The University is to have power to give pensions to retiring Readers according to circumstances, as the Senate may think fit.

Another arrangement for increasing the teaching power in the University is the appointment of University lecturers.

The General Board of Studies acting in conjunction with any Special Board may choose as Lecturers in the department of study for which the Special Board is formed such College Lecturers as they may think fit, who are willing, with the concurrence of their respective Colleges, to throw open their lectures to all students of the University.

The Lecturers so chosen are to be called University Lecturers, and each of them shall receive from the University an annual stipend of 50*l.*

No one is to be appointed to this office who does not receive from his College an annual stipend of at least 200*l.* as Lecturer, irrespective of the income of a Fellowship or other College emolument; the office of University Lecturer becomes *ipso facto* vacant if the holder of it ceases to hold the office of College Lecturer or receives from such office a less stipend than 200*l.* a year.

The number of University Lecturers and their connection with the Special Boards of Studies shall be determined from time to time, provided that when fit persons can be found the whole number shall be not less than thirty [one-half to be appointed before the end of the year 1882, and the rest before the end of the year 1884].

There is only one other point of the Statutes which we need analyse on the present occasion; this refers to the duties of Professors and Readers.

It is laid down that it shall be the duty of every Professor and Reader *as well to devote himself to research and the advancement of knowledge in his department* as to give lectures in every year.

It is impossible to estimate the good these words will do to the cause of research in England, where so many of our Professors sink to the level of mere traders. They should, though perhaps less necessary at Cambridge than elsewhere, be put up in letters of gold on the Senate House.

It will be sufficiently clear from the foregoing that with the great increase of teaching power which the Statutes confer the University should rise phœnix-like from its ashes, and that the present condition of things will be entirely changed.

How Cambridge in the new order of things will stand as compared with other Universities, and the lines along which future work and reforms may run, are questions so interesting that we may return to them and others on a future occasion.

AURORÆ

Auroræ: their Characters and Spectra. By J. Rand Capron, F.R.A.S. (London: E. and F. N. Spon, 1879.)

IN Mr. Gore's delightful book on the "Art of Scientific Discovery," it is said that "during the prosecution of an original investigation, the area of question and discovery enlarges as we proceed, and the research in some cases develops into such complexity and magnitude, that solution of its questions appears for a time hopeless. Generally, however, when that discouraging point is attained, the subject begins to clear, and by persistent research is gradually reduced to order, and is found to conform to a few general laws or principles."

The first part of this paragraph is only too apt a description of the present stage of the inquiry into the causes and nature of the Polar aurora. The striking character of the phenomenon itself, its evident connection with electric and magnetic disturbances, its unaccountable spectrum, and the relations which various observers have believed they had detected with solar spots, and coronal rays, are powerful stimulants to scientific curiosity. But so far the most painstaking researches have failed to seize the connecting link which should unite these various aspects into one organic whole; and we can only hope that the concluding sentence which we have quoted may be a prophesy of ultimate success. Under such circumstances Mr. Capron has done good service to science by collecting in a compact form the whole information which we possess on the subject, for it is only by careful study of what is already known that we can decide on the point of attack which gives the best hope of further conquest.

The first four chapters of the book are taken up with descriptions of specific auroræ. Among these we are sorry to miss a fuller account of the careful and accurate observations made by Lieut. Weyprecht during the Austrian Arctic Expedition of 1872-4. His description of arctic auroræ, as quoted from Payer's "New Lands Within the Arctic Circle," is exceedingly graphic and picturesque, but the original paper[1] as read before the Imperial Austrian Academy of Science, with its accurate classification of auroral forms, seems to have escaped the author's notice, as it is not even named in the list of papers in the appendix.

In Chapter V. the question of sound produced by the northern lights is discussed with the result that the balance of evidence is against it. Upon the height o

[1] "Die Nordlichtbeobachtungen der österreichisch-ungarischen arctischen Expedition 1872-74," von Carl Weyprecht, vorgelegt 17 Mai, 1877.

auroræ the most diverse conclusions are quoted, trigonometrical measurements giving results varying from a few thousand feet up to 1,000 miles, while there are several well attested instances in which auroral rays have been seen actually between the observer and terrestrial objects. If these latter observations are correct it is evident that auroræ may be produced near the earth's surface, and consequently in air of considerable density. They are supported by the fact that the lower trigonometrical measurements are less liable to fallacy than the higher, since in the latter it may always be objected that observers at different stations might have seen different arches, or that the auroral arch in general is merely a perspective illusion produced by the termination of vast numbers of parallel rays at the same height. Additional observations of auroræ seen between the observer and mountain-tops or other elevated objects would be of great scientific interest.

Another very important line of inquiry noted by Mr. Capron is that of the connection of clouds and auroræ, some types of cirrus cloud so much resembling auroræ in their forms and arrangement that it is very probable that in some of the reported cases of daylight auroræ the observers may merely have noted arches of cirrus. On the other hand, it is by no means unlikely that some form of cloud, especially that which consists of small particles of ice, may be illuminated by electric discharges, and be the actual material basis of the phenomenon. In this connection the coincidence of auroræ with mock suns and similar appearances is of interest, since these indicate the presence of minute ice-crystals in the upper air. The Whitby fishermen, on September 23 of this year, reported a considerable aurora, and on the same night the moon, "prior to being obscured by clouds, seemed to shed a radiant glow straight up and down" (probably a rudimentary *paraselene*).[1] If aurora really is ever visible by daylight, it would seem almost incontestable that it must consist in some form of mist capable of reflecting as well as of emitting light, for the light of the brightest aurora is very inferior in *intensity* to that of the moon's surface, and the moon by daylight only appears like a faint white cloud. An aurora is a very brilliant one which lights the earth as brightly as the full moon, and yet it probably covers a great part of the sky, while the moon's diameter is only half a degree.

On p. 47 Mr. Capron summarises a most interesting investigation of Donati's on the time of appearance of the great aurora of February 4, 1872, in which he shows that it did not appear everywhere really simultaneously, but *at the same local hour*, as if it depended, like celestial phenomena, on something fixed and external to the earth and its rotation. If this were more than a mere coincidence it would be of the utmost importance, as proving the cosmical character of the aurora, and it is very desirable that the investigation should be repeated as soon as a sufficiently extended display presents the opportunity. Probably there is already such information stored in meteorological registers for whoever will take the trouble to seek it out.

In Chapter VII. some observations of the moon during eclipse are described, and it is suggested that the curious red lighting of the shadowed portion may be due to lunar aurora. Spectral observations, however, seem to lend no support to the theory. It is noted that the colours of Jupiter's bands seem brightest during periods of auroral frequency.

[1] *Friends' Schools Nat. Hist. Journ.*, November 15.

The suggested connection between auroræ and zodiacal light is dismissed as unfounded, the latter evidently being some form of reflected sunlight, and having a totally different spectrum. The relation of the aurora to the solar corona seems almost equally shadowy, depending solely on a supposed coincidence of *one* of the lines in the coronal spectrum with a faint band of doubtful position in that of the aurora. We entirely sympathise with the author in his protest against the identification of spectra by the mere coincidence of *single* lines. Such coincidences within the limits of observation with instruments of small dispersion are exceedingly numerous, and the only safe ground of identification is that of likeness of general features, or at least coincidence of many lines.

The latter half of the volume is mainly devoted to the discussion of the auroral spectrum and its supposed coincidences. A reference to the plate and catalogue of auroral lines (p. 104), however, is sufficient to show that it is little use as yet to compare these measures with the accurate determinations of solar and spark lines, only one line out of the nine or ten given being positioned with any approach to accuracy or general agreement of the observers, even to the third figure. It is much to be hoped that Mr. Capron's suggestion of photographing the spectrum may prove practicable, and after his extraordinary success with the lines of vacuum tubes, as evidenced in his recent work on "Photographic Spectra," we can hardly doubt it. Dry plates are now prepared of extraordinary sensitiveness, and there is practically no limit to the time of exposure which may be employed.

We may briefly summarise, however, the results of comparison, so far as it is possible to compare with such defective measures.

Perhaps the first supposed identification of the auroral spectrum was that of Procter, who announced the correspondence of the bright yellow-green line with a band in a vacuum tube, which he supposed to be due to oxygen, but afterwards ascribed to a hydrocarbon impurity. We should not allude to this here, since the correspondence broke down under high dispersion, the auroral line proving slightly more refrangible than that of the tube; but that we wish to give a word of explanation as to the constant recurrence of these carbon lines, which have proved misleading to many experimenters. As is well known, the glass tubes and apparatus employed in such researches are made by the use of a blowpipe fed with coal-gas. The imperfectly burnt products of combustion inevitably pass into the comparatively cool glass tubes, and some of them, such as naphthalene, being of high density, they are condensed on the inner surfaces, and obstinately retained. When, however, they are subjected to the high vacuums of the Sprengel pump, they slowly volatilise, and being good conductors of the electrical discharge, become frequently so brilliant as completely to mask the spectrum of the small residue of other gas in the tube. By heating the tube strongly during exhaustion and "washing out" many times with the pure gas of which the spectrum is desired, these accidental spectra may be got rid of, or at least, so much paled as to betray their character as interlopers. This, however, is an amount of labour hardly to be expected of those who make tubes in a commercial way, and it is to be regretted that in Mr. Capron's painstaking research, he was compelled to employ such tubes instead of preparing them for himself. In a future research we would suggest the employment of tubes thoroughly heated and washed out with air in the first instance, and then worked with a blowpipe fed with pure hydrogen.

Unfortunately throughout, the tubes employed both by Mr. Capron and by Dr. Vogel seem to have been of doubtful purity. That figured on plate xiv. as hydrogen, contains bands of most suspicious resemblance to those of nitrogen, while the oxygen tubes, beside the one or two lines which seemed peculiar to themselves, gave others which were proved by direct comparison, to coincide with those of carbon and hydrogen, though the relative intensities seemed somewhat altered.

Supposed coincidences have been pointed out by Ångström, Vogel, and others, between the auroral spectrum and those of the various gases, such as oxygen, nitrogen, and hydrogen, which are present in the atmosphere. Unfortunately these coincidences do not extend to the one bright line which has been accurately measured, but only to the fainter ones, the positions of which are so doubtful that they might be made to correspond with any spectrum the lines of which were tolerably numerous, so that, intrinsically probable as they may be, we cannot regard them as positively established.

Absolutely no coincidence has been made out between the bright yellow-green line of the aurora and a principal one of any other known spectrum, and the same may be said of the sharp red line which occasionally flashes out in the spectrum, of red auroræ. Mr. Capron, however, points out that the green line coincides with a faint atmospheric absorption band, while the red line seems to occupy the position of the well-known *a* line of the solar spectrum, which Prof. Smyth has shown to be due to dry air.

It would not be fair to conclude our notice of "Auroræ" without a few words of praise to the admirable illustrations, several of which are chromolithographs. Of these perhaps the best in artistic effect is a facsimile of a water-colour drawing of a white aurora seen by the author at Kyle Akin in Skye. But in fact the whole appearance of the book suggests at first glance art rather than science, and we should suppose it is but rarely that a purely scientific treatise has appeared in so ornamental a dress.

OUR BOOK SHELF

A Treatise on Metalliferous Mines and Mining. By D. C. Davies, F.G.S. 8vo. (London: Crosby Lockwood and Co., 1880.)

THE objects of this book, as stated in the preface, are "to describe in a concise and systematic manner the conditions under which metallic ores are found in different countries in the world," and further, "by defining the zones occupied by the various metallic ores to lessen somewhat the amount of unsuccessful search for them." For the first purpose the author notices a large number of mines in various parts of the world, partly from his own observations and partly from accounts published in special journals and in the transactions of scientific societies; and for the second, he deduces from such descriptive matter certain general conclusions, which, in their more important points, are as follows:—

"Gold and silver never occur in strata newer than the carboniferous period."

"Copper ores with trifling exceptions are only found in the lower Cambrian carboniferous and new red sandstone formations."

"The highest horizon of lead ores is in the carboniferous limestone."

The conclusions are apparently derived from the study of phenomena in Wales, and to render them universally applicable all that is necessary is to reconstruct the geology of the rest of the world to suit them, which the author does in a thorough-going fashion. Thus the system requires for Cornwall that the age of the granites should be Laurentian, and the killas and other schistose rocks Cambrian, Silurian, Devonian, &c., in regular succession; and therefore the author concludes that the received view which makes the granite post-carboniferous is a mistake, and corrects his authorities accordingly, even when quoting their observations. Thus in reproducing Dr. Foster's account of the Hay Tor iron ores he disputes their probable carboniferous age, and states that they may belong to an older group, and that possibly of a still older age are the deposits of the West of Ireland, which are found interstratified on the basaltic and porphyritic rocks that skirt the west coast. It appears from a preceding page that by these are meant the iron ores of Antrim, which occur in miocene basalts on the north-east coast between Larne and the Giant's Causeway, and about whose age no question can possibly be raised by any one with the smallest geological knowledge.

Much of the information concerning foreign mines is exceedingly inaccurate, indeed it is difficult to see whence some of it is derived. For example, on p. 240, in a paragraph describing the zinc ores of Silesia, it is stated that the calamine of that country averages 20 to 30 per cent. of metallic zinc, which by selection and dressing is brought up to 70 per cent.; that in 1876 sixty-four mines produced 31,315 tons of zinc ore, and a reference to a paper by Huene in the *Journal* of the German Geological Society is given as an authority. As these statements are contrary to what is generally known upon these subjects, an attempt has been made to verify them; and it appears that (1) the average yield of the Silesian zinc ores in 1876 as smelted was 11·84 per cent.; (2) the production of zinc ores in Silesia in 1876 was 449,374 tons; (3) the paper by Huene, published in 1851, has nothing whatever to do with Silesia, as it describes some zinc mines at Bergisch-Gladbach near Cologne.

The above examples taken quite at random will be sufficient to show the generally untrustworthy character of the book. H. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Why the Air at the Equator is not Hotter in January than in July

THE following, I think, is the explanation of Mr. Fisher's difficulty (NATURE, vol. xx. p. 577), why the January temperature at the equator when the earth is in perihelion is not much higher than in July when in aphelion. The temperature to which Mr. Fisher refers is the ordinary temperature as indicated by the shade thermometer, which of course is simply that of the air. The difficulty is more apparent than real, for if we examine the *indirect* results which follow from the present distribution of land

and water, we shall see that there is no reason whatever why the air at the equator should be hotter in January than in July.

It is well known that, notwithstanding the nearness of the sun in January, the influence of the present distribution of land and water is sufficient to make the mean temperature of the whole earth, or, what is the same, the mean temperature of the air over the surface of the earth higher in July than in January. The reason of this is obvious. Nearly all the land is in the northern hemisphere, while the southern hemisphere is for the most part water. The surface of the northern or land-hemisphere, for reasons to which I need not here refer, becomes heated in summer and cooled in winter to a far greater extent than the surface of the southern or water hemisphere. Consequently when we add the July or midsummer temperature of the northern to the July temperature of the southern hemisphere, we must get a higher number than when we add the January or midwinter temperature of the former to the January temperature of the latter. For example, the mean July temperature of the northern hemisphere, according to Dove ("Distribution of Heat on the Surface of the Globe") is 70°·9, and that of the southern hemisphere 53°·6; add the two together and we have 124°·5, which gives a mean for both hemispheres of 62°·3. The mean January temperature of the northern hemisphere is 48°·9, which, added to 59°·5, the mean January temperature of the southern hemisphere, gives only 108°·4, or a mean of 54°·2. Consequently the air over the surface of the globe is hotter in July by 8° than in January, notwithstanding the effects of eccentricity. It is obvious that, were it not for the counteracting effects of eccentricity, the difference would be much greater. Ten thousand years ago, when eccentricity and the distribution of land and water combined to produce the same effect, the difference must have been far greater than 8°.

But it will be asked, How can this affect the air over the equator, which is not situated more on the one hemisphere than on the other? It is true that those causes have but little *direct* effect on the air at the equator, but *indirectly* they have a very powerful influence. The air is continually flowing in to the equatorial regions from both hemispheres. In fact, the air which we find there is derived entirely from the temperate regions. In July we have the northern trades coming from a hemisphere with a mean temperature as high as 70°·9, and the southern trades coming from a hemisphere with a mean temperature not under 53°, while in January the former trades flow from a hemisphere as low as 50°, and the latter from a hemisphere no higher than 60°. Consequently the air which the equatorial regions received from the trades must have a higher temperature in July than in January. The northern is the dominant hemisphere; it pours in hot air in July and cold air in January, and this effect is not counterbalanced by the air from the opposite hemisphere. The mean temperature of the air passing into the equatorial regions ought therefore to be much higher in July than in January, and this it no doubt would be were it not, let it be observed, for the counteracting effects of eccentricity. The tendency of the present distribution of land and water, when our northern winter occurs in perihelion, is to counteract the effects of eccentricity. But ten thousand years ago, when our winters were in aphelion, that cause would co-operate to intensify the effects of eccentricity. In fact, it would actually more than double the effects then produced by eccentricity. Now if the influence of the present distribution of land and water is so great as not merely to counteract but to reverse the effects of eccentricity to the extent of making the mean temperature of the earth 8° warmer in July than in January, it is not surprising that it should be sufficient to make the equatorial regions at least as warm in the former as in the latter period.

The fact that the equator at present is not hotter when the earth is in perihelion, instead of being an objection to the theory that the glacial period was due to an increase of eccentricity, as Mr. Fisher supposes, is in reality another strong argument in its favour, for it shows that a much less amount of eccentricity would suffice to induce a commencement of glacial conditions in the northern hemisphere than would otherwise be required, were it not for the circumstance to which Mr. Fisher refers. This objection, like many others which have been urged against the theory, arises from looking too exclusively at the *direct* effects of eccentricity.

There is another cause which must also tend to lower the January and raise the July temperature of the equator, viz., the northern trades pass further south in January than in July, and consequently cool the equatorial regions more during the former than the latter season. This general tendency of the trades to lower the temperature of the equatorial regions more in January than in July is of course subject to modifications from the monsoons, the rainy seasons, and other local causes; nevertheless, so long as the present distribution of land and water endures, so long will eccentricity have a counteracting effect upon the temperature of the air at the equator, which but for that would be hotter in July than in January.

Mr. Fisher somewhat misapprehends what he designates my "fundamental proposition." What I stated was "the temperature of a place *other things being equal* is proportional to the heat received from the sun." Those who have read what I have written on this point will remember that what I mean is, that if the temperature of any place depended alone on the direct heat of the sun that temperature would be proportional to the amount received. But then there is no such spot on the face of the globe—there is no place where heat or cold distributed by ocean or aërial currents does not affect the temperature—and I have in "Climate and Time," pp. 41–44, proved that, with the exception of the Arctic regions, there is no part where the temperature is so much affected by those currents as the equator. Were it not for the cooling effect produced by them the equator would be uninhabitable. No knowledge whatever as to the intensity of the sun's heat can be obtained from observations on the temperature of the air at the equator. The comparatively cold air flowing in from the temperate regions has not time to be fully heated by the sun's rays before it rises as an ascending current and returns to the temperate regions from whence it came. More than this these trades prevent us from being able to determine with accuracy the intensity of the sun's heat from the temperature of the ground; for the surface of the ground in equatorial regions is kept at a much lower temperature by the air blowing over it than is due to the intensity of the sun's heat. It thus becomes a very intricate problem to determine how much the surface of the ground is kept below the maximum temperature by the heat absorbed by the moving air.

I may add that although my estimates of the lowering effect resulting from the decrease of the sun's heat arising from increase of distance were computed according to Newton's law, yet I distinctly stated that this law holds only approximately true, but that nevertheless, for reasons given at p. 34 of "Climate and Time," it would be found near enough for my purpose.

James Croll

A Possible Consequence of our Present Weather

I have observed on several occasions that abnormally cold weather in November has been followed by an unusually mild mid-winter and January. These may possibly have been mere accidental coincidences, or they may be connected by a link of causation thus. Our climate, and more especially our winter climate, is largely influenced by the Gulf Stream, and whatever augments this raises our winter temperature, and *vice versâ*.

How, then, is the Gulf Stream likely to be affected by an unusual prevalence of Arctic winds and unusual cold in these latitudes? Such winds, must, to some extent, drive the waters of the Atlantic towards the source of the Gulf Stream, and tend to heap them there, and if there is any truth in the theory which attributes ocean currents to differences of oceanic temperatures, the present unusually cooled waters of the temperate zone will co-operate with the winds and augment this accumulation by their underflow. I do not mean that these combined actions are reversing the Gulf Stream at the present time, but simply that they are exerting a counter action or retarding influence which must result in augmenting the normal magnitude of the reservoir, or tropical accumulation, the outflow of which constitutes the Gulf Stream, and that thus the volume and velocity of the tropical waters which usually flow towards our coast will be augmented when the pressure of the present Arctic winds shall cease, and that our climate will be influenced accordingly. If I am right we may, in spite of present symptoms, or rather on account of them, have an unusually warm Christmas season and January.

This idea is not thrown out as a mere weather prophecy, but as a suggestive hypothesis and an incentive to what appears to me to be a very important and a much neglected branch of meteorological research, viz., systematic observation and record of the variations of the Gulf Stream. The countries whose coast is washed by this beneficent river of ocean are deeply interested in its movements. The Norwegians have already done something towards recording its variations, but so far as I can learn we, who are almost as deeply concerned as they are, have done little or nothing.

It may be that our agricultural troubles of the past three years are in some measure due to its disturbance; if so, it is of national importance that we should study its variations in order to learn whether they are reducible to law, and thus capaple of anticipations sufficiently reliable to induce prudential preparation for their national consequences. W. MATTIEU WILLIAMS

Stonebridge Park, Willesden

[With the extreme desirableness of an immediate and systematic observation, by European nationalities, of the temperature of the Gulf Stream, and of variations in the rate and direction of movement northwards from the tropics of the warm water and of the cold water southwards we very cordially concur. As another illustration of the practical utility of a better knowledge than we now possess of this subject, we may refer to the higher temperature and consequently larger evaporation than usual of the Atlantic in lower latitudes, along with a lower temperature, and consequently lower evaporation than usual farther north, in the beginning of the winter of 1878-79, as being in all likelihood one of the chief causes which brought us the miserable weather of the last twelve months. It is far from being beyond the reach of science to show how the larger evaporation from the more southerly regions of the Atlantic continued to spread itself over Europe further to south than usual, from which resulted the more southerly course pursued by our European storms, with the accompanying plague of east wind and rains over the British Isles, and the commercial distress thus deepened and prolonged. The importance of the inquiry is all the greater when it is considered that the past three years have impressively taught us how, not in India only, as shown by Blanford, but also in our British climate, certain types of weather, such as cold, warm, wet, or dry, when once fairly set in, tend to repeat themselves, and stamp their character on whole seasons or even a succession of seasons. It is by such lines of research that something more than a mere guess of the weather of coming seasons is to be obtained.—ED.]

The Climate of England

WILL you permit me, as a student for twenty years of the phenomena and laws of weather, to express my surprise that in meteorological tables or records, and weather notices in general, so little attention is bestowed upon the direction of the wind? It is true that in the daily forecasts issued from the Meteorological Office, this has been made for some time past a prominent, and, to my mind, the most valuable feature. Still the point has by no means been adequately dwelt upon by writers upon meteorology, the result being the loose and utterly unscientific talk we are accustomed to hear upon the very first principles of the problem of climate.

What is more common than to hear people remark that the climate of England has changed within the last few years? Their main ground for saying so is our having had for four or five seasons winters of exceptional mildness, followed last year by one of as remarkable severity and duration, and to all appearance likely to have following it one of not very different character.

The popular idea of climate has always seemingly been that of something affixed to the soil, a feature as fixed and characteristic as the rivers or mountain chains. Now, strictly speaking, there are for us but two real sources or loci of climate, the pole and the equatorial belts; the cold heavy currents of air from the Arctic regions flowing south, to take the place of the light warm air so rarefied by the sun's heat as to form a comparative vacuum. The aërial set of flux and reflux thus tending to be set up along meridian lines is deflected eastwards by the rotation of the earth on its axis, with the result that in our part of the earth at least the wind is found to blow from some point of west to east for much about 200 days out of the 365. So limited is our sea-girt insular area, that within a few hours, depending on the velocity of the wind, the whole breadth of Great Britain is traversed, so that instead of breathing a climate engendered by local conditions, and to be called our own, we live in an atmosphere reaching us from abroad, and modified by the conditions through which it passes to us (into which I forbear at present to enter in detail). Observation combines with theory to establish the primary fact that what may be called the ruling line or axis of prevailing wind in our island is that from south-west to north-east approximately. Along this line may be said to take place, in the main, the perennial contest of opposing air-currents, on which depends the character of our seasons, the light warm balmy breath of the equatorial current, or so-called Gulf Stream, having to battle with the dry, heavy, chilling atmospheric masses bearing down direct from the Polar regions, or circling over the steppes of Russia, or the uplands of Scandinavia. Drawing a line at right angles to this, or from north-west to south-east, we shall find that so long as the wind keeps well within the south-westerly aspect of this diagonal, frost either sharp or long is with us impossible, and as an immediate response to the vane veering or backing from one side to the other, a rise or fall of the thermometer is to be observed, which may vie with that due to the sun's place in the zodiac. The mercury may be seen to stand as high in January as in June. If we ask why the four or five winters preceding the last severe one were so exceptionally mild, the proximate answer is that during the months when the sun's power continued low, we enjoyed a succession of south-westerly winds which tempered "winter's flaw." Last year, on the contrary, the wind kept early and persistently to the northerly and easterly quarters; and were proper tables available, I believe that an abnormal prevalence of those Polar currents would be shown to have marked the later seasons of this most exceptional year.

The problem is thus shifted a step.

What we have to inquire into is the cause or causes to which is due so exceptional and persistent a flow of wind from one alternative quarter to the other.

To aim at anything like a forecast of winter or summer weather before knowing what the prevalent set of the aërial currents is to be, is to invert the essential conditions of the problem, and to put the cart before the horse. It is for meteorologists, I would urge, to concentrate their attention upon the causes or laws, which determine or disturb the periodical motions of the earth's envelope, especially as it oscillates to and fro across the limited and exceptionally situated group of the British Islands. Simple as such a suggestion may appear to men of science, the notices they have as yet given us will by no means, I believe, show it to be superfluous. It is the conviction that the primary and elementary conditions of the problem are far from having been grasped by the general public that has led me thus far to trespass upon your space.

Gray's Inn, December 2 ALEXANDER TAYLOR

A Correction

A FEW weeks ago I had some correspondence with the late Mr. J. Allan Broun on the subject of my communication to NATURE, vol. xx. p. 54, in the course of which he drew my attention to an error in my value for the barometric oscillation corresponding to 1° F. $\left(q = \frac{\Delta p}{\Delta t}\right)$ at Sibsagar. He said:—

"You had a note on the difference of results for Lucknow and Sibsagar both nearly at the same height; the values of q you made 0·017 and 0·028, the latter for Sibsagar should have been 0·018 or $\frac{\Delta p}{\Delta t} = \frac{0·477}{26·6}$."

I acknowledge the error, and take this opportunity of mentioning it as I fear Mr. Broun's article on the subject, which he told me was shortly to appear in NATURE, and in which he would most probably have drawn attention to my error, has been cut short by his sudden and lamented decease. His last letter to me containing the above correction was dated November 15, just a week before he died.

I may add that while the above error (which was due to my taking Δt to be 16·6 instead of 26·6) disqualifies Sibsagar from demonstrating that the value of q depends on the distance from the coast independently of the altitude, the rule is nevertheless generally evident, and can be shown equally well by taking Goalpara instead of Sibsagar with Lucknow.

At Goalpara h = 386 feet,

$$q = \frac{\Delta p}{\Delta t} = \frac{0·448}{18°·7} = 0·023.$$

E. DOUGLAS ARCHIBALD

Tunbridge Wells, November 29

Monkeys in the West Indies

IN his very interesting paper on "Tails," which appeared in NATURE, vol. xx. p. 510, Prof. Mivart says, "Monkeys are scattered over almost all the warmest parts of the earth save the West Indies, Madagascar, New Guinea, and Australia." As regards the West Indies the statement is not quite correct, and I am sure Prof. Mivart will be glad to receive the following information on the subject. In the islands of St. Christopher and Nevis, which form part of the division of islands commonly called the Lesser Antilles, monkeys are found in large numbers, and a planter friend in the former island, which I have recently visited, assured me that he had lately been obliged to appoint a "monkey-watchman" to protect the cane-fields and the sweet-potato fields of his estate from the destructive raids of bands of monkeys.

In the island of Nevis, which at one time must have formed part of St. Christopher, and which is now only divided from the latter by a very narrow arm of the sea, appropriately called "The Narrows," monkeys—the same as those of St. Christopher—exist in great numbers, and I may add that the tails are "perfectly prehensile," *i.e.*, "naked beneath towards the tip."

Of Trinidad I cannot speak from personal observation, but a scientific friend of mine, Dr. H. A. Alford Nicholls, who lately visited Trinidad, kindly writes to me as follows:—"Prof. Mivart has certainly made a mistake about there being no monkeys in the West Indies. I find, too, that in a work on 'Central America, the West Indies, and South America,' edited by the traveller, Bates, it is stated that there are no monkeys in the Antilles. You know more of the monkeys of St. Kitts and Nevis than I do, but I can tell you something of your Trinidad cousins. There are two kinds of monkeys in Trinidad, and as the fauna is continental, they will doubtless be found on the mainland of South America. One belongs to the Mycetes, and it is called the Red Howler, partly on account of its loud and hideous cries; the other, a diminutive specimen of the Cebidæ, is called the 'Sapajou;' it is a Cebus."

I shall be glad to supply any further information on the subject of monkeys in St. Christopher and Nevis.

Dominica, British West India, November 11 EDMUND WATT

Earthquakes in Iceland

IN NATURE, vol. xxi. p. 89, I see the earthquake which occurred in Iceland on September 24 last ascribed to "volcanic eruptions in the Krísuvík Mountains, a locality where eruptions have not been known within the memory of the present generation." The use of the word "eruption" here is misleading, for though the earthquakes, which frequently occur at Krísuvík, are no doubt caused by volcanic action, nothing of the nature of an *eruption*, in the usual sense of the word, has been known to occur there within the historical period. The boiling springs, mud caldrons, and sulphur deposits, for which Krísuvík is noted, are, on the authority of Prof. Bunsen (Letters to Berzelius), to be ascribed to a pseudo-volcanic action occurring at comparatively slight depths. Though slight earthquake shocks have frequently occurred, during the last eighteen months, while I was at Krísuvík, I have never observed that they had any effect on the boiling springs and other thermal phenomena.

The earthquake of September 24 last, though more violent than any other which I have experienced there, differed from the rest in no other respect. They are generally confined to the neighbourhood of the hot springs and sulphur beds, though the last was felt over a wider area, and seldom do any damage.

Edinburgh, December 1 W. G. SPENCE PATERSON

Diatoms in London Clay

I DO not know if diatoms have been observed in the London clay, or not. If they have not, it may interest many to know that I have discovered triangular, quadrangular, elliptical, and discoidal forms in the London clay of Sheppey. The frustules are frequently perfect, and the markings are plainly discernible as square-sided depressions or elevations; I am not certain which. One of the discoidal forms is an old friend, for I observed it in abundance two years ago; but as I then had no knowledge of diatoms, I passed large quantities by as pyritous concretions.

In my ignorance I stated in a paper on the well referred to (*Proc.* Geol. Assoc., vol. v. p. 357): "It should be mentioned that at and below 293 feet the clay was thickly studded with very minute disks of iron pyrites, each having a boss in the centre, and the edge slightly turned up all round. They were uniformly perfect, as much so as if cast in one mould."

A few days ago I saw *Anticodiscus oreganus*, and was struck by its resemblance to the disks I had seen in the London clay. As I had not preserved any of these, I set to work to get more, if possible, and last night I was fortunate enough to find several distinct species. W. H. SHRUBSOLE

62, High Street, Sheerness-on-Sea, December 2

Colour-Blindness

THE remarks of Mr. Everett at the close of his paper (NATURE, vol. xxi. p. 62) on Prof. Hering's theory, seem to be founded on a misconception. Prof. Hering assumes, not four, but six elements of colour-sensations connected by the equations—

$$B + W = 0\,R + C = 0\,B' + Y = 0.$$

The specification of any colour in his system contains there independent variables, and is of the form

$$D = a\,W + B'\,R + cb,$$

and it will usually take four equations to eliminate WR and B.

It must be noted that Prof. Hering assumes that the red-green and blue-yellow sensations never occur in nature pure, but always mixed with white. If this is granted I do not think that the result of Maxwell's experiments on colour-mixture will be found inconsistent with his theory. JOHN TENNANT

19, The Boltons, S.W., November 28

Intellect in Brutes

I OFFER the following illustrations of reasoning powers in animals, should you care to insert them.

1. Some years since, while hunting in Northern Michigan, I tried, with the aid of a professional trapper, to entrap a fox who made nightly visits to a spot where the entrails of a deer had been thrown.

Although we tried every expedient that suggested itself to us, we were unsuccessful, and, what seemed very singular, we always found the empty trap sprung.

My companion insisted that the animal dug beneath it, and putting his paw beneath the jaw, pushed down the pan with safety to himself; but though the appearances seemed to confirm it, I could hardly credit his explanation. This year in another locality of the same region, an old and experienced trapper assured me of its correctness, and said in confirmation, that he had several times caught them, after they had made two or three successful attempts to spring the trap, by the simple expedient of setting it upside down, when, of course, the act of undermining and touching the pan would bring the paw within the grasp of the jaws.

2. A Dandie Dinmont terrier, after the death of his mistress, was playing with some children in a room into which was brought a photograph (large) of her, that he had never previously seen. It was placed upon the floor leaning against the wall. In the words of my informant, who witnessed it, the dog, when he suddenly caught sight of the picture, "crouched and trembled all over, his whole body quivering. Then he crept along the floor till he reached it, and, seating himself before it, began to bark loudly, as if he would say, 'Why don't you speak to me?'" The picture was moved to other parts of the room, and he followed, seating himself before it and repeating his barking.

3. The dog whose demoralisation by the salute of a monkey was published in NATURE, vol. xviii. p. 77, recently had another encounter with one, and behaved in so sneaking a manner as showed that he had not forgotten his first impression.

Boston, November 22 C F. CREHORE

Electric Lighting

IN NATURE, vol. xx. p. 641, you say, "For the first time perhaps in the history of electric lighting two rival magneto-electric machines are illuminating the same hall." I can state an earlier instance, though not an exact parallel. At the annual fair of the American Institute, held in New York during September, October, and November, 1878, the main hall was illuminated by the Wallace-Farmer machine and light, and the machinery hall—directly communicating with it, by the Brush apparatus. The two halls form practically one.

ALEX. S. GIBSON

Norwalk, Conn., U.S.A., November 14

JEAN BAPTISTE ALPHONSE CHEVALLIER

THE death is recorded on December 1 of Prof. A. Chevallier, who deserves notice here as one of the Nestors of French pharmaceutical chemistry. He was born at Langues, in Lorraine, July 19, 1793. After completing a course of scientific study, he opened a pharmacy in Paris, where he soon attracted attention by his talent for investigation, as well as by his ability in scientific literary work. In 1825 he assumed the editorship of the *Journal de Chimie médicale*, and continued this labour until some years prior to his death, having as associates Payen, Pelouze, Robinet, Orfila, Péligot, Dumas, and other leading chemists of the day. Soon after entering upon his career as investigator, his merits were recognised by the government, and he gave up his business connections to accept the Chair of Chemistry at the École supérieure de Pharmacie, a position which he occupied up to the time of his death.

Among Chevallier's earlier researches should be mentioned his investigations on the absorptive capacities of living plants for various inorganic solutions, and especially his exhaustive studies in connection with Payne, on the hop and the potato, which attracted general attraction. In physiological chemistry notice should be taken of his detection of various poisonous metals, such as lead and copper, in normal organisms. The knowledge of French mineral waters is also greatly indebted to his numerous and exhaustive analyses, and the presence of arsenic in many springs was first signalled by him. The greater portion of Chevallier's life was devoted to the chemical phases of public hygiene, and in this connection he published a number of valuable papers on the detection and prevention of adulteration in a large variety of articles of food, methods of preserving food, disinfectants, &c. Of his devotion to the cause of scientific inquiry an interesting anecdote is related from the earlier part of his career. A case of poisoning was to be tried at Paris in which acetate of morphine had been used, and Chevallier, who had sold the salt to the murderer, was summoned as a witness. Anxious to have the full nature of this hitherto untried poison well established, and being limited as to time, he immediately undertook a thorough investigation of its toxic effects on his own system, and succeeded so well that at the trial he was able to give a detailed description of the symptoms attending the use of the drug in question.

As a scientific writer Chevallier was widely and deservedly known. His first work in 1824, in connection with Payen, "Traité des réactifs chimiques," reached a third edition in five years. In 1826-29 he published, with Richard and Guillemain, an extensive "Dictionnaire des Drogues simples et composées," in five volumes. In 1850 appeared his admirable "Dictionnaire des Altérations et Falsifications des Substances alimentaires, médicamenteuses, et commerciales," which reached a third edition in 1858, and was translated into other languages. Other important works were "Recherches sur les Moyens appliquées à la Conservation des Substances alimentaires" (1858), "Du Café, son Histoire, son Usage, etc." (1862); "Traité des Désinfectants sous le Rapport de l'Hygiène publique" (1862).

T. H. N.

THE SEWAGE OF LONDON

GENERAL SCOTT, in his recent paper at the Society of Arts, entitled "Suggestions for Dealing with the Sewage of London," deserves credit for having drawn attention to a subject which in itself must have especial interest for all residents in the metropolis, but which, from the manner in which he has dealt with it, possesses further attractions for those who have made the scientific aspects of the sewage question their study, in that he has really attacked this much-debated problem in an entirely new direction, and has in so far entered upon fresh ground. We do not remember that any previous investigator has set himself the task of examining into the composition and character of the suspended matters of water carried sewage coupled with the possibility of the mechanical separation by simple subsidence (1) of the heavier mineral particles or the detritus, and (2) of the lighter flocculent particles, which latter, consisting as they do mainly of the fecal matters, possess a far higher manurial value than the heavier substances washed from the roads and pavements.

The sludge deposited from sewage by one or the other systems of precipitation has received hitherto the chief share of attention from scientific men, and even when the possibility of recovering the solid matters in sewage by some system of straining or rude filtration, or the retention of such solids in tanks, in which the sewage is brought to temporary quiescence, has been considered, it seems on all occasions to have been the practice to regard the entire bulk of such deposits as an inseparable compound of very low value from the manure point of view. It is of course the manurial value of the ingredients contained in suspension and in solution in sewage which has been so frequently inquired into by chemists; and, beginning with the report of Dr. Hoffman and Mr. Witt in 1857, down to that of Messrs. Rawlinson and Read in 1876, a vast mass of valuable information concerning the nature, composition, and value of the manurial elements of town sewage has been accumulated. It has remained for General Scott to point out that—

1. A very large proportion of the solid suspended matters may be removed from sewage by simple subsidence.

2. That such matters may roughly be separated, the more valuable from the valueless, by the method in which such subsidence is accomplished.

3. That after such preliminary treatment, any chemical process for the clarification and partial precipitation of the dissolved impurities of sewage may be carried out far more readily, and under conditions rendering their success in an economical point of view one of greatly increased probability.

4. General Scott has indicated various simple methods for dealing with the silt and detritus removed from the sewage at a relatively small expense; of deodorising and fitting the sludge obtained by subsidence for the manufacture of a manure; and lastly, a mode of further purifying the London sewage by a system of chemical treatment whereby it may be rendered suitable for discharge into a river of large volume.

Assuming the dissolved impurities to be incapable of recovery unless the sewage water can be utilised for irrigation, the first object of General Scott's paper was to show how large an amount of harm was done to rivers and the dwellers on their banks solely by the solid matters contained in sewage. By means of extracts from the reports of the various Royal Commissions who have examined into this question, and the information furnished to the Metropolitan Board of Works by their own advisers, Messrs. Bidder, Hawksley, and Bazalgette, he proved that the deposits in the river, the mud banks, the foul emanations from which were most unhealthy, and the dangers to navigation were all due to the discharge of the solid ingredients of raw sewage into rivers and into the Thames.

General Scott next entered very minutely into the composition of the suspended matters of sewage. An estimate of the total weight of solid matters due to a mixed population of 3,500,000 persons, with a proportionate allowance for the fertilisers existing in the excreta of animals, together with the *débris* of the animal and vegetable substances which might find their way into the sewers, would manifestly represent the sum total of the organic matters in London sewage.

Concerning the gross annual amount of organic matters different estimates appear to vary very slightly, and in assuming them in the case of London at 50,000 tons per annum, there would seem to be but a small margin for error; the quantities of detritus, however, have been very differently stated by the various authorities. From the most reliable analyses of the London sewage, taken at all periods of the day and night, and in many different parts of the metropolis, there appears to be a tolerable unanimity in assigning the ratio of the organic to the mineral ingredient of the suspended matters to be as 1 is to 2. After a period of settlement it is found that the proportion is, by the subsidence of the heavier mineral particles, exactly reversed, as the larger portion of these valueless components of sewage impurities rapidly subside, entangling with them about ⅕th of the organic matters in suspension. General Scott proposes, therefore, a double system of tanks. The first set would consist of a series of shallow catch pits, in which the sewage will only be brought to a state of partial repose, and in which it will part with about four-fifths of the solid mineral matters and one-fifth of the organic matter. In the second set of tanks, in which more time will be given for the settlement of the matters in suspension, the sewage will be deprived of nearly all the remaining suspended impurities, namely, one-fifth of the mineral, and four-fifths of the organic matters. If we assume the gross weight of the organic matters at 50,000 tons per annum, the mineral ingredients will, according to the analyses quoted by General Scott, equal 100,000 tons, and the total of 150,000 tons thus obtained, is, in reality, a very low estimate of the amount of the suspended matters in London sewage. These matters, General Scott is of opinion, he could roughly separate in his tanks thus:—In the detritus tanks he would obtain 80,000 tons of mineral matters, together with 10,000 tons of organic matters; in the second set of tanks he would expect to find about 20,000 tons of mineral matters mixed with about 40,000 tons of organic matters. The exact percentage composition of this latter sludge would, he believes, after studying and comparing many analyses and valuations, be somewhat as follows:—

Organic matter (without nitrogen)	66·50
Nitrogen	3·50
Phosphoric acid 2·80 = tribasic calcic phosphate...	6·07
Potash	1·25
Sand and inert mineral matter	22·68
	100·00

In the debate which took place after the paper, Dr. Frankland, while admitting General Scott's process to be "worthy of trial," took exception to this estimate, and maintained that his experience was "that after the separation of detritus from London sewage, the maximum percentage of organic matter was 63, whilst the minimum was 21, the average being 39½, and these high percentages were obtained under exceptionally favourable circumstances, because, in the collection of these samples of sewage, little or none of the so-called detritus was mixed with it at all." He further stated that "he did not think it would be safe to calculate on more than 33 per cent. of organic matter in the dried sludge." This question of the possibility or otherwise of effecting a separation more or less perfect, of the mineral from the organic elements of the sludge lies at the root of General Scott's proposals, and while giving all due weight to Dr. Frankland's high authority, we are compelled to admit that General Scott's figures, many of them based on the analyses of Dr. Frankland himself, seem to point in the opposite direction to that pointed out by Dr. Frankland, as concerns the relative proportion of the mineral and the organic matters after settlement.

The question to be decided is, admitting the composition of the sewage solid to be in the first instance 2 mineral to 1 organic, can we reduce this proportion to 2 organic to 1 mineral, by bringing the sewage to a state of quiescence in tanks? This could be tried on a sufficiently large scale to settle the point at issue in a very short time, and as it is a question which to a great extent depends upon the result of actual experiment on a large scale, it is certainly one for the officers of the Metropolitan Board of Works to decide.

Passing over the theoretical values of the deposits, based upon their contents in nitrogen, phosphoric acid, and potash, which General Scott has dealt with very carefully, we come to the question of deodorising the sludge and its preparation as a manure. For the former purpose the employment of slaked lime is advocated, used in the small quantity of only ·66, or less than 1 per cent. of the total weight of the sludge. This slaked lime, made into milk of lime by the addition of water, is to be thoroughly incorporated with the sewage deposit, and a sufficient amount of crude superphosphate is then to be added, in order nearly, but not quite, to neutralise the lime. A crystalline precipitate of phosphate of lime is thus formed in the sludge, which greatly aids in the drying of the compound, or, to put it more correctly, facilitates the extraction of the water. Some of those who took part in the debate doubted whether General Scott, in his estimate of 20*s.* per ton on the dried material, which included the cost of chemical treatment, had made a sufficient allowance for the great labour and difficulty which would have to be incurred in drying the sludge for use as a manure. Dr. Voelcker, who pointed out that "he had gone very carefully into the figures in the paper, and was very glad to find that General Scott had avoided those exaggerations which frequently disfigured calculations of this kind," quoted some observations he had made tending to show that sewage sludge parted with water with extreme difficulty, though he admitted that after treatment with lime and phosphoric acid such sludge would dry with greater rapidity. In the various forms of filter presses now largely used for drying clay slip and expressing precipitates, very great improvements have recently been effected, and it has been stated on good authority that it becomes possible by their use to reduce the moisture in such materials as low as 50 per cent. There still remains, however, a large proportion of water to expel, and, as Dr. Voelcker stated, this can only be accomplished by means of artificial heat.

The question of the cost of drying sludge is one which possesses many features of interest, and the entire subject would be one well worthy of the special consideration of the Society of Arts at their annual conference on the treatment of sewage. We should like to have devoted more time to the calculations of General Scott of the theoretical value of the three chief fertilisers present in sludge, viz., nitrogen, phosphoric acid, and potash, as also to the expense of preparing soluble phosphoric acid, concerning which latter point Dr. Voelcker threw out some valuable suggestions during the discussion, but we must now conclude. We entirely agree with General Scott in his denunciation of the folly and imprudence of continuing to cast raw sewage into the Thames; he has certainly pointed out a way of greatly abating the present evil, and as the plan he advocates could be tried upon a sufficient scale at an almost nominal expense, we feel justified in urging with Dr. Frankland that this should be done, and we cordially echo his concluding observation, "that the Board of Works have no right to look for a profit in getting rid of the objectionable matter. If they can succeed in doing it without a loss or at a cost not greater than that involved in dredging it out of the river again, it ought to be done; because if sewage mud is deposited in the river there must be an obstruction to navigation, besides the putrefaction of organic matters which, when deposited on the banks of a tidal estuary, become very offensive, especially in warm weather."

So far as one can judge from the facts adduced by General Scott, his scheme promises to be more efficient for the ends aimed at than any hitherto proposed, and certainly it seems to us that the great scientific principles which are applicable to the subject have been kept well in view. And from our standpoint this must be the test of the efficiency of any scheme for the disposal of sewage. We fear that hitherto those with whom the decision rests as to what scheme shall be adopted for the disposal of the sewage of London have looked upon the question too much as one between rival "schemes," and considered far too much the supposed interests of rival "bodies," and too little the clear teachings of science and the welfare of the public. It is evident that for London, at least, the whole subject of the disposal of sewage will have very soon to be reconsidered, and we trust that the authorities concerned will take into their council reputable chemists and physicists, who we are sure, can have no interests more at heart than to see the unmistakeable teachings of science practically applied to the salvation of society.

THE NEW WEALDEN DINOSAUR

At the last meeting of the Geological Society, Mr. J. Whitaker Hulke, F.R.S., brought forward some new facts concerning the remarkable Dinosaur *Ornithopsis*, which cannot fail to interest both geologists and naturalists.

In the original collection of Wealden fossils made by Dr. Mantell, and acquired for the British Museum, were two fragmentary bones, the nature of which was somewhat doubtful. Dr. Mantell regarded and figured one of these as a tympanic bone of *Iguanodon*, at the same time pointing out that it presented some resemblance to a vertebra. Prof. R. Owen adopted Mantell's views, and figured it as the tympanic bone of *Iguanodon*, or, perhaps, of *Cetiosaurus* or *Streptospondylus*.

In 1869 Prof. H. G. Seeley pointed out that the fossil in question was undoubtedly a portion of a vertebra, and one of a new and very remarkable type. It exhibited points of comparison with the vertebræ of birds, in the lightness of its construction, and in the existence of great cavities penetrating into the centrum. Hence Prof. Seeley suggested for it the generic name of *Ornithopsis*.

In 1870 Mr. Hulke, who was at that time unaware of Prof. Seeley's determination of the vertebral character of the British Museum specimens, gave a description of the neural arch of a vertebra which he had discovered in the Wealden of the Isle of Wight. From the beautiful character of the groined entrance to the neural canal, Mr. Hulke was led to suggest the name of *Eucamerotus* as a provisional one for the new Dinosaurian genus which the specimen evidently represents.

He especially pointed out as of great interest the enormous size of these vertebræ, and the fact that they are built up of thin plates of very compact osseous tissue, with immense spaces of cancellous tissue between them. At a later date Mr. Hulke recognised the identity of his *Eucamerotus* with the *Ornithopsis* of Prof. Seeley.

In 1876 Prof. Owen again took up the study of the forms in the British Museum. He adopted Prof. Seeley's and Mr. Hulke's views as to the vertebral character of the fossils—but he rejected Prof. Seeley's generic name on the ground that the resemblance between these vertebræ and those of birds is merely superficial, and that the name of *Ornithopsis* is therefore misleading. Prof. Owen described two new forms presenting this peculiar structure in the vertebral column, and to these he gave the names of *Bothriospondylus* and *Chondrostosaurus;* he insisted that the large cavities seen in the fossil vertebræ were probably originally filled with cartilaginous substance, as is the case in the sharks and rays, and argued, therefore, that any comparison with the vertebræ of birds was a misleading one. Mr. Hulke and Prof. Seeley, however, while admitting that the structure does not necessarily imply the powers of flight in the forms possessing it, yet insist that in all probability the cavities in the vertebræ were true air-cells, and therefore that the structure is "bird-like;" on these grounds they maintain that the name of *Ornithopsis* ought not to be superseded.

In 1877 Prof. Marsh recognised among the numerous Dinosaurian remains obtained from Colorado a number of gigantic forms with vertebræ presenting the same peculiarities as are found in *Ornithopsis;* to these forms he gave the names *Atlantosaurus*, *Morosaurus*, *Apatosaurus*, *Allosaurus*, and *Diplocus*. Prof. Cope had simultaneously described three other forms—*Camarasaurus*, *Amphicœlias*, and *Epanterias*, all presenting the same peculiarities as are found in the English form *Ornithopsis*. One of the American forms, *Atlantosaurus* had a femur seven feet in length. When the two distinguished American palæontologists visited this country in 1878, they both recognised the specimens of *Ornithopsis* in Mr. Hulke's collection as presenting numerous points of resemblance with the new forms which they had described.

Now in the communication which he has recently made to the Geological Society, Mr. Hulke has described vertebræ from several parts of the spine of *Ornithopsis*. This he is enabled to do by the courtesy of the Rev. W. Fox, of Brixton in the Isle of Wight, who has long been such an indefatigable collector of the vertebrate fossils of the Wealden, and has permitted Mr. Hulke to make use of his materials. Mr. Hulke shows that while the dorsal vertebræ were closely bound together by processes, so that this part of the spine must have possessed great rigidity, as is the case with birds, the cervical vertebræ indicate the existence of the greatest mobility. But the point on which Mr. Hulke principally insists, from its bearing on the discussion which has taken place between himself and Prof. Seeley, on the one hand, and Prof. Owen on the other, is that the cavities and cancellous tissue are confined to the dorsal vertebræ, and do not occur in the other portions of the spinal column; this he insists is inexplicable, if, as Prof. Owen insists, the cavities in question had no functional character, but were filled up with cartilaginous tissue, while it finds a ready explanation in the supposition of Prof. Seeley and himself that they are truly pneumatic cavities. Mr. Hulke also points out that there are reasons for believing that some at least of the vertebræ referred to the genus *Cetiosaurus* belong to the new group of forms to which so much attention has been directed during the last few years.

There can be no doubt that there existed during mesozoic times, both in this country and on the American continent, a group of reptiles of gigantic dimensions, which presented such peculiarities of structure, especially in their vertebral column, that they must be placed in a distant sub-order of the *Dinosauria*. For this, perhaps the name of *Sauropoda*, suggested by Prof. Marsh, may be adopted.

The existence of this bird-like character of pneumatic bones in reptiles of such gigantic dimensions as these peculiar Dinosaurs undoubtedly were is certainly very startling and unexpected. At the same time we believe that neither Prof. Seeley nor Mr. Hulke favours the idea that the forms in question were capable of flight. Mr. Hulke promises shortly to add another to his valuable contributions to our knowledge of these forms by describing the limb-bones of *Ornithopsis* and its allies, and discussing the habits which a study of their structure seems to indicate. All geologists and naturalists will look forward eagerly for the promised memoir.

CASSELL'S NATURAL HISTORY[1]

The third volume of this well-illustrated and popular account of the animal kingdom contains descriptions of the Ruminantia by the late lamented A. H. Garrod,

[1] Edited by P. Martin Duncan, M.B. (Lond.), F.R.S., F.G.S. Vol. iii. London: Cassell, Petter, and Galpin, 1879.)

M.A.; of the Rodentia by W. S. Dallas; of the Edentata and Marsupialia by the Editor, and of the first two Orders of Birds by R. Bowdler Sharpe.

The ruminating animals are divided into the Bovidæ, the Cervidæ, the Tragulidæ, and the Tylopodæ. A little more attention to typographical details would have assisted in making this division more clearly perceptible. Thus the first three chapters are headed quite correctly, "Artiodactyla—Ruminantia: Bovidæ," while Chapter IV. is headed "The Cervidæ," and Chapter V. has no chief heading at all, although it treats of part of the Cervidæ, the Tragulidæ, and the Tylopodæ. Such a want of uniformity is apt to be a stumbling-block to the student, whose perplexity is no little increased when he finds the same confusion not only in the headings of the chapters, but also in the text itself. Thus, in the chapters on the Edentata the author seems only to have awoke up to the necessity of giving any details of the order as an order, when he had just finished all he had to write about the species contained in the order; and as a consequence, not only is the cart put before the horse, but the account of the order is far too short, and almost nothing is said as to the many anatomical peculiarities characterising it. So much for criticism, which we make in the interests of the work itself, which, if completed as begun, will doubtless form not only a work of useful reference to the general reader, but also will be most useful as an encyclopædia of zoology. To constitute it a complete natural history, of course the other kingdoms of nature will have to be also treated of.

For the antler-less deer (Tragulidæ) Mr. Garrod coined the useful word "deerlets." In respect of their toe-bones they seem to stand intermediate between the swine and the true ruminants. Each foot in the common pig possesses four toes, that corresponding to our thumb in the fore-limb and to our great toe in the hind-limb being absent. The bones of all the toes that are present are quite separate from one another just as in man, but those of the outer and inner digits in each limb are smaller than those which bear the larger hoofs. In the true ruminants, as is well known, these larger toes are partially fused together, the bones of the two central digits forming the "cannon bone," while the bones of the other toe are reduced to mere splints, or disappear. In the deerlets these bones are not blended at all in the fore-limbs of the water-deerlet of West Africa; in which, as in all the other species, the digits two and five are perfect from end to end. The want of antlers in either sex is another distinguishing peculiarity. We would gladly have had more details given us of this very interesting group, the scientific names of the species of which are in no one instance given.

The Lophiomys.

The chapters on the rodents are very well and carefully written, and the classification adopted is that proposed by Mr. Alston. The orderly sequence of the families in this section of the work might be commended as an example, and the scientific names of the species following their English names, in italics, is an immense improvement on the plan generally adopted throughout this work, and as a proof that the reader will find in this section new as well as interesting information, we quote the following account of perhaps the most remarkable rodent known:—

"The importance of an animal in the zoological system by no means depends either upon its size or on its abundance in the world; its rank in the classification is decided solely by peculiarities of organisation which distinguish it more or less from its fellows; and in many cases the creatures which are regarded with the most interest by the naturalist are those which seem most to withdraw themselves from general observation. A single genus, perhaps containing only one or two species, may, by a singular combination of characters, be so completely isolated from all the recognised allied groups that it cannot be placed in any of them, and accordingly a distinct family, possibly even an order, has to be established for its reception. Sometimes subsequent discoveries add to the number of species forming the group thus set up, and in this way the prescience of its founder is confirmed. Sometimes the group remains in its original condition, leaving us, according to circumstances, to regard the anomalous creatures of which it is composed either as a special development of their general type, or as the residue of a group which may have presented a greater variety of forms at some past period of the earth's history.

"The latter is perhaps the case with the curious little rodent which alone forms the present family, of which its original describer, M. Alphonse Milne-Edwards, writes as follows:—'In its general aspect it somewhat resembles certain opossums, and like these it is pedimanous (having the hind feet hand-like); but these are the only analogies it presents to the marsupials, and in its dental system, as also in the rest of its organisation, we easily see that it belongs to the order Rodentia. It differs, however, from all the members of this group by characters of considerable importance; I may even say that, by some peculiarities of structure it departs from all other mammals, and that we find in it anatomical arrangements of which we have hitherto had examples only in the class of reptiles.' After an exhaustive discussion of the characters of this curious little animal, M. Milne-Edwards comes to the conclusion that it is most nearly related to the members of the following family, and especially to the hamsters, although he found it impossible to unite it with them. In this course he has been followed by other writers.

"The general construction of the skull is the same as in the Muridæ, but from the temporal ridges thin plates are developed, which bend downwards, and articulate with similar plates springing from the malar bones, and thus completely arch over the temporal fossæ after a fashion only met with in certain reptiles, and especially in the Hawksbill Turtle (*Chelone caretta*). The whole upper surface of the skull is covered with minute but perfectly definite granules, arranged with much regularity, and these, which occur in no other mammal, give the skull a very peculiar aspect, such as may be seen in some fishes. As in the Muridæ, there are three molars on each side in each jaw, and these are rooted and strongly tubercular; the foremost in each series having three and the others each two ridges. Without entering in detail into the peculiarities described at great length by M. Milne-Edwards, we may say that in its general structure, and especially in that of the skeleton, the animal is murine, but with a very important distinction, namely, that the collar-bones, which are well developed in the rats and their allies, are here reduced, as in the hares and rabbits, so as to form only two small bony styles freely suspended among the muscles, and that the first toe in the hind feet, although not very long, is so attached as to be opposite to the rest, thus converting the organ into a prehensile hand which the animal uses freely in climbing. The cæcum is small.

Hoffmann's Sloth (from life).

"In its external characters this animal is as remarkable as in its anatomical structure. In general appearance, as stated by its describer, it has much resemblance to a small opossum, but the bushy tail and the peculiar arrangement of the hair on the body are met with in no marsupials. The head is small; the general form stout; the limbs short, and the hind ones not much longer than their fellows; and the ears are of moderate size and sparingly clothed with hair. The prevailing colour is blackish-brown, but a triangular spot on the forehead, a streak under each eye, and the tip of the tail, are white; and the long hairs which clothe the body and tail are dark only in the middle, the base and tip being white, as are also a great quantity of finer and shorter hairs which form a sort of under fur. But the chief peculiarity of the coat is to be found in the arrangement of the hairs of the body. The long hairs of the middle of the back and tail, some of which are nearly three inches in length, are capable of being raised into a nearly upright position, forming a sort of crest which gives the animal a very peculiar aspect, and this crest is separated from the pendulous hair of the flanks by a sort of furrow clothed with very peculiar hair of a greyish-tawny colour. These hairs are unlike any others known to occur among mammals. The apical part is of the ordinary construction; but the following portion down to the base is 'very rugose, and presents a spongy aspect, due to the interlacing, and, so to speak, felting of a multitude of epidermic filaments emanating from radiate cells, which constitute a perfect network of irregular meshes. Within the sort of sheath thus formed longitudinal filaments which break up into bundles of fibrils are to be seen.'

"Very little is known as to the habitat of this animal, which M. Milne-Edwards has named *Lophiomys imhausi*, the former name referring to the crested character of the back, the second commemorating the person who first brought the creature to the notice of naturalists. M. Imhaus, stopping for a few hours at Aden, on his way home from Réunion, saw a living specimen of this rodent in the possession of a Negro, from whom he bought it, but could learn nothing as to its origin. He inferred, however, that it had not been brought very far, and that its native country was either Southern Arabia, or some region in Abyssinia, or Nubia, on the other side of the Red Sea. This specimen was brought to France, and lived for about a year and a half in the Garden of Acclimatization in the Bois de Boulogne, where it fed upon maize, vegetables, and bread, slept during the day, and climbed with ease upon chairs and other convenient objects by the aid of its hinder hands. It never took its food in the fore-paws to carry it to the mouth as so many rodents do. When irritated it elevated the crest right down to the end of the tail, and defended itself by biting vigorously."

The chapter on the fossil Rodentia contains a large number of facts packed into a small compass; reference will be found in it to very many of the recent discoveries of rodent remains in the miocene deposits in America, and a detailed account is given of that remarkable fossil form called *Mesotherium cristatum*, by M. Serres, and for which Mr. Alston has formed a section of the rodents called Hebetidentata from their incisor teeth, which, instead of having the chisel-like edge so characteristic of the incisor teeth of all rodents, are continuously enamelled and are four in number in the lower jaw, and two in the upper. The skull and teeth of this strange form are figured; as Mr. Alston says, "It appears to have been a survivor, to pliocene times, of a much earlier type, which represented an era at which the Rodents were not yet clearly marked off from their allies. In fact, Mesotherium seems to continue *into* the order Glires, that line of affinity which Prof. Flower has pointed out as extending from the typical Ungulates through Hyracodon, Homalodontotherium, Nesodon, and Toxodon."

The following is an account of Hoffmann's sloth (*Cholœpus Hoffmanni*):—

"This is a sloth with two clawed fingers on the fore, and with three claws on the hinder extremities. Living specimens are occasionally brought to Europe, especially from Porto Rico, so that its general appearance may now and then be studied at the Zoological Gardens, in the Regent's Park. If it be looked at there in the day-time, it certainly merits the name of sloth, for it resembles a bundle of long, light, brown hair, fixed on the top of a bar of wood close to an upright branch, or huddled up in a corner on the ground; but in the morning, and also late in the evening, the creature begins to move slowly, and to look out for the food put for its use on the floor of the den. All the Hoffmann's sloths have pale brown hair, whiter at the tips, and a white face, showing a brown band across the nose, extending to a ring round each eye. They have also a long and full crest of hair on the neck, and the hair on the limbs is darker than that of the rest of the animal. Dr. Peters, who discovered this sloth, examined the skeleton, and found only six vertebræ in the neck, and in this it differs from the *Cholœpus* just noticed.

"When its food, consisting of carrots and lettuce, and bread-and-milk, is put down in the morning it is soon in movement, and enjoys its milk hanging down from a bar with its hind legs, and resting its back on the floor of the cage. It seizes the food between the claws and the long straight palm of the fore-foot, and passes it into its mouth, chewing actively with the molar teeth, especially with the first, which are sharp. It cares little for the spectators, and when it has finished, slowly mounts up into a corner of its little den and settles down to sleep. In the evening it becomes lively, for it is, and, indeed, all sloths are, nocturnal in habit. The hairless snout, of a light red tint, the absence of 'smellers,' the little eyes with a few hairs around them, and the broad forehead, give the animal a curious appearance. The hair is brushed back on the forehead, and comes around the very small ears on to the cheeks, and is whitey-brown, and this same tint is seen over the whole of the back in long slender hairs. But the under hair is light red or red-brown. The long and slender hand, with its two claws, contrasts with the rather bulky upper part of the limbs, and the flesh-coloured palms are very remarkable.

"The whole of the sloths lead very monotonous lives; their food is ever within their reach, and it is abundant, and they do not appear to have to compete much or at all in the struggle for existence with other animals. Their enemies are snakes and the carnivora, but it is evident that they are much more readily preserved by their habits from the latter than from the former. Leading such an uneventful existence, there is no great call upon their nervous energies or intelligence, and these are at a low pitch. The brain consequently is very simple in regard to convolutions, which are few in number and shallow."

The portion of this volume devoted to the birds is what might have been expected from so well-known an ornithologist as Mr. Sharpe. In the preparation of the chapters on the anatomy of a bird, he acknowledges his obligations to his colleague in the British Museum, Mr. Jeffery Bell, and an excellently well written chapter it is, though it ends a little abruptly; and the periods of incubation in the case of some of the best known birds might usefully have been added.

In the present volume, the two first orders, that of the birds of prey and of the picarian birds, are treated of, and the rest of the orders will probably form volume iv., the publication of which, we trust, will not be long delayed. While aware of the vast multitude of the feathered throng which Mr. Sharpe has to pass under review, might we suggest to him that it is very important that when he gives a paragraph to a sub-family, he might so arrange it as to let the reader discover without difficulty what species quoted really belonged to it? Thus, the arrangement on p. 310 is very perplexing. The sub-family of the cockatoos is of the same value, so far as classification goes, as that of the Amazon parrots or of the Conures, and yet there is no uniformity, so far as typographical details go, to indicate this. If there be a genus Androglossa, it is not alluded to, and for want of quoting, at least one species of the genus Nasiterna in the preceding paragraph, the "it" that was found at Mafoor by von Rosenberg must remain an unknown bird to the reader. There are said to be about thirty species of Amazon parrots known; which, then, is "the Amazon parrot" figured? The text is appealed to for an answer in vain. Not two lines are devoted to the Macaws. The same is very much the case all through: thus, the honey-guide is figured after Keuleman's sketch; eleven species are known, but neither is the name given of the species figured, nor is the name given of the species whose habits are described. The common goat-sucker, the whip-poor-will, and the lyre-tailed nightjar, are figured, and yet no scientific names for them are to be found. No doubt both author and editor will agree with us that the value of this work would be greatly added to if the good example set in this matter by Mr. Dallas were followed. The illustrations are in general very good, but is there not one egg too many in the nest of the edible-nest swiftlet? The general get-up of the volume—type, paper, and binding—are all that could be wished, and despite the few things in it which we think might be amended, we most cordially recommend it and its predecessors as very excellent volumes on the natural history of the mammals and birds.

PROF. HUXLEY ON TECHNICAL EDUCATION

AT the lecture by Prof. Silvanus Thompson, on "Apprenticeships," at the Society of Arts last week, Prof. Huxley was in the Chair, and in inviting discussion on the paper, said he would commence it by making a few remarks himself. He had listened to Prof. Thompson's paper with gratification, not only on account of the good sense it embodied, but also for a more selfish reason, inasmuch as it entirely accorded with the views which he, coming to the matter from a different side, had himself expressed. Unfortunately he had no personal acquaintance with the ordinary kinds of work in what were called handicrafts, but he ventured some two years ago in that very room to point his remarks with respect to technical education by the knowledge he possessed of medical education. He then expressed a hope that something real and practical would soon be done by the City Guilds, which had done him the honour of consulting him on this subject of technical education, and the advice he gave them was in precise accordance with the principles which Prof. Thompson had laid down that night. Whatever might be the merits or demerits of the old system of apprenticeship, it was as thoroughly doomed in the different kinds of ordinary handicrafts as it had been long doomed in physic. The only alternatives appeared to him to be of two kinds. In the first place, we ought to bring within the reach of the young people who were employed in our great manufactures the means of carrying on their education in the particular branches of business with which they were respectively occupied beyond the time during which the necessities of practical life obliged them to be at work in the workshop—that is to say, for a period corresponding virtually with what used to be their apprenticeship. One of his suggestions, therefore, was that there should be established in the neighbourhood of the great centres of industry schools to which young boys who are learning certain handicrafts could resort in order to receive instruction which would qualify them to work skilfully and intelligently at their trade. He likewise suggested that the guilds should employ part of their large funds in the establishment of a central institution, which should do for the teaching-power of the country that which such institutions as the École des Arts et Métiers in France, and the Polytechnicum at Zurich, did in their respective countries. In England there was not only a total absence of schools to which apprentices could resort, but there were no teachers competent to teach in such schools, even if they were established. He thought that the suggestions he made to the guilds were of a sound and practical nature, and calculated to advance the interests of technical education in this country. He understood Prof. Thompson to object to the existing elementary training in our Board schools on the ground of its technical nature and of its occupying the minds of the student entirely with book learning and matters which had no sort of bearing on his future life. No one endeavoured more earnestly than he, when he occupied a seat at the School Board, to remedy the evil of the exclusively book character of our ordinary school instruction. He did not entertain the slightest doubt that an extension of the Kindergarten system, including the use of tools and the knowledge of elementary machines, was a matter of great importance, but he could not think that the evil of not giving hand-work in the elementary schools was after all very great. Although it was a great thing to make skilled workmen, yet it was much more important to make intelligent men. The four or five years during which children ordinarily remained at school were not too much to devote to even an exclusive study of reading, writing, and arithmetic, and to the acquirement of some intelligent knowledge of geography, the elements of history, and the rudiments of physical science. On this point he might observe that no pupil was admitted to the Écoles d'Apprentis in Paris until he was thirteen years old, or unless he presented his certificate of elementary education. If we attained one half or a quarter of the good results reached in the Écoles d'Apprentis, the improvement in the condition of the average British workman would be exceedingly great.

In proposing a vote of thanks to Prof. Thompson for his paper, Prof. Huxley expressed his belief that, as far as London was concerned, it would be a scandal and a robbery if a single shilling were asked for out of the general revenues of the country for technical education. The City of London Guilds possessed enormous wealth, which had been left to them for the benefit of the trades they represent. If the people did not insist on the wealth being applied to its proper purpose, they deserved to be taxed down to their shoes. It would be well if those who had charge of these matters in the city of London would understand that they were morally bound to do this work for the country, and he hoped if they continued to neglect the obligation they would be legally compelled to do it.

NOTES

No more than justice has been done to Sir Joseph Whitworth by granting him a prolongation for five years for his process of manufacturing fluid-compressed steel. The powerful evidence brought before the Committee of the Privy Council as to the utility of this steel could not be resisted. Mr. James Wright, the Engineer-in-Chief of the Navy, stated that the invention "has met a want long felt for the principal parts of marine engines which have been subject to failures;" from his experience of it he has perfect trust in it. Mr. Hotchkiss, the patentee of the revolving cannon used by the French Government, stated that he never had occasion to reject a single *barrel* of the steel. The evidence from Mr. J. Davidson, of Woolwich, Mr. Purdey, the well-known gun-maker, and others, showed that by getting rid of the air-cells the steel answered perfectly, and is a better metal than had ever been produced by any previous process. Their Lordships were satisfied that it would in all probability be highly useful "in carrying out the highest achievements of engineering skill."

THE long-expected experiments by the *Thunderer* Gun Committee commenced on Tuesday at the proof butts on the Government marshes, Woolwich. In connection with these experiments, Sir William Palliser organised, and last week carried out, a successful series of experiments with a doubly-loaded gun, in order to ascertain whether double-loading was or was not the cause of the bursting of the *Thunderer's* gun. Five double charges were fired, each successive charge being increased in length. No sign of flaw or damage could be perceived. A similar result attended experiments with an air-space between the powder charge and the base of the projectile. But when shall we have a gunner like Froude to abolish experiments on the scale of 12 inches to a foot? The navy now build a paraffin boat for a few shillings, instead of a real one costing a quarter of a million to experiment with. What will the experiments, including the bursting of the gun, cost? If smaller experiments cannot be devised, no one has a right to say that Palliser's experiments on a smaller scale teach us nothing.

WE are glad to see that decisive action has been taken on the side of the United States for the acquisition of the ground in the neighbourhood of Niagara Falls as an International Park, and so preserve visitors from the innumerable annoyances to which they are at present subject. At a meeting of the Board of Commissioners of the New York State Survey, on November 20, Director Gardner, of the Survey, presented conclusions arrived at by the board at its meeting in Niagara last September, illustrated with maps, diagrams, &c. The plan proposed is to take a strip along the American bank, varying from 100 to 600 feet in width, extending two miles from the new suspension bridge to the head of the rapids, and plant it with trees, to shut out from view the ugly bazaars, manufactories, booths, and hotels which destroy the natural scenery of the banks. The plan also involves the purchase of Goat and Bath Islands, which, the Commission has reason to believe, can be bought. The proposed park will extend to and include Canal Street, in the village, over which the State now has jurisdiction. Director Gardner places the total amount required to secure all the property needed at 800,000 dols. The Commissioners thought the estimate too low. A report recommending that the State shall purchase the property will be prepared by Messrs. Dorsheimer, Stout, and Barnard. It is the unanimous opinion of the Commission that New York should proceed to reclaim her side of Niagara without reference to what Canada may do. One map, shown by Director Gardner, indicated that the recession of the Falls since 1842, when a trigonometrical survey was made, has been something over 100 feet.

FRENCH meteorologists have observed a curious analogy between the present season and the severe winter 1788-1789. This winter was observed and described by Cotte, one of the most celebrated French meteorologists. The frosty weather set in on November 25, and ended on January 13. On December 25 intervened a partial thaw. The end of January and February were relatively genial, and the frosty weather again set in on March 4, and kept on up to the end of the month. Frost was so intense that wine was congealed in cellars. The thickness of ice on the Seine was 18 inches, and the breaking of the ice happened only on January 20. Note was carefully taken of the minima observed in a large number of Continental cities. It was observed that the minimum of temperature happened in Germany on December 18, in France on the 31st, and in Russia only on January 5. During frosty weather the wind was almost always blowing from north-east with clear sky. Sometimes it was blowing from south, but then snow was falling, sometimes with great abundance.

THE quantity of snow which fell in Paris during the day of December 4 and the ensuing night, according to a calculation made by a member of the Municipal Council, amounts to 245,000,000 cubic feet for the interior of the fortifications. It has been estimated that the expense for removing by handwork and carting this immense quantity of snow, would be about 800,000 francs.

THE dates of the freezing of the Neva have been carefully observed from 1703. It has never frozen sooner than in 1805, on October 16, nor later than in 1740, when it froze on December 28. This year the date is November 15; the mean date is November 13.

SOME curious statistics of gas-lighting in Paris have been published recently. The greatest duration of public lighting is 14h. 30m., and smallest 5h. 25m. The cost of gas for public and private establishments is 2,000,000*l.*, about *one pound* per head for each inhabitant of Paris. The total consumption of gas is 6,500,000,000 cubic feet. In 1880 the Paris Municipality intends to enlarge its lighting expenses by 16,000*l.*, and 8,000*l.* for establishing new gas-lamps. No provision appears to be made for electricity.

THE excavations at Olympia under the auspices of the German Government have been resumed this winter with a force of 100 workmen. A statue of Nemesis, and heads of Titus, of a kneeling infant, and of Paionios' Nike have already been unearthed this season. The total number of works of art thus far excavated is sixty-seven, consisting of forty-one figures and twenty-six heads.

WE regret to have to record the death of Madame Louis Figuier, the wife of the well-known author of so many popular works in science. Madame Figuier has written a number of plays, and has been a fellow-worker with her husband in the publication of his "Théâtre Scientifique," which has appeared quite recently anonymously.

DR. H. TRIMEN, who leaves England to assume his appointment in Ceylon in January, is succeeded in the editorship of the *Journal of Botany* by Mr. James Britten, F.L.S., of the Botanical Department of the British Museum.

A METEOROLOGICAL station has been opened at Prato, thus connecting Fiesole and Florence with Pescia and Lucca.

TELEGRAPHIC communication between Paris and other cities of France and the Continent has been almost interrupted by snow. It is only in Germany that the telegraphic service has continued almost unimpeded, owing to the establishment of subterranean communications.

MESSRS. SAMPSON LOW AND CO. are about to publish Dr. August Weismann's "Studies in the Theory of Descent," with a prefatory notice by Charles Darwin, F.R.S., translated and edited, with notes, by Raphael Meldola. Part I.—On the Seasonal Dimorphism of Butterflies (with two coloured plates). Part II.—On the Origin of the Markings of Caterpillars; On Phyletic Parallelism in Metamorphic Species (with six coloured plates). Part III.—On the Transformation of the Mexican Axolotl into Amblystoma; On the Mechanical Conception of Nature. The German text, we are informed, has been carefully revised and brought down to date by the author, under whose supervision the chromo-lithographic plates have been accurately re-drawn and engraved.

WE understand that Mr. Anderson's long-promised work on Lightning Conductors will now be issued in a few days. Messrs. Spon, of Charing Cross, are the publishers.

THE well-known Boulak Museum at Cairo has been undergoing repairs, and the fine collection was deposited in a neighbouring warehouse under what seemed proper guardianship. But, the *Times* correspondent writes, robbers the other day broke in through the roof, and they must have been robbers of a certain rank of intellect, for some 80 or 100 scarabees of great value pecuniarily, and impossible to replace, as they related to the early dynasties, were abstracted, although they were things of no apparent worth to an ignorant person.

A CORRESPONDENT of the *North China Herald* understands that the director of the magnetic and meteorological observatory connected with the Roman Catholic mission establishment at Sikawei, near Shanghai, has good reason to suppose, after a careful study of the typhoon of July 31, that the Chinese typhoons, like the cyclones of the Bay of Bengal, do not have their centre eight points to the right from the direction of the wind (the face being turned against the latter), as is generally supposed, but from nine to ten points. It is certainly of the utmost importance to navigators that this conclusion of Père Dechevrens should be carefully investigated, to which end the cooperation of ship-masters is invited. They should forward observations of the barometer and thermometer, force and direction of the wind, mentioning the latitude, longitude, and height above the sea-level of the spot where their observations have been taken, the description of instruments used, whether the thermometer is attached to the barometer, and what corrections, if any, are to be applied, with general description of weather, &c.

We have received the seventh edition (November, 1879) of Prof. E. Morren's "Correspondance Botanique." There is no alteration this year in the plan or scope of this useful botanical directory for the whole world; but the necessary corrections and additions seem very carefully made up to the date of issue. The only noteworthy additions to the list of names for each country are in the case of France, which requires two extra pages, and Italy, which takes one page more than last year.

The Associated *Soirée* of the Literary, Scientific, and Art Societies of Liverpool was held in St. George's Hall yesterday. The programme was of a varied character, both literature, science, and art, being well represented upon it. The idea of thus uniting the various classes of societies in a large town is a happy one, and deserves imitation.

We notice from the November number of the *University College of Wales Magazine* that numerous important additions have been made to the museum of that institution, which now contains collections of very varied character.

Science Gossip for December publishes a useful list of naturalists who are willing gratuitously to assist learners of natural history and others, personally when practicable, otherwise through the post.

Prof. Newberry has reprinted his article on the "Geological Survey of the Fortieth Parallel" (New York, Appleton) from the *Popular Science Monthly*. We have at various times referred to the volumes of this magnificent work; Prof. Newberry's paper gives a good *résumé* of the whole.

The *Colonies and India* calls attention to the fact that a small quantity of flax grown in West Australia, which recently fell into the hands of an English manufacturing firm, was found to be of such excellent quality that a large demand has suddenly sprung up in the colony for both indigenous and cultivated flax.

The additions to the Zoological Society's Gardens during the past week include three Pin-tailed Whydah Birds (*Vidua principalis*) from Africa, presented by Capt. T. H. Bowyer Bower; two Common Chameleons (*Chamæleon vulgaris*) from North Africa, presented by Capt. Burke; a Mississippi Alligator (*Alligator mississippiensis*) from the Mississippi River, presented by Mr. W. G. Marshall; a Slow-worm (*Anguis fragilis*), European, presented by Mr. W. A. H. Bernard Smith; two Red River Hogs (*Potamochœrus penicillata*) from West Africa, two Elliot's Guinea Fowls (*Numida ellioti*) from East Africa, an Elephantine Tortoise (*Testudo elephantina*) from the Aldabra Island, deposited; two Prong-horn Antelopes (*Antilocapra americana*) from North America, a Slow Loris (*Nycticebus tardigradus*) from Malacca, a Laughing Falcon (*Herpetotheres cachinnans*) from Brazil, a Bar-tailed Godwit (*Limosa lapponica*), a Common Curlew (*Numenius arquatus*), two Pomatorhine Skuas (*Stercorarius pomatorhinus*), European, purchased.

OUR ASTRONOMICAL COLUMN

Orbits of Binary Stars.—In addition to elements of O. Σ. 235, which apppear in the recently-published "Handbook of Double Stars," Dr. Doberck has lately investigated orbits for the binaries 4 Aquarii and μ^2 Herculis, stars for which no similar computation had been previously made. He assigns a period of 129·8 years for the former, the passage of the periastre at 1881·80, and for the latter a period of 54·25 years, the periastre at 1877·13. The elements give the following angles and distances:—

4 Aquarii.					μ^2 Herculis.				
1880·5	Pos.	188·2°	Dist.	0·32″	1879·5	Pos.	241·1°	Dist.	1·05″
1885·5	,,	242·0	,,	0·22	1880·5	,,	247·1	,,	1·04
1890·5	,,	295·9	,,	0·32	1881·5	,,	253·4	,,	1·01
					1882·5	,,	260·1	,,	0·97

The extent of Dr. Doberck's investigations relative to the orbits of the revolving double-stars will be seen from the following nearly complete list of objects, for which we are indebted to him for the best systems of elements yet in our possession:—Σ 3121, μ^2 Hercules, O.Σ. 298, α Centauri, γ Coronæ Borealis, ξ Scorpii, Σ 3062, ω Leonis, *p* Eridani, Σ 1768, ξ Bootis, 4 Aquarii, τ Ophiuchi, η Cassiopeæ, λ Ophiuchi, 44 Bootis, μ^2 Bootis, 36 Andromedæ, γ Leonis, σ Coronæ Borealis, α Geminorum, ζ Aquarii, O.Σ. 235. It must be borne in mind, in order to appreciate the amount of labour involved in these researches, that in the majority of cases the orbits are not the results of rough or graphical approximations, but have been worked out with a degree of refinement, which exhausts the data actually at Dr. Doberck's command. He has made this subject as much his own as Prof. Julius Schmidt has in his case that of the variable stars.

Errors of the Lunar Tables.—Prof. Winnecke publishes observations of the moon made by Dr. Schur at the provisional observatory of the University of Strassburg in the year 1878, and the corrections required by Hansen's tables, and by the same tables as improved by Prof. Newcomb, who showed the large and increasing deviation of the tables would almost wholly disappear if, for the empirical term, an empirical alteration of the other term due to the action of Venus is substituted, and suitable alterations made in the elements of mean motion. The advantage derived by the introduction of Newcomb's corrections is seen to be very considerable, the signs alternating in the course of the year, and the corrections being generally small, while with Hansen unaltered there is a larger and uniformly negative correction throughout.

From the same observations there is deduced a correction to the mean semi-diameter adopted in Hansen's tables amounting to −1″·29. Soon after the appearance of these tables, Dr. Oudemanns, by a careful discussion of occultations and direct heliometric measures, inferred a correction of −1″·09. If the mean of these values be adopted, we shall have for the moon's mean semi-diameter, 15′ 32″·16. Dr. Oudemanns' paper will be found in vol. xxvi. of the *Monthly Notices* of the Royal Astronomical Society.

Re-Discussion of Ancient Solar Eclipses.—The publication of recent investigations on the motion of the moon, appearing to render a new discussion of the ancient eclipses of the sun desirable, the work has been commenced under the auspices of the Smithsonian Institution, by Mr. D. P. Todd, of the American *Nautical Almanac* Office. The computations so far relate to the eclipses of Thales, Larissa, Ennius, Agathocles, and Stiklastad, and to the two eclipses of the thirteenth century, which have formed the subject of an important memoir by Celoria, of the observatory at Milan. It is proposed to extend the original scope of the research to include a large number of ecliptic dates, and great facilities are expected from the use of Newcomb's Tables of Eclipses, which have recently appeared. We shall allude further to these tables in a future column. It will be seen that this interesting research is in excellent hands.

The Solar Parallax.—Mr. Downing, of the Royal Observatory, Greenwich, has made a determination of the sun's mean parallax from observations of Mars in declination at the observatories of Leyden and Melbourne, during the very favourable opposition in 1877, the same comparison-stars having been used at both stations. The observations were made between July and October, but Mr. Downing has only compared them on those days when planet and stars were observed at Leyden and

Melbourne on the same day or on the following day, so that the change in error of the places interpolated with second differences from the *Nautical Almanac*, has merely to be carried back for 9½ hours or carried forward for 14½ hours. The resulting mean solar parallax is 8″·96, and assuming that the probable error of a single observation of declination is 0″·5, the probable error of the result is ± 0″·051. The value obtained by Prof. Newcomb from similar observations in the year 1862 was 8″·855, nearly identical with that which Leverrier held to be pretty definitive, and which was given by the planetary theories, or 8″·86. In most of the national ephemerides, Newcomb's mean value, obtained in his paper on the sun's distance in the Washington Observations for 1865, or 8″·848, has been adopted; the *Connaissance des Temps* substitutes Leverrier's.

METEOROLOGICAL NOTES

MR. E. KNIPPING, Tokio, has written a brief account of three typhoons which occurred in the China and Japan Seas in September, 1878. In twelve charts and one diagram he sets down the paths of the three storms and the weather of each day from the 15th to 21st, when the third and most violent of the typhoons occurred. The heaviest squalls and gusts of wind were met with in the front part of the typhoon, or with north-east and south-east winds, whereas they are hardly mentioned in the ship's logs with south-west winds in the rear of the storm. The path of the typhoon was to north-west from 15th to 19th, to north on 19th and 20th, when it recurved to the north-east, following a course midway between Japan and the continent. Its rate of progress was 10 miles an hour on the average, rising to 25, and falling to 2⅓ miles an hour. The diagram, which summarises the author's views regarding the behaviour of the winds, seems to raise questions which call for further inquiry. Thus the south-east wind shows, near the centre of the hypothetical typhoon, an in-curving tendency, which becomes less and less on receding from the centre, till, towards the outskirts of the storm, it is represented as blowing outwards. On the other hand, the north-east wind, immediately contiguous, very decidedly in-curves near the outskirts of the storm, but on approaching the centre the incurvation becomes less and less till it disappears. The statement is made that at a distance of 900 miles from the centre, with a north-east wind, the centre of the typhoon bears right ahead, but with a south-east wind the centre bears south. For a satisfactory examination of the points here raised, and other points, such as the remarkable changes in the form of the typhoon while off the coast of Shanghai, fuller data are required, so that the positions of the centre at different times be more accurately ascertained. The publication of details of the data in an appendix to the work is equally necessary.

PROF. NIPHER'S *Missouri Weather Service Report* for October last is to hand, and is of more than usual interest. The returns show the weather of that State to have been unprecedently warm for the season, the mean temperature of St. Louis, viz., 63°·1, being the highest for any October of the past forty years. At the same time the rainfall was only 0·57 inch, being, with the single exception of 1872, when the rainfall was 0·29 inch, the driest October in forty years. The rainfall was unusually small over no inconsiderable portion of the State, extending to north-west of St. Louis, and in the extreme north-east it amounted only to about a ¼ inch, whereas, on the other hand, within a limited district immediately to southward round Cuba, and over a pretty extensive region in the west, lying to north and south of Kansas City, it exceeded 4 inches. The service is being ably and vigorously worked, eighteen new stations being added in November, so that there are now seventy-three stations, the results of whose observations are quickly sent broadcast over the State and beyond it, reaching Europe even in the third week of the following month. We observe with much satisfaction that the efficiency of this weather service is to be greatly enlarged by the active co-operation of the directors of the principal railroads, who have intimated their readiness to make meteorological observations a regular part of the duties of their station agents at points selected by Prof. Nipher himself.

IN connection with the meteorological work proper of the Missouri Weather Service, Prof. Nipher has been carrying out a magnetic survey of the State during the summers of 1878 and 1879, the expense of the survey having hitherto been met by private subscriptions. The results of this survey are given on a valuable map which accompanies the October Report, showing the lines of equal magnetic variation, and attention is directed to the tendency of the needle to set at right angles to those river-valleys which do not run north and south. A report on the climatology of Missouri is in course of preparation by Prof. Nipher, at the request of the State Board of Agriculture. It is with some surprise we learn that the expense of organising and carrying on this service has been wholly borne by two of the directors and Prof. Nipher. But this state of things the Americans are too sharp-sighted to allow to go on, it being in the interests of the State to provide that a service which is so energetically and effectually working out the climatologies of its various agricultural centres does not run the risk of being starved out for want of the few dollars required to meet its working expenses.

CAPT. TOYNBEE, in the *Journal* of the Meteorological Society for October, gives an interesting comparison of the temperature of the Atlantic during the Decembers of 1877 and 1878 from observations made on the temperature of the sea every four hours of these months by Capt. Watson, of the Cunard steamer *Algeria*. The result shows that for the outward and homeward passages to America the part of the Atlantic traversed by the *Algeria* was 3°·2 warmer in December, 1878, than in December, 1877. A comparison is also made of the mean temperature of the British Isles, and from observations at about forty stations it is shown that the December of 1878 was 8°·0 colder than that of 1877, "in spite of the fact that the sea to the westward was more than 3°·0 warmer." The higher temperature of the sea in December, 1878, would appear not to have extended far to northward, seeing that on the west of Scotland the sea was half a degree colder than in 1877, and in Farö 1°·7 colder, whilst on the north-west of Iceland the sea during December, 1878, was 0°·2 warmer. The interest attached to such an inquiry centres in the point that 8°·0 greater cold over the British Isles during 1878 as compared with 1877 may have been brought about in consequence of the fact that the Atlantic to west-south-westward was more than 3°·0 warmer. It is, for example, possible that this abnormal distribution of temperature in the Atlantic was more or less immediately connected with the more southerly course taken by our European storms since the end of October, 1878, from which have inevitably resulted the unusual prevalence of easterly and northerly winds and the cold weather we have had since. An inquiry more practically important could scarcely be suggested to meteorologists than an investigation of the point suggested many years ago by Sabine as to there being a possible connection between the temperature of the tropical and subtropical waters of the Atlantic during the autumn months and the severity or mildness of our European winters; and certainly no more suitable period could be selected for the inquiry than the last two years, a twelvemonth's warm, fine weather having set in during October, 1877, and a period of cold weather, exceptionally protracted and severe, having commenced in the end of October, 1878.

GEOGRAPHICAL NOTES

AT the meeting of the Geographical Society, on Monday evening, Mr. Wilfrid S. Blunt read a paper entitled "A Visit to Nejd," in which he gave an interesting account of a journey made last winter in company with his wife, Lady Anne Blunt, from Damascus southwards to Jôf and the Jebel Shammar in Central Arabia. The results of Mr. Blunt's expedition may be thus briefly summed up. The oases of Kâf and 'Ittery have now been visited and the Wady Sirhan explored by Europeans for the first time. By taking barometrical observations along its entire length, Mr. Blunt ascertained that the Wady Sirhan from Ezrak to Jôf lies on nearly a uniform level of 1,800 feet above the sea, from which he thinks that it was formerly an inland sea, and is miscalled a Wady or valley. Along the whole distance he roughly surveyed the pilgrim road, marking the position of the wells and the reservoirs made by Zobeyde. Mr. Blunt has also constructed a map of the Jebel Shammar district. The most interesting outcome of his journey, probably, is the collection of a series of facts relating to the physical condition of the great sand desert of Nefud, and in some material respects his observations are at variance with those of Mr. Palgrave. Mr. Blunt appears to be the first to call attention to the deep horse-shoe hollows, called by the Arabs *fulj*, with which the whole surface of the plain is pitted.

IN the present critical state of affairs between China and Japan in regard to the suzerainty of the Loochoo Islands, much interest attaches to an official document issued in the latter country on the subject. All the Loochoo Islands, the Japanese maintain, are connected by certain geomantic signs in the earth with the Japanese province of Satsuma. The forty-eight characters of the Japanese alphabet are in use there, having been communicated to the islanders by Minamotonotametono. As regards language, they use a mixture of Chinese words and the Japanese alphabet in their literature. They call their own kingdom Okina, or otherwise, Okinawa. As regards religion, they worship Yi Shih, the Great Spirit of Japan, besides other divinities. In many of their domestic customs, too, the Japanese maintain that their practice indubitably indicates their origin.

THE new number of *Les Annales de l'Extrême Orient* contains some ethnographical notes on Thibet by the Abbé Desgodins, illustrated by a map of that country and the neighbouring regions.

THE just published part of *Le Globe* contains a paper by Dr. E. Dufresne, entitled "Une station d'hiver pour les phthisiques dans les Hautes-Alpes," and a third article by M. Venuikof on geographical discoveries in Asiatic Russia.

THE *Bulletin* of the Antwerp Geographical Society contains the text of the "Résolutions et Vœux," presented by the section of the late Commercial Geography Congress at Brussels, and adopted by the general meeting.

AT the last sitting of the Paris Society of Geography a letter from M. Sibiriakoff, one of the promoters of Nordenskjöld's North Asiatic Expedition, was read. This generous gentleman proposes to the Society to send a handsome subscription, in case a French expedition is sent to these parts. But it does not appear likely this suggestion will be taken into consideration.

M. HERTZ, the founder of *L'Explorateur*, the first popular journal of geography established in Paris, died a few days ago at the age of fifty. He was a member of the Council of the Geographical Society and one of the promoters of the Commercial Geographical Society.

U.S. NATIONAL ACADEMY

THE National Academy of Sciences held its semi-annual meeting at Columbia College, New York, October 28th–30th. Prof. W. B. Rogers presided. The meeting was welcomed by Prof. F. A. P. Barnard (President of Columbia College), as being the first use that has been made of the new building recently constructed and not yet quite finished, on the western front of the college grounds; thus appropriately inaugurating it in the interests of science. Prof. Rogers opened the meeting with a few brief but eloquent remarks, descanting on the far-reaching character of the researches which are now most prominently before the scientific world. As instances he cited the proofs brought by Prof. Whitney of the discovery of human remains in the pliocene; the evidence adduced by Mr. Lockyer, showing that in the sun many of the elements may prove to be compounds; the marvellous expositions of "radiant matter" in Mr. Crookes's experiments; and the striking discoveries in the uses of electricity and the telephone. Prof. Rogers is not ready to accept all the new theories which accompany these novel conceptions, but he feels assured that we are on the road toward new truths. The present age, like that which preceded the Newtonian era, has brought together a vast and somewhat chaotic mass of observations, out of which great principles shall be determined. In this work it is to be expected that some of the members of the Academy will bear an active part.

Dr. Henry Draper read a paper on the photography of star spectra, which we gave at p. 83.

Prof. C. A. Young contributed some "Spectroscopic Notes." He showed the want of true achromatism in the ordinary achromatic object-glass. By special arrangement of apparatus and the use of high dispersive powers, he has divided several spectral lines hitherto regarded as basic. The abundance of double lines in the spectrum has a meaning that needs to be investigated; as a curious fact, it is comparable to the excessive number of double stars that the telescope reveals. Prof. Young is prepared to indulge in a doubt as to whether the dark lines are really produced by absorption.

Dr. J. J. Woodward, Surgeon, U.S.A., read an elaborate paper on original researches reported in the second medical volume of the "Medical and Surgical History of the War of the Rebellion." This is a work published by the U.S. Government in several large quarto volumes. In preparing the work, Dr. Woodward consulted 124 different authors. His studies were aided by the use of the very large number of specimens in the pathological collection of the U.S. Army Museum. For various representations, *e.g.*, showing the cicatrices of diphtheritic ulcers, photography and the heliotype were employed. The special researches applied chiefly to diseases of the internal organs, such as dysentery and intestinal catarrhs. The minute changes indicating the beginnings of disease were closely studied. Dr. Woodward's conclusions tend to confirm the more recent and advanced views of pathology.

Dr. J. C. Dalton presented some observations on the structure of the human brain. He divided all brain matter, including the part which extends into the spinal column, into two kinds, the white and the gray. He proceeded to show that the gray kind was in three deposits, which are connected with one another—the spinal cord, the cerebral ganglia, and the extension into the outer sheath of the brain. The connection between these portions was shown to be continuous. The true shape of the corpus striatum and its connection with, as a part of, a circular organ called the surcingle, was demonstrated; and it was also shown that the lobes of the brain presented the appearance of being lapped together and doubled over around the crus cerebri. In the discussion that followed, Dr. Woodward stated that the brain had been so prepared by a peculiar process, that a single one was sawed into 1,000 slices for microscopical examination.

Prof. A. Guyot presented some remarks on a new map of the Catskill Mountains, and on the topographical relations of that mountain group to the adjacent regions of the Appalachian system. The excellent work that has been done by Prof. Guyot in the survey of the Catskill region was described some months ago in a paper read before the New York Academy of Sciences: copies are now furnished of the original map that was then exhibited. The object of the present paper was to call attention to the geological problems exhibited by the Catskill plateau. The author did not regard the carving of the mountains as glacial work, though the evidence of glacial scratches was not wanting. The process which had taken place, he thought, was an elevation of the whole district. But at the time of that rise the Adirondack formation was already in position, and by it the Catskill plateau was squeezed as it rose. The mountains which now occupy the place of that plateau were left by erosion, their valleys being carved out by the rivers. Prof. James Hall, in the discussion which followed, expressed himself as delighted with the adhesion of so good an observer as Prof. Guyot to this theory of the formation of mountains by erosion, and not by their separate upheaval. Prof. Rogers described an instance where one of the Shenandoah Mountains could scarcely have been formed by a separate upheaval, for all its strata were horizontal from bottom to top; but the surrounding region was full of the evidences of disturbance.

Prof. James Hall exhibited some new and remarkable forms of crinoids from the Lower Helderberg formation. These specimens were obtained partly in New York State, and partly in Tennessee. They were from three to four inches in diameter, and of varying shapes, no two alike, though mostly spheroidal; some were hemispherical or much flattened; others were turbinated. It was at first suspected that these were expansions of the bulbous root of crinoids, but subsequent observations indicated that these are the summits of the animal. They are made up of polygonal plates, but the arrangement is not distinctly radial, and its stellate character is greatly obscured. The specimens, which are now quite numerous, seem to be overgrowths, and present great difficulties in classification.—Prof. Hall read also a paper upon another Silurian fossil, *Lycopodites vanuxem*. This has been regarded as a plant, allied to the ferns: a more thorough study of the subject has convinced Prof. Hall that this fossil was an animal form. It is found in quantities that cover many acres with a thickness of five to fifteen feet. The attention of the Academy was also called to the question as to the classification of *Stomatophora*, a coral found upon masses of favosite, and in the same horizon as the curious crinoids. In the discussion which followed, Prof. Newberry called attention to the sponge-like appearance of the crinoid specimens, suggestive of a missing link between crinoids and sponges.

Prof. Asaph Hall read a brief paper on this year's observations on the satellites of Mars. The discrepancies of position of Deimos are very small. It is found that Phobos comes to its greatest elongation 44 minutes before the place as computed : its period as now ascertained is 7h. 39m. 13·996 sec.

A paper by Prof. Joseph Le Conte on the old river-beds of California, was read in the absence of its author, and attracted much attention. These river-beds are now in process of being washed out by hydraulic mining, in the search for gold ; and it is in them that some of the earliest traces of prehistoric man are alleged to have been discovered. Prof. Le Conte does not regard the hydraulic method of attack as promising to yield many fossils in good preservation ; it is more likely to destroy all traces. The mode of formation of the old river-beds, which are found in Middle California, is peculiar. Their rivers had been completely displaced and have formed new channels, sometimes parallel, and sometimes even at right angles to the old ones. The new channels are cut perpendicularly through 2,000 to 3,000 feet of slate rock. The old channels are filled with boulders and pebbles; capped with a conglomerate layer, described as "trifaceous," the product of a volcanic overflow, with few pebbles. Under ordinary circumstances the tendency of rivers to clear their own channels is effective, though sometimes operating at long intervals. If the load of detritus is too heavy, it is deposited ; but eventually there comes a time when the river is no longer overloaded, and then it proceeds to tear up and remove its previous deposits. Thus at the present time the Colorado River is underloaded, and is cutting its channel, while the Platte is overloaded and filling up; the Yuba River has filled a depth of 15 feet within the past 20 years. But in the old river-beds under consideration, the deposit has been capped and protected by a volcanic overflow. We find evidences of this lava flood over a vast district, but not extending to the British possessions. Prof. Le Conte is inclined to fix the period of the lava flow as at the boundary between the tertiary and quaternary. Whitney and other geologists have referred the gravel of these river-beds to the pliocene; Prof. Le Conte thinks that the fossils indicate the approach of a change to the quaternary, and that the passage from the pliocene to the glacial epoch was gradual. To review the whole procedure, he begins with the elevation of the Sierras, when a general drainage system was constituted without much tendency to erosion. Glaciers formed and were melted, and thus were provided the boulders and gravel. Then came the lava flow, which destroyed the old drainage system, and compelled the rivers to seek new channels. The further elevation of the Sierras had renewed the glacial operations, which in some instances had wholly swept away the lava and replaced it by a different class of deposits. The paper elicited a very lively discussion, in which all the geologists present took part. Prof. O. C. Marsh is inclined to give full weight to the views of Prof. Whitney and Clarence King, who have been long in the field and have studied the subject very thoroughly. Prof. Marsh said that he himself has picked out fossil remains from these river-beds, which were unquestionably pliocene, and of animals living in a tropical climate. The volcanic outbreak certainly took place in the pliocene, and before the glacial epoch ; of this he had assured himself by observing the position of layers of basalt. We find the remains of man in this position—in the pliocene, along with remains of sloths and other tropical animals. We concede that these animals were there in that era. Why must we suppose that the remains of man were brought thither by some accident? It seems more reasonable to believe that man was there in that warm climate, in which he could live, than that he came in with the cold and the glacial era.

"Our Memory for Colour and Luminosity," was the subject of an essay by Prof. O. N. Rood. He proposed to give a few results from a series of experiments recently begun and not yet completed. It is generally supposed that while we have a distinct memory of different colours, such, for instance, as those which are called "primary," we do not remember with definiteness, particular shades of colour or specific mixtures of white and black. Nearly all optical instruments in which there is a provision for comparing either colours or amounts of luminosity, are constructed with great care so as to bring as nearly as possible into contact the colours or shades to be compared. The prevailing notion seems to be that we do not retain for ten seconds an exact memory of a given shade or tint. Prof. Rood exhibited the apparatus by means of which he tested the correctness of this notion. Two disks were so arranged that either one could overlap the other in any required proportion. The disks were of different colours, which blended into a given tint when the disks were rapidly revolved—a tint having a known percentage of each of its components. Let us suppose that this tint was obtained by thus blending 43 parts of yellow with 57 parts of red. Prof. Rood wished to ascertain how near to that proportion he would get when he reproduced that tint from memory. So he took a glance at it while the disks were revolving. An assistant then disarranged the disks, and afterwards proceeded to rearrange them, making the blended tint more or less yellow as directed by Prof. Rood, until the colour attained corresponded to the latter's recollection of the original tint. The original having 43 per cent. of yellow, the reproduced colour had—on an average of many trials—42·6 per cent. of yellow. This was when only a minute elapsed between looking at the tint and reproducing it. The largest variations from the mean were not over ½ of one per cent., a difference of tint so slight as to be just barely perceptible when it is shown by direct contrast and the superposition of the differing shades. When an hour was allowed to elapse before the colour was reproduced from memory, the tint obtained averaged 45 2 of yellow, showing an error of 2·2 per cent. error. Reproductions 24 hours afterwards gave 47·5 ; *i.e.* 4½ per cent. Equally near results followed in testing the memory for other mixtures of colours, such as yellow with green, and blue with green. The amount of error in several of these instances was exhibited to the Academy by means of the apparatus, and was scarcely distinguishable. This power of memory for colours might, however, be peculiar to this experimenter : to test that point, a similar set of observations were made upon his assistant's memory, with as good results. There was a single and curious exception. During one of the experiments a cord in the apparatus snapped ; this incident so distracted the assistant's memory of a given tint that his reproduction of it was utterly at fault ; but immediately afterwards he regained his usual average of correctness. The reproduction of grays, that is, mixtures of white and black, is attended, as might be supposed, with a somewhat larger average of error ; but the experiments on this point are not yet complete. From what has thus been shown it is evident that the memory of definite tints is fairly accurate, so that it can be depended upon within certain limits. Hence the juxtaposition of tints to be compared in spectroscopes and other optical instruments is not always necessary. The instruments themselves can be made far less complicated and costly where this feature of cons ruction is not required. Observers can be trained to an accurate memory of tints and even of differences of luminosity. Prof. Rood showed also some apparatus for obtaining a quantitative analysis of the effect of contrast upon adjacent colours. It was shown, for instance, that the colour of a small disk on a large ground was overwhelmed by its background to the extent of 12 per cent. In the discussion on this paper, Prof. Trowbridge, of Columbia College, stated that his students in drawing, preparatory to a course of engineering, were required first to make a draught from a model, and then, the next day, to reproduce the draught from memory. Several of these drawings, with the duplicates from memory, were exhibited ; they gave conclusive proof that the memory of form under such circumstances may be cultivated to a high pitch of accuracy.

Prof. S. P. Langley gave a brief account of a portion of his researches on the radiation of the solar atmosphere. These have demonstrated the decline of heat-radiating power from the centre to the edge in a certain series ; and also a decline of light-radiating power in a totally different series, the light near the centre having a blue tinge while that of the outside edge is chocolate red. The apparatus used in these researches was exhibited. About thirty years ago Secchi ventured the assertion that there was a marked difference of temperature between the northern and southern hemispheres of the sun. Prof. Langley afterwards disproved this by experiment, and placed the facts before the French Academy. Somewhat recently two Frenchmen, Messrs. Cruls and Lacaille, announced to the Academy, (through the Emperor of Brazil, who is a corresponding member) that they had verified the original observations of Secchi. They stated that the heat of the northern hemisphere of the sun was to that of its southern, as 100 to 75. Prof. Langley has since carefully repeated his experiments, and is satisfied that there is not a demonstrable difference in the heat of the two hemispheres. In the course of 400 observations he has found only fractional differences of less than one per cent., and since there is no systematic relation between these, they are to be ascribed to such errors as we may reasonably expect.

A second paper from Dr. Joseph Le Conte was read, on the glycogenic function of the liver, being a continuation of a paper on the subject read at a previous meeting and since published. The theory which is advanced in these papers and supported by certain experiments, is as follows:—Food passing into the liver is there changed into materials fitted for the blood, the albumenoids into nitrogenous and saccharine substances, the amyloids into glycogen or "liver sugar." In preparing sugar for the blood, the liver exercises its chief function by supplying easily combustible fuel. The combustion of this fuel takes place in the capillaries, whither oxygen is also carried by the blood. With regard to the place of combustion being in the capillaries, in contact with tissue, there is no longer a question; the novelty claimed by Dr. Le Conte is in respect to the preparation by the liver of the fuel for this combustion. He does not concede that the tissues are themselves burned in the process. He regards the liver as a sort of storehouse, and asserts that the fuel it provides one day may not be consumed till the next day in the capillaries. Many arguments were brought to bear in support of these views. The paper elicited a brilliant discussion in the meeting, for although the main point, the alleged function of the liver, was cheerfully conceded, a question was raised as to the use of the word "combustion" in describing vital processes; such use of the term being ably opposed by Dr. J. Lawrence Smith, who regards oxygen as serving an alimentary rather than a destructive purpose in the animal economy, while Dr. G. F. Barker argued that a true combustion was performed where the oxygen united with carbo-hydrates and the process was accompanied by evolution of heat.

A paper delivered by Dr. George F. Barker had for its title "On Arago's Experiment." It bore reference to the theory which asserts that a wire becomes a magnet during the passage of electricity. This was called in question about fifteen years ago by Prof. Franklin Bache, of Philadelphia (brother of the late Alexander Dallas Bache of the U.S. Coast Survey). He found that when the magnetic field was cut in two by means of a disk of cardboard, a wire that had previously supported a quantity of iron filings, suddenly dropped them. He inferred that the support of the filings had not been due to the wire being a magnet during the passage of the current, since the current was still passing when they dropped. Their previous support, before the interference of the cardboard, was therefore to be attributed either to their magnetic adhesion to one another, or to the direct influence of currents circulating in the magnetic field which were cut in twain by the cardboard. Dr. Barker has been experimenting with a very powerful magneto-electric machine of the Wallace pattern. It was capable of heating a quarter of an inch gas pipe, three feet long, to bright cherry redness in a minute. Its current was used with a copper wire in Dr. Barker's experiments: the question at issue being whether this copper wire became a magnet during the passage through it of the electric current. A five inch iron spike was held under and close to the wire; the gravity of the spike was lessened, but not sufficiently to support it, even when it was brought within the 1000th of an inch of the wire. But as soon as the spike actually touched the wire, it stuck fast, was wholly supported, and arranged itself transversely to the wire. When the spike was withdrawn from the wire by only the 1000th of an inch, it fell, being no longer sufficiently attracted. Dr. Barker regards this as showing that the attraction in the wire is greater than that in the field. The wire was then passed perpendicularly through a hole in a glass plate on whose upper surface iron filings were sprinkled; these, when the current was passed through the wire, arranged themselves on the plate in concentric circles around the wire, thus indicating that such was the direction of the currents in the magnetic field. When the spike was placed near the wire and parallel to it, but suspended by the upper end, the lower end moved in the direction of the field-currents, throwing the spike out of perpendicular. These observations were regarded by Dr. Barker as evidence that the wire becomes a magnet in the experiment of Arago.

Prof. J. S. Newberry delivered a paper on the vegetation of the Atlantic coast of North America in the cretaceous period. He began by briefly sketching the position of the cretaceous in the United States (and specially the lower cretaceous), along the eastern base of the Appalachian chain. A large collection of fossil leaves from this horizon, obtained in the green sands of New Jersey, was exhibited; it included many leaves from trees of the salix family, in great variety; and leaves and twigs of conifers; the specimens were of remarkable beauty and clearness of detail. These fossils indicate that the dawn of the cretaceous period in this country was attended by a temperate climate. It seems probable that the plants of that period spread from America to Europe before the tertiary age, and were destroyed by the glacial epoch, after which, an Asiatic flora, spreading westward, filled the void. In a discussion upon this paper, Prof. Marsh stated his belief that these fossil leaves were older than the lowest cretaceous marls of New Jersey, in which we find crocodilian and other remains indicative of a warm climate. A similar question had arisen about fossils from Dakotah; animal remains at first regarded as cretaceous, but now known to be Jurassic. Local proximity of formations differing widely in age, is not uncommon at the West. Within fifteen or twenty feet of a place where he picked out remains of dinosaurs, crocodiles and the like, he had found at fifty feet lower depth, the ichthyosaurus. Dr. Newberry said that the clays referred to in New Jersey underrun the marl beds, and are a shore deposit, probably a freshwater one. Prof. Marsh hoped that these localities would be very thoroughly explored. Up to the present date we know of no cretaceous mammal; this is the most serious break in our palæontological record. Prof. Rogers mentioned that certain fossils obtained in Virginia sandstones had been classed as Wealden, but he was inclined to consider them as on the border line between cretaceous and Jurassic. He regarded the position of the New Jersey fossils as yet open to question. Prof. Newberry sketched on the blackboard a sectional view of the strata in the New Jersey locality. Prof. Marsh suggested that these conifers and willows may have grown in elevated positions, on mountain sides, where they would have a temperate climate though it was tropical at the base of the mountains; and that these forests might have been dislodged by flood or avalanche, and carried down into the swamps at the base. It was long supposed in Europe that there was no angiospermic flora below the miocene, and when Prof. Marsh picked up there the leaves of an angiosperm in the cretaceous, the specimen was regarded as a great curiosity. In this country such fossils were abundant; but as to the Jurassic flora we know too little to speak with any certainty. Prof. Rogers stated that an investigation of Virginia and Maryland clays, now in progress, would probably solve this question; and Prof. Newberry expressed a similar hope in regard to certain researches on the shores of Buzzard's Bay, Mass.

A second paper by Prof. Newberry was descriptive of some interesting deposits of gold and silver ores in Utah and Colorado. Specimens were shown of sulphate of baryta with ruby silver. The Horn silver mine of Utah had $20,000,000 of ore in sight; the footwall was limestone; the sandstones are full of the impressions of plants, the plants themselves being replaced by horn silver. Such impregnation by a metal is rare, but there are parallel instances with copper, in New Jersey, in porous sandstone. Near the Horn silver mine is one of a conglomerate rock containing a rich argentiferous galena, going down at least 200 feet, and yielding $50 to $60 to the ton. A similar class of deposits has been found in Colorado, in the district of the Silver Cliff mine, a region of trachytic rock like that of the Horn silver district. It would appear that when the trachyte had been heated so as to be softened, while in the shape of balls of various sizes, the ores had coated them and filled their crevices. The ground is covered with this rusty-looking rubbish. At depths of 150 feet in it, silicified wood is sometimes found, and occasionally free gold, or "wire" gold. A man named Bassick, a sailor who had been round the world, and was quite penniless, picked up one of the rusty trachyte lumps and succeeded in having it assayed; the yield was $50 to the ton. He was thus led to the discovery of what is now known as the Bassick mine, which he eventually sold for $1,000,000. Silver Cliff is distant about six miles; it is a hill of shattered rock—breccia which has been cemented together; the mining operations there have gone 250 feet below the surface, into a zone of oxidized ore; the rock of the hill itself is worth $50 to $60 per ton, and its quantity is simply enormous. From other mines specimens were exhibited containing large quantities of arsenic, the ore being also accompanied by veins of orpiment and realgar. Specimens from Leadville mines showed the progress of change from carbonate to galena ores. The limestone surface had been eroded, and then porphyry was poured over it; the fissure veins were formed in this contact. The famous Leadville deposits are not so rich as had been supposed; specimens picked out for assay were very choice; in general the ore contains iron and a great deal of silica. There are two gold mines in Leadville, one of which is ferruginous quartz. The town itself is vile. Its climate is repulsive. It is at an elevation of 10,500 feet, and water is scarce, so that the whole place is covered with at least 5 inches of dust. There is no sewerage, and this dust is the filth of the town; the air is full of it, and it must be inhaled with every breath of the dwellers there. But every man in Leadville believes himself potentially rich, and has a mine or a claim for sale. Speculation in claims, and mere gambling in fractional ownerships, is the principal business. Prof. Newberry had seen the law papers in the examination of a mining property where no less than 14 claims overlapped one another. There is really valuable mining property in abundance, not yet developed, in Colorado and Utah; but the properties that are put on the market for sale in New York are generally worth little or nothing, and will tend to discredit investment in all Western mines.

Prof. J. Lawrence Smith gave an informal account of some recent researches for new elements. A few years ago he found a field of research in the cerium and yttrium minerals, and was well satisfied that he had obtained a new substance, which he named mosandrum, in the cerium group. Since then he has been studying the components of samarskite, and has found, he believes, two new elements, one of which he calls columbium, and the other he proposes to name in honour of his friend and the instructor of his youth, Prof. William B. Rogers. But having much other business requiring his attention, Prof. Smith has done little in that line of research, since then, except to purify some mosandrum. Not wishing to delay the progress of discovery, he turned over a mass of the earthy material to Messrs. Lafontaine and Lecoq Boisbaudran, who have since announced several discoveries. The new elements are not yet separated; the supposition of their existence is based upon observations on their absorption spectra. Prof. Smith has great doubts whether this method is trustworthy. He found that a given solution showed a different spectrum the second day from that of the day before. The addition of nitric acid in greater or less strength was found to alter a spectrum to an extent fully as great as would be considered indicative of the presence of a new metal. But in nitric acid itself there is nothing to provide these new spectra. Hence a doubt is thrown over all discoveries that rest exclusively upon absorption lines. There are probably 8 or 10 new earths in the yttria group. Of the newly announced metals, Prof. Smith thought philippium was more likely to prove real than most of the others. In the discussion that followed, Dr. Barker pointed out that the colour of a solution affected its spectrum. He regarded the discoveries based solely on absorption spectra as not to be trusted until supplemented by chemical tests.

The other papers read at the meeting were as follows: "On the Mean Pressure of the Atmosphere over the United States at Different Seasons of the Year," by Prof. Elias Loomis; "Questions as to a very Direct and Simple Method of Ascertaining the Ellipticity of the Terrestrial Spheroid," and "The Completion of the Theory of Parallel Straight Lines," by Prof. Stephen Alexander.

The meeting closed with a brief address by its presiding officer, Prof. Rogers. In the course of his remarks he expressed a wish that hereafter some measures should be taken for a more general and widespread invitation to the public to be present at the meetings of the Academy. This suggestion will probably be adopted.

WM. C. WYCKOFF

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following Statutes, which the University of Cambridge Commissioners contemplate making for the University, having been communicated to the Council of the Senate, the Vice-Chancellor hereby gives public notice thereof in the University.

"The University shall have power to adopt as an affiliated College in any place within the United Kingdom or in any part of the British Dominion any institution founded for the education of adult students, with such conditions as to the provision of lectures, and as to the rules and arrangements for the students, as may be determined from time to time by Grace of the Senate. Students of the institution who shall have continued members of it for such length of time, not less than two years, and shall have attended such lectures, and passed such examinations, as may be required from time to time by Grace of the Senate shall, if admitted as members of the University, be deemed to have kept already three of the terms required for any degree."

"Students in Science, who having already taken a degree in Arts, Law, Medicine, or Surgery, have given proofs of distinction in Science by some original contribution to the advancement of Science, and having done all that is required by the statutes and Ordinances of the University, may be admitted to the title of Doctor designate in Science, and shall afterwards be created Doctors at the time prescribed by the University."

"The management and regulation of the Botanic Garden, together with the appointment and removal of the Curators, Superintendents, Officers, and servants employed therein, shall henceforth be vested in a Syndicate consisting of the five Governors and Visitors appointed by Dr. Walker, that is to say, the Chancellor, or in his absence the Vice-Chancellor of the University, the Master of Trinity College, the Provost of King's College, the Master of St. John's College, and the Regius Professor of Physic, together with such other persons as may be appointed from time to time by Grace of the Senate."

The Syndicate appointed on May 31, 1877, to consider how to encourage students to read for honours in more than one tripos, in consequence of urgent representations on the part of head masters of public schools, have made a sixth and final report, leaving the Board of Natural Science Studies to propose the necessary and more than formal changes required in the regulations. With this exception, the Syndicate consider the duties committed to them to have been completely discharged.

Lord Rayleigh, we are glad to learn, has consented to become a candidate for the Chair of Experimental Physics at Cambridge; the election takes place to-morrow.

Mr. E. B. Tawney, F.G.S., Assistant to the Woodwardian Professor, who has made most valuable donations to the Woodwardian Museum, has had the degree of Master of Arts conferred upon him. Every geologist and palæontologist who knows Mr. Tawney will be glad to see this recognition of his merits.

THE number of matriculated students attending the University of Edinburgh this season is 2,510, the number of students in medicine being 1,138, in law 363, and in divinity 74. There is an increase, as compared with last year, in all the faculties, that in medicine being 96, and the total increase 178.

THE Court of Assistants of the Cordwainers' Company being impressed with the importance of the City Guilds employing part of their funds in the establishment of a central institution for the promotion of technical education, have, in addition to a grant of 250*l*. per annum already made, voted a donation of 500*l*. towards the building fund, on condition that the total sum agreed to be subscribed for that purpose be in their opinion adequate to the satisfactory fulfilment of the object contemplated.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 27.—"On the Structure of Serous Glands in Rest and Activity." By J. N. Langley, M.A., Fellow of Trinity College, Cambridge. Communicated by Prof. Michael Foster, M.D., F.R.S.

The Parotid Gland of the Rabbit.—The alveoli of the gland can be observed in the living state without serious interference with the blood circulation. When the gland has been quiescent for several hours, the alveolar-cells are granular throughout, and the outlines of the cells are only faintly marked as clear lines without granules. When the gland secretes, the granules disappear from the outer borders of the alveolar-cells, that is, from that portion of the cells nearest the basement membrane. After prolonged secretion, very few granules are left in the cells; those that do remain in any cell form a thin layer at its inner portion, that is, at the portion bounding the lumen, and stretch outwards, also as a thin layer, along the cell-sides a variable distance from the lumen.

In an alveolus during secretion, the cells separate from one another slightly near the lumen; thus the lumen stretches out for a short distance between the cells; it becomes larger, at the same time, by the diminution which takes place in the size of the cells.

The above described changes occur whether the secretion is induced by giving food to the animal, or by giving it pilocarpin, or by stimulating the sympathetic nerve running to the gland. The two zones of the fresh state are not preserved by alcohol and other reagents.

Osmic acid shows some considerable differences between the resting and the active gland, the chief amongst which is the more equal staining of the substance of each alveolar-cell in the active state.

The Parotid Gland in the Rat, Cat, and Dog behave in rest and activity like the parotid of the rabbit in a corresponding condition. The living condition in these cases, however, has not been observed in the glands with intact blood-circulation.

In one case where the sympathetic nerve of a dog was stimulated, a saliva was obtained from the parotid, of unusual character. The saliva clotted readily, and contained 8·3 per cent. of solids, of which 7·8 per cent. were organic substances. Jacobson's nerve was uncut. The much more rapidly flowing saliva following subsequent injection of pilocarpin had a slightly lower percentage of salt than the slowly secreted sympathetic saliva. In several cases in other glands I have also seen a diminution in percentage of salts, notwithstanding an increased rate of secretion of fluid.

The Sub-maxillary Gland of the Rabbit undergoes changes in activity similar in the main to those which occur in the parotid. The changes are, however, less marked; the granular condition of the gland has a less direct relation to the state of hunger of the animal.

The sub-maxillary gland has one very characteristic feature, the transition- and some of the ductule-cells contain, in life, granules more distinct and larger than those contained in the alveolar-cells. How far these disappear during secretion is uncertain.

As in the parotid so in the sub-maxillary, reagents do not preserve the normal appearances. The secreting gland treated with osmic acid shows alveolar-cells much more evenly stained throughout than does the resting-gland.

The deep black staining of the transition-cells with osmic acid described by Nussbaum does not take place if the gland be treated with osmic acid only; the deep coloration is the result of a subsequent treatment with alcohol. With osmic acid alone, the ducts stain darker than any other part of the gland.

I must uphold my previous objection to Nussbaum's view that ferment is formed in the transition-cells and not elsewhere. Briefly my objections were that the ductule-cells, in their method and depth of colouring behave like the transition-cells, and that the black coloration of the transition-cells with osmic acid does not occur if the gland is previously treated with absolute alcohol, in which the ferment is said by Nussbaum to be insoluble.

I can in the main confirm Bermann's description of a "tubular gland" in the sub-maxillary of the rabbit.

The Infra-orbital and Lachrymal Glands of the Rabbit show an outer clear and an inner granular zone in activity even more distinctly than the parotid. In both these glands osmic acid preserves more nearly the living appearances. The two zones if present normally, are also present after treatment with osmic acid.

In the *Mucous Glands* during secretion the changes in life are less readily followed, but they are probably similar to those mentioned above. In rest the alveolar-cells form granules like the alveolar-cells of a serous gland; but in the former case the granules are of nearly the same refractive power as the surrounding substance and so not conspicuous. In activity the granules are used up, and disappear first from the peripheral parts of the cells.

"Report on Phyto-Palæontological Investigations on the Fossil Flora of Sheppey." By Dr. Constantin Baron Ettingshausen, Professor in the University of Graz, Austria. Communicated by Prof. Huxley, Sec. R.S.

Physical Society, November 22.—Prof. W. G. Adams in the chair.—New Members, Prof. Reilly and Prof. Heath, of Cooper's Hill Engineering College.—Prof. Guthrie exhibited a new photometer in its crude form and demonstrated its action to the meeting. It consists of two fixed plane mirrors inclined to each other at an angle. The rays from the two sources of light to be compared, are allowed to fall on these mirrors, those from one source, say that on the right hand, falling on the right hand mirror, and those from the left hand source on the left hand mirror. These rays are again reflected from the mirrors at right angles to their former paths and thrown upon a semi-transparent screen where their relative intensities can be compared by the eye of the observer between the mirrors and each source of light; a revolving shutter is interposed. These shutters are formed of brass disks and they are both mounted on the same axis which can be turned by hand or otherwise. They would completely screen the light from the mirrors were it not that each is provided with four radial apertures or slots through which the rays can pass. The slots on the side at which the brighter source of light is placed are narrower than those on which the weaker source is placed. The latter slots are made adjustable in size by sliding blinds and a scale is added to measure the degree to which they are closed. On revolving the shutters the reflection of the rays to be compared are seen side by side and (owing to persistence of images on the retina) continuously on the screen placed in front, and they are brought to equality of brightness by closing or opening the blinds of the adjustable shutter. When this is so the ratio of the respective orifices of the shutter as given by the scale is the inverse ratio of the luminous intensities compared. Prof. Adams remarked that the speed of rotation should be such as to produce a uniform field of light on the screen, a result which hand-turning was not very conducive to. Prof. Foster observed that the use of this new photometer might be less fatiguing to the eye than those photometers which presented a steady beam to the eye undiluted with intervals of darkness during which the light is cut off, as on the instrument before the meeting.—Prof. Reinhold then read a paper by Prof. Rücker of the Yorkshire College, Leeds, on a suggestion as to the constitution of chlorine offered by the dynamical theory of gases. If a gas of density δ consists of molecules each of which possesses *no* degrees of freedom, and if also the inter-molecular forces are negligable, the specific heats at constant pressure (Cp) and at constant volume (Cv) are connected by the two well-known equations,

$$(1) \quad (Cp - Cv) \quad \delta = \cdot 0694$$

$$(2) \quad \frac{Cp}{Cv} \dots 1 + \frac{2}{m+e}$$

where e is a quantity which depends upon the potential energy of a molecule; hence if Cp is given by experiment Cv can be calculated from the first equation, and then $m + e$ is known from the second. Regnault determined the specific heats at constant pressure of 35 gases, and from the experiments of E. Wendemann and of Wullier it appears that his values are correct within 6 per cent., and that $m + e$ can be calculated very approximately from the above equations if Cp is given. One of the chief difficulties of the thermo-dynamic theory of gases has been to attribute to m and e values which would at once lead to the observed ratios of Cp and Cv and satisfy any rational supposition as to the interior mechanism of a molecule. Kundt and Warhng proved that for mercury $\frac{Cp}{Cv} = 1\cdot 666$, which is consistent only with the supposition that the atoms of mercury are smooth rigid spheres; and Boltzman and Bosanquet have pointed out that for a smooth rigid surface of revolution $\frac{Cp}{Cv} = 1\cdot 4$, a number agreeing closely with the experimental value for air, O, N, H, CO and NO. The molecules of these gases may therefore be constituted of two spheres rigidly united, or, as Prof. Rücker suggests, bound together by forces which prevent their separation of their surfaces while leaving them otherwise free to move. The principal object of Prof. Rücker's paper was to point out an interesting fact connected with the application of this theory to chlorine.

The maximum number of degrees of freedom which a molecule composed of n smooth rigid spheres could possess would be $3n$, but the forces in play between the spheres might reduce this number. Thus the value of $m + e$ could not exceed but might be less than $3n + e$. When the molecule consists of two atoms $e = o$ but for complexer molecules we should, *cæteris paribus*, extract its value to increase with the number of molecules. From two tables of results calculated by him, Prof. Rücker, however, finds that for a number of simple and complex gases and vapours the value of $m + e$ is for each substance less than $3n$ (or the maximum possible value of m), while for the majority of chlorine compounds examined the reverse statement holds good, that is, the value of $m + e$ is generally greater than $3n$. This difference may be explained by supposing that for chlorine e is abnormally large, and that the spheres are not necessarily in contact; or that n has been taken too small, that the symbol Cl_2 is incorrect, and that the chlorine atom contains a larger number of sub-atoms than has been supposed, a supposition which accords with the recent researches of Prof. Victor Meyer on the vapour density of chlorine. Prof. Rücker also finds that the ratio of the specific heats of bromine and one of its compounds studied (C_2H_5Br), agree with those of chlorine and the corresponding chlorine compounds. Dr. Shettle, of Reading, then read a paper on the influence of heat upon certain forms of induction coils considered more especially in relation to the inductive power which the blood exercises on the various structures of the body. The author found that when a copper and a zinc wire were insulated from each other by parchment paper and paraffined silk, and wound in close proximity to each other, an (induced) current was indicated on a galvanometer whose terminals were connected to the neighbouring ends of the zinc and copper wires respectively, the other ends being left free. When the latter were connected across the deflection was *nil*. On raising the temperature of the two wires by causing hot water to flow inside the coil into which they were wound the deflection was largely increased. These experiments lead Dr. Shettle to imagine there is a similar action in the animal body. The heart is made up of nerves and muscular fibres winding spirally, and some of these wind round each other so as to form a spiral cord round which the blood capillaries also wind. Dr. Shettle compares these nerve and muscle bundles to the coils of zinc and copper wire in his experiments, and infers that electric currents may be induced in them as in the wires. The flow of the warm magnetic blood would also tend to produce currents in them. Dr. Shettle further drew attention to the fact that animals live and move in a magnetic field, and that electricity must be generated in them by their movements internal and external.—Mr. Emmott exhibited Crossley's form of microphone, which consists of four short rods of carbon jointed loosely into four blocks of carbon so as to form a square. It is used as a transmitter for telephones, and Mr. Crossley regularly transmits the services of a church with it to several hearers. Its speaking, singing, and whistling powers were successfully demonstrated to the meeting.

Paris

Academy of Sciences, December 1.—M. Daubrée in the chair.—The following papers were read:—Observations on M. Trecul's last note relative to chlorophyll, by M. Chevreul. He asks whether chlorophyll is a constituent part of the organ, or is only accessory and without organic activity.—On some properties of glucoses, by M. Peligot. By action of alkalies on glucose, he obtains a crystalline substance (which he calls *saccharine*), having the composition of ordinary sugar, or saccharine, not yet sugar. In presence of yeast it does not ferment; its taste is not that of sugar, but almost *nil*, with a slight after-bitterness. The common view, that saccharine matters should be regarded as polyatomic alcohols, is not (M. Peligot thinks) confirmed by production of this new substance. In the action of lime on glucose, a true saponification occurs.—Note on the crystalline form and optical properties of saccharine, by M. Des Cloizeaux. The optical phenomena do not enable one to conclude with certainty whether saccharine belongs to the rhombic or the clinorhombic system.—Questions relative to phylloxera addressed to M. Thenard, by M. Fremy.—Reply to these questions by M. Thenard. This relates to the use of sulphide of carbon, and its effects on vines.—Demonstration, by means of elliptic functions, of a theorem in the theory of the libration of the moon, by M. Gyldén.—Note on the measurement of quantities of electricity, by M. Hirn. He calls attention to M. Villari's demonstration that the action of the spark of Leyden batteries on the magnetic needle is proportional to the quantities accumulated, and seeks to show that this law is in harmony with those he himself has indicated as to the effect of continuous currents; (he expresses a wish that M. Villari's important memoir might be published *in extenso* in French).—Periodic movements of the ground revealed by spirit levels, by M. Plantamour.—This gives results of a year's observations at Secheron from October 1878. The east side went down with decreasing temperature until June, (there being a pretty exact parallelism between the curves); then the east rose until the beginning of September, in a much greater proportion than the exterior temperature. From 32·8mm. the greatest depression to the east, on January 15, to the maximum of elevation 19·5 mm. on September 8 gives 52·3mm. as the total amplitude of oscillation during the year, (or 28·08s). There was generally besides a daily movement, with amplitude on September 5, of 3″·2. The minimum is usually between 6 and 7·45 a.m. the maximum twelve hours later. In the meridian direction, the movements of the ground are much less; the total amplitude for the year was only 4″·89. They show an unexplained anomaly relative to the movements east and west. The daily movements in the meridian are very rare, irregular, and small. It seems, then, that at Secheron there are periodic movements of rise and sinking of the ground, and that, generally, they are determined by the exterior temperature. Perhaps the configuration and nature of the ground have also some influence.—Establishment of scientific and hospital stations in Equatorial Africa, by M. de Lesseps. It has been decided by the French Committee of the African Association to establish such stations between Zanzibar and the Gaboon; the Chambers have voted 100,000 fr. for the purpose.—Astronomical junction of Algeria with Spain; international operation under General Ibañez and M. Perrier, by the latter.—Note rectificative of M. Viallanes's opinion regarding phylloxeric spots in the environs of Dijon.—M. Lamarre described an electric phenomenon lately observed by him during a fall of snow at Cherbourg. Luminous *aigrettes* appeared at the points of his umbrella.—Determination of curves and surfaces of two surfaces which have double or stationary contacts with each other, by M. Zeuthen.—On series relative to the theory of numbers, by M. Lipschitz.—On a dynamometric brake regulated automatically, by M. Carpentier.—Separation of phosphoric acid from sesquioxide of iron and alumina, by M. Derome.—On the constitution of stag's horn, by M. Bleunard. It is an inferior homologue of coagulated egg-albumen. It is more hydrated than albumen.—Determination of chlorine in different grains and forage plants, by M. Nolte. Chlorides form part of all vegetable food.—Rhythmic contraction of muscles under the influence of salicylic acid, by M. Livon. A rhythmic tetanic period with contractions decreasing in intensity, precedes exhaustion.—On the mode of distribution of phosphates in muscles and tendons, by M. Jolly.—Influence of different colours on the development and respiration of infusoria, by M. Fatigati. The respiration is more active in violet than in white light, and less active in green than in white.

THURSDAY, DECEMBER 18, 1879

BOSTON AND HARVARD

To the common remark that nowhere in the United States does an Englishman feel himself so much at home as in Boston; a student of science may add that nowhere else does he meet with so much to remind him of the intellectual activity and enthusiasm for science that mark the great centres of life in the old country. Boston can boast of one or two of the oldest and most active scientific societies in America, which for generations have gathered together and sustained an able succession of workers. In the neighbouring venerable Harvard it enjoys a perennial fountain whence it may draw for ever fresh stores of inspiration and encouragement. This influence of the University is everywhere apparent. Among those who take a lead in promoting science by discovery and exposition among the Boston citizens, Harvard men occupy always a foremost place. A stranger, however, with leisure and opportunity to note some of the more salient features in the scientific life of Massachusets soon comes to realise the pervading influence of one man. He sees it in the ordinary cultivated society of Boston, he meets with it at every turn in Harvard, he finds it uniting as a common bond of sympathy the younger scientific men of the state. The name of Louis Agassiz has become a household word in the community, and, among the scientific workers, sounds as a rallying cry to unite them for common sympathy and support. Great as were Agassiz's solid contributions to the literature of science, they form a monument to his genius not perhaps more honourable or enduring than the impetus which his example and ceaseless enthusiasm gave to the progress of science in his adopted country. To have written the immortal "Recherches sur les Poissons fossiles" and to have founded so vigorous a school of science at Harvard combine to give him a high place in the temple of fame.

It is delightful to hear in general conversation in Boston spontaneous recognitions of Agassiz's eminent services. Many stories are current of his indomitable courage in carrying out schemes for the advancement of his favourite studies, of his consummate address, which enabled him to win over into active assistance men who were disposed to be indifferent if not hostile. One interesting anecdote is told of a dinner party at which he was present, when Mr. Ticknor gave an account of an early meeting of the British Association. At the Geological Section there had been a paper on fossil fishes, and, said Mr. Ticknor, one speaker who evidently knew the subject profoundly, proceeded to show the audience the characters of the types of ancient fishes, and remarked that he had no doubt a specimen would yet be discovered exhibiting a certain structure, which he illustrated by a drawing on the board. Murchison, who was in the chair, thereupon pulled out from a drawer a specimen which had just come up from Scotland and had not yet been exhibited. It completely bore out the prognostication. Agassiz had been listening to the tale with undisguised interest, and when Mr. Ticknor turned round and pointing to him said, "There is the man," he started up flushed with excitement and exclaimed, "It was the proudest moment of my life." Such anecdotes affectionately preserved show how he lives in the memory of the community he strove so earnestly to benefit. The little misunderstandings which are always sure to arise in the pathway of a man absorbed in one great aim are now forgiven and forgotten. Men remember that it was not for himself but for the cause of science that he solicited and strove.

Among the younger men of science the influence of the teaching and example of Agassiz has been profound. It is not that they have adopted his views or even that they have chosen his branch of science. On the contrary many of them have espoused evolutionary doctrines against which he protested, and have taken to sciences remote in subject from his. But he infused into them a genuine love and enthusiasm for scientific progress. By this common sentiment they are united in a bond of sympathy which cannot but be very helpful to their own studies and to the advancement of science. One of the most interesting tokens of this community of feeling is the establishment of a club or society which has no name, no office-bearers, and no laws, but which has for its object the reunion of its members for social intercourse at stated intervals. It began its existence in a meeting of two or three of Agassiz's students, and now it has drawn into its circle most of the scientific zeal and ability of the younger men of the district. Nor is it wholly confined to the younger generation. At one of the simple but most excellent and jocund dinners of the club the writer of this notice found the genial and universally beloved veteran in botany, Dr. Asa Gray, as well as that long-tried explorer of the deep sea, Count Pourtales.

Nor among the benefits bequeathed to Harvard by Agassiz can we forbear an allusion to his son. With enthusiasm not inferior to that of his father and with an ample fortune for the furtherance of his views, the present distinguished keeper of the Museum of Comparative Zoology is gathering together at Harvard the most extensive and valuable collection of recent invertebrate zoology in the world. So far as exhibition space will admit, a large and varied series of specimens is displayed. Some departments are marvellously rich. The dredgings by Prof. A. Agassiz and Count Pourtales have supplied a large suite of living corals, some of them undistinguishable from Tertiary Mediterranean species. In one of the rooms is an altogether unique collection of crinoids from the Carboniferous Limestone of Burlington. A European accustomed to the usually fragmentary condition of palæozoic echinodermata can hardly at first believe that these exquisite specimens of many species and genera, with every plate and joint in position, come from so ancient a formation. As at Yale, cellars are crowded with treasures awaiting examination and display. The work-rooms attached to the Museum are likewise full of material in all stages of investigation, and bearing witness to the amount and value of the original research carried on here by Prof. Agassiz, Count Pourtales, and their assistants. The only regret a visitor can justly express is that the plan of the building has not secured a larger amount of internal light. The windows at the sides form the only entrance for light, and they are not large or numerous enough for the size of the rooms. Would it not be possible, in the contemplated additions to the Museum, so to modify the plan as to secure, at least for the exhibition galleries and floors, some amount of light from the roof?

H

Within the walls of the Museum Prof. J. D. Whitney has accommodation for geological work. He is engaged in the completion of the memoirs of his great Californian survey. He has recently issued the first part of an exhaustive monograph of the auriferous gravels of California, which is published in the *Memoirs of the Museum of Comparative Zoology*. One of the most generally interesting and important features in this essay is the cautious and masterly way in which the author states the evidence for the existence of human remains in the gravels beneath sheets of basalt, and at a depth of 130 feet from the surface. It is impossible to resist the cogency with which he marshals the facts and maintains the genuineness and high antiquity of the Calaveras skull. The second portion of the memoir, devoted to a discussion of the origin of the auriferous gravels and of the glacial phenomena of the Pacific coast and of North America generally, is awaited with much interest. Prof. Whitney, in the course of his prolonged researches in the west, made a large and important collection of rocks. These are now being carefully investigated by his associate, Dr. M. E. Wadsworth—a young petrographer, who in recently taking the degree of Doctor of Philosophy at Harvard, presented, as his thesis, a remarkable essay on rock classification, largely based on these collections. The Professor, with the devotion to geology which has characterised his long and distinguished career, carries on this work at his own expense. The results will be published in full in the *Memoirs of the Museum of Comparative Zoology*.

There is much more than the name of Cambridge to remind one of its namesake at home. Its quiet air of studious retirement, its quaint buildings and tree-shaded walks have much of the mother-country about them. One or two features of the place, however, are characteristically American. Thus in the great library at Gore Hall, most of the work of receiving and distributing books is done by young women, and done, too, with a noiseless decorum and celerity worthy of all praise. A magnificent Memorial Hall to those graduates of Harvard who fell in the late Civil War bears witness in its crowded lists of names that culture and courage may go hand in hand. The simple eloquence of these lists, where every class and division of the faculties is represented, brings home to the mind in a startling way the terrible realities of a war. May the occasion never arise for another range of tablets either there or here!

While Harvard is necessarily the great centre of scientific research, much admirable work is done in Boston in the way of practically expounding science. The Institute of Technology has for its primary object the education of the community in these branches of scientific knowledge conducive to progress in the arts and industries of life. In pursuance of this aim the methods of tuition are so practical and thorough that the results must be felt far beyond the industrial circles. Established mainly through the enlightened zeal of the present venerable President of the National Academy, Prof. W. B. Rogers, it began a few years ago to languish, but its founder has recently come back to its rescue, throwing himself into its affairs with all his old heartiness and kindliness until, freshened and stimulated by his influence, it is once more shooting up into lusty vigour. But besides this establishment, wholly devoted to scientific instruction, the Boston School Board has made the practical teaching of science an important part of education in the public schools. At an early age the pupils are led to take an interest in physiology by references to the experience of their own bodies, and thus the laws of health are firmly lodged in their minds. From simple beginnings they are conducted through successive years of progress and are well grounded in physics, chemistry, botany, and zoology, until before they leave, if they choose to go so far, they are found at work in laboratories repeating experiments, making analyses, or dissecting plants or animals. The thoroughness of the whole system, and the length to which such State-paid education goes (for it must be remembered that all this training is free), would make most members of our School Boards stand aghast, were any utopian to propose its introduction in this country.

A student of science from this side of the Atlantic besides finding himself at home among lovers of science in New England is astonished and gratified to find that if he has himself done anything to advance our knowledge of nature, his work is as well known there as at home. The welcome he receives is all the heartier from men who have long known him by name and have come already to regard him as in some measure a personal friend and fellow-worker. A brotherhood of this kind, so cosmopolitan, so genuine, and so kindly, carries with it an enduring helpfulness. One comes away from a participation in it strengthened and cheered, with wide enlargement of ideas and sympathies that seem to fill the mind with aspirations and to brace the whole frame for endless exertions to achieve them. Undoubtedly, in spite of all that demagogues may declaim, there is in American society of the more cultured kind a deep undercurrent of affection for the old country. It shows itself in many ways and sometimes crops up unconsciously and almost to the confusion of the native-born American as if he would rather be thought indifferent in the matter. The writer is tempted to conclude with an illustrative story told him by a Harvard friend to whom the incident occurred. Some years ago, just at the time that the famous pamphlet, "The Battle of Dorking," was making a stir in the States as well as here, this friend was in Kentucky with an acquaintance of his who, like so vast a number of his countrymen, had been engaged in the Civil War, and had lost heavily in friends and fortune. This man knew well what were the horrors of war, yet after he had finished reading the pamphlet, and was appealed to by his companion as to what he would do if the picture drawn in its pages were a reality instead of a fiction, he paused and after a little reflection replied, "Well, I think I'd have to go for the old country." There are many thousands of Americans who would have no objections to thrash England themselves, but who would not sit quietly and see the castigation bestowed by any other people.

A. G.

PLANTÉ'S "RESEARCHES IN ELECTRICITY"

Recherches sur l'Électricité. Par Gaston Planté. (Paris, 1879.)

M. GASTON PLANTÉ has published, under the above title, the elegant and important electrical researches which he has pursued with so much success during twenty years, and with many of which the readers of NATURE have been made familiar from time to time.

The basis of these experimental researches is the *secondary battery*, originally devised by Ritter, but which in M. Planté's hands has become developed into what is practically a new and important source of electricity. M. Planté, by employing for his secondary cells large plates of lead immersed in dilute sulphuric acid, charged by a small Bunsen's or Grove's battery, and by arranging the secondary cells in such a manner that they can be charged in multiple arc, and discharged in series, obtains during the ten minutes or so during which the discharge continues currents not only of as great electromotive force as would be obtained from a Grove's battery of a much larger number of cells, but also of much greater "quantity;" the internal resistance of these secondary cells being excessively small.

In studying the construction and operation of these secondary batteries, M. Planté has brought to light a large number of interesting facts. He finds that such batteries improve with use, the two lead electrodes gradually becoming spongy, thereby holding in loose combination larger quantities of the oxygen and hydrogen gases, respectively, than new plates of lead. He observes several highly suggestive analogies between this electro-chemical accumulation of the energy of the current, and the electrostatic accumulation of the Leyden jar. This analogy extends even to the existence of a residual charge. It appears that the electromotive force of such a cell well charged may be as high as 2·7187 volts, while the internal resistance may be as low as 0·05 ohm, and that the actual quantity of the primary current which may be realised after being thus accumulated amounts to 88 per cent. These data are given amongst the stores of information in the first section of M. Planté's work. The second section treats of the practical uses which have been made by M. Trouvé and others of the currents from secondary batteries, and which embrace a wide range of applications, chief amongst which is the application to surgical cautery by means of wires raised to a white heat, for which operation a powerful current of short duration only is required. Another suggestion, to employ such batteries as accumulators of the current supplying electric lights, has already been seized upon by more than one inventor, amongst others by Mr. Edison.

The third section of the work before us deals with sundry phenomena produced by the discharge of the powerful currents of large secondary batteries. To obtain these effects M. Planté has used batteries of from 200 to 800 secondary elements. Luminous liquid globules and delicate flame-like aureoles are produced at the surface of liquids when the current is led into them under certain conditions: even a globule of fused mica has been produced by the current, and wandered about in a manner suggestive of the alleged behaviour of the "balls of fire" sometimes accompanying violent thunderstorms. The discharge may even be employed to write upon glass which is etched away under the negative pole of the secondary battery. The many analogies presented by these experiments with some of the less understood of natural phenomena, globular lightning, auroræ, and wreathed lightning discharges, &c., are treated in detail in the fourth section. M. Planté considers the "Fire of Saint Elmo" to be a phenomenon of discharge of negative electricity, whilst he compares the globular lightning to the phenomena observed in the discharges at the positive pole of his batteries. One of the most curious of his speculations is that concerning the spiral nebulæ, which he compares with the spiral forms produced at the negative pole when dilute acid is electrolysed by a moderately strong current between copper electrodes in the presence of a powerful electromagnet. These "electrodynamic" spirals consist of streams of particles of oxide of copper whirled off from the end of the electrode and which, conducting the current, undergo a rotatory displacement under the influence of the neighbouring magnet. These spirals, which therefore indicate the lines of flow of the current, resemble the spirals obtained by the present writer in iron filings under the joint influence of a magnet and a current traversing it longitudinally, and which differed from those of M. Planté in indicating lines of magnetic induction, not lines of current flow. So strongly does the analogy of form weigh with M. Planté that he asks (p. 243) whether the nucleus of a spiral nebula is not truly an "electric focus," and "whether the spiral form is not probably determined by the presence in the neighbourhood of strongly magnetised heavenly bodies!" Another astronomical analogy is discovered by the author between the sun-spots and certain "crateriform perforations" which are produced in moistened paper beneath the positive pole of the secondary battery.

The fifth, and last part of the work, explains the construction and operation of the author's "rheostatic machine," which is a series of mica condensers which are charged in multiple arc from a battery of 600 or 800 secondary elements, and discharged in series in very rapid succession. This instrument is capable of producing almost continuously the effects of intense discharges of statical electricity, and promises to prove of great utility as an instrument of research.

We have preferred to give the reader a brief *résumé* of the contents of this delightful narrative of researches, rather than to criticise in detail the many salient points which it presents. Experimental researches of the present day are seldom conducted with such patient and ingenious endeavour as those now published in M. Planté's volume. The student of electrical theory will find in them but little that he did not know before. The phenomenal not the theoretical aspect of the question is ever uppermost; and in default of theory there is a tendency to ride *the analogies* too hard. But none can help admiring the beauty and originality of the experiments here recorded, nor doubt the very high value of the results obtained. There will, too, be many readers who will long that all treatises on experimental science were written in so clear, concise, and elegant a style as that of the author.

SILVANUS P. THOMPSON

NATURAL HISTORY OF THE ANCIENTS

Gleanings from the Natural History of the Ancients. By the Rev. W. Houghton, M.A., F.L.S. Illustrated. (London: Cassell, Petter, and Galpin, 1880.)

THIS interesting volume consists of a series of short lectures treating of most of the animals known to the early inhabitants of Egypt, Palestine, Assyria, Greece, and Rome, from the oldest historic period down to about the middle of the third century of the Christian era. Referring to his sources of information the author expresses his acknowledgments to the Biblical and Assyrian records and the classical writers of Greece and Rome. Alluding to Aristotle's work, "The History of Animals," he quotes Lewes's well-known remarks thereon, which, while he will not fully endorse, he yet on the whole agrees with.

The author warns the reader not to expect an exhaustive treatise on the subject; the avowed object, as the title indicates, being but gleanings picked up almost at random from a spacious field; indeed, a volume quite as large might be written on only those domestic animals known to the ancients. If not a complete history, these "Gleanings" are, however, very pleasant reading, deeply interesting to the intelligent student, and making him wish for more. In some cases a little more information would be useful, and we would venture to suggest to the author that in another edition he might with advantage add more details about the very early history of some of the best known of the animals which he has selected for notice. Thus the Egyptians were the only people amongst the ancients who habitually domesticated the common cat; with them it was a great favourite, and we would certainly have liked a little more of what the author could have told us about the cat as it is found in an Egyptian home; had it a pet name there? and is it not strange that the children of Israel do not seem to have come across it during their lengthened sojourn in that strange land? In another edition the references should be quoted at greater length; thus the general reader could scarcely be expected to know that the translation of Prof. Gubernati's interesting work on "Zoological Mythology" is referred to as "Guber. Zool. Myth."

The Egyptian dog is acknowledged by the author not to come up to the standard of modern European views of canine beauty; but he is not so severe on them as Mr. Mahaffy, in whose eyes the house-dogs appear to have been worthless curs, and the hunting-dogs more like those lanky creatures kept by some of the Irish peasantry for an occasional Sunday coursing match (Mahaffy, "Prolegomena of Ancient History"). The author states that the Egyptian monuments anterior to the date of Amosis (about B.C. 1500), of the eighteenth dynasty, give no representation of horses, but considers it would not be safe to conclude from negative evidence that the horse was not introduced into Egypt anterior to that date. Leaving the date of the papyrus Sallier to be settled by experts, but presuming it from Mr. Goodwin's Essay ("Cambridge Essays," 1858) to relate to events about the time of the Exodus, we find such allusions as "The horses of my lord are well," and "His ploughshare, which is of metal, corrodes, the horses die through the labour of ploughing;" the latter is very remarkable for being part of the complaint of an agricultural tenant; these would show that at this date—possibly the date of the years of famine—horses, were then employed in field work.

The common pig formed part of the farmyard stock of the Egyptians, and the author thinks that they were kept as probably useful in treading in the corn after it was sown, and he quotes Herodotus and Ælian as describing the process; neither author says anything about the pigs being muzzled when performing this useful part, but they are shown as such on a Theban sculpture referred to.

The section about the pigeons might be greatly expanded; there is next to nothing told us about the pigeon as known to the Egyptians and Hebrews, and though there is a woodcut from an Assyrian sculpture showing hare and birds, yet there is not a word in the text as to the hare being known to the Hebrews and Assyrians.

The second part of the volume on wild animals is nearly equally interesting as the first. In it we read of the lion, hyena, stag, wild bulls, boar, vulture, pelican, ostrich, and many other birds, as well as of several species of fish, known in the olden times.

OUR BOOK SHELF

Bulletin des Sciences Mathématiques et Astronomiques. Deuxième serie, tome iii., avril 1879. (Paris.)

THIS number opens with abstracts of works by H. Lemonnier ("Mémoire sur l'Élimination," Paris, 1879); E. Schering ("Analytische Théorie der Determinanten," Göttingen, 1877); and an interesting note by S. Kantor ("Quelques Théorèmes nouveaux sur l'Hypocycloïde à trois Rebroussements"). Our present object is, however, to take notice of two long articles by M. G. Darboux, (α) "Sur un nouvel Appareil à Ligne droite de M. Hart" (7 pp.) (β) "Recherches sur un Système articulé" (42 pp.).

(α) is founded on a five-bar linkwork, described by Mr. Hart in the eighth volume of the *Proceedings* of the London Mathematical Society (p. 288), which M. Darboux looks upon as a construction of great interest. The writer explains Mr. Hart's method and slightly generalises it, getting the following results: (1) an ellipse and Pascal's limaçon can also be described by the linkwork; (2) a movement of a straight line which always remains horizontal whilst its several points describe vertical straight lines. By means of a duplication of the apparatus, "on pourra poser une table sur ces droites, et l'on aura ainsi la disposition la plus simple connue, permettant de réaliser un mouvement parallèle dont les applications sont évidemment très-variées."

(β) is a discussion of Mr. Kempe's "recherches très-interessantes" "On Conjugate Fourpiece Linkages" in the ninth volume of the *Proceedings* of the same Society (pp. 133-147). M. Darboux remarks that Mr. Kempe has considered one interesting case only, that, viz., "où les équations sont des identités et où par conséquent la déformation de la figure est possible." He praises the ingenuity of the method employed, and says that Mr. Kempe has arrived at a large number of solutions of a problem which, *à priori*, would be thought to have none. He then proceeds to attack the question in a more general manner, connecting the problem with the use of Mr. Hart's apparatus, referred to in his paper (α). "La marche qui j'ai adoptée repose d'une part sur l'emploi des *grandeurs géométriques* dans le plan et sur leur expression bien connue au moyen d'une variable complexe, et d'autre part sur les recherches que j'ai publiées récemment[1] et d'après lesquelles la théorie du quadrilatère articulé est identique à celle d'une cubique plane, que j'appellerai *cubique associée au quadrilatère.*"

Denoting the outer quadrilateral of Mr. Kempe's figure by $MNPQ$, and the inner by $M'N'P'Q'$, M. Darboux calls them respectively the quadrilaterals T, U, and the associated cubics he calls the cubics T, U, and taking $t, t', t'', t''', u, u', u'', u'''$ as the co-ordinates of a point in space with reference to the two cubics, he finds the conditions that a certain group (4) of equations between these co-ordinates shall be satisfied by an infinite number of values of the t's and u's. He regards these equations, when the movement of the figure is possible, as establish-

[1] P. 109 of the *Bulletin* for March, 1879.

ing a correspondence between the t points of the cubic T associated with the quadrilateral T, and the similarly determined u point, and proceeds to examine all the cases in which this correspondence is uniform, *i.e.*, when to a point of each curve corresponds a single point of the other curve. He then shows that all other cases may be reduced to this case of uniform correspondence. His conclusion, after a discussion of these equations of condition, is that *there are no other solutions besides those deduced from the uniform correspondence* cases. He establishes coincidences with most of the cases discussed in Mr. Kempe's paper, and arrives at one new case, viz., when Mr. Kempe's triangles reduce to straight lines coinciding with the sides respectively of T and U.

Our object has been to draw attention to what we look upon as a valuable pendant to the last-named gentleman's Researches in Linkworks.

Lecture Notes on Physics. By C. Bird, B.A., F.R.A.S. (London: Simpkin, Marshall, and Co., 1880.)

THE author says in his preface that the book "may be supposed to represent the notes, somewhat expanded, which the teacher would desire the class to take down and learn." If so, the "notes" before us would certainly merit a good deal of attention from the teacher's red-ink pen. Of its 178 pages, 68 are taken up with examination papers of the Science and Art Department. The various branches of physics are very unequally treated. Occasional blunders are frequent. Thus on p. 27 we are told that "Writing m for the refractive index, the critical angle for any medium is $\frac{1}{m}$." On p. 2 Laplace's correction of the velocity of sound for the adiabatic conditions is stated to be the ratio of the two specific heats of air, when it should be the square root of that ratio. On the very next page we are told that the amplitude of a sound-wave varies inversely as the *square* of the distance from the source, and that *therefore* the intensity falls off in the same ratio; whereas in fact the intensity is proportional to the square of the amplitude. Under the heading "Electrometers" we observe that the only instruments named are the quadrant pith-ball electroscope, the torsion balance (which is not even described), and the unit-jar! But one could hardly expect accuracy of an author who allows himself to talk about "force" being "converted into heat."

Diagrams of Zoology. Sheet I. and II., with handbooks thereto. By Dr. Andrew Wilson. (Edinburgh and London: W. and A. K. Johnston.)

THESE sheets are meant to serve as important adjuncts in the way of illustrating a series of lectures on the classes to be met with in the animal kingdom. They have been drawn and coloured under the direct superintendence of Dr. A. Wilson, and are accompanied by a handbook to each sheet which contains full descriptions of each figure. They will no doubt be found most useful for the purposes of science classes in our public schools, and in them illustrations of recently described forms will be found. For example, under the kingdom of the protozoa, we find no less than five figures representing that low form of animal life called by Hæckel *Protomyxa aurantiacea*, one of the Monera.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Exploration of Socotra

WOULD you allow me, on behalf of the Committee of the British Association for the Advancement of Science for the Exploration of Socotra, to state in your columns that we are anxious to find a competent naturalist to proceed to Socotra early next year, the gentleman whose services we had hoped to secure being unfortunately unable to undertake the task. The expedition will be but a short one, as it would be useless to remain in the island after April.

It would be desirable that the explorer should have some acquaintance with Arabic and some local knowledge of the surrounding districts.

Monkeys in the West Indies

IN reply to the inquiries of Mr. Watt (NATURE, vol. xxi. p. 132), I send you the following extract from the *Proceedings* of this Society for February 13, 1866.

"Mr. Sclater called the attention of the meeting to three monkeys recently received from the Island of St. Kitts, West Indies. Mr. Edward Greey, Fellow of the Society, having reported the existence of monkeys in a wild state in considerable numbers upon this island, had been urged by Mr. Sclater to attempt to obtain some specimens, in order that it might be ascertained to what species they were referable, as it had always been believed that there were no native Quadrumana in the Lesser Antilles. Through the assistance of Mr. John Carden, of St. Kitts, Mr. Greey had succeeded in obtaining a specimen of this monkey, and two others from the same island had at the same time been presented to the Society by Mr. H. B. Cameron, Superintendent of the R.W.I.M.S.P. Company, at St. Thomas's. The animals were undoubtedly referable to the common green monkey (*Cercopithecus callitrichus*, Geoffr.) of Western Africa, and must have been introduced years ago, as they were stated to be now very abundant in the woods of St. Kitts, and to cause great damage to the sugar-plantations."

As regards Trinidad, where true American monkeys (*Cebidæ*) are certainly found, it should be recollected that, zoologically speaking, Trinidad is not one of the Antilles, but a little bit of Venezuela, broken off at no very remote period.

Prof. Mivart and Mr. Bates are, therefore, correct in saying there are no *indigenous* monkeys in the Antilles.

Is Mount Unzen a Volcano?

IN a recent visit to the Simabara Peninsula, about twenty miles east of Nagasaki as the crow flies, an opportunity was afforded me of ascending "Unzen," a mountain which rises about 4,700 feet above the sea (by aneroid). If tradition is to be believed "Unzen" is an active volcano, the subterranean fires of which have been slumbering since the close of last century, when a disastrous earthquake, accompanied by a volcanic eruption, destroyed 53,000 of the inhabitants of the district. But I failed to find any trace of a recent volcano, which, wherever it may be, is certainly not situated in the higher peaks of the mountain, where popular belief has located it. From the sea-level up to the highest summit a porphyry is the ever-prevailing rock, which varies somewhat in different parts of the peninsula. True it is that from many points of view Unzen has somewhat the form of a truncated cone, but there the resemblance ends.

There are, however, three hot sulphur springs, which may help to explain the popular error on the subject. One of them is situated in the fishing village of Wohama, at the foot of the mountain, and close to the water; a strong odour of sulphuretted hydrogen scents the air, and the thermometer placed in the water rose to 112° F. Rather more than 2,000 feet above the sea are the hot springs of Kojeego and Unzen. In the former place the water bubbles up into a pool some ten or fifteen yards across, with a temperature of 182°, while at Unzen the hot springs are on a far more extensive scale, numerous springs bubbling away furiously over an area of several acres, which is completely destitute of vegetation. The ground is often so hot that with a thick pair of boots one cannot stand long on the same spot. The thermometer rose as high as 202°, which would be only about 6° below the boiling-point of water at that elevation, and a dense cloud of white smoke ascended into the air which was strongly impregnated with the same sulphureous odour. The chemical and thermal influences of these hot sulphur springs have produced a singular effect on the porphyry of the immediate locality; while the rock has a tendency to lamination, its disintegrated felspathic constituents whiten the whole surface, and the neighbouring hill-slopes overlooking the springs are as white as any chalk-cliffs from the same cause. This phenomenon is only to be found in the immediate vicinity of the hot springs.

It is with the hope that these few notes may be the means of eliciting further particulars, especially as regards the history of this so-called volcano of Unzen, that I venture to send them to NATURE. H. B. GUPPY, Surgeon H.M.S. *Hornet*

H.M.S. *Hornet*, Nagasaki, October 13

Astronomical Subject-Index

I AM preparing for publication, by the Royal Dublin Society, a review of the progress of astronomy during the present year, consisting of a classified index catalogue of books, memoirs, and notes on astronomical subjects published since the beginning of the year, and, secondly, of a short account of the contents of the more important papers in the various branches of astronomy.

Any person who has felt the want of such a "subject index" could assist materially in the undertaking by sending me, as soon as possible, the titles of such papers as seem likely to be overlooked on account of having been published in less widely-diffused periodicals or transactions. In particular I would be glad to hear of papers published quite recently in transactions or proceedings of learned societies, as these often are not distributed until some time after their publication.

Distinguishing Lights for Lighthouses

A propos of your article on Sir William Thomson's letter in the *Times*, and the dangers to ships from bad systems of distinguishing the lights of different lighthouses, I send you the accompanying graphic account by my brother, Mr. J. P. Thompson, of a narrow escape from shipwreck which occurred to him during the autumn of the present year, and which illustrates the urgent need for reform in the adopted system.

SILVANUS P. THOMPSON

"All went well till off Ushant, when the wind began to rise, and by Saturday afternoon the Channel was heaved up by what was logged as a 'moderate gale' from the south-west. This kept freshening every hour, and at 7 P.M., when the lamps were being lit, the captain said we should have a very 'dirty night,' and he accordingly donned his oilskins and 'sou'-wester.' The atmosphere began rapidly to cloud, and at 9 o'clock you couldn't see more than a ship's length or two ahead. As we were in a crowded track of vessels, the watch look-out was doubled. . . . At 11 I was on deck again, and found all looking out eagerly for either the St. Agnes (Scilly) or the Wolf Light, the latter being near the Cornish coast. Of these lights the St. Agnes shows a white light at each revolution of a minute, whilst the Wolf is the same, but with a flash of red between. The sea was very phosphorescent, and this dazzled the eye when looking for lights. I was set as a look-out on the starboard quarter, and many times had to go aft for the captain to see how she lay by the compass abaft (she was being steered at the wheel in an iron wheel-house on the bridge.) . . . About midnight we sighted a light, and on timing it, found it to be a white light of a minute's revolution; we looked in vain for a red flash between the whites, as we knew we ought to be near the Wolf. But in the fog not a 'smell of red' could be discerned, although by the rate at which we passed it we must have been very near it. Supposing, then, that there was no red flash, this must be the Scilly light, and the captain accordingly steered more easterly, so as to fetch the Wolf. He nevertheless hardly thought we had got so far to the west as the Scilly, so he ordered a sharp look-out to be kept for breakers or land. At 3.30 I turned in again, but at 4 A.M. I suddenly heard the look-out cry out 'Land! breakers ahead!' and then I heard the captain run to the telegraph, and heard the bell ring in the engine-room, and the captain's sonorous voice calling 'All hands! square away the yards! 'bout ship!' I jumped up, and ran on deck, and there right ahead the fog had just lifted to show us we were almost ashore, heading straight on Penzance; so near, indeed, were we that I could have easily counted the houses. Happily the ship, answering her helm well, came round beautifully, and at the same time the fog closed again, hiding the shore and the dreaded rocks. So after all it *was* the Wolf light we had sighted, *but the fog had prevented us from seeing the red flash*. It was a narrow escape, though; and then we had to beat back in the teeth of the gale, and it took us six hours to beat back to the Land's End."

The First "Sin"

IT occurred to me lately, whilst reading in the September number of the *Contemporary Review*, an article by Lenormand called "The First Sin," that it may be possible to turn another page of that very interesting history of ideas, the reading of which appears to be one of the great tasks allotted to this century. Although it seems unlikely that the idea suggested to me by the article has not also occurred to others, I cannot discover that anything has been said about it, for the author seems strangely enough to lead one to the door, as it were, and leave one there without opening it; I should therefore like, if you will permit me, to lay it before your readers, and hear what they have to say about it.

My idea is this: that the tradition of a tree of life, and also of a tree of the knowledge of good and evil, both connected with a sin and a catastrophe, probably originated in man's first acquaintance with the effects of intoxication.

Lenormand himself connects that tradition with the worship of Bacchus (and also with the theft of fire in a piece of a tree by Prometheus, and with that of the apples of the Garden of the Hesperides). It seems strange, therefore, that he goes no farther, more especially as he himself points out that the representations of the tree on the monuments of different nations are always referable to those from the fruit or foliage or crushed branches of which an intoxicating liquor is derived; from the Soma tree, that is, and the palm and the vine.

There is no need to burden your pages with proofs and quotations, as any one interested in the subject can procure the magazine now at half price; I will merely add to my suggestion that, as the primitive notion of life must have been characterised by warmth and motion, and the first effects of the fruit of the tree would also be, probably, warmth and excitement, exhilaration and the temporary exaltation of some of the faculties, it would easily come to be looked upon as a "tree of life;" and that, the after-effects being bad and degrading, it would thereby become a tree of the knowledge of evil as well as good, and also the cause of a fall into a lower state of being.

May I add a suggestion concerning the serpent always connected with the tree, as on the early Babylonian cylinder figured on p. 91 of George Smith's "Chaldean Account of Genesis"? It appears to have represented the principle of evil very early, probably long before it was connected with the tree, and to have been at first the sea, which in a storm was the chaos out of which everything was formed, and which, as it seemed to swallow up sun, moon, and stars, and to bring forth the storm-clouds—those monsters with which the sun-god fought with his arrows the lightnings—came also, not unnaturally to represent the destructive principle. But how did it become a serpent? May it not have been the singular resemblance that the edge of the sea—as seen from a moderate height in a calm—bears to a huge serpent—now blue, now white, according to the amount of foam—winding and writhing about the earth, and eating out its rocks and shores, that caused its destructive attributes to be transferred to the serpent? A common name may have been the means. The resemblance is especially striking when the eye looks along the shore, as in the bend of a bay.

Another suggestion. Some years ago, when reading the description of the locality of the Battle of Beth Horon in Dean Stanley's work on Palestine, it seemed to me to point to the origin of the tradition of the sun and moon standing still at the command of Joshua, and I do not think it has been noticed. In any valley lying north and south, if one goes up the western hills as the sun sets to the valley, when one reaches the summit the effect of a new day and a fresh supply of sunlight is very striking. This sensation must have been strongly felt by the warriors of Israel, when, after pursuing their enemies up the pass, the still sunlighted valley beyond broke upon their sight; and I cannot but think that, figuratively expressed, as it would be, and with much exaggeration, in the triumphal song sure to have been made and sung after the victory, it may well have originated the tradition of a standing still of the sun; the moon would follow suit. The songs are said to be the oldest parts of the Bible, and "Jasher" or "The Upright" may have been the singer or recorder of the lost song of triumph. J.

The "Encyclopædia Britannica"—The Nile

THE volume of the Nile is made a thousand times greater than the truth in the new "Encyclopædia," vol. vii. p. 706, art. Egypt, by an error copied from the last edition. The same mistake occurs in Rawlinson's "Herodotus," vol. ii. p. 7, Note GW.; in the Geographical Society's *Journal*, vol. xix.; in Fullarton's *Gazetteer*, and probably elsewhere, and some fables have been founded on it.

I observed the error myself some years ago, after being perplexed by it in some rainfall estimates, and mentioned it to the late Sir Gardner Wilkinson, who intended to have it corrected; but there has been no fresh edition of the "Herodotus," and it has escaped revision in the "Encyclopædia." As it illustrates a special danger, easily overlooked, in copying French figures, it deserves perhaps a few lines in NATURE to put it right.

In English notation we mark decimals with a point, and use commas to divide periods; but the French generally use commas to mark off decimals. The authority for the volume of the Nile is Linant's measurement, given by Clot Bey in the "Aperçu général sur l'Egypte," tome i., pp. 40, 41, and the figures are given as follows, in cubic metres of water discharged into the Mediterranean at full flood in twenty-four hours:—

English authorities	705,514,667,440
Linant	705 514 667,440

The last three figures are decimals, and the quantity is in millions, not in thousand millions. ALBERT J. MOTT

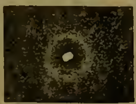
Lunar Rings

ACCORDING to your suggestion I have followed up my experiments with lunar light on bromo-gelatine plates, and at midnight on November 28, for the third time at full moon period I



obtained on one plate three well-defined rings round the photographic image of the moon with 1 minute, 1½ minute, and 2 minutes' exposure.

The 1 minute exposure is fainter than the above woodcut, the 1½ minute the same in density, and the 2 minutes' exposure is denser and more defined; while six consecutive nightly observations previous to the 28th failed to give any vinculum or indication of refraction of light.

One of the six taken on the night of November 24 with *two hours'* continuous exposure gave a bright clean well-defined line 2½ inches long, gapped here and there by passing clouds, but not the slightest indication of blurr or dispersion was shown on the brightest parts of the line.

Whether the cause which produces these rings at full moon phase *only*, depends upon the greater effulgence of lunar reflection at that particular time; whether it is cosmical or atmospheric in its nature, or optical or chemical, there can be no doubt that there is refraction of the lunar light; the existence of a dark space between two luminous (or more correctly speaking actinised regions) as manifested by the above annular *periodical* impressions is a clear indication of the dispersion of light, but how, why, or where the decomposition takes place is not so obvious.

Sunderland, December 5 GEORGE BERWICK

Stag's Horns

IT is well known to be the universal belief in the Highlands that stags eat the horns they shed, and every gillie will tell you that no one ever picked up a horn. Can any of your readers inform me what really becomes of them?

There must be abundant opportunities of observing the whole process in places like Windsor Park, where red deer are kept in a domesticated state. G. W. H.

ON A NEW COPYING PROCESS

A VERY elegant process has recently been introduced into this country for copying and multiplying letters and documents. It is known by various names, according to the etymological skill of the makers. One calls it a "hektograph," another less pardonably calls it the "centograph," while yet another, to bridge the gap between ancient Greek and modern English, styles it the "printograph." But whether it is introduced by these names, or the polygraph, the compo-lithograph, or the velocograph, the principle is the same; though the details are slightly varied in each case. A slab of gelatinous material in a shallow tin tray forms the type. The letter is written with a special ink on any kind of paper, and when dry is placed face downwards upon the jelly, and allowed to remain a minute or more. On removal it is found that the greater part of the ink has been left behind on the jelly. It is only necessary to place pieces of paper on the latter, and on their removal they are found to be perfect fac similes of the original copy. The number of copies obtainable varies with the ink, the most potent being aniline violet, such as Poirrier's. With this a hundred copies may be produced. Others, such as Bleu de Lyon, Bismarck brown, or Roseine,[1] yield forty to fifty. It was with a view to determine the principles which govern this beautiful process, that I made an examination of the subject. The slab consists of gelatin and glycerine, with carbolic or salicylic acid to prevent fungoid growth, and in the "chromograph" a quantity of barium sulphate is added, which gives the slab a white, enamel-like appearance.

If a hot, strong solution of gelatin in water be prepared,[2] and then a certain quantity of glycerine stirred in, the whole mass will become solid in cooling. This might at first sight appear to be a solution of gelatin in water *and* glycerine; but such is not the case, the gelatin being quite insoluble in glycerine. When the aqueous solution solidifies, the gelatin still retains the water, but the large quantity of glycerine being dispersed through the mass, makes the whole into what is practically *a very fine gelatin sponge containing glycerine in its pores.*

The moisture-loving nature of the glycerine prevents the "sponge" from getting dry, while the insolubility of the gelatin in the glycerine prevents its becoming liquid. When the copy is placed on the jelly, the glycerine comes out to meet the ink, for which it has an intense liking. All the suitable inks are freely soluble in glycerine. Some, too, contain acetic acid either in the free state or in combination with bases as in rosaniline acetate. The acetic acid exerts a solvent action on the gelatin, so that it will be found that after taking off some impressions with an acetic acid ink, as the "multiplex," the jelly will be etched wherever the ink has come into contact with it. As long as any of the ink remains on the jelly, the glycerine will come out of the pores to keep it moist, but when the whole of the ink has been removed the flow of glycerine ceases, and the parts become quite dry. If the ink is not entirely removed by taking a sufficient number of impressions, and the jelly left, after a lapse of twenty-four hours the remaining ink will be absorbed by the jelly. It is necessary, therefore, that the copies should be taken off as soon as possible, so as to avoid the defect caused by the spreading of the ink.

Most of the makers suggest, that directly the slab is done with, the type should be washed off. The hektograph and most others require that the water should be warm, but the finely divided barium sulphate in the chromograph, renders the surface less tenacious, and the impression may be removed with cold water.

Where practicable, it is better in all cases to leave the slab for twenty-four hours, when the old impression will be quite absorbed, and not interfere with a new one.

This gelatin copying process has been received with so

[1] A very potent and easily prepared ink which will yield a hundred copies, may be made by dissolving rosaniline in a cold-saturated solution of oxalic acid. It must be allowed to dry spontaneously.

[2] 4 oz. gelatin dissolved in 6 oz. water, and 20 oz. glycerine, sp. gr. 1·26, previously warmed, stirred in. Any air bubbles in the gelatin are removed before the addition of the glycerine. A cheaper compound which answers equally well, but is rather darker, consists of Scotch glue 6 oz., water 8 oz., glycerine 20 oz. These quantities make a slab 10 × 13 × ¼.

much favour by the public, that it shows there is a great want for some rapid means of getting a limited number of copies of letters, &c.; and seeing that any number of colours may be used in the original drawing, Mr. Norman Lockyer has suggested that it would be of much use in laboratories, for the multiplication of original sketches of biological specimens, and even for spectra charts, and so save much of the time spent in making duplicate copies. The gelatin slab cannot be said to be perfect, as it is liable to be affected by atmospheric changes; but, bearing in mind the fact that the whole is simply a sponge filled with a compound capable of liquefying eertain inks, it is reasonable to hope and expect that chromography is only the pioneer of a process, which shall possess all its advantages and none of its defects. R. H. RIDOUT

THE ANIMAL HEAT OF FISHES

THE belief that fishes are *cold-blooded*, that is, that they take on the temperature of the water which surrounds them, with no power to resist it, and that they develop little or no animal heat themselves, is still held by many even scientific observers. This belief is based partly upon the well-authenticated fact that fishes have been frozen and thawed again into life; partly upon the statements of many travellers who have found them living in water of a very high temperature (Humboldt and Bonpland recording the highest, 210° F.); and further, that a thermometer inserted into the rectum of some living fish freshly drawn from the water has been repeatedly found to indicate temperature corresponding very closely to that of the water itself.

During the past summer, and in connection with the operations of the U.S. Fish Commission at Provincetown, Mass., Surgeon J. H. Kidder, of the U.S. Navy, was detailed to make some systematic observations upon the subject of fish-temperatures with a view to setting the question upon a secure basis of actual experiment. Thermometers were made expressly for the purpose by Mr. John Taglialne, of New York, of unusual delicacy, registering about 10° F. each, and recording fifths of a degree. These were used in connection with Negretti and Zambra's deep-sea thermometers, and all the instruments were deduced to a single standard by frequent comparisons, so as to insure *relative* accuracy. The fish were taken with a line, and their temperatures observed at once, care being taken that no considerable change in temperature occurred during the time consumed in bringing the fish to the surface. The observed temperatures were then compared with that of the water as recorded by a Negretti-Zambra thermometer sunk to about the depth from which the fishes were taken. The first observations, made by inserting the thermometer into the rectum of the fish, agreed with the generally-received opinion, showing but little higher temperature than that of the surrounding water.

The mode of experiment was then somewhat modified. Considering the fact that the intestinal canal of a fish is in close contact with the thin and scarcely vascular walls of the abdomen, which is surrounded by the water in which the animal swims; and, further, that the arterial blood comes from the gills, where it has been spread out as thinly as possible and brought into the closest contact with the surrounding water—a process well calculated to cool it quickly to the same temperature—it follows that neither the interior of the rectum nor the arterial blood would appear to have the same value as representing the body-temperature in fishes that those parts possess in mammals and birds. It is rather in the venous circulation and the branchial artery that we should seek for the heat which must certainly be developed in the chemical processes of nutrition and waste, and in connection with active muscular movements. In the remaining experiments of the series—about ninety in number—the fish was therefore opened at once, and the bulb of the thermometer inserted into the cavity of the heart, or branchial artery, with the results indicated in the following table, which shows the averages:—

Fish.	Temp. of surrounding water.	Rectum.	Venous blood.	Remarks.
Cod	° 39–42	° + 0·98	° + 4·63	
Haddock	,,	+ 1·30	+ 5·30	Spawning.
Pollock	42	+ 2·40	+ 4·50	
Hake	,,	+ 2·40	+ 9·80	Spawning.
Bluefish	70–73 *	+ 0·25	− 1·55	
,,	,,	+ 0·50	+ 1·70	
Young mackerel † ...	65 *	+ 4·10 ‡	+ 5·25 §	
Do. do. (*Scorulus dekayii*) ‖	60 *	—	+ 2·30 §	
Sculpin	60 *	+ 0·80	+ 3·20	
Eel Pout ¶	—	+ 3·00	+ 6·00	
Flounder	42	—	+ 3·00	
Dogfish	42	+ 4·40	+ 12·00	Oviducts contained mature young.
Do. young from oviduct	42	—	+ 20·60	

It appears from these experiments that fishes do develop a measurable quantity of animal heat, which is more apparent during the spawning season, and much greater in elasmobranchs (as is to be expected from their more perfect digestive and assimilative apparatus) than in other fishes. It also appears that the measure of this animal heat is to be sought in the venous blood, and not in the intestinal canal or arterial blood.

The limits of this preliminary note will not permit us to go into an enumeration of the difficulties of observation or the measures taken to guard against the errors likely to attend them. Nor is the number of observations (ninety-five in all) sufficient to warrant the offering of these figures as a final statement of the *degree* of animal heat presented by the several fishes observed. All that can be said to be proved so far is the fact that fishes do manifest animal heat, and in considerable quantities, sufficient to warm again, to the extent of from 3° to 12°, blood that has been cooled in each circuit to the temperature of the surrounding water. Details will be given in the forthcoming report of the United States Fish Commission.

In the single instance of a lower temperature than that of the water, observed in five blue-fish, all taken on the same day, it may be that the individuals experimented on, being taken at the surface, had just come up from a much greater depth and colder stratum of water. There seems to be no conceivable provision by which a fish can maintain a temperature below that of the surrounding water, cooling by evaporation being out of the question. The young dogfish from its mother's oviduct showed a temperature 8° higher than that of the mother herself, for the obvious reason that its blood, not coming into contact with the water by its gills (the umbilical sac was still attached), was not cooled otherwise than mediately, through the blood of the mother.

NEW MODES OF SHOWING DIFFERENT CHARACTERISTICS OVER SMALL ARCS IN AZIMUTH FROM THE SAME LIGHT-HOUSE APPARATUS

WHERE a light on a rock or island has to illuminate constantly the whole horizon, the ordinary dioptric fixed apparatus is all that is required. But when, as at

* Surface-swimmers. † "Sinkers." ‡ Stomach, through œsophagus.
§ Temperature taken in blood flowing from heart, the organ being too small to admit the thermometer.
‖ This rare species, not seen in Massachusetts Bay for thirty years, appeared, young, at Provincetown last summer in considerable numbers.
¶ *Zoarces anguillaris.*
The sign "+" indicates excess, and "−" deficiency, as compared with temperature of water.

many places, there is a shoal at some distance from the lighthouse, or where a reef of rocks projects seawards from the shore, it sometimes becomes necessary to adopt means for keeping vessels clear of such dangers at night, as, for example, near Souter Point, where Mr. Douglass and Mr. J. T. Chance employed successfully the electric light for guarding a rock near the shore. What is wanted in such cases is to cover not only the danger itself but some area of the surrounding sea by a characteristic which is different from that of the main light.

If in front of a fixed light apparatus whose optical property is to parallelise the rays in the vertical plane while not interfering with their natural divergence in azimuth, there be placed an arrangement of straight horizontal shades or screens similar to the Venetian blinds which are used for house windows, the means will be supplied for easily producing different distinctions. The breadth of those blinds must be such as to subtend from the central flame the same angle as that over which the necessary distinction has to be shown at sea. By opening and shutting simultaneously and *gradually* the different leaves of the blind, there will be produced the same characteristics as those of an ordinary revolving or flashing light, according as the leaves are moved slowly or quickly and kept shut for a certain period, and these distinctions will be accompanied by the necessary gradual waxing and waning of the emergent rays. By simultaneously opening and shutting the leaves of the blind *suddenly*, and keeping them open so as to show a fixed light for a certain length of time, and then keeping them shut so as to produce darkness for a certain length of time, the effect of an intermittent light in which there is no waxing or waning of the rays will obviously be produced.

Should it be considered desirable to vary the appearance over the given arc so as to show a gradually increasing length of light period when a vessel is approaching the danger, the maximum period when it is opposite to it, and a correspondingly shortening period as the vessel leaves it, a single straight opaque mask placed outside of the apparatus, and revolving horizontally and with uniform speed on a vertical spindle will produce the result. For while the periods of *change* will remain the same over the whole arc the *duration of darkness* will gradually increase as the danger is approached, and gradually decrease after the danger has been passed. And if this vertical shade be made to rotate at a slow and uniform speed it will produce the effect of a revolving light, and if at a quick speed it will produce the effect of a flashing light, with this difference that the flashes *will recur with only an instantaneous interval of darkness*, and in both cases there will be a gradual waxing and waning of the rays.

By these very simple and cheap expedients a fixed light illuminating the whole horizon (by means of a flame of he ordinary size in relation to the focal length) can easily be made to show accurately over any limited angle in azimuth the effects of the different distinctions referred to, and these combinations will therefore supply a desideratum which is often much wanted in coast illumination. In some experiments which were made all these characteristics were successfully produced by the two modes described.

Where no light is required in any part of the horizon but in one small arc only, as, for example, in illuminating the middle of a long narrow Sound, all the rays proceeding from the lamp should be spread equally over that arc. A fixed holophote with an opaque disk revolving horizontally in front on a vertical spindle will, if condensing prisms are placed between the disk and the holophote, produce either a revolving or flashing light according to the speed of its revolution, but without any intervening period of darkness. If colour distinction be required and a revolving disk of glass be substituted for the opaque mask the characteristic effect produced would be that of a revolving red and white light *without any intervening dark period between the flashes*, which would gradually dissolve into each other from red to white and then from white to red.

Edinburgh, October 22 THOMAS STEVENSON

A FEAT IN TRIANGULATION

A NOTEWORTHY advance in geodesy has recently been accomplished by the junction of the network of measurements covering a large portion of the surface of Europe, with the African continent. The entire triangulation of Algeria was completed by French engineers some time since, and extended to the edge of the Sahara, in lat. 37°. M. Perrier, who had directed in a great measure the triangulation of Algeria, has for the past eleven years been seeking the means of joining the network in that country with the perfect trigonometric system covering the surface of Spain, France, and England. The importance of such a junction is easily appreciated when we consider what notable changes in the accurate conception of the shape of the earth and of the length of meridians has been effected by measurements on a much smaller scale.

For such an undertaking the most careful and painstaking preparations were requisite. As the result of his reconnaissances between 1868 and 1872, M. Perrier found that from all the trigonometric points of the first order between Oran and the frontiers of Morocco, the loftier crests of the Sierra Nevada on the Spanish coast opposite, were visible in exceptionally clear weather. Arrangements were subsequently made with the Spanish Geographical Institute for the mutual and contemporaneous execution of the proposed plan. A corps of Spanish officers, under the direction of the well-known General Ibanez, was detailed for this purpose, while the French Minister of War placed a division of officers from the *État-Major* under the command of M. Perrier. The leaders chose for stations in Algeria the summits of Mount Filhaoursen and Mount M'Sabiha, west of Oran, and in Spain the summits of Mount Tetica and Mount Mulhacen, the latter of which is the most elevated point in the kingdom. The directions and distances between these four points were computed as carefully as possible, and preparations were then made for the final and determinative observations. At the Algerian stations the nature of the country and its inhabitants necessitated the use of a numerous force of soldiery as well as of means of transport.

In order to insure the accuracy of the observations, which required the passage of signals over a distance of 270 kilometres, it was decided to make use of solar reflectors and powerful lenses. The efficacy of such apparatus for even greater distances had already been tested by M. Perrier; still for the measurements in question they appear to have utterly failed to answer the expectations based upon them, not a single solar signal being visible from any station. Fortunately, the success of the observations did not rest entirely upon this one system of signals. Preparations had likewise been made for the employment of the electric light, and on the summit of each mountain one of Gramme's electro-magnetic machines worked by engines of 6-horse power had been placed in position.

On August 20 last, all the stations were occupied, and the electric lights were displayed throughout each night. Then the patience of the observers was submitted to a lengthy proof. The mists rising from the Mediterranean totally prevented the exchange of signals, until after a delay of twenty days, one after another the electric lights became visible even to the naked eye. Perrier compared the intensity of the light on Tetica nearly 270 kilometres distant, to that of α in Ursa Major, which rose near by. The observations were continued from September 9 to October 18, when this task for which such extensive preparations had been made, was completed in the most satisfactory manner. With its completion we come into possession of trigonometric measurements of the most exact nature, extending from lat. 61° in the Shetland Islands, to lat. 34° on the southern frontier of Algeria.

The extension of this network southward and eastward in Africa, desirable as it is for the elucidation of many nice points in geodesy, is unfortunately scarcely possible in the immediate future, and science must rest content with gaining a foothold in the great continent.

T. H. N.

A NEW STANDARD OF LIGHT[1]

IN the pamphlet before us we have a proposal for a new form of standard light, and the author has shown some considerable skill in drawing out his method of producing it. We cannot do better than quote his opening paragraph as showing the requisites of a standard that the author deems necessary. He says:—

"No exact measurement of any quantity, even with the most accurate and sensitive test measures available, can reasonably be expected unless the standard by which the unknown quantity is to be gauged is perfectly constant in itself; or if nature does not permit of such a desirable state of things, the causes to which the variation of the standard are due should be known, and in addition also, their quantitative effect on the standard, in order to be able to introduce a correction whenever accuracy of measurement should permit, and circumstances necessitate it."

The want of a standard of light has long been felt in physical researches, and the British Association has acknowledged the impossibility of obtaining scientific measures with the ordinary standards, and has appointed a committee to consider the question of fixing such a standard of white light, that a unit of light may be capable of accurate definition. It must not be forgotten that up to quite recent times the principal necessity for a standard at all has arisen through the introduction of gas into our dwellings and streets, and it has only been necessary to adopt one which should give the comparative illuminating powers of any variable qualities of gas. In fixing such a standard the points to be looked at were (1) that the standard should be capable of easy and exact reproduction; (2) that the colour of the light should be approximately the same; and (3) that in varying states of barometric pressure and temperature, proper corrections in the results of the comparisons should be feasible. It will be seen further on that a fourth desideratum should be introduced for scientific work. Perhaps on no subject has more attention been paid to small details than in the production of a standard candle, and as a result, when burnt under proper conditions, it gives fairly correct values of the illuminating power of gases.

In the record of Mr. Schwendler's experiments with the standard candle as against his new standard of light, we have some startling variations in the light of a standard candle, but we feel sure that, had the proper conditions been observed, there would never have occurred such a tremendous difference as 72 per cent. We are more convinced that ordinary precautions could not have been rigidly observed when we find that some of the comparisons were made after the candle had been freshly lighted. In gas photometry it is well known that the standard candle should burn at least a quarter of an hour before it can be considered to have settled down to a steady light. The standard candle, however, is not a nice unit of light; and two years ago Mr. Vernon Harcourt introduced to the notice of the British Association a gas standard which seems to meet every requirement. By making a mixture in a small gasholder of one part of the most volatile spirit from American petroleum which distilled at 50° C. with 600 of air, or seven of the vapour with twenty of air, he produced a gas which, whilst almost insoluble in water, was permanent at all ordinary temperatures and pressures, and which was of a known composition and easy of manufacture. A jet of such a gas could be compared with the ordinary coal-gas, and any variations affecting the one would equally affect the other. The colours of the standard and coal-gas lights are also approximately the same. It seems that a standard of such a character meets the requirements for comparing the illuminating value of different coal-gases. Mr. Schwendler proposes to use the light radiated from platinum foil, when raised to incandescence by an electric current, as a new standard, and we agree that a solid instead of a gaseous body as the source of illumination is a step in the right direction. The standards made, however, appear to have been used for determining the illuminating value of the light produced by dynamo-electric machines under varying conditions of speed of armature and resistance in circuit, and it is in reference to this that we will first judge of its probable effectiveness, since for gas measurements the standards already existent suffice. Some dynamo-electric machines are advertised as generating the light of 50,000 candles, and we will suppose for the moment we are comparing such a light with Mr. Schwendler's standard.

Now it may be safely said that a standard candle, farther away than twenty feet from the photometer, would give too small a light to be practically of use as a standard, whilst if approaching the photometer within one foot the magnitude of the illuminating source would seriously affect any accurate results. In the first case the electric light would have to be about 4,500 feet away from the photometer and in the last about 220 feet. For ordinary photometric work even the least of these distances would be objectionable. The platinum standard employed by Mr. Schwendler is only about ·7 of a standard candle, and these distances would have to be increased nearly 20 per cent.

For practical measurements of this description a candle-power of fifty candles is a far preferable value, which it would be difficult to attain by the method proposed. In this case we have the distances reduced, and if the electric lamp is fixed at a distance of 100 feet, we have the movable standard ranging between twenty feet and three to four feet, and the readings become easy and are not subject to be seriously affected by the magnitude of the illuminating source; in fact, the errors of observation then become of larger magnitude than any error arising from this cause. Another point which we have to note is that as far as the colour of the light from the platinum standard is concerned, it possesses very little advantage over the ordinary gas or candle flame, and it would be impossible, or at all events incorrect, to give the illuminating value of a light such as of that produced by the electric arc in terms of the new standard; some recent experiments have demonstrated that the red light emitted by one square mile of the hollow crater in the positive carbon is equal to about the red light radiated by 40,000 standard candles, whilst the mean green light of the former is equal to the mean green light of about 135,000 of the latter, and until such a time as the relative physiological values of green and red light are accurately known it will be impossible to give any true estimate of the illuminating power of the electric light by ordinary photometric comparisons. Both in magnitude and colour, then, the proposed platinum standard of light seems to fail for measuring light produced by high temperatures.

We now turn to the details of the lamp itself. We have, firstly, a U-shaped piece of thin platinum foil cut out about 20 mm. in total length, each limb of the U being about 3 mm. in breadth, the tops of which are clipped in thick metal clips. The usual arrangements are made for passing a current through this foil, the amount being registered by a galvanometer in circuit. A

[1] On a New Standard of Light. By Louis Schwendler. From the *Journal* of the Society of Bengal, vol. xlviii. Part ii., 1879.

glass shade is also employed for steadying the light, by keeping off convection currents. There seems to be an objection to this form of lamp for accurate scientific work, where it may be necessary to use an *image* of the source of illumination. For instance, in certain spectroscopic comparisons of different lights only a small portion of the image of the incandescent platinum would fall upon the slit. Now the first difficulty that would be met with would be as to the part of the platinum that would emit a standard light. Near the contacts the heat would be conducted away so rapidly that the colour of the light would be of a different tint.

Again, presumably near the middle of the limbs of the U-shaped foil the temperature would be slightly higher than at the outsides; in fact, no two portions of the foil would be exactly at the same temperature.

For work, then, of this class, the standard seems to fail in an important particular.

The writer of this notice made many experiments on this point some years ago, and it was this objection that led him to abandon the idea of a platinum standard light of a form somewhat similar to that of Mr. Schwendler.

For a standard perfectly suited to scientific work, perhaps the following definition will be found tolerably exact:—It should be a body (solid or liquid), some known area of the surface of which can be kept at a high constant temperature. It seems probable that a combination of a body of good with one of a bad conductivity will eventually be found to offer suitable materials for a really trustworthy standard.

It would be unjust to conclude this notice without paying a testimony to the great value of the experiments which have been carried out by Mr. Schwendler in this research. It is quite possible that a modification of his platinum standard may be constructed which will eliminate the defects which are to be found in it. It is certainly a step in advance of the gas or candle standard for everything beyond merely technical work, but it is not of the same accuracy as other scientific units. W. A.

FLOW OF VISCOUS MATERIALS—A MODEL GLACIER

THREE or four years ago an experiment was arranged by Mr. D. Macfarlane and myself for the purpose of showing the flow of a viscous mass and for illustrating glacier motion. The experiment then commenced gave rise to others of a similar nature. These experiments have proved so interesting that I venture to describe some of them to the readers of NATURE.

Shortly after his discovery of the true nature of glacier motion, the late Principal Forbes was much pleased when one of his students, now the Rev. C. Watson, of Largs, showed him a quantity of shoemakers' wax which had been gradually flowing down on the bottom of a vessel accidentally left on an incline. Forbes was delighted with the wax, and considered it an admirable illustration of viscous flow. This was told to me in conversation some four years ago, and it occurred to me that a pretty illustrative glacier might be made with shoemakers' wax, and we proceeded to construct it. The model glacier has been shown year after year to the natural philosophy class in Glasgow, and has proved interesting and instructive beyond expectation.

A little wooden ravine was constructed, with a number of steep declivities and precipices and some more gentle slopes. There is one place, also, where the ravine is narrowed by projections inwards, which nearly meet each other. At the upper end of the ravine there is a flat part, on which ordinary shoemakers' wax is piled—as where snow collects at the upper end of the natural ravine; and from this collecting-ground the material flows down steadily through the ravine, giving on a small scale a most perfect display of the flow of a semi-solid material. At the beginning of each winter session a supply of shoemakers' wax is given at the top, and during the session the flow goes on slowly and steadily; hardly perceptible from day to day, but progressing from week to week, and from month to month. Every one knows what a brittle substance shoemakers' wax is at ordinary temperatures. A lump of it allowed to fall on the ground flies into a thousand pieces. Watching this brittle apparent solid flowing down an inclined plane, brings very vividly before the mind the real nature of the glacier's flow. To imitate on the small scale Forbes's celebrated experiment of planting a row of stakes in the glacier, in order to compare the flow in the middle with the flow at the edges—the experiment which really established the fact of *viscous* flow—I have sometimes put a row of dots of white paint across our pitchy glacier. In a few days the more rapid motion of the middle portion, and the less rapid motion of the parts near the edges, is made apparent. There are others of the glacier phenomena which are also beautifully imitated by the shoemakers' wax. Little crevasses are sometimes formed, though not very often owing to the great effect of temperature on the plasticity of the material; and the cross-markings that are noticeable at the foot of a glacier are brought out extremely well.

Last year Sir William Thomson commenced a new and curious experiment on shoemakers' wax as a viscous material. A large circular cake of it about eighteen inches across and three inches thick was made. This was put into a shallow cylindrical glass vessel, which was filled with water to keep the temperature from varying with any great degree of rapidity. Below the cake a number of corks were put, and on the top there were put some lead bullets. The result has been that in a year the corks have floated up through the wax, and are coming out at the top; the bullets have sunk down through the wax, and have come out at the bottom; and this, it is to be observed, has gone on while the wax was at all times in such a condition as to be excessively brittle to any force suddenly applied, such as a blow from a hammer, or such as would be occasioned were the cake of wax to be allowed to fall on a stone floor. J. T. BOTTOMLEY

THE SCOTTISH ZOOLOGICAL STATION

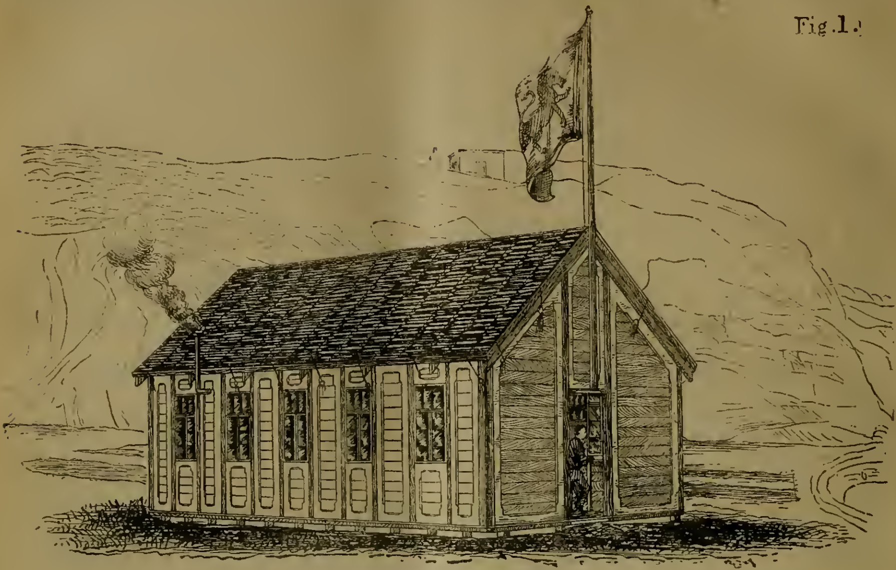
SOME months ago the opening of a zoological station on the Scottish coast was mentioned in these pages. This station—the first enterprise of the sort in Britain—has been established in connection with the University of Aberdeen, and under the directorship of the Professor of Natural History, Dr. Ewart, who was, this year, assisted in the conduct of the station by Mr. Patrick Geddes.

The site chosen was the little fishing station of Cowie, about half a mile north of Stonehaven, and fifteen miles south of Aberdeen. But one of the chief advantages of the station is that it is not a fixed building of brick or stone, but a movable one of wood, which can be taken, if necessary, to a new place every year, and, after the season's work, taken down and packed up for the winter.

The annexed cuts give an excellent notion of the appearance and internal arrangements of the place. It is a wooden structure (Fig. 1) about 32 feet long by 16 wide, supported on low wooden piers and having a thin wooden roof covered over with sailcloth. In each of the longer sides are five windows, in one of the shorter sides the door, in the other two windows. Inside (Fig. 2), a partition divides the building into two parts—a larger, the laboratory proper, with eight out of the ten side windows, and a smaller, the library and director's room, with two of the side and both end windows.

In the library there is a bench or working-table (Fig. 2, *T*) running round three sides, with shelves (*S*) above, for books, apparatus, and bottles. In the laboratory there is a table (*T*) to each window, intended to accommodate two students, and provided with sliding-shelves (T') for holding the worker's books of reference. Between every two tables is a shelf, of the same height as the table, with two drawers (D), one for each student, and above them

Fig. 1.

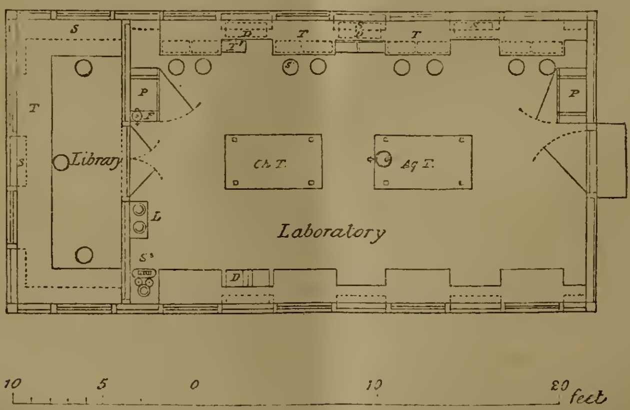


The Scottish Zoological Station—Elevation.

are other shelves (S) for holding bottles for specimens. The tables are fixed bracket-wise to the wall, and are remarkably firm and free from vibration.

In the middle of the room are two large tables, one (*Ch. T*) intended for chemical work, and provided with a sufficient supply of reagents, spirit-lamps, test-tubes, &c.;

Fig 2



The Scottish Zoological Station—Plan. *Aq.T*, aquarium table; *Ch.T*, chemical table; *D*, drawers; *F*, filter; *L*, wash-hand basins; *P*, presses; *S*, shelves; *S'*, stools; *St*, stove; *T*, working tables; *T'*, sliding shelves.

the other (*Aq.T*) bearing a large cask kept replenished with fresh sea-water, and several bell-jar aquaria of various sizes for living specimens. These latter were a great object of attraction to the numerous visitors to the station.

At each end of the room is a large press (P), used for stores; on one of these stands a filter for fresh water (*F*), and on the other side of the library door is a small table (*L*) with washing-apparatus. The whole building is warmed by a stove (*St*).

The station is neatly painted outside, and is rendered a very conspicuous object, both from sea and land, by the royal standard of Scotland, which floats from a flagstaff over the door.

Besides microscopes, dissecting-dishes, bottles, aquaria, books, &c., the station is well fitted with dredges, trawls, and canvas buckets for shore-collecting, and also provides wading-shoes, tarpaulins, and sou'-westers.

There are two boats attached to the establishment, a small fishing-smack and a "tub." But as these were often unable, owing to unfavourable weather, to sail beyond the mouth of the bay, a small steamboat is urgently needed to complete the efficiency of the station.

An Aberdeen fisherman was hired for the season, to take charge of the boats and to act as general factotum.

The Station was formally opened by Mr. Romanes on August 8, but the work actually began on the 3rd, and was continued until September 25. Altogether there have been sixteen workers, mostly Aberdeen students, the rest visitors from London and elsewhere. Several of these went out shore-collecting every day, a few dredged when practicable, and two dredging expeditions were made in H.M. gunboat *Netley*, the second of the two being a great success.

The fauna of the Aberdeen coast is not a remarkably rich one, but still a very respectable number of specimens was obtained in one way or another. I am indebted to Mr. A. W. Russell, M.A., of Marischal College, for a list of all the species collected; the list is too long for transcription, but may be abstracted as follows:—

	Genera.	Species.
Porifera	3	5
Hydrozoa	13	16
Actinozoa	6	8
Turbellaria	5	5
Hirudinea	1	1
Chætopoda	14	23
Echinodermata	13	20
Pycnogonida	2	2
Crustacea	12	30
Polyzoa	9	10
Tunicata	5	7
Mollusca	40	57
Pisces	5	7
	128	191

It is definitely decided that, next summer, the Station is to be pitched at Cromarty Firth, a far more promising locality than Stonehaven Bay. By that time it is hoped that the funds, which are wholly derived from voluntary contributions, will be in a sufficiently flourishing condition to admit of the purchase of a steamboat.

It would not be a very great matter, one would think, for our English universities to follow the example of Aberdeen, and to provide themselves each with such an establishment on some part of the English coast; and the benefit to their students, who get to think of nudibranchs, echinoderms, and cœlenterates as opaque, dull-coloured things in bottles, would be simply incalculable.

In the meantime I can, from experience, cordially recommend all English students of biology who are minded to begin research, as well as those who wish for nothing more than a thoroughly pleasant holiday and an opportunity of studying their science from the too-neglected "natural history" side, to spend two or three weeks of the long vacation at the Scottish Zoological Station.

T. JEFFERY PARKER

THE FOSSIL LOVERS

MISS ANN GELICA kindly sends us her reply to Bret Harte's Geological Madrigal, which she assures us is addressed to her. To enable the reader to understand the young lady's reply we prefix "Dear Bret's" verses:—

A GEOLOGICAL MADRIGAL
(*After Shenstone*)

I have found out a gift for my fair,
  I know where the fossils abound,
Where the footprints of *Aves* declare
  The birds that once walked on the ground;
O, come, and—in technical speech—
  We'll walk this Devonian shore,
Or on some Silurian beach
  We'll wander, my love, evermore.

I will show thee the sinuous track
  By the slow-moving annelid made,
Or the Trilobite that, farther back,
  In the old Potsdam sandstone was laid.
Thou shalt see, in his Jurassic tomb,
  The Plesiosaurus embalmed;
In his Oolitic prime and his bloom,—
  Iguanodon safe and unharmed!

You wished—I remember it well,
  And I loved you the more for that wish—
For a perfect Cystistidian shell
  And a *whole* holocephalic fish.
And O, if earth's strata contains
  In its lowest Silurian drift,
Or Palæozoic remains
  The same,—'tis your lover's free gift!

Then come, love, and never say nay,
  But calm all your maidenly fears,
We'll note, love, in one summer's day,
  The record of millions of years;
And though the Darwinian plan
  Your sensitive feelings may shock,
We'll find the beginning of man,—
  Our fossil ancestors in rock.

My Reply to Dear Bret's Madrigal

Thy epistle, dear Bret, I've received,
  And trust thou'lt not think me too bold,
If I frankly acknowledge I'm grieved
  At the thought that to thee I've been cold.

How sweetly thou managest wooing!
  What a way to my heart thou hast found!!
Abandoning billing and cooing,
  Thou tell'st me where fossils abound.

For ever henceforward I'm thine,
  To view Ornithichnites I'm sighing;
(Don't delay,—for a ramble I pine),
  To find them *in situ* am dying.

Tridactylous, struthious, and huge;
  With phalanges nicely indented,
Entombed when Dame Nature with rouge.
  The marl and the sandstone beds painted.

If thou wilt but extract me a femur,
  With matrix just near the trochanter,
I'll abandon all maidenly tremor,
  And at once name the day, thou enchanter.

I'll only make one stipulation:—
  That, avoiding hotel, inn, and tavern,
We improve the time-honoured lunation,
  And our honeymoon spend in a cavern.

There I'll labour, content in the fetter.
  To find, happy thought! if I can,
A dear second husband and better,
  A petrified pithecoid man.

A. G.

NOTES

LORD RAYLEIGH has been elected to the Chair of Experimental Physics at Cambridge, in succession to the late Prof. Clerk Maxwell.

A COMMITTEE has been appointed to receive subscriptions for the purpose of commemorating the retirement of Dr. Andrews from the vice-presidency of the Queen's College, Belfast, by a bust or portrait to be placed in the College, and a prize or scholarship to be founded in the same institution in connection with chemical science.

WE hear with regret that the Epping Forest Committee have rejected Mr. Alfred R. Wallace, whose candidature for the post of Superintendent of the Forest was supported by so many eminent men of science and also by a large number of the local inhabitants. The successful candidate is Mr. Alexander McKenzie, a landscape gardener, who may doubtless prove an able superintendent; but it is unfortunate that a man of Mr. Wallace's ability and knowledge should have failed to obtain a post which he could so well have filled for the benefit of the nation.

DR. PERCY has resigned the lectureship on metallurgy at the Royal School of Mines.

THE Rev. John Brown Maclellan, Vicar of Bottisham, Cambridgeshire, has been elected Principal of the Agricultural College, Cirencester, in place of the Rev. John Constable, who has resigned owing to ill-health. Mr. Maclellan is a distinguished classical scholar, having taken high honours in that department at Cambridge. He is the author of a work on "The Fourth Nicene Canon and Election and Consecration of Bishops," and of "A New Translation of the New Testament." We have failed to discover the special qualifications of this scholarly vicar for the position of head of an Agricultural College, which if anything is scientific. Of course the institution is a proprietary concern, and the Council has a right to do as it likes. By the by although this College has a charter, it has no right to the title of "Royal" which it assumes.

M. JANSSEN has been unable to see the sun for a number of days, owing to the almost constant prevalence of cloudy weather; but he states that, according to the results of his latest observations, the number of spots on the sun is very small, as well as the number of faculæ. He supposes that this last circumstance may be connected with the rigour of the present winter, although he is not in a position to state whether these faculæ are on the surface of the sun or produced by some change in the intervening medium. The construction of M. Janssen's observatory at Meudon has been interrupted by the inclemency of the weather. It will be resumed next spring. Meanwhile M. Janssen is completing his system of observation. An automatic instrument worked by a weight will take six photographs of the sun every twenty-four hours with a 9 inch refractor. The construction of a large refractor for observing celestial bodies is also proceeding.

OTHER three days' *Thunderer* gun experiments were made during the past week; the experiments will be resumed in a fortnight.

THE Belgian State-prize of 5,000 francs (200*l.*) which is awarded by the Royal Academy of Sciences every five years for scientific work was this year awarded to the director of Brussels Observatory, M. Houzeau, in recognition of his latest work, "Uranométrie générale, avec une Étude sur la Distribution des Étoiles visibles à l'Œil nu." There is another prize of 2,500 francs (100*l.*) awarded annually by the king, which was to be given away for the second time this year, and specially referred to architecture, but no worthy recipient could be found, although no less than ten different works had been submitted to the committee of judges.

THE University of Göttingen has become the possessor of a magnificent herbarium, containing over 40,000 specimens of plants from all parts of the world. It was left to the University by the late director of the Göttingen Botanical Gardens, Prof. Grisebach. There is no doubt that it is by far the largest collection of plants ever brought together by any single individual.

THE late Herr von Nathusius has left a very valuable library, consisting almost exclusively of works on natural history and agriculture, and numbering some 5,000 volumes. Besides this there is an osteological collection of some 2,500 animal skulls, 300 skeletons and parts of skeletons, a collection of some 20,000 pictures illustrative of animal life, and finally, a collection of about 8,000 samples of wool. Everything is in perfect condition, and arranged in the most scientific manner. The collections being of great value for agricultural museums, the Prussian government intends to purchase them for the Museum at Berlin. Their value is estimated at 60,000 marks (3,000*l.*), and a present they remain still at Hundisburg, near Magdeburg, the seat of the deceased statesman.

THE death is announced of M. Claude Etienne Minié, the inventor of the carbine of that name. He was born in Paris in 1804.

A FORTNIGHTLY scientific contemporary makes the following extraordinary announcement concerning the late award of medals by the Royal Society:—"The Copley Medal to Prof. Rudolph J. E. *Clamins*, of *Rome*, for his researches upon heat; the *Davey* (*sic*) Medal to M. P. E. Lecoq de Boisbaudran, for his discovery of gallium; a Royal Medal to Mr. William Henry *Perkins*, F.R.S., for his long-continued and successful labours *in geology and physical geography*"! Was there ever such a nice "derangement of epitaphs?" The italics are ours.

THE frost having continued in Paris, the Seine was frozen on December 9. The maximum of cold was observed about one o'clock in the night from 8 to 9. $-24°$ C. has been observed at Montsouris in the shade, $-25°$ at La Varenne St. Maur, $-27°$ at Versailles.

IT has been suggested by the *Temps* meteorological editor, that the whole of Europe and a large part of Asia and Northern America being covered with snow, the appearance may be analogous to the red spot discovered on Jupiter by astronomers, and this may be considered as an indication that some unusual cooling influence prevails on the whole solar system.

MRS. CHAPLIN AYRTON has received the degree of M.D. from the Medical Faculty of Paris. She presented an elaborate thesis "On the General Dimensions and the Development of the Body among the Japanese."

THE Thames Embankment system of electric lighting has been extended to the Victoria Station of the Metropolitan District Railway. The station, we learn from the *Times* report, is 350 feet long, 50 feet wide, and 40 feet high. There are two platforms, each 15 feet wide, the railway space between them being 20 feet wide. There are ten lights in all, of which five are placed over the down-platform, dividing the length into spaces which are unequal owing to the interference of constructive details. Over the up-platform are four lamps, which alternate with the five on the other side so as to afford an equable distribution of light. The tenth lamp is placed centrally over the foot-bridge which connects the up- and down-platforms. The lights are produced and maintained by the same steam-engine which is maintaining the forty lights on the Embankment and the ten on the bridge. The engine is, therefore, now maintaining a total of sixty lights—a point of considerable importance. Of still greater importance, perhaps, from a scientific point of view, as the *Times* remarks, is the distance to which the present machinery is transmitting the current. The distance marked on the map of the District Railway between their station at Charing Cross and that at Victoria is 2,383 yards, or 1·354 mile. The length of wire between the two stations, however, owing to curves and losses necessarily attending the laying, connecting, and fixing, is about 1·65 mile. The whole circuit is thus equal to a length of 3·30 miles. The ten lights are on two circuits, and are maintained by the two spare circuits of the Gramme machine which supplies the ten lights on Waterloo Bridge. The loading wire is similar to that used on the Embankment, being a cable of seven strands of No. 19 B. W. G. copper wire, highly insulated. The wires are laid through the tunnel of the railway, being fixed against the walls. There is a switch arrangement at the Victoria Station, so that the lights are started and extinguished on the spot, and are thus locally under control. This new development of electric lighting means something more than that sixty lights are now being successfully maintained from a single engine of twenty horse-power nominal. It means that very considerable distances have been bridged over, and that, other things being equal, the application of electricity for illuminating purposes can be carried to distances from the source of power previously unbelieved in and by some unthought of.

Mr. Thomas Fletcher, the well-known maker of scientific apparatus, of Museum Street, Warrington, must be a man of considerable public spirit, as well as enterprise. From a circular letter he has sent us we learn that a few friends interested in scientific matters, have decided to meet every Thursday evening for the winter months, at his house, with the object of discussing new or interesting scientific matters. The meetings will be informal, simply a social gathering of those interested in the progress of science. If the movement is appreciated by a larger number than can conveniently be accommodated, the question of forming a scientific club will afterwards be raised. The laboratory will, for the evening, be converted into a smoke room, and any apparatus will be at the service of all. Both these privileges will, we are sure, be largely appreciated. These meetings, Mr. Fletcher is careful to state, will be so arranged as to be little or no cost to himself, and therefore they will, so far as room permits, be open to all interested in matters likely to be brought forward, all being at perfect liberty to come and bring any friends. We heartily wish success to Mr. Fletcher's efforts to foster a love of science in Warrington.

Various statements have recently been published regarding the probable time of completion of the St. Gothard tunnel; few of them are correct. On Oct. 31 last, at 8.15 A.M., the boring machine on the northern side reached the centre of the tunnel at a depth of 7,460 metres. The meeting of the boring machines, however, cannot possibly take place before February next year. At the beginning of November there were still 717 metres of rock to be removed, and 50 metres per week is considered to be a fair average. On October 1 last the borings were some 261 metres short of the original programme, and on that day only 7,821 metres (total) of the tunnel were complete (instead of 11,579 metres, as stated in the original programme). A serious obstacle has quite recently been encountered in some soft strata, the enormous pressure of which has up to the present resisted all attempts at successful penetration. The most solid beams are bent like reeds after a little time, and a resistance-wall of 1 metre thickness was completely crushed. Another of 2 metres' thickness is now being constructed. The boring machine is useless in these strata, and only hand labour can be employed.

The works for the railway across the Isthmus of Tehuantepec have been commenced. The line will be 150 miles long.

The director of the zoological station at Trieste, Prof. Claus, of Vienna, has issued a report on the work done at the station since its opening in 1875 up to the end of 1878. It appears that no less than twenty-two zoologists have worked at the station (including ten Austrians and seven Germans), besides thirty-four students of zoology. Apart from a large number of smaller communications issued by the station, thirty-eight important scientific publications owe their origin to work done at that institution.

At Magdeburg a grand agricultural exhibition will be held from May 28 to June 6, 1880, in celebration of the fortieth anniversary of the foundation of the Magdeburg Agricultural Society.

For the International Piscicultural Exhibition which will be opened at Berlin on April 20, 1880, a great number of specimen-collections have been already promised. Complete illustrations of the state of pisciculture in the various countries will be sent from Sweden, Norway, Italy, Holland, China, Japan, Canada, and the Malay Islands. Several crowned heads and the free cities of Hamburg and Bremen will award prizes to the exhibitors.

The Paris Municipal Council has not yet taken any final decision on the question of gas *versus* electricity. At all events the Commission will propose to use Jablochkoff lights for illuminating the Place de l'Opéra, and new experiments will be tried in the green room of the opera for deciding whether the Jablochkoff or Werdermann light will be selected for the interior.

Details of the Temesvar earthquake of November 21 last are now to hand. It appears that two separate shocks were felt, a violent one at 12.5 A.M., and a weaker one shortly before 2 A.M. Numerous chimneys, vaults, cellars, &c., fell in in the town as well as in the surrounding villages. A third shock followed at 5.45 P.M., and a fourth one a little later. On the following days the shocks continued and were also noticed at Szakalhaza, Vukova, Stamora, Blazsova, Lippa, and other places in the district.

Two shocks of earthquake are reported from Switzerland: one at Geneva on December 4, at 5.34 P.M., Greenwich mean time; the other at Berne, Bale, Aarau, and Schaffhausen, on December 5, at 2.32 P.M.

Many of our readers will be glad to know that Messrs. Macmillan and Co. have published a translation of Pasteur's "Études sur la Bière," under the title of "Studies on Fermentation," by Messrs. Frank Faulkner and D. Constable Robb. The original work we noticed at length in Nature, vol. xv. pp. 213, 249.

A dangerous and infectious disease among bees is reported from Italy. It is caused by a microscopical fungus, and spreads with alarming rapidity. However, winter is not a favourable season for its propagation, and salicylic acid solution is said to be an infallible remedy against the disease.

In the course of some excavations now going on in the bed of the Rhone, near Geneva, many interesting objects, assigned by archæologists to the age of polished stone, have been brought to light, the most curious of which is a scraper of jade, highly finished, and in a condition as perfect as when it left the hands of the workman. The question arises, the *Times* correspondent states, and is being warmly discussed by the learned in lacustrine lore, how this instrument, made of a mineral which exists in a natural state only in Asia, can have found its way into the Rhone gravel at Geneva. Was jade ever an article of trade between the West and the East in prehistoric times, or is this scraper a solitary specimen brought by Aryan wanderers from the cradle of their race on the Hindoo Koosh? As yet no satisfactory solution of the problem has been suggested.

THE *School of Mines Quarterly* is the title of a journal published under the auspices of the Chemical and Engineering Society of the School of Mines, Columbia College, New York, the first number of which has been sent us. It contains several good articles on chemical and engineering subjects. There seems no keeping pace with the scientific enterprise of our friends on the other side of the water.

FRIEDLÄNDER AND SON, of Berlin, have sent us their new Catalogue of Standard Publications in Astronomy and Geodesy, brought up to the present time.

A FOURTH edition has been published of Mr. Thomas Christy's useful *brochure* on "Hydro-Incubation in Theory and Practice, a Guide to Commercial Poultry Farming." We have referred to the previous editions; the whole of the matter in this edition is stated to be new.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mr. F. G. Lightfoot; a Bonnet Monkey (*Macacus radiatus*) from India, presented by the Rev. E. C. Ince; a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by Mr. F. E. Colenso; a Black-headed Jay (*Cyanocorax nigriceps*) from South America, two Brant Geese (*Bernicla brenta*), European, purchased.

OUR ASTRONOMICAL COLUMN

THE COMET OF 1652.—The observations of this comet made by Hevelius between December 20, 1652, and January 8, 1653, it is remarked by Pingré, were probably the most precise, and certainly the most complete, of all; generally the observations were very rough. They were mostly collected, he adds, in a short dissertation published at Padua in 1653, which would appear to be that by Argoli, entitled "Andreæ Argoli Brevis Dissertatio de cometâ ann. 1652, 1653 et aliqua de meteorologicis impressionibus." Halley's orbit, the only one for this comet which figures in our catalogues, was calculated upon the observations of Hevelius.

Zach found another series of observations, which Pingré probably had not seen, and which upon reduction and discussion may prove to be second only to those of the Dantzic astronomer in merit; indeed, he thought they might be even more precise. These observations were made by an ecclesiastic residing at Rome, an Englishman, one calling himself, or being called by others, *Riccardo de Albis*, a name which, Zach suggests, is probably to be read *Richard White*, and he conjectures that he was probably a Jesuit of the Anglican College, where we know that another English Jesuit, LeMaire, Boscovich's assistant in geodetic work, also observed. The observations were sent from Rome in January, 1653, by a certain Raffaelo Magiotti to his good friend Candido del Buono at Florence, with a commission to present them to Prince Leopold of Tuscany, brother of the reigning Grand Duke Ferdinand II. Magiotti mentions that he had procured the observations with difficulty since De Albis himself intended to print them, *con molte puntualità*. Whether he did so or not does not appear; his name is not mentioned in the cometographies, and though Lalande enumerates some twenty publications referring to the comet of 1652, there is none under the name of De Albis. We are told that he observed with a good quadrant, but there is no reference to telescopic sights, though Zach says, with two such opticians as Campani and Divini at this time in Rome, it may well have been that he had telescopic aid.

The observations in question appear in Angelo Fabroni's little known "Lettere inedite di Uomini illustre," as a supplement to his greater work published at Pisa in 1768. They were made between December 21 and January 3, "hora 2 post occasum solis," and consist of distances from conspicuous stars. It may be of interest to reduce the observations of this scientific Englishman, and to calculate an orbit upon them; a strict copy was given by Zach in Lindenau and Bohnenberger's *Zeitschrift für Astronomie*, vol. iv.

In the same communication will be found some observations by a Roman patrician, one Arcieri, with "a good telescope of 9 palms, by Eustachio Divini." He saw the comet for the first time on December 19, "instar nubeculæ rotundatæ et candicantis, e cujus centro quiddam subricundum instar prunæ emicabat, ejusque diameter visiva erat 10 circiter minutorum." On December 21, its diameter was fifteen minutes. It seems to have been well seen on the following night, when we read "Porro cauda illius (quæ rarissima quidem erat, tenuissimaque) in oriente vergens, æquabat longitudine spatium pene 8 graduum, et dimetiens visiva excreverat jam ad 20 fere minuta." On December 23 it appeared much more obscure, but on December 24 at the fourth hour of the night the tail was brightest, the head being one degree from the Pleiades. Five nights later it was distant "circiter 30 minutis à capite Medusæ versus Plejadas, multum imminutus obscuratusque, nullumque caudæ vestigium apparebat." On January 1 it was as bright as a star of the fourth magnitude, and two nights later was hardly equal to one of the fifth.

Pingré remarks that in the judgment of Hevelius and Comiers this comet almost equalled the moon in size. It was nearest to the earth on December 19, when its distance was 0·13 of the earth's mean distance from the sun, so that it approached our globe as close as its orbit admits.

METEORS ON OCTOBER 19.—M. E. Block, of Odessa, records a notable shower of meteors on the morning of October 19, between 3h. and 5h.; he says he had not previously seen so many meteors. In an interval of ten minutes he counted fourteen which passed through the field of his comet-seeker, two degrees in diameter; the radiant was at β Aurigæ, or in about R.A. 88°, Decl. 45°. This radiant agrees nearly with No. 92 in Major Tupman's list.

GEOLOGICAL NOTES

UPPER DEVONIAN ROCKS OF THE NORTH OF FRANCE.—In a recent communication to the Geological Society of the North of France, Prof. Gosselet has brought forward some important new data, obtained from some fresh railway-cuttings between Féron and Semeries, as to the classification and palæontology of the Upper Devonian rocks. Arranging the Upper Devonian into an inferior group—the *Frasnien* comprising the zone of *Rhynchonella cuboides* and that of *Cardium palmatum*, and a superior group—the *Famennien*, in which are placed the Schistes de Famenne, the Psammites de Condros, and the Calcaire d'Etrœungt, he proceeds to show that in sections exposed in the railway-cuttings with a perfect conformable succession of strata and of fossils, the zone of the Psammites de Condros, so well marked elsewhere in the north of France and Belgium, is absent. He regards this arenaceous series to be represented in the district between Avesnes and Fourmies by argillaceous shales. It is easy to recognise at least an upper and lower member in the Famennian group. The former is distinguished by the prevalence of Carboniferous forms, particularly *Spirifer laminosus*, the latter by the rarity of Carboniferous forms and by the abundance of *Cyrtia Murchisoniana*. Every fresh section which tends to elucidate the relations of the Devonian rocks to the formations below and above them possesses a special interest for British geologists.

TERTIARY QUARTZITES OF THE ARDENNES.—Dr. Charles Barrois has laid before the same Society an interesting paper on the extension of the Lower Tertiary beds of the Paris basin across to the Palæozoic plateau of the Ardennes. He shows that the lower members, consisting of sandstones and conglomerates, can be traced by their fragments for a long distance to the north-east, and that these fragments, like our own Grey Wethers or Sarsen stones, are portions of deposits which have been gradually broken up and weathered in place. The existence of these boulders has long been recognised and they have been variously explained, being sometimes considered as drifted blocks. Dr. Barrois, however, demonstrates their true origin by tracing them step by step to their source in the Grès Landéniens. He makes some suggestive remarks regarding the superficial alteration of some of these rocks. In the centre they are undoubted sandstones, but towards the exterior they become progressively harder till they pass into true quartzite. He even obtained specimens of sandstone covered with a mere coating of quartzite two centimetres in thickness. He observed that in proportion as they are traced eastward, that is, into tracts where they must have been longer exposed to atmospheric influences, the alteration penetrates further into them. A microscopic examination failed to afford him any clue to the process of alteration. The quartzite when examined in thin sections appears as a true quartz-sand, the grains of which are so minute that no interstice can be seen between them. It is an excessively compact rock, in which a matrix is hardly appreciable.

Pyrenees Marble.—In another paper Dr. Barrois gives information regarding the *Marbre Griotte*, now so largely worked for ornamental purposes in the Spanish and French Pyrenees. This rock, usually regarded as Devonian, and placed on a parallel with the red limestone of Westphalia and Nassau, is shown by him to rest unconformably on Devonian strata in the Western Pyrenees, to be covered by a *Productus* limestone of true Carboniferous date, and to contain in itself a fauna which, by its crustacea (*Phillipsia*), and more especially by its *Goniatites*, must be regarded as Carboniferous. He therefore concludes that the Griotte limestone or marble constitutes the basement member of the Carboniferous system of the region in which it occurs.

Petrography in Spain.—The progress of petrography is well illustrated by the appearance of an essay on the evolution of volcanic rocks in general and of those of the Canaries in particular, by Don Salvador Calderon, of Arana, just published in the *Annals* of the Spanish Society of Natural History. He reduces all the rocks of the Canary Islands into two grand categories—a sanidine-amphibole group and a plagioclase-augite group. Thus, out of a paste of augite and plagioclase he conceives that all the rocks of the second category may have been formed, with the addition of other accidental minerals, and by a variation in the proportions. So that at the end of the one series he places a nepheline-basalt containing sanidine, and he traces a gradation from this rock through the disappearance of the sanidine, the successive appearance of hauyne and olivine, and the final predominance of the latter mineral, till he reaches the felspathic basalts, dolerites, and modern lavas. He discusses the evolution of volcanic rocks under four periods:—1. The Lava period, in which section he treats of the vitreous fluidity of lava, the influence of temperature, pressure, and water in the formation of the rock, and the possibility of an arrangement or liquation of the component elements of the lava while still melted within the volcano. 2. The Refrigeration period. Here he discusses the crystallisation of the lava, noting particularly the results of the evaporation of the interstitial water, the formation of the "micro-fluctuation" structure, the development of porphyritic crystals, and the effects of sublimation. 3. Changes in the rocks after solidification; divided into (1) mechanical, which include fractures on the great scale, cracks in the paste of the rocks, fissuring of the crystals, and the formation of cavities and globules; (2) physical, embracing the phenomena of devitrification; and (3) chemical, under which are placed serpentinisation, zeolitisation, natrolitisation, &c. 4. The Decomposition period. Under this heading the author, citing the researches of Durocher, Bischof, and Delesse on the permeability of rocks by meteoric water, and the changes thereby produced, gives a brief account of the nature of the alterations of some of the more prevalent minerals in the rocks of the Canary Islands and elsewhere. The paper is illustrated by a few drawings of microscopic structures.

GEOGRAPHICAL NOTES

Further details are to hand concerning the sojourn of the Russian, Lieut. Tjagin, and a colony of Samoyedes in Novaya Zemlya during last winter and summer. The object of Tjagin's stay on the island was to complete the arrangements for a station for the help of shipwrecked sailors, and to carry out a series of meteorological observations for a whole year. Tjagin arrived at the harbour of Karmakul on August 15, 1878. By September 13 the necessary buildings of wood were completed, and the meteorological instruments installed, and by October 3 all the Samoyedes were collected about the station. The autumn of 1878 was dull, rainy, and cold. The mean temperature was about 4° Centigrade. The first frost was on September 26. The first snow fell on the 28th, and the sea froze on October 10. Ice-crust and drift-ice were seen on the sea in the middle of October, and the harbour of Karmakul, as well as all the small bays, were covered with ice on November 13. But Moller Bay did not freeze during the whole winter, except among the islands which lie thick along the coast. The melting of the snow began with the first thaw, about the middle of May, and the first green was seen on the cleared spots near to the snow-heaps. On June 14 the islands were covered with verdure and flowers, but the harbour of Karmakul and the little bays were not free from ice till July 16, and the small lakes July 22. The mean temperatures were in November, $-9°\cdot8$ C.; February, $-17°\cdot8$; March, $-11°\cdot8$. During the five winter months the mean was $-12°\cdot2$. In January the temperature sank to $-32°\cdot1$, and rose in November to $+0°\cdot8$, and in January to $+0°\cdot2$. The movement of the atmosphere varied from complete calm, rare mild winds from south-west and north-west, strong winds from east-south-east, rising to raging storms, which greatly impeded hunting operations. The quantity of snow which fell was inconsiderable; it snowed seldom, but the strong land winds drove the snow from the distant hills and the neighbouring heaps towards the west, and often covered the houses up to the roof on one side, while on the three other sides the snow was blown clean off the ground. Tjagin returned to Archangel on August 17 with two orphans belonging to one of the Samoyedes who died during the winter. He maintains that wintering in Novaya Zemlya is quite practicable, especially for Samoyedes. The practicability of erecting a refuge station with provisions has also been proved. But a store of provisions is absolutely necessary, as it seems impossible to obtain by hunting anything like a sufficient quantity of animal food during the winter.

Details have reached this country of the expedition led by Mr. Alexander Forrest into the unknown north-eastern part of Western Australia. Forrest left the Beagle Bay, south of King's Sound, on April 20 last, with seven companions and twenty-six horses, proceeded to the mouth of the Fitzroy River in 17° 41′ lat. S., and 123° 36′ long. E., investigated this unknown river as far as its sources in a mountain ridge 2,000 feet high, in 17° 42′ lat. S., and 126° 10′ long. E., then followed a tributary to its source in a mountain chain (in 18° lat. S., and 127° 40′ long. E.), crossed these mountains and discovered a large river in 128° 10 long. E., which he followed for nine miles. The eastern boundary of the colony was reached in 16° 50′ lat. S., and 129° long. E. Here almost all provisions failed the travellers, yet they proceeded on North Australian ground to the Victoria River, and reached Catherine Station of the overland telegraph (forty four miles south of Port Darwin) on September 18, in a very exhausted condition. Fifteen out of the twenty-six horses had perished, and three more had been killed and eaten. Mr. Forrest reports that he discovered 20,000,000 acres of excellent pasture land, of which a large proportion would be well adapted for growing sugar cane, rice, coffee, &c. Water was everywhere in abundance, except on the last twenty-two miles of the march. The numerous natives the party encountered all behaved in a most friendly manner.

A telegram from Col. Prshevalski has been received *viâ* Pekin. It appears that the traveller and his party reached Shatshkoo at the end of June, after marching through the Shami desert, which in its centre rises to an elevation of 5,000 feet. The oasis of Shatshkoo, situated at an altitude of 3,500 feet, is very fertile. On the south it is bounded by a mountain side which begins at Lake Lob-Nor, and is covered with eternal snow in many places. The travellers intended remaining on the mountains until the end of July, and then to proceed to Hlassa.

We have received from the U.S. Survey copies of several new maps of recently surveyed regions, beautifully finished. They are the Yellowstone National Park, on a scale of two miles to one inch; parts of Western Wyoming, South-eastern Idaho, and North-eastern Utah, and part of Central Wyoming, on the scale of four miles to one inch; a drainage map of portions of Wyoming, Idaho, and Utah, on the scale of eight miles to an inch.

Heft I. for 1878-9 of the *Mittheilungen* of the Hamburg Geographical Society, is entirely devoted to Africa. Dr. G. A. Fischer, of Zanzibar, contributes a valuable original paper on the Wapokomo Land and its inhabitants; Herr A. Woermann, a Hamburg merchant, discusses the products of West Africa from a commercial point of view; Dr. Hubbe-Schleiden, in a learned and elaborate paper, discusses the Negro's capacity for culture.

In the December number of *Petermann's Mittheilungen*, Dr. Junker describes in considerable detail the results of his journeys in 1877-8 to the west of the White Nile, from Lado to about 29° E. long., and south to 3° 15′ N. lat., results of great importance for a knowledge of a scarcely known region.

News from Zanzibar announces the safe arrival of the united Belgian expedition at Ugogo.

SUN-SPOTS AND THE RAINFALL OF PARIS

In a paper on this subject by Mr. C. Meldrum, F.R.S., read at the Meteorological Society of Mauritius, after some preliminary remarks, the author said :—

The rainfall observations made at the Observatory of Paris formed perhaps the longest series on record. They were commenced in 1689, and, with the exception of twenty-six years, viz., 1697-98, 1755-72, and 1798-1803, they had been continued to the present day.

From 1689 to 1870 there had been, according to Dr. Rudolph Wolf and Prof. Fritz, seventeen years of maximum and seventeen years of minimum sunspot. Now it would be seen from the following table showing the years of maximum and minimum, and (as far as possible) the rainfall in each of them at the Paris Observatory, not only that more rain had fallen in the former than in the latter, but that throughout that long period there had, as far as could be ascertained, been only two exceptions to the rule that the maximum were wetter than the minimum years.

Min. years.	Rainfall.	Max. years.	Rainfall.	Dif.
	mm.		mm.	mm.
1689	513·0	1693	613·5	+ 100·5
1698	?	1705	372·7	?
1712	573·3	1717	478·8	− 94·5
1723	229·9	1727	370·0	+ 140·1
1733	210·2	1738	400·0	+ 189·8
1745	337·3	1750	564·5	+ 227·2
1756	?	1761	?	?
1766	?	1770	?	?
1775	534·4	1779	560·1	+ 25·7
1784	442·5	1789	500·2	+ 57·7
1798	?	1804	703·1	?
1810	437·0	1816	545·6	+ 108·5
1823	457·0	1829	559·8	+ 102·8
1833	502·9	1837	547·5	+ 44·6
1843	542·2	1848	575·2	+ 33·0
1856	565·3	1860	655·2	+ 89·9
1867	565·1	1870	417·8	− 147·3

From the above table it followed :

1. That the mean rainfall of the thirteen minimum sunspot years in the second column was 454·6 mm., and of the fifteen maximum years in the fourth column 524·3 mm., giving a mean annual excess of 69·7 mm. in favour of the latter.

2. That the results in the fifth column, of direct comparisons of the rainfalls in thirteen minimum with the rainfalls in thirteen maximum years, gave a mean excess of 67·7 mm. in favour of the latter.

3. That comparing the rainfall in each minimum year, from 1689, with that of the *following* maximum year, there were only *two* minimum years (1712 and 1867) in which the rainfall had not been less than in the maximum year.

4. That comparing the rainfall in each maximum year, from 1693, with the rainfall in the *following* minimum year, there was, as far as was known, only *one* maximum year (1705) in which the rainfall was not greater than in the minimum year.

5. That, as a rule, therefore, the rainfall of a maximum sunspot year was greater than that of either the preceding or following minimum year ; a circumstance which seemed to indicate a tendency, at least, to a periodic variation in the rainfall of Paris.

The most important feature was, not that on the whole the rainfall of the maximum had exceeded that of the minimum years, but that the excess had occurred in eleven out of thirteen cases. This frequent repetition of the same phenomenon pointed to a periodicity. A mere excess of rainfall in the maximum years, as a whole, could not have done so ; for such an excess might have happened if only a much smaller number of the maximum years had been wetter than the preceding or following minimum years. But that was not the case. From 1723 down to 1867 there was not, as far as the observations went, an instance in which the rainfall of a maximum year did not exceed that of the previous and next minimum year.

To the possible objection that the years of maximum and minimum sun-spots of the seventeenth and eighteenth centuries had probably not been so well determined as those of the nineteenth century, it could be replied that the results for the nineteenth century, also, showed that the rainfall had been greater in the maximum than in the minimum years. From 1804 to 1867 there had been six maximum and six minimum years. Now in every case the rainfall of the former exceeded that of the latter, and the mean excess was 86·1 mm.

Since 1867 there had been only one maximum year, viz., 1870, and the next minimum year was not yet known. It was true that the rainfall of Paris in 1870 had been comparatively small, and it was not improbable that it would be less than that of the next minimum year ; but if such should be the case it would be the only exception to the general rule since the commencement of the century, if not since 1705.

The total rainfall at the Paris Observatory in the seven maximum years, since 1800, was 4,004·2 mm., and in the six minimum years 3,069·5 mm. A rainfall of 934·7 mm., therefore, would be required in the seventh minimum year to restore the balance ; and there was very little chance of this, the greatest recorded rainfall, since the observations had been commenced, having been 703·1 mm. in the maximum year 1804, and the least 210·2 mm. in the minimum year 1733.

The average duration of the sun-spot cycles was, according to Wolf, 11·1 years. The last five complete cycles, starting from a minimum year, were from 1810 to 1867. Taking in each of these cycles the three years of most and the three years of fewest spots, and comparing the rainfall of Paris in the former triennial periods with that in the latter, it was found that the rainfall in each minimum period was less than that in the following maximum period. The figures were as follows :—

Minimum periods.	Rainfall.	Maximum periods.	Rainfall.
	mm.		mm.
1810—12	1531·5	1815—17	1561·4
1822—24	1453·2	1828—30	1718·2
1832—34	1380·1	1836—38	1700·0
1842—44	1455·3	1847—49	1602·7
1854—56	1522·8	1859—60	1658·7
1865—67	1751·7	1870—72	1628·5

It would be seen, however, that the rainfall in the minimum period 1865-67 exceeded that in the maximum period 1870-72 of the cycle which had commenced in 1867 (and the end of which was not yet fully known), the rainfall of 1866 having been abnormally great. But as the rainfall in the three years 1871-73 (1817·9 mm.) when the sun-spots were still numerous, had exceeded that in the three years 1865-67, the usual excess in the maximum periods may have only been somewhat retarded.

By forming, in the manner described on previous occasions, a mean cycle out of the five cycles from 1810 to 1867, and comparing the rainfall of Paris with the sun-spots for each year, the following mean results were obtained :—

Years of mean cycle.	Rain variation.	Spot variation
	mm.	
1	− 2·3	− 32·3
2	− 20·3	− 19·2
3	− 22·2	− 1·1
4	+ 15·3	+ 30·2
5	+ 47·5	+ 40·0
6	+ 40·0	− 29·8
7	+ 12·6	+ 11·3
8	− 17·0	− 1·2
9	− 23·3	− 12·8
10	− 22·7	− 21·1
11	+ 2·0	− 23·6

The above table showed that both the spots and the rain were above (+) or below (−) their respective averages in the same years of the mean cycle, except the last, and that they both attained their maximum in the same year, namely, the fifth. The discrepancy, with respect to *sign*, in the eleventh year, was owing to the years 1854 and 1866 having been abnormally wet.

From the maximum year 1816 to the maximum year 1870 there had also been five complete cycles, which, omitting fractions, gave the following results :—

Years of mean cycle.	Rain variation.	Spot variation.
	mm.	
1	+ 20	+ 23
2	+ 14	+ 14
3	+ 5	+ 5
4	− 10	− 6
5	− 10	− 19
6	− 19	− 32
7	− 9	− 37
8	− 1	− 25
9	− 2	+ 2
10	− 1	+ 31
11	+ 24	+ 45

Although in both tables the rainfall variation was not so regular as the sun-spot variation, yet there was a remarkable parallelism. At all events, both tables showed that the rainfall was greatest when the spots were most numerous, and on the whole, least when they were fewest.

From the several results now obtained it was concluded that any relation that might subsist between the rainfall of Paris and sun-spots was direct, instead of inverse, and that excessive rainfall in the present minimum period, or year, would be merely an exception to the general rule.

M. Flammarion was careful to state that the recent wet weather and paucity of sun-spots might have been only a coincidence. Were the far more frequent cases (during nearly two centuries) of comparatively wet years and seasons when solar maculation was greatest, and of comparatively dry years and seasons when it was least, also mere coincidences? Various considerations had led to the conclusion that they were not.

The circumstance that the sun's physical state, as indicated by the changes that took place in and above the photosphere, was subject to periodic variations, afforded ground for supposing that corresponding variations took place on and near the earth's surface. As a matter of fact, it was now universally admitted, although long contested, that terrestrial magnetism and auroras were subject to variations corresponding directly with those of the sun. Would it, then, as M. Flammarion had asked, be at all surprising to find that meteorological phenomena were subject to similar variations?

Supposing it were fully proved that the rainfall of the whole globe varied directly as the amount of sun-spots, it could not be expected that the law would invariably hold good everywhere. At any given place there were exceptions to every meteorological cycle. For example, on an average, the diurnal temperature increased from near sunrise to an hour or two after noon, and then decreased; but in many parts of the world there were frequent exceptions, and these were so great that the coldest and warmest hours might respectively occur at any time of the day or night. Yet there was a daily cycle of temperature corresponding with the position of the sun. Again, there was a diurnal oscillation of the atmospheric pressure, which, within the tropics, was very regular, though now and then disturbed or entirely masked, but which, in many extra-tropical countries, could not be determined except by taking means of hourly observations carried on for many days. Hourly barometric observations made on ten or more successive days, or cycles, in high latitudes, might not show a trace of the mean diurnal oscillation, which nevertheless existed.

It could not be said, then, that because the rainfall of a place did not invariably increase and decrease as the sun-spots did, there was no rainfall cycle corresponding with the sun-spot cycle. On the contrary, considering the capriciousness of the climate of Paris, it was somewhat surprising that a mean of the rainfall for only five cycles gave such results. There were many five consecutive days on which hourly observations would not give more favourable results for determining the daily march of the pressure of the atmosphere. But while there were 365 cycles of the diurnal oscillation of the barometer in one year, the same number of eleven-year rainfall cycles, if such cycles existed, extended over 4,051 years; so that it was easier to discover the former than the latter by observations at a single station. If the rainfall of Paris and the sun-spots had been observed and compared for as many sun-spot cycles as there were cycles of the diurnal oscillation of the barometer in one year, an eleven-year cycle of the rainfall might now be as well established as the diurnal cycle of the atmospheric pressure or the diurnal cycle of the temperature of the air. But the number of sun-spot cycles during which observations of the rainfall had as yet been made were few. Was it necessary, then, to wait thousands of years before it could be known whether or not there was an eleven-year rainfall cycle? It was believed that such was not the case. The problem might be solved in a much shorter time.

If the total annual precipitation over the whole globe were accurately known for eleven years, and if it were found that it was not a constant quantity, but increased from a minimum in the first year to a maximum in the fourth or fifth, and then decreased to a minimum in the eleventh, there would be a strong probability that this variation was due to some cause operating from without, and that that cause resided in the sun. For to what could such a phenomenon be attributed but to a variation in the action of the great central luminary upon which the production and condensation of aqueous vapour depended? And if continued observation of the total precipitation over the globe showed repetitions of the same variation during several periods of which the mean length was about eleven years, it would be somewhat difficult to avoid the conclusion that the sun's radiant energy was subject to a corresponding variation, even if no trace of such variation had as yet been discovered.

Suppose, now, that in the course of time it were found that there was a periodic variation of the physical state of the sun, and that this variation had the same duration and characteristics as the previously known variation in the amount of aqueous precipitation, would it not be concluded that the latter variation was intimately connected with the solar variation, although the nature of the connection might be a mystery?

Similarly, it might be argued that if the sun, upon which aqueous precipitation depended, was subject to variation, precipitation would be subject to a corresponding variation.

Since, then, it was an established fact that the sun, as shown by a periodic increase and decrease of spots, faculæ, and eruptions, extending over a period of about eleven years, was subject to variation, it might reasonably be inferred that there was a similar variation in aqueous precipitation. And if actual measurements of the total annual amount of precipitation over the globe during *one* sun-spot cycle showed a variation similar in every respect to the solar variation, it would be concluded, not only that there was a rainfall variation, but that probably it was intimately connected with the sun-spot variation.

Theoretically, then, the object should be to ascertain the annual rainfall of the globe. If this could be done for a few sun-spot cycles, the question of a corresponding rainfall cycle would be settled. But the total annual precipitation could not be ascertained; for, in addition to other obstacles, some parts of the earth's surface were inaccessible.

It was more than probable, however, that, supposing a rainfall cycle existed, observations made at numerous points, in both hemispheres, would detect it in a comparatively short time. If, for example, in the course of a few sun-spot cycles, the rainfall in many remote parts of the world, and under every variety of climate, afforded strong evidence of corresponding cycles, if the evidence became stronger as the number of observing stations increased, and if a mean of all the results showed a rainfall variation closely agreeing with the sun-spot variation, it would be difficult to resist the conclusion that the rainfall had a periodicity connected in some way or other with the solar periodicity.

Now, taking only the four sun-spot cycles from 1824 to 1867, so as to avoid objections to earlier observations, it had been found, as shown at former meetings of the society, not only that the rainfalls of the British Islands, the Continent of Europe, America, India, Mauritius, the Cape, and Australia, had, as far as could be ascertained, been greatest when the sun-spots were most numerous, and *vice versâ*, but that a mean of all the observations taken at 138 stations gave the following results, when compared with the sun-spots for the same four cycles:

Years of mean cycle.	Rainfall variation.	Spot variation.
	in.	
1	− 2·0	− 38·2
2	− 0·9	− 22·7
3	+ 0·8	+ 5·7
4	+ 1·9	+ 33·3
5	+ 1·9	+ 41·9
6	+ 1·8	+ 30·7
7	+ 1·1	+ 13·1
8	+ 0·2	− 1·5
9	− 0·5	− 12·1
10	− 0·8	− 21·7
11	− 2·0	− 28·0

The above table showed that the rainfall and sun-spots were, with a single exception, both below or above their respective means in the same years, and it would be seen that as the one increased or decreased, so did the other.

The *separate* results for Europe, America, India, and the stations in the Southern Hemisphere were similar. Those for Europe, for example, derived from observations taken at ninety-nine stations, were as follows :

Years of mean cycle.	Rain variation.	Spot variation.
	in.	
1	− 0·7	− 37·2
2	− 1·7	− 22·8
3	− 0·6	+ 4·4
4	+ 0·8	+ 33·0
5	+ 1·2	+ 43·8
6	+ 1·8	+ 32·9
7	+ 1·7	+ 14·3
8	+ 1·4	− 2·9
9	− 0·3	− 16·6
10	− 1·1	− 24·7
11	− 0·1	− 24·0

Similar results were obtained by taking the sun-spot cycles *separately*. Those for the cycle 1856–67, were as follows :—

Years of cycle.	Rain variation.	Spot variation.
	in.	
1	− 2·2	− 39·7
2	− 1·8	− 39·9
3	− 0·8	− 16·9
4	+ 0·9	+ 24·3
5	+ 1·9	+ 56·9
6	+ 2·5	+ 57·6
7	+ 2·0	+ 38·1
8	+ 0·6	+ 12·4
9	+ 1·0	− 13·9
10	− 1·5	− 34·1
11	− 0·4	− 45·0

The observations at many single stations, when treated by themselves, gave similar results. Those for Edinburgh and Bombay from 1824 to 1867, and for the Cape of Good Hope from 1843 to 1867, were as follows :—

Years of mean cycle.	Rain variation.			Spot variation.
	Edinburgh.	Bombay.	Cape.	
	inch.	inch.	inch.	
1	− 2·8	− 9·0	− 2·3	− 37·2
2	− 1·8	− 5·8	− 2·2	− 22·8
3	+ 0·7	+ 1·3	+ 0·4	+ 4·4
4	+ 2·4	+ 7·3	+ 3·1	+ 33·0
5	+ 3·3	+ 3·5	+ 2·6	+ 43·8
6	+ 2·8	+ 2·4	+ 3·2	+ 32·9
7	+ 0·5	+ 3·8	+ 4·3	+ 14·3
8	− 0·4	+ 0·7	+ 0·8	− 2·9
9	− 1·0	− 1·9	− 2·8	− 16·6
10	− 2·5	− 0·3	− 3·9	− 24·7
11	− 1·7	− 1·9	− 3·3	− 24·0

It had also been found that the levels of the principal rivers of Europe, and those of the great American lakes, had on the whole varied with the amount of sun-spots.

Such were a few of the results for the four sun-spot cycles from 1824 to 1867. Now it was important to remark that the evidence had increased as the rainfall observations had increased. Hence, with the large number of observing stations now spread over the world, it was inferred that a few more sun-spot cycles would settle the question of a corresponding rainfall cycle, if it was not settled already.

Another way of testing the matter in a comparatively short time was to compare, as far as possible, the daily, weekly, or monthly rainfall of the globe with the sun's-spotted area; for the amount of sun-spots varied much in the course of a year.

The results for the sun-spot cycle which commenced in 1867, and which probably was now closing, were not yet fully known, but there was reason to believe that they would be similar to those obtained for former cycles. It could already be stated that a mean of a large number of observations made in all parts of the world showed that the rainfall in the years 1870–72 had been greater than that in the years 1865–67, and judging from the severe droughts that had occurred in India, China, Japan, Australia, South Africa, South America, &c., since 1876, it was not improbable that the rainfall of the last three years had been less than that of the years 1870–72. In 1877 and 1878 the Nile, at Cairo, was lower than it had been for many years, showing that in the regions drained by it there had been a deficiency of rain. There had also of late years been a gradual decrease in the depth of water in the upper portions of the Amazon, so that navigation had sometimes been impeded, and this was supposed to be due to a general diminution of rainfall in the interior of South America. Moreover, various parts of the United States had lately been suffering from drought.

It would appear, then, that the circumstance that the rainfall of Paris had for a long period been greater in the years of maximum than of minimum sun-spots, was not a mere coincidence, but the result of a general law, and a similar remark applied to the rainfalls of many other public observatories.

There were, as might be expected in the case of so fickle an element as the rain, great local exceptions to the general law, though not greater or more frequent than exceptions to the general laws of other cycles; but, as far as had yet been ascertained, the rainfall of the globe varied directly as the sun-spots varied, the deficiency at some places in the maximum years being more than made up by the excess at others, and the excess in the minimum years reduced by a proportionately greater deficiency elsewhere.

Great fluctuations occurred near the epochs of maximum and minimum, but at a large majority of stations the rainfall in the three years of most sun-spots was almost invariably greater than that in the three years of fewest sun-spots.

The general rainfall cycle for the whole globe might be conceived to be made up of a number of local cycles differing more or less among themselves and from the general cycle, according to local conditions, and in some places the general cycle might be reversed.

From this point of view, it was possible that, although the recent rainy weather in Western Europe, at a time when there were few or no sun-spots, was a deviation from the general law, yet it was not an exception to the particular modification of it which prevailed in that part of the world. As a matter of fact, the rainfall of Western Europe was considerably above the average in 1844–45, 1845–55, and 1866–67, that is at intervals the mean length of which was eleven years, and at times when there were few sun-spots. But Western Europe was only a small part of the earth's surface; and from such a deviation, it could not be inferred that the rainfall, *generally*, was above the average in the minimum years.

In Mauritius there had been continuous observations only since 1852. Since that time the rainfall had on the whole been considerably less in the minimum than in the maximum years, but it would take some time to eliminate the effects of local causes.

SCIENTIFIC SERIALS

Zeitschrift für wissenschaftliche Zoologie, 33 Bd., 1 and 2 Heft, October 29, with seventeen plates.—F. E. Schulze, researches upon the structure and the development of the sponges; eighth notice.—On the genus Hircinia of Nardo, and on Oligoceras, a new genus, Plates 1 to 4. The genus of Nardo equals Stematumenia of Bowerbank; Sarcotragus, O. Schmidt; Filifera, Lieberkühn; and Polytherses of Duchassaing and Michelotti. The structure of the filaments—algæ of some authors—is fully discussed. The new genus Oligoceras is established for a new species (collective) from Lesina, which, though a fibrous sponge, is almost destitute of fibrous material. —Prof. E. Selenka, on the germ lamellæ and the arrangement of the organs in the Echinidæ, Plates 5 and 7.—Prof. A. Weismann, Contributions to the natural history of the Daphnidæ, No. 6 and 7, with Plates 8 to 13.—Prof. P. Langerhans, on the worm fauna of Madeira, with Plates 14 to 17.

SOCIETIES AND ACADEMIES

London

Royal Society, November 27.—"On the Changes in Pepsin-forming Glands during Secretion," by J. N. Langley, M.A., Fellow of Trinity College, Cambridge, and H. Sewall, B.Sc., Fellow of the Johns Hopkins University, Baltimore, U.S.A. Communicated by Prof. Michael Foster, M.D., F.R.S.

The Œsophageal Glands of the Frog.—In a frog three to four days after food, the alveoli of the œsophageal glands are, in the living state, granular throughout. The outlines of the cells are not visible.

Shortly after food is given, the granules thin away at the peripheries of the alveoli, and thus render the alveolar outlines more obvious. This thinning proceeds so rapidly that in a few hours there is a well-marked clear zone in the outer part of each alveolus, the part nearest the basement membrane.

Later the clear zone becomes larger, the granular zone becoming smaller, but as the clear zone enlarges it ceases to form in section a ring, it dips down into the granular zone at intervals.

Nuclei are not seen either in the resting or the digesting gland.

The points mentioned above as observable in the fresh tissue, can also in the main be observed in glands treated with osmic acid; the border granules, however, stain more deeply and readily than the central granules. The mucous cells are fewer in the active than in the resting glands; it is only in the fresh state that they appear granular.

The granules we consider as stored up cell-products, which, on suffering molecular re-arrangement during the secretion, give rise amongst other substances to the proteid ferment.

We cannot agree with Nussbaum's view that the depth of staining with osmic acid is a trustworthy index of the amount of ferment present in the cells. On his view, it appears to us, the border, rather than the central, granules should be connected with the ferment.

The Gastric Glands of the Newt (*Triton tæniatus*).—In the newt, the glands were observed through the muscular coat of the stomach with a rapid capillary circulation still going on.

Twenty-four hours after feeding, the glands of the fundus are thickly granular throughout; about three hours after feeding, the maximal change takes place; it corresponds in the main to that already described for the œsophageal glands of the frog.

The glands recover their granular appearance comparatively quickly; in six hours after feeding, the granules have usually again crept up to the periphery; they then increase in number throughout the cells up to about the twenty-fourth hour. Later than this they diminish somewhat; in six days the peripheries of the glands have become more sparsely populated.

In *Triton cristatus* the digestive changes are of the same nature, but much less pronounced.

The Gastric Glands of Stickleback.—In the gastric glands of the hungry fish the granules thin away somewhat from the centre to the periphery; the lumina are inconspicuous. Three to five hours after feeding, the lumina are much larger, the granules are aggregated about it, leaving a peripheral clear rim, the glands are more unequal in size, some having lost more granules and diminished more in size than others.

The Gastric Glands of Mammals.—In the glands of the fundus of the stomach of all mammals investigated, viz., dog, cat, rat, and rabbit, the chief cells are, in rest, crowded with conspicuous granules; the border cells are either without conspicuous granules or are finely granular.

During digestion the granules in the chief cells diminish.

The stomach of the rabbit has certain structural peculiarities; the principal of these is that a large portion of the greater curvature contains glands, in which the chief cells are not coarsely granular. The glands of the greater curvature contain scarcely more pepsin than the glands of the smaller curvature and pylorus. But in the smaller curvature and pylorus there are few if any border cells, whilst there are many in the greater curvature.

Hence the border cells are not directly connected with the formation of pepsin.

The glands of the fundus contain a very much larger amount of pepsin than the glands of the greater curvature; that is, where there are coarsely granular chief cells there is a large amount of ferment.

Further, during digestion the fundus-glands contain less ferment than in hunger—a fact observed first by Grützner—and it is during digestion that the chief cells have fewest granules.

Hence the conspicuous granules in the chief cells are directly connected with the formation of ferment.

Since in passing from the fundus to the greater curvature we meet all stages of granularity in the chief cells, and since the chief cells of the greater curvature do not differ in any essential point from the pyloric gland cells, we conclude with Heidenhain that the pyloric gland cells and the chief-cells of the fundus are fundamentally the same. We consider, however, the chief cells of the fundus to be a highly differentiated form of the pyloric gland cells, a form more especially designed for the production of pepsin, and probably other solids of the gastric secretion.

December 11.—"Thermo-Electric Behaviour of Aqueous Solutions with Mercurial Electrodes," by G. Gore, LL.D., F.R.S.

In this research the author has examined, by means of a new form of apparatus, the thermo-electric properties of a number of liquids in relation to mercury. The liquids include those of acid, neutral, and alkaline reaction. The results obtained are arranged in a table or series, with the solution at the top, in which hot mercury was the most positive at 180° F., and that at the bottom, in which it was most negative, the amount of deflection of the galvanometer needle with each solution being stated.

Another table is also given, in which the solutions are arranged according to the relative degrees of electro-motive force of the currents obtained from them. This series was arrived at by employing two similar apparatus with different solutions in each and ascertaining the difference of strength of their currents by passing the two currents simultaneously in opposite directions through the coils of a differential galvanometer, the amount of difference of deflection produced by each two consecutive pairs being given.

The results obtained from this research have not revealed any very striking phenomena nor disclosed any relation to chemical action or property, but are reasonably explicable upon the hypothesis that the rise of temperature of the liquid is attended by a change of molecular arrangement of the solution, of such a kind as to enable a portion of heat to be converted into an electric current.

The most peculiar phenomenon observed was, that if a solution of a salt, made with distilled water freed from dissolved air, was divided into two equal parts, one of which had been heated and cooled without loss of water or other constituent, previous to making an experiment, the non-preheated portion gave a stronger current than the other, probably in consequence of a change of molecular arrangement of the solution produced by the heating. The method may therefore be employed for detecting molecular differences in conducting liquids having the same che ical composition.

In the class of cases in which the differences of molecular arrangement were the least and the currents the most feeble, the direction of the currents was the most uniform. This is in accordance with the common truth in science, that the smallest phenomena are the most constant.

The author has ascertained by separate experiments of a different kind that mercury, when sufficiently agitated with solutions neutral to test paper, of salts of the alkali metals, renders some of those liquids feebly alkaline; the effect, however, is so slight, requires such extensive and long-continued contact of the substances that it appears consistent with the view that chemical action is not the cause of the currents in these thermo-electric experiments.

"Quantitative Spectroscopic Experiments," by Prof. G. D. Liveing, M.A., F.R.S., and Prof. James Dewar, M.A., F.R.S.

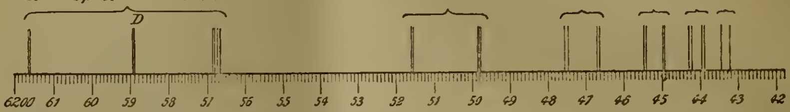
"On the Spectra of Sodium and Potassium." By G. D. Liveing, M.A., F.R.S., Professor of Chemistry, and J. Dewar, M.A., F.R.S., Jacksonian Professor, University of Cambridge.

The authors notice that as seen in the electric arc in one of their lime crucibles, there are in each spectrum several lines hitherto undescribed, which make the whole very regular and symmetrical. The authors have generally used carbonates of the metals, sometimes chlorides.

The pair of lines (5155, 5152) are sharply defined, and have no other line close to them; but the bright green pair, or fifth group (4983, 4982), are diffuse lines, usually seen as one band, but noted by Lockyer to be a double line, and have a third line on their more refrangible side. The authors feel sure that there ought to be a fourth line in this group, but have never been able to detect it.

The sixth group consists of a pair of lines sharply defined. The first only of this pair is described by Lecoq de Boisbaudran. The seventh group is a pair of lines with diffuse edges, which the authors have seen reversed as fine dark lines in the middle of diffuse blue bands. The first only is described by Lecoq de Boisbaudran. By putting some titanic oxide into the crucible the titanium line 4666·5 was seen between the sodium lines, and the authors have no doubt that it is sodium which gives the winged appearance to the corresponding ray in the solar spectrum. The eighth group is a more sharply defined pair, the ninth a diffuse pair, the tenth group again a more sharply defined pair,

Dia. 1 Spectrum of sodium in the arc



and the eleventh group a very diffuse pair, sometimes seen as a continuous band dividing as the sodium evaporates. The twelfth group is a diffuse but narrow band, which the authors have not seen divided, and the thirteenth group a diffuse broad band nearly bisected by the iron line 4325.

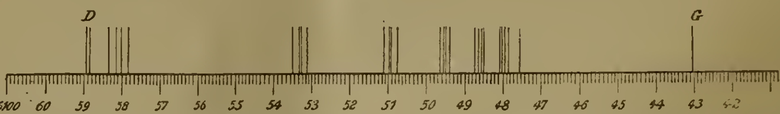
The successive groups become fainter and more diffuse as they are more refrangible, at the same time the distance between successive groups diminishes. Their positions are shown on the accompanying diagram to a scale of wave-lengths. It is worthy of note that every alternate group is much more sharply defined than the others. Moreover, it is only the diffuse groups (3) (5) (7) which show reversal except the first group, in the orange, which, however, is more difficult of reversal than the others. The whole series, exclusive of D, looks very like repetitions of the same set of vibrations in a harmonic progression; the first (visible) term consisting of the six vibrations represented by the orange pair (6160, 6154) and the four lines of group (3); the next term of the five lines of the fourth and fifth groups, one of the six vibrations being now too faint to be seen; the next three terms, of each of which only four lines are visible, consisting of the six and seventh, the eighth and ninth, and the tenth and eleventh groups, and the last term of the two faint bands of the twelfth and thirteenth groups.

Simple harmonic relations can be found to subsist between some of the groups, for instance, the wave-lengths of the fifth, seventh, and eleventh groups are very nearly as $\frac{1}{15} : \frac{1}{16} : \frac{1}{17}$, but the whole series cannot be represented as simple harmonics of one set of six vibrations with any probability. The smallest numbers, which are nearly proportional to the reciprocals of the wave-lengths of groups (1), (4), (6), (8), (10), (12), are 81, 97, 105, 110, 113, 115; and these numbers are only approximately in the same ratios as the reciprocals of wave-lengths.

Lines closely corresponding to all these lines except the faint ones of the 3rd and 5th groups, and the last two groups are found in the solar spectrum.

The potassium spectrum as seen in the arc, leaving out of account the two pairs of lines in the red and that in the violet, consists of a series of groups of four lines each, succeeding one

Dia. 2. Spectrum of potassium between D & G



another at shorter intervals and becoming fainter as they are more refrangible. They all are more or less diffuse, markedly more so on their less refrangible edges. They are shown on the accompanying diagram to a scale of wave-lengths.

The first and least refrangible group of this series consists of the four lines to which Lecoq de Boisbaudran assigns the wave-lengths 5831, 5812, 5801, 5783. The second of these lines (5812) is much less strong than the others as seen in the spark. In the arc they are all nearly equal in brightness, but the authors have not seen the second line reversed. Six groups of four lines each follow.

The sixth group has lines of about the wave-lengths 4808, 4803, 4796, 4788.

The seventh group is too faint and diffuse to be distinctly resolved. The wave-length of the least refrangible edge is about 4759.

None of the last three groups are seen by Lecoq de Boisbaudran, and they are too diffuse for exact measurement; on the other hand, he gives several other lines which are not noticed in the arc.

As in the case of sodium the repetition of these quartets of lines at decreasing intervals with decreasing brightness and sharpness as they proceed from the less to the more refrangible, gives the impression of a series of harmonics; but the wave-lengths do not seem to be in a simple harmonic progression, though simple harmonic relations may be found between some of the groups.

Linnean Society, December 4.—Prof. Allman, president, in the chair.—Mr. W. Carruthers exhibited a bottle of Pteropods (*Spirialis retroversus*) obtained in abundance by Dr. J. Grieve in the Gareloch, Ross-shire, Scotland, in July. A letter from Dr. Grieve was read, wherein he states that these mollusca swam rapidly to the surface, rising with a perpendicular fluttering motion, and having reached the top they raised their wing-like appendages above their heads, and thus upholding them motionless, would then drop quietly to the bottom. Some of the pteropods would occasionally stop half way, and paddle back to the surface to repeat the falling motion; seldom or ever did they swim along the surface. Dr. Grieve did not witness the creatures use their wings (epipodia) as feet to walk or crawl along the bottom, as A. Agassiz has stated to be the case.—Dr. Maxwell Masters gave a communication on certain relations between the morphology and the functions in the leaves of conifers (see *Science Notes*).—Prof. P. M. Duncan next read a paper on a synthetic type of Ophiurid. This specimen was dredged by Dr. Wallich in the *Bulldog* expedition, 1860, fifty miles north of Cape Valloe, East Greenland, and from a depth of 228 fathoms. On casual inspection this brittle-star might be regarded as an Amphiuran, but the spinulose disk and hooked side-arms oppose this notion. Again, resemblances to species of *Ophiothrix* suggest themselves, but the large scaling of the disk, absence of tooth papillæ, and the presence of accessory pieces around the aboral edge of the upper arm-plates, are distinctive characters, and which to a certain extent are indicative of Ophiolepian affinities, but the dental apparatus does not conform. Thus in shape and dental characters it (*Polyopholis echinata*) approaches *Amphiura*; spinules and arm-hooks are those of *Ophiothrix*; and the accessory plates resemble those of *Ophiolepis*. Provisionally the author places it among the family Amphiuridæ, and he remarks that, though rare, such forms cast doubts on the value of the characters employed in the classification of the Ophiuridæ.—Mr. C. B. Clarke followed with a paper on Indian Begonias. This is supplementary to the author's account of the group iu Sir J. D. Hooker's "Flora of British India." It treats of the classification of the whole genus (*i.e.*, order) except *Hillebrandtia* and *Begoniella*, and it is maintained that it (the group) can be naturally divided into the six subgenera employed in the "Flora of British India." The author discards the differences in the stamens and styles for subgeneric characters, and employs exclusively the structure and dehiscence of the fruit.—The following gentlemen were elected Fellows of the Society:—Messrs. Samuel Wright (St. Neots, Huntingdon), George Malcolm Thomson (Dunedin, N.Z.), J. Otto Tepper (Adelaide), Henry B. Spotton, (Ontario), John Cameron (Bot. Gard., Bangalore), Major Collet (Kurrum Field Force), and Sir Samuel Wilson (Victoria).

Chemical Society, December 4.—Mr. Warren De La Rue, president, in the chair.—The following papers were read:—On the comparative value of different methods of fractional distillation, by F. D. Brown. When fractional distillation is carried out on a large scale, either or both of two well-defined processes can be used: in the first "washing" the mixed vapours are passed through several layers of liquid obtained by their own partial condensation; in the second "cooling" the mixed vapours are partially condensed by allowing radiation to take place or by passing them through a coil kept at a given temperature; in both processes the liquids of highest boiling-point are kept back, and a better distillate is accordingly obtained. The author concludes that there is an essential difference between washing and cooling. The best distillate is obtained by keeping the still-head at the lowest possible temperature compatible with the passage of vapour into the condenser; he has contrived an apparatus to carry out this principle, and has obtained with it very satisfactory results.—On the influence exerted upon the course of certain chemical changes by variations in the amount of water of dilution, by M. M. P. Muir and C. Slater. The authors find that the amount of chemical change which ensues when solutions of calcium-chloride and sodium-carbonate are mixed decreases as the dilution increases, but when solutions of strontium-chloride and sulphuric acid, or barium chloride and potassium oxalate are mixed, various irregularities in the amount of chemical change are noticed as the dilution increases. These irregularities the authors have studied in detail; they conclude that they are due to the entire system being brought into a state of strain, the principal forces of which this stress is compounded being the force tending to produce cryohydrates and other hydrated molecules, the force tending to split up these molecules and the force tending to separate, and so to impart greater mobility to the chemically active molecules of the system.—On the influence of temperature upon the decomposition of barium chloride by potassium oxalate in aqueous solution, by M. M. P. Muir.—On α and β phenanthrene carbonic acids, by Dr. F. R. Japp. The author, since preparing the alpha acid with Dr. Schultz, has obtained a purer specimen melting at 266°; from a syrupy liquor left in the preparation of the calcic phenanthrene sulphonate, the author obtained the beta acid melting at 250°–252°; he also prepared the sodium and barium salts and studied the oxidation products of the acid. He discusses the constitutional formula of phenanthrene, and concludes that this substance consists of three benzene nuclei, one of which shares four adjacent carbon atoms with the two others.—On some derivatives of phenylacetic acid, by P. Philipps Bedson. The author has separated para- and ortho-nitro-phenylacetic acids, their bromo derivatives, a dibromo body, and a β bromonitro-phenylacetic acid, with its amido derivative.

Geological Society, November 19.—Henry Clifton Sorby, F.R.S., president, in the chair.—Edmund Knowles Binns, and John Dawson, were elected Fellows of the Society.—The following communications were read:—Supplementary note on the vertebræ of *Ornithopsis*, Seeley (=*Eucamerotus*, Hulke), by J. W. Hulke, F.R.S., F.G.S.—The author in this communication describes several cervical and trunk vertebræ of this remarkable Dinosaur. The former are characterised by great length; the anterior articular surface is strongly convex, and the posterior correspondingly hollow. In place of the side chamber characterising the trunk vertebral centra, is a long shallow pit. An upper and a lower transverse process are given off from an upper and a lower plate, which project from the side of the centrum above the pit, and these are connected by a short, forked cervical riblet. The neural arch is dwarfed, and there is no spinous process, and no zygosphenal and zygantеal mechanism. The structure of these vertebræ indicates a long, mobile, and light neck. In the trunk the convexity of the anterior articular surface lessens in passing from the neck to the loins, the anterior ball gradually subsiding till the great articular surface becomes plane, the posterior surface retaining, however, a slight hollowness. The trunk vertebræ have superadded to the ordinary articular processes a mechanism comparable to zygosphene and zygantrum, which must have given great fixity to this part of the vertebral column, contrasting strongly with the flexibibility of the neck. The longitudinal side chambers reach their greatest development in the vertebræ referable to the fore part of the trunk; they lessen toward the loins, and are absent from the neck, which is regarded as conclusive of their pneumaticity, and against their having been occupied by cartilaginous and fatty tissues, which might have equally occurred through the whole length of the vertebral column, and not been limited to a particular region in close vicinity to the lungs. The whole construction affords a notable illustration of immense bulk attained with the use of the smallest quantity of bony tissue, which occurs in the form of very thin sheets or plates. The transverse and spinous processes are strengthened by flying buttresses. The vault of the neural canal is beautifully groined, whence the original name *Eucamerotus*. The author then pointed out the family resemblances between the Isle of Wight Wealden form and the new Colorado Dinosaurs, which have many points in common, but are both generically and specifically distinct from *Ornithopsis*. — On the concretionary patches and fragments of other rocks sometimes contained in granite, by J. Arthur Phillips, F.G.S. There are two classes of inclusions, (1) the result of the abnormal aggregation of the minerals constituting the granite itself, containing generally more plagioclastic felspar, mica, or hornblende than it, with some other distinctions: most probably concretions formed contemporaneously with the solidification of the mass; (2) fragments of included schistose or slaty rock, often not very highly altered, caught up from the rock-masses through which the granite has forced its way.—Certain geological facts witnessed in Natal and the border countries during nineteen years' residence, by the Rev. George Blencowe. Communicated by the Rev. H. Griffith, F.G.S. Shales and sandstones are the prevalent rocks from the coast for about twenty-four miles inland. Here is a protrusion of granite; beyond the sandstones come ferruginous shales, with scattered boulders of trap on the surface. The northern third of Natal is white sandstone, formed into hills and ridges by denudation, with a long trap-capped plateau near Helpmakaar. Coal-seams occur in the sandstones. There are frequent vertical pipes in these sandstones which, the author thinks, mark the site of trunks of trees, round which the sand-beds had accumulated. Rorke's House and Isandhlwana are near the above plateau. Near the former is an extinct mud volcano. A remarkable "vitreous shale" is found near the Buffalo; isolated pinnacles of it occur at the spot where the few survivors of the fight crossed that river. A range of mountains, with mural escarpments, remnants of an ancient plateau, rising to a height of some 2,000 feet above another plateau which is 5,000 to 6,000 feet above the sea, extends for about 500 miles from the north of Natal to near Cradock in the Cape Colony; they are sandstone horizontally stratified, capped by trap. Some other geological features are described. The Transvaal consists of undulating hills of soft limestone, a sandstone range, and a country rich in metals,—iron-ore, cobalt, nickel, copper, and gold occur, as well as plumbago.

Zoological Society, December 2.—Prof. Newton, F.R.S., vice-president, in the chair.—A letter was read from Mr. E. L. Layard, F.Z.S., advocating the desirability of a fixed scale of colour for use among naturalists, in describing the plumage and pelage of birds and other animals.—A letter was read from Mr. R. B. White, C.M.Z.S., of Medellin, U.S., of Colombia, S.A., on a mode of protecting plantations from the ravages of an ant (*Atta cephalotes*).—A communication was read from Dr. G. E. Dobson, C.M.Z.S., containing notes on some species of chiroptera, from Zanzibar, with descriptions of new and rare species.—A communication was read from Prince Ladislas Lubomirski, containing the description of a collection of shells made in High Peru, by Messrs. Jelski and Stolzman.—Mr. G. French Angas, C.M.Z.S., read a paper in which he gave the descriptions of two new species of helix (*Eurycratera*) from south-east Betsileo, Madagascar.—Mr. Arthur G. Butler, F.Z.S., read a paper on some Arachnida of Madagascar and the Mascarene Islands, in which an account was given of a collection of spiders recently received by the British Museum from Réunion and Mauritius, through Mr. H. H. Slater.—Lieut.-Col. H. H. Godwin-Austen, F.Z.S., and Mr. G. Nevill, C.M.Z.S., gave descriptions of two collections of land shells obtained at Perak and in the Nicobar Islands by Surgeon-Major E. Townsend and Dr. F. Stolizka.—A communication was read from Dr. A. Günther, F.R.S., containing a notice of a collection of mammals and reptiles recently received from Cyprus by Lord Lilford.—Dr. F. Day, F.Z.S., read a paper upon the fishes of Weston-super-Mare, a locality he had lately visited in order to inquire into some species described by Yarrell and Couch as found on this coast. Mr. Day also gave some account of the results of Lord Ducie's trawling investigations in Ballinskelley Bay, on the Coast of Ireland, and described a specimen of the long flounder received from Mr. M. Dunn of Mevagissy, in Cornwall.

Institution of Civil Engineers, November 18.—Mr. W. H. Barlow, F.R.S., vice-president, in the chair.—The paper read was on tunnel outlets from storage reservoirs, by Mr. C. J. Wood, M.Inst.C.E.

December 2.—Mr. Bateman, F.R.S., president, in the chair.—The paper read was on "The Passenger Steamers of the Thames, the Mersey, and the Clyde," by Mr. W. Carson, M.Inst.C.E.

PARIS

Academy of Sciences, December 8.—M. Daubrée in the chair.—The following papers were read:—On the satellites of Mars, by M. Tisserand. By a different analysis from that of Prof. Adams, he concludes that, if Mars be homogeneous, or if the law of densities in it be the same as in the earth (a certain flattening being supposed), the orbits of the two satellites, Phobos and Deimos, will always coincide with the planet's equator, or at least will diverge from it very little.—Remarks on saccharoses, by M. Berthelot. He calls attention to the resemblance of the new substance, saccharine, in general reactions and crystalline form, to trehalose.[1]—Relation between the heat of solution and the heat of dilution in complex solvents, by M. Berthelot. The difference between the two heats of solution is equal to that between the two heats of dilution, observable when there is added to the concentrated liquor before and after having dissolved in it the third substance, the water necessary to bring it to the state of dilute liquor.—On the protochloride of copper, by M. Berthelot. This relates to heat of solution and heat of formation.—Reply to the two questions about chlorophyll in M. Chevreul's last note, by M. Trécul. Crystals of chlorophyll dissolve without residue in alcohol and ether. Each grain, in plants, composed of protoplasm and the chlorophyll it has secreted, should be considered a particular living organ.—Agronomic map of Seine-et-Marne, by M. Delesse. This shows the comparative fertility of the land, and its features, physical, chemical, geological, &c.—Experiments with divergent ajutages, divided into several parts by plates, by M. De Caligny.—On a function of direction in the flight of insects, by M. Jousset de Bellesme. Birds can, but insects in general cannot, alter at will the angle at which the wing is vibrated (the muscles of insects are not inserted in the wing, but in the piece of thorax which supports them). Direction of flight is determined in insects by altering the relative position of the centre of gravity and the axis of sustention, the former being most commonly displaced, and in some cases by movements of the abdomen, in others, of the elytra, in others, of the balancers.—Experiment relative to transport of phylloxera by the wind, by M. Faucon.—On the direct visibility of the photospheric network of the sun, by Dom Lamey. On November 16, observing the sun with a 6-inch equatorial at Grignon (Cote d'Or), he saw quite well that two spots on the left side were surrounded by a reticulated region. With a weak magnifying power the crateriform aspect was manifest.—On series relative to the theory of numbers, by M. Lipschitz.—Coloured rings produced at the surface of mercury, by M. Guébbard. Having carefully cleared off the grey pellicle which forms on the surface of mercury, breathe on the clear metal. Beautiful ring systems are formed in light by the layer of condensed vapour. They contract as evaporation diminishes the thickness. Better results are had by dropping a volatile oil on the surface, and the best with collodion. Diluted with ether, the latter gives pellicles which can be detached, after having regulated their thickness and colours, at will, and transferred to paper.—Reply to M. Trécul and M. Chevreul regarding crystallised chlorophyll, by M. Gautier.—Influence of phosphorus on the urinary secretion, by M. Cazeneuve. Experiments on the dog and the cat show that phosphorus, given in toxic doses, causes increase of urea, phosphoric acid, sulphuric acid, the total nitrogen, and iron. The author disagrees with the view of certain physiologists who regard the liver as the principal organ formative of urea.—On alcoholic fermentation (re ly to M. Berthelot), by M. Cochin.—On the inferior Pyrenomycetes of New Caledonia, by M. Crié.—Note on the general circulation of the atmosphere on the surface of the globe, by M. Brault. The fourth and last of the author's series of maps of winds is now published; it relates to the Pacific. M. Brault points out that the problem of atmospheric circulation falls into two parts; finding what the circulation would be if all the earth were covered with water (it would be in a system of zones oscillating from south to north, and *vice versâ*), and finding in the actual circulation what is due to the presence of continents and unequal distribution of land and sea. The former question is best studied in the southern hemisphere.—On a glazed frost observed at Angers on December 4, 1879, by M. Decharme. It commenced about 8 A.M., after a night of strong east wind, and lasted till 4 P.M.

[1] In last week's "Paris," on this subject, the phrase "or saccharine, not yet sugar" should read "or saccharose, yet not sugar."

INDIAN ENTOMOLOGY

Descriptions of New Indian Lepidopterous Insects, from the Collection of the Late Mr. W. S. Atkinson, M.A., F.L.S., &c. Part I. *Rhopalocera*, by W. C. Hewitson, F.L.S.; *Heterocera*, by Frederic Moore, Assist. Curator, India Museum. With an Introductory Notice by Arthur Grote, F.Z.S., &c. 4to, pp. 1-88, with Three Coloured Plates. (Calcutta: Published by the Asiatic Society of Bengal, 1879.)

THE hot valleys of the Himalayan regions of our Indian Empire have always justly had especial interest from an entomological point of view. The number of peculiar and apparently strictly endemic, forms of insects already known from this region is great, and principally in the larger species, for even now we know less of the smaller insect-forms of North India than we do of many other less familiar districts not under the advantage of British rule. Indeed, with a few notable exceptions, much of the knowledge we now possess is not precisely of modern origin. The somewhat numerous military expeditions to, and across, the Himalayas, undertaken within the last quarter of a century, and the great recent extension of tea and cinchona plantations in these regions, have not resulted in a corresponding increase in materials for a Himalayan insect-fauna. In some respects it may be said that we are likely to know more of the entomology of the Lake region of Africa, or of the Amazons region of South America, than of a vast and varied district, for the most part under the government of our own countrymen, and of a commercial importance second (to us) to no other. Still, important and wonderful discoveries have been made of late years, but they are perhaps eclipsed by the acknowledged existence of forms discovered long ago which would have become almost traditional were it not that the "types" exist in collections, and that they were duly described and delineated with infinite care in works that are no longer modern. As a summary, then, to the foregoing short introduction to a notice of a modern work on Indian Entomology, it may be briefly stated that a great deal of our knowledge was initiated before the present generation, and has not since been adequately supplemented.

But, as before-mentioned, there have been notable exceptions, and of these the most notable exists in the fruits of the labours of the much-lamented and talented Mr. Atkinson, an entomologist who, before he left this country for India, had acquired a training in entomological pursuits that his keen powers of observation enabled him to use to the best advantage in the intervals of official duties during a long residence in our Eastern Empire. For a very faithful sketch of Mr. Atkinson's career in India, the introductory notice at the commencement of the part of the book now under consideration, from the pen of Mr. Arthur Grote, suffices so far as it goes, and nothing is more to be regretted than the melancholy *finale*. Mr. Atkinson left India on three years' leave, for the purpose of scientifically working out the results of his labours, and died almost suddenly in Italy, before having had time to unpack his stores; and science lost the benefit of what could not have been otherwise than one of the finest original works on Indian entomology that has appeared, or probably ever will appear.

The collections remain (but more or less dispersed); the MS. notes possibly remain also, but they have not been made use of; the more important personal knowledge was buried with its possessor. The collections passed nominally into the hands of the late Mr. Hewitson, but the larger and scientifically more important portions ultimately went to Germany.

So far this notice has been introductory and historical; it remains to refer more particularly to the book. At the outset nothing strikes one as more to be deplored than that Mr. Atkinson himself could not have recorded the results of his labours. In that case we should, without the slightest doubt, have had a complete list of the species observed by him, with copious biological, and comparative faunistic, notes. As it is, we are compelled to put up with a bare mechanical description of the new species, with only a few words on biology, added by Mr. Grote from his long experience in India. The few new butterflies are described by Mr. Hewitson, and this part was probably the last work done by him, the proofs having been corrected on his death-bed. The far more numerous and more important *Heterocera* were confided to the care of Mr. Frederic Moore, by Dr. Staudinger of Dresden, who became their possessor. It would have been impossible to find a more competent entomologist for this task; there is certainly no one who possesses a more exhaustive knowledge of Indian lepidopterous insects. We believe Mr. Moore has commenced, and will finish, the undertaking in the most thoroughly conscientious manner, and this first part treats mainly upon the *Bombyces*, a group in which North India is superabundantly rich, and which Mr. Moore has very closely studied.

If, then, we find fault with the work it is not with especial reference to Mr. Moore (its principal author), but rather to the system pursued, one which is especially the attribute of writers on exotic Lepidoptera, and which will continue so long as lepidopterists are without a general and intelligible generic guide. We find numerous species referred to genera as described by Walker, Felder, &c., and new genera based on characters compared with these. We ask, would it be possible for any entomologist to identify a vast majority of Mr. Walker's generic (or specific) descriptions without referring to the types? and if not, what, from a scientific point of view, is the use of them at all? In the case of Felder ("Reise der *Novara*") it is somewhat different, but the importance is equal. Had that author lived there is little doubt that full and comparative descriptions would have been to hand; as it is, we have little more than an extensive series of beautiful and accurate figures with names applied to them, or with a few words of diagnosis. If our lepidopterists will consent for a few years to an interruption in this interminable and eminently unsatisfactory work of bare "descriptions," and combinedly commence and continue an exhaustive illustrated generic synopsis, they will earn for themselves more fame hereafter than they appear to foresee. Their present system of working only tends daily to render the subject more complicated.

The plates in Part I. of this work are of the greatest excellence so far as they go, and the colouring appears to warrant the extreme praise of not being overdone. But we confess to being more pleased with certain parallel plates on the Lepidoptera of the Dutch Indies that have recently appeared in the *Tijdschrift voor Entomologie* (the publication of the Entomological Society of the Netherlands). Our English plates of butterflies and moths too often remind us irresistibly of the sheets of figures of these insects (often beautifully executed) that appear in the shop-windows to be utilised as "scraps," or in any way the purchasers may think fit. That in the majority of cases they serve to identify the species is probable, but they lack the slightest delineation of structural details other than those shown in the general outline of the body and wings. The figures of moths are innocent of legs, innocent of neural details, innocent of palpi (unless these organs be more than usually prominent), and equally innocent of other indications that are now often considered of importance.

Many of the species here described and figured have their evident palæarctic analogues; but, in the absence of a complete list of those found by Mr. Atkinson and other Indian observers, it is impossible to form an idea as to the general nature of the Himalayan lepidopterous fauna.

R. McLachlan

MINERAL DEPOSITS

Die Lehre von den Lagerstätten der Erze; ein Zweig der Geologie. Von Dr. Albrecht von Groddeck. 8vo. pp. 350. (Leipzig, 1879.)

IN this volume the phenomena characteristic of mineral deposits are concisely treated in a manner suited for students' use. The descriptive matter is arranged under three heads, the first dealing with the forms of lodes, beds, &c., and their relations to the containing walls or "country" rocks, the second with the contents, or more particularly, with the distribution in the deposits themselves of such contents in the shape of valuable minerals; while the third is a "system of mineral deposits" arranged under different sub-sections, such as original and reconstructed deposits, beds stratified and massive, veins and other deposits filling cracks and hollows, &c.; each particular case being referred to a so-called type bearing a special name. The fourth and final section contains a theory of the origin of mineral deposits in general.

Of the matter contained, much is reproduced from the late Dr. B. von Cotta's "Lehre von der Erzlagerstätten," the last edition of which was published in 1861, the remainder being for the most part derived from papers by various authors that have appeared for the last twenty years, in different German journals, devoted to geological and mining matters.

The principal novelty is the arrangement of the third part, and this is not very satisfactory, the fifty-six types making up the "System" being based partly on structural and partly on topographical considerations, the grouping being too artificial to be of any real geological value. Thus, for example, deposits of chromic iron ore in serpentine are said to belong to the "Wooded Peak" type, because an occurrence of this kind has been reported from a place bearing that not very distinctive name in New Zealand; the famous old mines of Chessy and Montecatini are examples of the Mednorudjansk type, whose "characteristic" is given as follows: "Pyritic ores . . . in unstratified (*massigen*) rocks oftenest Diorite Gabbro and Olivine rocks (serpentine)." This particular deposit, named as the type perhaps better known as the Nishne Tagilsk malachite mine does not, however, occur in unstratified rocks, but in a mass of chloritic, argillaceous, and talcose schists, inclosed in upper Silurian limestones; the author having been led into a mistake by not properly looking up his authorities, the account relied upon being one published in a German journal twelve or thirteen years ago.

In another case, the Tellemarken-Cornwall type, the characteristic is "Lodes in sedimentary rocks, preponderating contents quartz and copper ores in varying proportions, less common are barytes, carbonates, and silicate of zinc, tin-stone, galena, &c." The examples given of this type appear to show that the copper ores of Tellemarken are not in veins in stratified rocks, but in quartz strings in granite dykes, a tolerably common class of occurrence in Scandinavia, and about as much unlike the ordinary type of Cornish lode phenomena as can well be imagined.

Many other examples might be adduced of the incongruities arising from the author's method of classification.

The accounts of the different districts are very disproportionate in value, especially in non-German countries. Thus Cornwall is dismissed in a page and a half, reproduced from Cotta's work, and the whole of the carboniferous limestone lead regions of Central and Northern England are included in a word or two about Derbyshire and Cumberland, the Silurian districts of Wales not receiving any notice. Iron ores are still more capriciously treated, the thin, stratified, spathic and clay band ores of Westphalia taking the first place, while the mighty deposits of Styria are allowed eight lines. No mention is made of either Mokta-el-Hadid, Hodbarrow, or any other of the great mines in the Furness, Ulverstone, or Whitehaven districts, Sommorostro or any other of the Bilbao mines; and, generally speaking, the great sources of supply to the iron-smelters in Western Europe are conspicuous by their absence. Against this we have to set tolerably complete notices of the iron ores of the United States, derived for the most part from Dr. Wedding's Pennsylvanian Exhibition Report.

The work being primarily intended for the use of German students may perhaps account for the circumstance that in the references only German writers are noticed, and this is so completely carried out, that in the few cases where an English or American authority is named, the titles of their works are not given. This is the more to be regretted, as the use of original memoirs might in some cases have prevented the appearance of errors in the text, obviously due to the second-hand sources of information usually relied upon by the author. The careful study of a single good memoir, such as that of the late Prof. Axel Erdmann on the Dannemora Mines, for example, would probably be of more value as a means of preparing a student for recording original observations, than the most complete knowledge of the types of the very artificial system contained in the work.

H. B.

OUR BOOK SHELF

The Climate of Eastern Asia. By Dr. H. Fritsche, Director of the Imperial Russian Observatory at Peking. Pp. 210, Maps 18. (Printed at the *Celestial Empire* Office, Shanghai.)

IN this memoir Dr. Fritsche has very fully gathered together the various meteorological observations which have been made in Eastern Asia up to the present time, and discussed them in such a way as to cast additional light on the laws of meteorological phenomena ruling in that part of the globe. With the aid of the fresh information obtained from the observations of the past dozen years which it may be remarked have been made with instruments generally of improved quality and at known heights above sea-level, he has made several important rectifications on the isothermal and isobaric lines of Eastern Asia; and stated with more adequate emphasis than has been done heretofore the extraordinary climatic influence of that enormous mass of unbroken land practically destitute of lakes and of the cold arctic currents which wash its eastern coasts.

In winter, atmospheric pressure is high on the continent, and the general movement of the atmosphere being from north-west and north, intensely cold air-currents set in southward from the arid wastes of the interior, and are carried into lower latitudes than in any other quarter of the globe. Hence the mean temperature of January in the territory of the Amoor is 18°·0 lower than that of the eastern coast of North America in the same latitudes; and even at Canton, which is just within the tropics, the temperature sometimes sinks to freezing and snow falls. On the other hand, in summer atmospheric pressure is low on the continent, and the prevailing winds being south-east and south the cold ocean currents flowing along the coast from the north powerfully affect the climate in moderating the summer-heat for some distance inland. Dr. Fritsche's isothermals show that this influence is much greater than is usually indicated on isothermal charts. An extremely interesting comparison of climates is made by an elaborate discussion of their monthly and annual absolute maxima and minima of temperature, but the conclusions would have been more valuable as well as more telling if the methods of observation had been uniform throughout. Indeed, in dealing with extreme temperatures, want of uniformity of observation frequently lays a complete arrest on all discussion.

Dr. Fritsche places in a striking light the influence on climate respectively of the warm waters of the Gulf Stream and of the colossal dry continent of Asia. In January the difference between the mean temperature of the North Pole and that of the equator is, according to Dove, 106°·0. Now, since Western Europe, which is the same distance from Eastern Asia that the equator is from the Pole, has a January temperature 50°·4 higher than that of Eastern Asia, it follows that the influence of the distribution of land and water on the mean temperature of January is nearly a half of that occasioned by latitude.

An elaborate comparison of Buchan's charts of isobaric lines for the coasts and islands of Eastern Asia with recent observations is made, with the result of an average error of one millimetre (0·040 inch). Much, however, remains to be done in settling this important physical datum of the climate of Asia; and it can only be satisfactorily accomplished by the substitution of mercurial for aneroid barometers where such are used, a more accurate determination of the heights above sea-level, and the establishment of additional meteorological stations in eastern and northern Siberia.

Report on the Pathological Histology of Epizoötic Pleuropneumonia. By Charles S. Roy, M.D. (London: published by the British Medical Association, 1879.)

AMONG the many infectious diseases which domestic animals are subject to, pleuropneumonia of cattle is one of serious importance to this, and indeed to every country. Owing to the facility with which infection spreads, the comparatively long duration of the malady, and the high mortality of the affected animals, an epidemic outbreak of this disease inflicts heavy losses on the holders of live stock and on the community at large as the consumers of articles of food derived from cattle. Every contribution to elucidate its intimate pathology, is, therefore, of value, not only in furthering a better understanding of this particular malady, and thus probably enabling us to grapple more successfully with its prevention, but also in throwing light on infectious diseases in general.

The British Medical Association, by the assistance of grants, which it bestows with laudable liberality in all cases where they are deservedly needed, has for some years been foremost in promoting the advancement of the various branches of medical science, and it has in a similar manner enabled Dr. Roy, at the suggestion of Dr. Burdon Sanderson, to carry out an important investigation into the anatomy of pleuropneumonia. To enumerate all the details of this investigation would be more than is possible in a short notice like this, and, probably more than is customary in this journal, but some of the more important results may be here briefly mentioned.

In the earlier stages of the disease the lymphatics, especially those of the sub-pleural plexus and of the connective tissue separating the individual lobules of the lung tissue, are found very much distended, being filled with an exudation which at first is chiefly fibrinous, but later on becomes crowded with cells of various sizes. The lung-tissue itself is the seat of an inflammatory process, which is chiefly characterised by the "absence of uniformity"; in some parts it is similar to what is known to pathologists as lobular pneumonia, in others it resembles croupous pneumonia. In this respect the pleuropneumonia does not differ from the lung affection in many other infectious diseases.

Dr. Roy states that in some parts of the lung there is also a hypertrophy of the muscular tissue of the parenchyma, and illustrates this with a drawing, viz., Fig. VII.; but to this we must take exception, for this figure illustrates merely the structure of a normal infundibulum, very distinct as such by its epithelium and muscular tissue.

As the morbid process advances, large sections of the lung tissue become involved in the inflammatory change, and amongst them the bronchi themselves and the lymphatic trunks leading into the bronchial lymphatic glands. No distinct evidence of the presence of minute organisms in the affected parts could be obtained.

That the malady involves, to a great extent, the lymphatics of the lung, Dr. Roy learned by first making a special investigation into their distribution in the normal lung of cattle, and as the result of this investigation several important facts were ascertained: the individual lobules possess a certain independence from one another both in their blood- and lymph-vessels; the subpleural or superficial lymphatics form a stellate plexus for each lobule; the efferent branches of this plexus join the peribronchial and perivascular lymphatics. In this last respect the lung of cattle differs from that of many other animals, for in these latter there exist special vessels leading from the subpleural plexus through the ligaments of the lung to the root of this organ.

The Report is accompanied by ten lithographed drawings illustrating very capitally the more striking features of the morbid process. We should have liked, however, to see their number increased by several additional drawings showing the distribution of the lymphatics of the normal lung.

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Temperature of the Air at Various Levels

In a treatise recently published at Prague,[1] the author, Mr. Schlemüller, proposes to establish a formula, by which the temperature of the atmosphere at any level above the surface of the earth could be calculated, a similar calculation giving also the height of the atmosphere.

Mr. Schlemüller's train of reasoning is about this:—

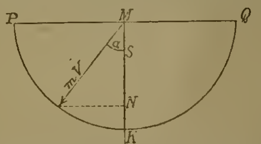
The temperature of a gas is dependent on the *vis viva* of the motion of its molecules. Now, the molecules of the air moving *upwards* are gradually *losing* their *vis viva* by the action of gravity, whereas, in moving *downwards* they *gain* velocity by the same action. It is, therefore, evident that the molecules must have more *vis viva* in the lower strata of the atmosphere than at higher levels, that is to say, the temperature of the atmosphere must *decrease* as the height *increases*.

If we know the velocity of an air-molecule at the surface of the earth, we can easily calculate the maximum height to which it can move when going up vertically. This height is the height of the atmosphere. At the upper limit of the atmosphere the molecules have no velocity at all, the temperature is there at the absolute zero. (It must be remembered that the author treats of an atmosphere not exposed to radiation.)

Now, these ideas are not new, as the author himself admits on page 9 of his treatise. He has, however, added to them two new suppositions of his own, and to these we shall confine our attention.

First, the author supposes that at any temperature of a gas the molecules have a certain velocity, which is *equal* for all of them, that is to say, the molecules move in all possible directions, but altogether at the same speed. This is, of course, a hypothesis, which can neither be proved nor refuted; it is, however, admissible. The other supposition of the author, however, is quite erroneous, and so the results arrived at by means of it are also valueless. Mr. Schlemüller supposes that the molecular velocity of gases has not been calculated rightly as yet, and he therefore proposes to correct the error. His own words are as follows:—

"Let M be a point of the wall PQ inclosing the gas. The molecules will strike this point in all directions, each of them having a mass m, and moving at a certain speed V. All the striking forces form, therefore, a hemisphere, whose radius is equal to



mV, the wall PQ being the basis of it. The acting componen of the striking force is evidently $MN = mV \cos \alpha$. All the possible components $mV \cos \alpha$ represent, therefore, ordinates of the hemispherical surface mentioned before, taking PQ as a basis."

As there is no preference for any of the directions, the mean striking force acting on the wall PQ will be measured by the mean value of all $m V \cos \alpha$, viz., by the ordinate of the centre of gravity of the hemispherical surface. As, however, this centre of gravity is situated at half the length of the radius MK from PQ, the mean value of the striking force will be $m u = \frac{m V}{2}$[2] or $u = \frac{V}{2}$ and $V = 2u$, that is to say, *the mean component of the molecular velocity taken at a right angle to the wall PQ is equal to half the actual velocity.*"

"Considering all this, we shall be able to establish a relation between the molecular velocity, the volume, and the mass of a gas inclosed in a cubical vessel. We shall follow the method indicated by Joule,[1] and introducing into the calculations throughout the mean value $\frac{V}{2}$, instead of V we get for V double the ordinary value, viz.:—

$$V = 2\sqrt{3 g P_0 V_0 (1 + \alpha t)}$$

g being the acceleration of gravity, P_0 the normal pressure, V_0 the volume of one kilogramme of the gas at 0° C. (32° F.), $\alpha = 0,00365$ the coefficient of dilatation, t the temperature in Centigrades above the freezing-point."

It seems that Mr. Schlemüller is not aware of the fact that Clausius fully twenty-two years ago published a very elaborate treatise,[2] in which he calculated the molecular velocity, supposing the molecules *to have equal velocities, but to move in all possible directions.* Now these are exactly the conditions supposed also by Mr. Schlemüller, and yet Clausius has found, just as Krönig before him—

$$V = \sqrt{3 g P_0 V_0 (1 + \alpha t)}$$

instead of Mr. Schlemüller's double value.

In another way Briot[3] has found the same result, whereas according to the theory published by the late Prof. Maxwell,[4] the molecular velocity is—

$$V = \sqrt{\frac{8}{\pi} g P_0 V_0 (1 + \alpha t)}.$$

There are thus pretty many calculations published already, all of them, according to Mr. Schlemüller, being wrong, and even *very much* wrong (viz., by 100 per cent.).

It can be shown, however, that the fault is Mr. Schlemüller's, and not Krönig's, Clausius's, Briot's, or Maxwell's. Mr. Schlemüller, according to his own statement, accepts the calculation given by Krönig (which he ascribes to Joule), simply replacing the value V by $\frac{V}{2}$. Now, in Krönig's final formula the value V^2 occurs, and this value is arrived at by a double step. First, it is shown that the force with which a molecule strikes the wall is proportionate to its velocity V; secondly, the *number* of strokes occurring in one second is shown to be also proportionate to the value V. Thus the final result is found to contain the value V^2. If the molecules are supposed to move in all possible directions, it might perhaps be admissible to make the mean striking force of a molecule proportionate to the *mean normal component* $m\frac{V}{2}$, (being the mean value of all $mV \cos \alpha$) but it is quite wrong to replace V simply by $\frac{V}{2}$, when the *number* of strokes is calculated. If a molecule of a gas contained in a cubical vessel is moving in the direction of one side of the vessel, it will strike one of the walls $\frac{V}{2a}$ times per second, V being the velocity and a the length of the vessel's side. If, however, the molecules move in all possible directions, it would be quite erroneous to suppose that the mean number of strokes per second will be $\frac{\frac{1}{2}V}{2a}$, viz., that V can be replaced simply by $\frac{V}{2}$. But that is exactly what Mr. Schlemüller does. The problem is not very easy indeed, and certainly not so simple as Mr. Schlemüller seems to think. The elaborate calculations of Clausius and Maxwell are a sufficient proof of that.

Mr. Schlemüller, having thus found his value of V, proceeds to calculate the decrease of *vis viva* of a moving molecule corresponding to a given increase of elevation above the surface of the earth, or, in other words, he calculates the decrease of temperature towards the higher regions of the atmosphere. The result found by him is a fall in temperature of 1° Centigrade to every 175·611 m. or 1° F. to 106·7 yards. Calculating further the height of the atmosphere, viz., the height which can be reached by a molecule starting at a given speed from the surface of the

[1] Der Zusammenhang zwischen Höhenunterschied, Temperatur und Druck in einer ruhenden nicht bestrahlten Atmosphäre, sowie die Höhe der Atmosphäre. Von W. Schlemuller. (Prag: Dominicus, 1880.)

[2] By a misprint the original has $\frac{m N}{2}$

[1] For we ought to know the formula for the molecular velocity was first given by Krönig.

[2] This paper was also published in the *Phil. Mag.*, 4th series, vol. xiv. p. 108.

[3] "Théorie mécanique de la Chaleur," chap. ix. § 141.

[4] *Phil. Mag.*, 4th series, vol. xix. p. 22.

earth, and going vertically upwards, Mr. Schlemüller finds the height of an atmosphere

Of pure oxygen	43,360m., or 27 miles
Of pure nitrogen	49,360m., or 31 miles
Of watery vapour	76,980m., or 48 miles

These results are, indeed, fair approximations to the ordinary values.

At the end of his treatise the author gives some formulæ which are destined to serve for the measurement of heights by means of the barometer and thermometer.

On p. 10 there is a curious statement. Supposing the air or gas to be inclosed in a vertical "narrow tube," the author thinks that the molecules will be able to make vertical movements only, and he introduces, therefore, into his calculations the mean value of the vertical components of their velocity, viz., $\frac{V}{2}$. The result is that, according to Mr. Schlemüller, the temperature in a narrow vertical tube, open at top and bottom, increases four times faster towards the bottom than in the free atmosphere. What the author considers to be a "narrow tube" he shows on p. 12, where he applies his rule to a pit or well (!). It is not too much to say that a perpetuum mobile might be constructed on that principle.

Mr. Schlemüller's formulæ for measuring heights might be perhaps accepted by some who would take the numerical results given by the author as a sufficient proof of his theory. It is, however, impossible that a theory resting on false assumptions should give correct results, and the coincidence of the results given with data derived from other sources is only apparent. First these data themselves are so varying that it is not very difficult to produce a number approaching pretty closely to some of them; on the other hand, the results calculated from a theory which supposes an atmosphere not exposed to radiation *ought not* to coincide with data derived from the *actual* atmosphere, which is far from fulfilling the conditions supposed by the theory.

Alternative Interpretation of Sensation

THE curious optical phenomena which form the subject of Mr. Ackroyd's letter (NATURE, vol. xxi. p. 108) have their analogues, as many have probably observed, in other orders of sensation. When travelling by railway, or indeed in any closed vehicle, I have often noticed that, if passing objects be shut out from view, it is possible with a little effort to mentally reverse the direction of the train, so that if sensation only were concerned, there would be no doubt as to this reversed motion. Another example of this choice of interpretation is also afforded by the sensations of motion, but in a slightly different way. Standing low down by the water, on a moving steamer or on a bridge over a rapid stream, we can at will either *feel* that we are moving through the water or that we are stationary while the water is flowing by. The same, or at any rate a very similar, choice is presented when the clouds are scudding over the moon's disk; we can either see the moon travelling behind unmoving clouds, or the clouds passing rapidly across the moon.

It would appear from the above facts that we have in certain cases the power of selecting from the experiences which have been associated with a given set of sensations that one which we wish the sensations to convey. It is difficult to see how this can be explained without admitting a certain amount of freedom of will, as the sum of our previous experience, including the sensation itself, is the same, whether we choose to go backwards or forwards, to stand still or to move on.

Curious Incubation

INDIAN birds avail themselves largely of natural heat in incubating; as breeding-time generally begins in March, the hot weather is generally well on by the time the eggs are laid, and as the temperature of the air is never below a minimum of 98° – 100° during the day, the eggs are but little sat upon except during the night, and so rest and duty are combined judiciously.

On one occasion I collected birds' eggs, and, until I could blow them, I used to place them in a drawer of my office table, and there they would lie for two or three days until I had leisure. One day, while writing, I heard strange sounds from this drawer, and opening it found a young crow (*Corvus splendens*) emerged from its egg. On a second occasion I similarly found a young myna. I tried hard to rear these strange hatchings, but failed.

One day I saw a kite's nest in the top of a fan palm, and sent up a native to bring down the contents, which turned out to be eggs. In a spirit of mischief I placed them, without saying anything to any one, under a hen which was sitting upon ducks' eggs, and awaited the result. Two days after, my fowl-man came to me with a long and solemn face, and asked permission to address me. That accorded, he mysteriously whispered, "My lord, a great wonder has occurred in the fowl-house; a marvel has happened; devils have been hatched in the fowl-house." Then began a *tableau* of descriptive acting which I cannot reproduce. "Did not I place ducks' eggs under that hen, and, my lord, have not ducks flat feet like this (flattening and extending his hand), and noses like this (compressing his thumb and index-finger); have they not, my lord?" On my solemnly assenting, he proceeded: "But these devils, my lord, have feet like this (clawing all his fingers), and noses like this (hooking his thumb and index together at his own nose)? Oh! my lord, what shall I do?" "Well, let me see these devils," I replied, sympathisingly; and we walked off to the fowl-house and found the hen sitting dazed beside her basket, in which were five recently-hatched kites. The *finale* was tragical, for the poor hen abandoned both her eggs and the kites, and the latter would have died had I not had them replaced in their nest. As it was, the ducks' eggs were abandoned.

R. F. HUTCHINSON

THE GEOLOGY OF THE HENRY MOUNTAINS[1]

THE Henry Mountains are a group of five peaks, ranging in height from 7,000 to 11,000 feet above the sea, which rise out of the table-land, now so well known to all students of physical geography, to which the American geologists have given the name of the Colorado Plateau.

They are situated in Southern Utah, and are crossed by the meridian of 110° 45′ and the thirty-eighth parallel.

They stand close upon the northern bank of the Colorado, which flows past their base in a cañon 1,500 feet in depth.

Mr. Gilbert's account of the geology of these mountains is specially interesting to the student of physical geology, on account of the explanation it contains of the machinery by which their uplift was brought about. His views have certainly the merit of novelty, and at the same time the evidence in their favour, if not quite conclusive, carries with it considerable weight.

All previous speculation on the subject of mountain-building may be grouped under two heads. Nearly all mountain ranges have a central axis or core of crystalline rock. By the older geologists this crystalline mass was looked upon as intrusive, and it was believed that the violent injection of a huge body of molten matter had lifted up the stratified rocks through which it forced its way, and shouldered them off on either side, giving them a dip coinciding in direction and approximately in amount with the slopes of the chain. A section across a mountain chain would show, according to this view, an anticlinal arrangement of the bedded rocks with a body of intrusive rock in the centre, and it was the intrusion of this central mass that was believed to have caused the upheaval. The force, then, which according to this view, raised mountains to their present elevation, was of the nature of a *thrust acting vertically upwards*.

Never, perhaps, did any theory collapse more completely than this when it came to be subjected to the test of examination in the field. As mountain chains were one by one investigated by geologists, the anticlinal arrangement of their rocks which this theory required was found to be more and more conspicuous by its absence. Marked peculiarities of structure were indeed found to be so universally present in mountain chains, that no range of hills was deemed worthy of that title

[1] "Report on the Geology of the Henry Mountains." By G. K. Gilbert. (Washington, 1877.)

unless it possessed them. But these characteristic structures were vastly different from the simple anticlinal tilting which the earlier speculators had believed to be the typical arrangement of the beds in a mountain chain. It was found that the rocks had been folded into a number of very sharp troughs and arches whose axes ran roughly parallel to the trend of the chain. The radii of some of the curves were measured by miles, while in other cases the beds had been puckered up into minute and complicated convolutions. Frequently the arches had been canted over, and inversion of the beds had been produced. Slaty cleavage had been largely developed, the planes of cleavage having the same general bearing as the axes of the range. Faulting had taken place on a large scale, and the rocks were often jammed and mashed together till a state of confusion that defied description had been produced.

No single thrust acting vertically upwards could have brought about such results as the repeated folding, the inversion, the cleavage, and the smashing; but everything pointed to powerful pressure acting in a horizontal direction which had wrinkled up a vast thickness of strata into mighty folds, and sometimes jammed them together till they became little better than a mash of shattered and ruined rock. The crystalline core was in some cases nothing more than the result of intense metamorphism; and where it was intrusive, there was every reason to think that the molten or pasty rock had been driven up through fissures by the squeezing which the rocks had undergone; in fact, so far from the crystalline centre being the cause of the upheaval, its presence was only one of the results which almost necessarily followed from the way in which that upheaval had been brought about.

All the facts then seemed to show that mountain chains had not been uplifted by a force acting vertically upwards, but had been ridged up by a *squeezing force acting horizontally* on a very thick mass of strata.

That denudation carved into shape the mass as it rose was soon realised, but we are here concerned only with the early stages in the genesis of a mountain chain.

Now one point of great interest in the geology of the Henry Mountains, is that they seem at first sight to form a striking exception to the law of arrangement, perhaps we might more properly say disarrangement, which prevails so widely in mountain chains. They might also, to a casual observer, seem to supply a case where the structure assigned by the earlier geologists to mountain ranges, and which has been looked for in vain so often, does really exist.

Careful investigation, however, shows that neither of these suppositions would be true.

The structure of the Henry Mountains is simple when compared with the complicated foldings and disturbances so characteristic of mountain chains. In the case of each of these mountains the strata are arranged in dome-shaped fashion dipping outwards in all directions from the centre. The strata of the plateau from which they rise are all but horizontal; around the base of each mountain the beds bend up and "rise, slowly at first, but with steadily increasing dip, till an angle of 45° is reached. The dip then steadily diminishes to the centre, where it is nothing." In some cases the beds slope away from a single centre, in others a great arch is made up by the confluence of a number of smaller domes.

Widely different as this arrangement is from the complicated contortion and disturbance usually met with in mountain chains, the Henry Mountains furnish no exception to the broad generalisation that mountain chains always exhibit intense convolution and smashing of their rocks. For the Henry Mountains are in no sense a mountain range. They are a group of peaks, each of which is an isolated individual; they show little or no tendency towards a linear arrangement; "they would prove perfectly intractable in the hands of those geologists who draw parallel lines through groups of volcanic vents by way of showing their trend. They are as perfectly heterotactous as they could be made by artificial arrangement."

In the case of several of the Henry Mountains the centre of the hill is seen to be occupied by a core of intrusive trachyte, from which intrusive sheets and dykes are given off. Reasoning from analogy Mr. Gilbert believes that in those cases where no such core can be seen, there still is one present under ground, but as yet uncovered by denudation. The upper surface of these cores is arched, and seems to run parallel to the bedding of the overlying rocks. It certainly looks as if we had here a case when strata originally horizontal had been bent up into a dome by the injection from below of a mass of molten rock. And this is the explanation adopted by Mr. Gilbert, but his views differ widely from those which the earlier geologists would have maintained had they been acquainted with these mountains. The earlier speculators gave to their intrusive masses a wedge-shaped form, representing them as broadening downwards and extending to the lowest depths to which geological speculation ventured to penetrate. The intrusive cores of the Henry Mountains, on the other hand, are represented by Mr. Gilbert as bounded on their under side by a horizontal plane and as resting on horizontal strata. They have, in fact according to him the shape of a huge plano-convex lens, with its flat face downwards; the curved surface is however rather a portion of an oblate spheroid than a sphere, for the trachytic masses are somewhat flattened on the top; some of them too are oval rather than circular in plan. To an intrusive mass of this shape he gives the name of a laccolite, from λάκκος, a cistern, and λίθος, stone.

His theory of the genesis of a laccolitic mountain is as follows:—Lava was pumped up through a chimney or fissure and at a certain point in its upward course spread itself out between two adjoining beds in the form of an intrusive sheet; by farther additions of lava from below the sheet is thickened, the overlying strata are more and more arched, till at last they are bent up into a dome.

Of course this involves the stretching of the overlying strata; in the case of one of the domes it is calculated that there must have been an extension of 300 feet in three miles. Mr. Gilbert has shown that this elongation is rendered possible by the fact that at the time of their flexure the beds were loaded by a crushing weight; directly the tension exceeded the limits of cohesion, and a fissure was torn open, or rather directly a fissure would have been torn open had the bending taken place at the surface, the weight of the pile of strata overhead crushed together the walls and closed the rent. That a cover of rock, perhaps 7,000 feet, and possibly 11,000 feet in thickness, would tend to this result is clear enough, but that it did not always prevent rupture is shown by the numerous dykes associated with the laccolites. Mr. Gilbert has attempted to show by mathematical calculation that at a given depth the overlying strata could not be lifted if the area of the laccolite falls short of a certain value. His method involves certain assumptions which render it somewhat unsatisfactory, and his conclusion seems to be inconsistent with the explanation he gives of the formation of a laccolitic mountain; for according to him the first step in that process is the production of an intrusive sheet. This in itself involves the uplifting of the beds above, and his calculations show that no uplifting could take place till the sheet had reached a certain size.

The failure, however, to solve by mathematical methods a problem of this difficult nature by no means implies a rejection of the theory. A much more important matter is the examination of the evidence by which the existence of these peculiarly shaped bodies of intrusive rock is supported. Mr. Gilbert has evidently seen enough to satisfy himself on this point, and we are quite willing to put every confidence in the statements of so accurate and skilful an observer; at the same time we cannot help feeling some regret that he has not been a little more explicit in his description of the sections which lay open the characteristic form of the laccolite. The horizontal base and the undisturbed state of the underlying strata are the first points on which we wish to be thoroughly assured. It is stated that "in five instances one side of the dome of strata has been washed away, exposing the core of trachyte to its base, and showing undisturbed strata beneath." We do not doubt the statement, but we should have been better satisfied if these cases had been described more in detail in the special account of the separate mountains. The views of the Marvine laccolite in Figs. 43 and 44, if we understand them aright, do seem to be conclusive on the point of the horizontal base; but the evidence would have been more convincing if these plates had been explained at greater length in the text. In fact, the one fault we have to find with the book is the difficulty of understanding the illustrations; they are not striking from an artistic point of view; in some the letters of reference are so indistinct that they can be found only with the utmost difficulty, and we confess that by some we have been fairly beaten; we should, for instance, very much like to know which is the laccolite in Fig. 33.

Again, the evidence for the parallelism between the upper surface of the laccolite and the bedding of the overlying rocks, has hardly been brought out with sufficient distinctness; after a comparison, for instance, of Figs. 25 and 26, an invidious critic might have something severe to say about the proportion which the part of the laccolite actually seen bears to that which is admittedly theoretical.

But we have made these remarks in no captious spirit; we wish merely to express our fear that the acceptance of Mr. Gilbert's ingenious speculations may be hindered by a lack of detail in the statement of the evidence he brings forward in support of them.

Assuming Mr. Gilbert's theory to be sound and good, it is not likely that the Henry Mountains are the only ones constructed on the laccolitic type. Mr. Gilbert is inclined to class under this head a number of mountains in the western territories, grouped together under one type by Dr. A. C. Beale, in a paper in No. 3 vol. iii. of the *Bulletin* of the United States Geological Survey. We cannot say that there is anything in Dr. Beale's description which would lead us to assign these mountains to the laccolitic group; and in one case, that of the Elk Mountains, the careful account given in the Report for 1874 of the Geological and Geographical Survey of the Territories, seems to show that they form a normal mountain range ridged up by horizontal pressure.

There is one problem which has been always more or less of a puzzle to the student of volcanic phenomena, on which Mr. Gilbert's speculations may possibly throw considerable light: we mean the formation of pit-craters. Mr. Scrope showed how these singular depressions had probably been blown out by one single explosion of unusual violence, and Mr. Judd has suggested their connection with intrusive sheets. If we suppose a rapid accumulation of lava in a laccolitic mass, and a sudden development within it of steam of high tension, we shall have exactly the conditions suitable for producing one of those explosions which there is every reason to think have been the cause of pit-craters.

The work contains a long and elaborate chapter on "Earth Sculpture," which space will not allow us to do more than mention, and concludes with a chapter on Economics, in which the author insists with almost pathetic earnestness, that the Henry Mountains, full of interest as they are for the geologist, can never be put to any profitable account commercially, unless possibly in parts for grazing. Nature would seem here to have laid herself out to frame a district which should have attractions for no one but the student of pure science.

A. H. G.

FINNIC ETHNOLOGY

A DECIDED stage in the progress of Finnish studies is marked by the sumptuous work on "Finnish Crania," recently published by the native ethnologist, Gustavus Retzius.[1] Continuing the investigations of his father, Anders Retzius, this distinguished anthropologist has at last been enabled to arrive at some definite conclusions both as regards the type itself and its geographical area. The elder writer was a warm advocate of what may be called the Finno-European theory, which is still popular amongst a certain school of fearless anthropologists, and which, since the discovery of the Cuneiform writings, has received a fresh impulse and a wider extension. This is not the place to discuss the angry question of the Finno-Ugrian relations to the Accad language and civilisation of Babylonia. But many enthusiasts will probably be disappointed to hear that the younger writer abandons his father's position, and deals a severe blow to the doctrine of a former wide-spread diffusion of the Finnish race over the greater part of Central and Western Europe. The laborious attempts of many ingenious philologists to discover traces of Ugrian affinities in the Italic and Teutonic tongues, and even to remove the Etruscan from the Aryan to the Ural-Altaic family, can scarcely be regarded as at all successful. On the other hand, a few ancient skulls presenting certain traits characteristic of the same race, together with some hatchets and other stone implements picked up here and there analogous in form to those often dug up in Finland, offered far too flimsy materials to supply a solid basis for such a vast superstructure. Hence it is not perhaps surprising that in the light of further investigation and more serious research the theory should prove to be somewhat visionary.

History had already pointed out that during the ascendency of the Goths from the Baltic to the Euxine the Finns were found nowhere to the west, but only to the east and north of that line; in fact in their present homes on the Volga, in Finland, round about the great Russian lakes, and more recently along the southern shores of the Gulf of Finland. It might doubtless be argued that at this period the race had farther west been already absorbed by the Slavs and Teutons of Aryan stock, intruders from Asia. But no reliable data can be appealed to in support of this position. The authenticity of the stone hammers and other objects of Oriental form said to have been found in France and elsewhere is now questioned, while the philological argument never gets beyond the purely etymological stage.

Hence Gustavus Retzius adopts the view now fast gaining ground, that instead of being the aborigines of Western and Central Europe, the Finns are amongst the most recent arrivals from Asia. Their own traditions point to the Altai region as their true home; the national usages and the spirit of the popular songs embodied in the great epic, the Kalevala, are all Asiatic rather than European, and the uninterrupted stream of their migrations westwards may still be clearly followed from their most advanced outposts in the Scandinavian peninsula through Finland, along the Volga and Kama valleys, over the Urals, and up the Obi basin to the probable cradle of their race in the Sayan highlands.

The narrower, though scarcely less interesting question of the position of the Finnic branch in the Ural-Altaic family is still surrounded with difficulties, which seem to be intensified rather than removed by the conclusions of M. Retzius. While the Finnish language is no doubt fundamentally connected with those of the other members of the group, the physical features of the race present

[1] "Finska Kranier." Skildrade af Gustaf Retzius, Stockholm, 1878.

many striking deviations from the ordinary Mongol standard. The elder Retzius had long ago distinguished four more or less marked ethnical groups in Finland itself, apart altogether from the intruding Swedes, Russians, and other foreigners. These, however, are now reduced to two only, which a careful investigation of the materials supplied by archæology, tradition, the Norse Sagas, the old national songs and philology, combined with an extensive study of a vast number of crania and living subjects, have enabled the younger writer to fix with some approach to precision.

Of the two, the Tavastian and the Karelian, he regards the latter as the genuine national type, in this differing from the commonly received opinion. The Karelians, occupying the country more to the east, are of slighter build, but better proportioned and taller than the Tavastians, of a light brown complexion, with longer head, narrower and less heavy features, long, straight, and pointed nose, dark hazel eyes, chestnut or dark hair falling in ringlets over the shoulders, open and animated expression, though still with a serious cast. The Tavastian, on the contrary, is of a much more solid, compact, and coarse build, middle size, light or ashy complexion, but always lacking the rosy tints peculiar to the Teutonic peoples, with straight silken hair of a flaxen colour, and often yellow at the tips, broad square head, short snub nose, dilated nostrils, slightly oblique greyish blue eyes, sullen and unsympathetic expression.

This description obviously corresponds far more closely with the common Mongoloid type than does that of the Karelians. Yet in the writer's opinion the latter are the true descendants of Illmarinen, the hero of the Kalevala, and the scene of his exploits is laid in the region still occupied by them. The Tavastians he regards as a distinct ethnical element of doubtful affinities, though allied on the one hand with the Esthonians of the Baltic provinces, on the other possibly with the Lapps of the Arctic regions.

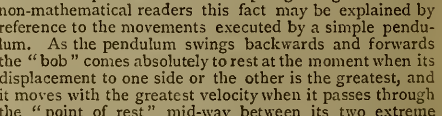
The question, as already remarked, has been advanced one stage; but much remains to be done before we can expect to see all the difficulties removed by which it is surrounded. Meanwhile it seems impossible to agree with M. Retzius, that the Karelians, rather than the Tavastians, represent the true Finnish type. Both have, no doubt, largely absorbed foreign elements. But if both are alike branches of the Mongolo-Tatar family, as has been hitherto supposed, and as their speech appears to place beyond question, it follows that of the two the Tavastians must be regarded as the nearest to the common stock. The Karelians are, of course, much the finer race, both physically and intellectually, and national prejudice may, therefore, feel inclined to regard them as the purer branch. But, ethnologists will probably be disposed to look on the improvements as due rather to a greater absorption of foreign elements, Teutonic or Slav, if not Lithuanian. They occupy a country which may well have been peopled by some of these races before their arrival, whereas the dreary lacustrine region of Tavastland must have been all but destitute of inhabitants previous to its occupation by the advanced wave of Finnish migration.

A. H. KEANE

RESEARCHES ON TELEPHONE VIBRATIONS

DR. RUDOLPH KONIG, the well-known constructor of acoustical apparatus, has recently brought before the Physical Society of Paris a research of the highest interest, upon the difference of phase which exists between the vibrations of a transmitting and a receiving telephone. In a paper published more than two years ago, Prof. du Bois-Reymond discussed the conditions which determine the intensity and the phase of different sounds transmitted telephonically; and from theoretical considerations deduced the conclusion that sounds of low pitch suffered greater loss by transmission than shrill ones, and that every simple vibration was retarded in phase by a quarter of an undulation. The former of these actions would produce an alteration in the timbre of the voice as received at the end of the line: the latter effect would remain unappreciated by the ear, since the retardation of phase was the same for waves of all periods. More recently Helmholtz has attacked the question in a paper in the *Annalen* of Wiedemann ("Telephon und Klangfarbe"), and, with a theoretical treatment of the question based upon somewhat deeper analysis, has deduced the results that all sounds are weakened by transmission in almost a constant proportion irrespective of their pitch, and that the difference of phase between the vibrations of transmitter and receiver are very small. Dr. König has endeavoured to put these conflicting speculations to the test of experiment, and with marked success.

It may be well, perhaps, to indicate the elementary considerations which led du Bois-Reymond to predict the existence of this hitherto unobserved difference of phase. The currents by which sounds are carried from the transmitter to the receiver in the Bell telephone are induction currents, excited in a coil of insulated wire by the vibrations of the iron diaphragm in front of the permanent magnet which serves as a core. The intensity of these induced currents is greatest when the vibrating diaphragm is moving with the greatest velocity. But the maximum *velocity* of the diaphragm does not occur at the moment when the *displacement* of the diaphragm is greatest. To non-mathematical readers this fact may be explained by reference to the movements executed by a simple pendulum. As the pendulum swings backwards and forwards the "bob" comes absolutely to rest at the moment when its displacement to one side or the other is the greatest, and it moves with the greatest velocity when it passes through the "point of rest" mid-way between its two extreme positions. Mathematically, the matter is equally simply stated. The displacement of a body executing a simple harmonic motion is determined by an equation of the form $u = a \cos \frac{2\pi t}{T}$, where the values of u pass through a regular series of maximum and minimum values as t increases. These successive values are geometrically represented by the heights of the ordinates of the well-known harmonic curve or *sinusoid*, the distances along the horizontal axis O x being proportional to the times. Thus the telephone diaphragm originally at rest begins to move towards the magnet under the influence of the voice. The displacement, which at the origin is nothing, increases until at A it becomes a maximum. Owing to its elasticity the diaphragm flies back, and passing rapidly through its point of starting suffers a displacement in an opposite sense. These movements are graphically represented on the harmonic



curve by the passage of the curve across the axis at B to its minimum or greatest negative displacement at C, the curve recurring from the point D. Now the equation which represents the *velocity* of the moving point will be obtained from the equation of the displacement by differentiating with respect to time. This gives us an equation of the form—

$$\dot{u} = -\frac{2a\pi}{T}\sin\frac{2\pi t}{T} = \frac{2a\pi}{T}\cos\left(\frac{2\pi t}{T}+\frac{\pi}{2}\right),$$

which is, neglecting the constant coefficient of amplitude, geometrically represented by another harmonic curve of identical form, but shifted on so that it begins at a point *a*, or a quarter of the length of the curve O O from the origin. In this second curve the heights of the ordinates represent the varying velocities of the diaphragm, the velocity being nothing at *a* when the displacement at A is a maximum, and being at a maximum at *b* when the diaphragm in flying back passes through its point of rest or has no displacement. Now of these two curves the former corresponds in phase to the movement of the diaphragm of the transmitting telephone, while the second curve corresponds to the variations of velocity, and therefore of the current transmitted, and consequently also corresponds to the motions of the diaphragm of the receiving telephone. Hence it is easy to understand that there exists a difference of phase of one-quarter of an undulation between the movements of the diaphragms of the transmitting and receiving telephones, which will be either a retardation or an apparent acceleration of phase according to the sense in which the transmitted currents traverse the coil of the receiving telephone. These considerations apply only to the telephone of Bell or its modification by Gower, in which the vibrations of the transmitting diaphragm generate the current. They do not apply to the transmitters of Edison and Hughes, which merely regulate the current. In these instruments the strength of the current is proportional to the *displacement*, not to the *velocity;* hence there is no retardation of phase.

The memoir of Helmholtz, which, by introducing certain considerations respecting the mutual inductive actions exercised upon one another by the individual turns of wire in the coil of the telephone, arrived at a somewhat different conclusion, and was principally devoted to the question of the timbre of the transmitted sounds. The previous researches in physiological acoustics of this distinguished physicist had shown that differences of phase affecting individual tones of a compound "clang" do not produce any effect which the ear can detect. This important law the present writer has, however, shown elsewhere to be true only when one ear receives the sound, and to hold no longer in the case of binaural hearing. The equations of Helmholtz indicated the unexpected result that the difference of phase between the vibrations of transmitter and receiver was a quantity so small that practically it might be altogether disregarded, and he arrived at the conclusion that all sounds were transmitted by the telephone with an equal proportionate degree of intensity independent of their pitch, and therefore with unaltered timbre. Here again, however, the writer of this article has shown that the relation between the thickness and diameter of the vibrating diaphragm affects the distribution of the magnetism induced in it by the magnet, as to whether it is lamellar or radial in character, and that this distribution has influence on the timbre of the sound emitted by the receiving telephone, the notes of higher pitch being better given by the disk in whose magnetisation the lamellar distribution preponderates, while the lower ones are better given with a preponderating radial magnetisation. The whole question of timbre of the emitted sounds requires further careful study.

The experiments which M. König has executed entirely confirm the *à priori* reasoning of du Bois-Reymond as to the existence of a difference of phase. Instead of using two vibrating diaphragms, Dr. König takes two tuning-forks accurately tuned to unison, each of them being placed in front of the magnet of a telephone whose disk has been removed, and which are united in the usual manner by wires. The first of the forks being set into vibration with a violin-bow, the second immediately begins to vibrate. The phase of each of the forks is next observed. This has been done in several ways: firstly, by direct comparison of each fork in turn with the vibration-microscope; secondly, by applying the well-known optical method of Lissajous, compounding together the two vibrations rectangularly by throwing a ray of light on to small mirrors attached to the two forks, and reflected from one to the other and then on to a screen. The figure thus produced exhibited unmistakably a difference of phase of an exact quarter of an undulation. A further experiment on compound tones was made with the same general arrangements; two forks, differing by three octaves, being made to take up, one as transmitter the other as receiver, sounds whose higher vibrations were eight times as rapid as the fundamental tone. Here again the difference of phase experimentally found for the higher tone was one quarter of a vibration.

Incidentally two very important facts have been observed by Dr. König. In experimenting he found that a tuning-fork, vibrating in front of the magnet of a telephone *whose circuit is closed,* comes to rest in a much shorter time than the same fork vibrating freely away from the telephone; also that this weakening of the sound is greater in proportion as the distance of the fork from the pole of the magnet is smaller, and also is greater for small amplitudes of vibration than for large ones. These results are not without interest in their bearing upon Mr. Edison's recent attempt to construct a dynamo-electric machine, in which the moving parts should be attached to a large vibrating tuning-fork instead of to a rotating axis. Doubtless the inventor's idea was to get rid of the friction accompanying rotation; for, as the vibrations of the tuning-fork are very nearly simple harmonic motions, and as the simple harmonic motion is the only type which can be propagated without loss by friction through a body, the motions of whose parts are coincident in phase, it might be anticipated that there would be less waste of energy in a "harmonic" engine than in a rotatory one. The important fact however remained behind that by far the greatest part of the work of driving a dynamo-electric machine was not spent in overcoming friction, but in doing the work of moving closed conductors across a magnetic field, a work which, to produce an equal amount of current, requires equal power, whether the motion be one of rotation or of "harmonic" vibration. Many years ago Foucault demonstrated the reality of this resistance to motion by spinning his gyroscope between the poles of an electromagnet; and with a Gramme machine, and also with a Holtz machine, the increased effort necessary to sustain rotation when work is being done is a familiar fact. Dr. König has now demonstrated the existence of a similar phenomenon in the case of the vibrations of the tuning-fork, which comes much sooner to rest when it is doing electrical work than when it is doing no work. SILVANUS P. THOMPSON

ON THE EOCENE FLORA OF BOURNEMOUTH

ON several previous occasions these columns have called attention to the eocene plant remains obtained at Bournemouth. The Palæontographical Society has undertaken their publication, but as this must be spread over many years, it may not be undesirable to note from time to time the principal additions to the flora as they come to light.

The specimens which I have collected this year may reach about a thousand. Among the more important are two from the marine beds east of Boscombe. One is a portion of the stem of a cactus measuring two feet three inches by three inches, showing eighty bosses of spines cleared from the matrix. A section which I have made of this presents a flattened ellipse in which the pulp is replaced by sand and the woody stem has sunk down to the lower side, though still preserving the characteristic radiating structure. The cuticle is now thin and glossy black, and bears the spines, varying from two to a dozen on each boss, arranged in the usual spiral order. Heer described similar spines from Bovey as those of a palm, notwithstanding that the regularly spiral arrangement of the clusters is perfectly shown in Mr. Fitch's drawings.

The second of the specimens is the largest of several branches with leaves, of a Sequoia-like conifer, which abounds in the higher beds east of Bournemouth Pier, yet has not been found in those west of it. The foliage and branching might be almost equally taken for *Sequoia gigantea*, *Araucaria Cunninghami*, *Creptomeria japonica*, or *Arthrotaxis selaginoides*. The stem is slightly curved and does not branch for ten inches, but then forks into six slightly diverging branchlets, each some six inches long. Two of these terminate in swollen buds which would perhaps have borne cones, and another ends in a compact cluster of budding needles without any swelling, and might have produced the male flower. This branchlet, and the great number of others that have been formed with it, were evidently shed from the trees exactly as they are seen to fall from the similar conifers at Kew. Nothing beyond branches clothed with leaves have been found, and we have only the peculiar Araucaria-like swelling of some of the terminal buds to guide us. On the other hand, branches very strongly resembling these have been found by Baron Ettingshausen at Häring with Sequoia cones attached. I think however that this resemblance to Sequoia should not at present have too much value attached to it, because both genera appear to have lived contemporaneously, perhaps from Oolitic times, until the present day.

Ettingshausen has detected what he considers the flower and a scale of Sequoia among the specimens just obtained from the Lower Bournemouth beds, so that the view I put forward that some of the coniferous twigs associated with Bovey ferns were identical with *Sequoia Couttsiæ* of Bovey is somewhat confirmed. It is again most fortunate that I was able last year to obtain a twig of one of the commonest Alum Bay conifers, formerly referred to Taxites, Cupressites, &c., with the peculiar fruit of Podocarpus, recognised by Dr. Carruthers, attached to it, and it now seems probable that there are several distinct podocarps in our eocenes.

The remains of palm obtained this year are few but instructive. I was fortunate in obtaining from a small isolated patch of clay imbedded in sand, the spathe of a palm; a slab ten inches square covered with over twenty fruit stalks; and about eighteen inches of the upper part of the broad pinna of a feather palm. There is hardly room to doubt that these all belong to the same species, and its accurate determination in that case is a matter of almost certainty.

One exceptionally large fossil dicotyledon was obtained. This is a peltate, bluntly lobed leaf fifteen inches long from the foot of the leaf stalk to the tip, and ten inches across, and is considered by Ettingshausen to be near Cecropia.

Another striking specimen is not only a perfectly new, but one of the finest ferns yet discovered. My attention was called to it by a lady, who was watching my work and whose quick eye caught sight of the unusual venation even before I did, and we gradually brought to light an almost perfect palmate pinna, large enough to occupy a plate in the monograph now being published by the Palæontographical Society. The position of the sori bodering each lobe is distinctly traceable, and this character with its membranous texture and very slender rachis place it almost unmistakably in Adiantum,[1] while the anastomosing veins further define it as belonging to the sub-genus Hewardia, now confined to tropical America. I am the more pleased with this discovery since small mutilated fragments had already attracted my attention and been figured, without our possessing any satisfactory clue to their identity. I have named it *Hewardia regia*.

[1] Or possibly Lindsæa, sub-genus Schizoloma.

While on the subject of ferns, I am pained to have to refer again to a statement I made in this paper with respect to the well-known eocene representative of *Osmunda javanica*. The Rev. Prof. Heer cannot take the expression of an opinion different to his own, in the spirit in which it is meant, however courteously it may be expressed, and I regret that I have hitherto had the misfortune to feel compelled to differ from his conclusions upon almost every subject. In a footnote to a small pamphlet entitled "Die Aufgaben der Phyto-Palæontologie," which was only accidentally brought under my notice, he replies in a manner which renders further discussion impossible. He affects to suppose that I, a much younger man, would venture to differ from him without having reasons founded on new and positive data to justify my doing so. I select one of the instances in which he thinks proper to tell me I do not speak the truth, not because this one is more easy of proof, but because it immediately concerns my present work for the Palæontographical Society. I have accurately traced the figure of what he calls *Pecopteris lignitum*, the figure of his *Dryandra rigida*, and a piece of a fossil Osmunda from Bournemouth. They are so like each other and unlike anything else that nothing need be added. Heer's voluminous work

Dryandra rigida, Heer (Skopau). *Aspidium lignitum*, Heer (Skopau). *Osmunda lignitum* (Bournemouth).

has certainly not tended to simplify the determination of this particular fossil. He had described it as *Aspidium lignitum*,[1] *Dryandra rigida*,[2] and *Pecopteris lignitum*,[3] supposing it to be a Hemitelia, and not until two years after Stur[4] had proved it to be an Osmunda, does it appear in one of his works, without further explanation, as *Osmunda lignitum*.[5] Yet the fossil agrees with the well-known *O. javanica*, which ranges from Kamschatka to Java, so exactly, and in such minute particulars (as detailed in the second part of our monograph upon ferns, in course of publication) that it seems impossible to excuse such a series of mistakes. With unexampled carelessness he has permitted the lithographer, in every one of the works quoted, to distort and make the leaf an impossible one by colouring the lower pair of veins as if they were the margins of the leaf. Having decided, in his own mind, in describing the flora of Bovey Tracey, that this Osmunda was a tree fern, he connected with it, stems, young shoots, and what he calls rhizomes, which never belonged to it, the latter resembling the stem of the Australian grass tree. Two very characteristic statements are founded on this erroneous belief, one that "in the shade of the forest throve numerous ferns, one species of which (*Pecopteris lignitum*) seems to have formed trees of imposing grandeur," the other, that *its* stems with those of Sequoia "certainly contribute the greatest amount of lignite." The real facts are that this was not at all an arborescent fern, and that no vestiges even of the trunks of

tree-ferns have ever been found in English eocenes. In the same way on the evidence of three seeds, which he supposes to be grape stones, and some cactus spines, we read that "the trees of the ancient forest were evidently festooned with vines, beside which the prickly Rotang-palm twined its snake-like form." Indeed, in addition to the error he committed in calling them miocene, all Heer's determinations of the Bovey Tracey plants require revising.

The Alum Bay leaf bed, familiar to geologists for twenty or thirty years, appears at last to have almost given out, for the leaf bearing pipe-clay is washed away to such an extent that a fortnight's stay scarce yielded a dozen of the commoner leaves. The unusual rainfall has also nearly obliterated the Hempstead section, and the face of the hill resembles a glacier of mud, which has carried trees and bushes, in place of rocks, into the sea. A lady, my brother, and myself had the misfortune to select that route home, returning from Gurnet Bay when darkness was coming on. The only passage over the deep and perfectly soft mud streams lay through the dead brushwood which fringed them. The tide was high on one side, and up the escarpment on the other lay mud and brushwood of the most impenetrable character, while with a tide still rising and darkness increasing, it appeared as hopeless to attempt to retrace our steps as to press on.

The following, from my note-book, has even less connection with fossil leaves, but the experience may be of use to geologists visiting the district.

At Alum Bay a large area of weathered chalk, usually supposed inaccessible, can be explored without much danger, for it is almost everywhere possible to descend to the sea-level between the Needles and the beacon on Freshwater Down. The face of the cliffs is traversed by numerous faintly marked tracks, which it is difficult to suppose could ever have been of service except to smugglers, for the shore line is rocky and not used by fishermen. Those who appreciate the bolder coast scenery of our white chalk will be repaid by climbs even of 500 or 600 feet, to the perfect solitude of the water's edge. If accompanied by ladies, a rope will be found a proper precaution and useful in lessening the exertion to them. One of the easiest ways is directly under the beacon, and there is a path down into Scratchells Bay, just inside the railing of the fort, whence at low tide the second of the Needles can be reached.

At Bournemouth we had a rather narrow escape. I foresaw that during this year's digging unusual caution would be necessary, owing to the heavy and saturated state of the cliff. I was obliged, however, to go through some fifteen feet of sand to reach a lower bed from which I expected to get pinnæ of *Goniopteris Bunburyi*. I had dug out a piece of this bed from end to end; a distance of about twenty feet by three or four feet wide; and the cliff above this narrow excavation consisted of some fifteen feet of vertical coarse sand, capped by indurated ironstone, and a thick black clay bed, above which the cliff sloped away at an angle. To expose a little more of the leaf bed we ventured at one point to slightly undermine the verticality of the cliff, before replacing the sand and clay we had dug out. During a pause for lunch sand fell twice upon the leaf bed cleared for work and was shovelled off. On a sudden loose pieces seemed to be falling all along the face of our pit, and with no more warning than an impulse to throw ourselves out of danger, huge boulders of clay and ironstone tore by—which from their weight were afterwards immovable to us—our excavation was completely filled in, and our tools still lie buried under the *débris*. I was helplessly buried for a few minutes up to my shoulders in sand, anticipating another slip, which fell soon after I was extricated.

J. STARKIE GARDNER

RECENT EXPERIMENTS ON RADIATION

EXPERIMENTS on radiation have a twofold interest. Accurate measurements of the increase of radiation due to an increase of temperature have of course a great theoretical value, but in addition to this, there is the practical question of a possible measure of temperature by means of the radiation of a body. It is this practical question with special reference to the temperature of the sun which seems chiefly to induce experimenters to study the subject with improved methods. It has led at any rate Mr. Rossetti to furnish a most valuable contribution to the study of radiation.[1]

Newton was the first to give a formula connecting the quantity of heat radiated by a body with the temperature of the body; but his formula was not sufficiently accurate, and has been replaced by another first given by Dulong and Petit. But Dulong and Petit's formula also breaks down when the difference of temperature between the radiating body and the inclosure is large.

Mr. Rossetti, trying to improve on Dulong and Petit's formula, deduces from his experiments the following for the radiation of lampblack:—

$$y = a\,T^2 (T - \theta) - b\,(T - \theta),$$

where y is proportional to the thermal effect of the radiation, a and b are constants, and T and θ are the temperatures of the body and the inclosure, as measured on the absolute scale. This formula seems certainly to be as far superior to Dulong and Petit's as this latter was to Newton's. The last term generally is but small compared to the first, and Mr. Rossetti believes it to be due to the effect of the surrounding air, although we do not quite see how this can be. The following experiments prove how accurately the formula may be made to represent the facts. The constants a and b were obtained by measuring the radiation of a Leslie's cube filled with water or mercury, and gradually heated up to 300°. A piece of copper foil covered with lampblack was then heated in a flame of alcohol. The temperature of the flame lies between 390° and 400°; and two numbers obtained by means of the above formula were found to lie between these limits. The radiation of a red hot copper sphere was then determined, and its temperature independently measured by means of a calorimeter. The temperatures obtained by the two methods were 762°·1 and 763°·6 respectively.

In order to find the temperature of the copper sphere account was of course taken of the emissive power of copper as compared with lampblack. For this purpose, Mr. Rossetti has invented an ingenious method to determine this emissive power of various metals at the temperature of the Bunsen flame. That a formula obtained by means of experiments made between 0° and 300° C. should give such accurate results for a temperature of 760° is already a good proof for the usefulness of the formula, but Mr. Rossetti has pushed his verification even further. A cylinder of oxychloride of magnesium was heated in a flame of coal-gas and oxygen. The temperature was found to be about 960°, and in a flame it was found to be 2,167° and 2,397° in two experiments. Platinum melted easily in the flame, and hence the temperature could not have been far wrong.

Before Mr. Rossetti can apply his formula to determine the sun's temperature, he has to determine the absorptive effect of our atmosphere; but we shall not enter here into this part of the question. The sun's *effective temperature* is the temperature he would have, if he had the emissive power of lampblack. Mr. Rossetti finds this effective temperature by his formula to be a little below 10,000° C. Taking account of the fact that the sun himself is surrounded by an absorbing atmosphere, and accepting some data given by Secchi for the amount of this absorption, the temperature of the photosphere is found to be above 20,000° C.

[1] Reale Acc. dei Lincei (3) II. 6 Jan. 1873.

Prof. Langley's observations[1] were chiefly made with the view of shewing that the low estimates of the solar temperature which have recently been made on the basis of Dulong and Petit's formula must be wrong. Prof. Langley compared directly the heat and light received by the sun with that received by the hottest luminous source he could find. He chose the mass of liquid steel obtained in the Bessemer process. The result was that the solar heat radiation was at least eighty-seven times as strong as that of the liquid mass. It is impossible to compare this result directly with the values obtained by Mr. Rossetti; but a rough idea of a fair agreement may be obtained. Mr. Rossetti fround the solar radiation to be about forty times as strong as the radiation of a lampblack body in the hottest oxyhydrogen flame he could obtain. Taking account of the emissive power of iron, we find that the radiation of the molten steel must have been a little more than half that of a black body in the oxyhydrogen flame which is possible. Prof. Langley also compared the intensity of light sent out by his two sources, and naturally found a much larger difference. We do not agree with Prof. Langley's remark that the solar light radiation is a more trustworthy indication of the total difference between the sum of all degrees of radiant energy than the heat. In fact the heat radiation is the only correct indication of the total radiant energy.

Another interesting contribution to the study of radiation was lately made by Mr. Nichols.[2] Mr. Nichols heated a platinum wire to successive degrees of incandescence by an electric current, and compared the intensity of the luminous radiation in different parts of the spectrum with the incandescence of another platinum wire kept at a constant temperature by means of an electric current. There is a great experimental difficulty in determining the temperatures of the wires, and Mr. Nichols had to content himself with measuring simply their increase in length. Matthiessen's formula will give an approximate idea of the real temperature, but it must be left to future measurements to decide how far Matthiessen's formula can be applied to high temperatures. The chief part of Mr. Nichols' work consists therefore in finding the luminous radiation of platinum, not on an absolute scale, but in terms of an incandescent platinum wire of fixed but unknown temperature. In order to reduce his measurements to an absolute scale Mr. Nichols compared the radiation of his standard with the luminous radiation of the sun, and then employed Lamansky's measurements of the heating effects of different parts of the solar spectrum. The solar spectrum is however a bad medium of comparison, owing to its discontinuous character. There is, for instance, such a strong atmospheric absorption near D that the radiation of the region near D is seriously weakened; which weakening is entirely dependent on atmospheric conditions, and therefore makes comparisons taken at different times illusory. Thus the final curves obtained by Mr. Nichols for the absolute radiation of platinum wire at different temperatures show a discontinuity near D which is evidently produced by the above-mentioned cause, especially as Mr. Nichols did not use sunlight, but light reflected from clouds.

Mr. Nichols also tries to deduce from his experiments the fact that platinum a little below its melting point has a much larger absorbing power than at ordinary temperatures. The whole argument rests however on the assumption that the temperature of a platinum wire is the same as that of a lampblack body when the relative intensity of red and blue light given out by the lampblack body is the same as that given out by the platinum wire. That is to say, Mr. Nichols assumes that the emissive power of platinum is the same for rays of all refrangibilities. But it is evident from Mr. Nichols' own measurements that the temperature of a petroleum flame (used by Mr. Nichols) determined in this way is found much too high. It does not require a large correction in this temperature to bring the value of reflective power of platinum at the temperature and by Mr. Nichols to the same value as that found by Provostaye and Dessains for ordinary temperatures. In the memoir of Mr. Rossetti, an idea of which we have tried to give above, this reflecting power of platinum is directly measured at a temperature of the Bunsen flame, and was found to be strikingly in accordance with the number given by Provostaye and Dessains.

ARTHUR SCHUSTER

[2] "Ueber das von glühendem Platin ausgestrahlte Licht," E. L. Nichols. Göttingen: E. A. Huth.)

NOTE ON A CONSOLIDATED BEACH IN CEYLON

A SOMEWHAT interesting consolidated beach exists on the west coast of Ceylon, a few miles to the north of Colombo. The writer had only one opportunity of visiting and examining for a short time this formation: but there are certain features in connection with it that cannot fail to be of interest, however short the examination may be. The beach extends continuously in almost a straight line for about four or five miles, and is manifestly in process of formation at the present time, as some portions of it are so soft that they can be easily crumbled in pieces by the hand, whilst others are much harder than gneiss, and can only with the greatest difficulty be fractured by means of a heavy hammer. Between these extremes are all gradations of hardness, and the ordinary shells of the coast may be found in almost every part of the beach more or less firmly embedded in the rock. The highest part of the formation is just within reach of the waves at high tide; but it is difficult to ascertain with any degree of accuracy how far it extends into the sea, on account of the difference between high and low tide being only about two feet. The beach is seen at a glance to be composed chiefly of a faint brownish-coloured rock, with frequent strata of black material of very varied thickness and irregular shape. An examination of specimens shows that the brown rock is composed almost entirely of quartz fragments, and that it possesses only a low specific gravity (2·91), whilst the darker portions are extremely heavy as well as extremely hard. Several specimens gave a specific gravity of 3·9, 3·93, 3·94, the dried sand, freed from its carbonate of lime by means of dilute hydrochloric acid, possessing a specific gravity of 4·32. A microscopic examination of this sand and also of sections of the rock showed that the chief constituent, and that which gave it its dark appearance, was magnetite, corundum in various forms being also present, with here and there a fragment of quartz. One noticeable point was that the fragments of the harder constituents were in nearly every case hardworn, and rounded, whilst the quartz showed traces of recent fracture in the shape of sharp edges and angles. The size of these fragments varies very considerably, those of magnetite ranging from ·005 inch to ·02 inch, whilst those of quartz are much larger, frequently reaching ·04 inch. The corundum fragments are intermediate in size and rounded in form. It must be remembered that these specimens were taken from only one part of the formation, near the centre of its length and about the limit of high tide. In other positions the fragments will, no doubt, vary very much, the size depending in a great measure on the power of the current to carry them along the coast and up the beach. It was a matter of regret to the writer that he was not able to inspect carefully both extremities of the reef, and examine fragments from many different portions of it. The cementing material of the beach is carbonate of lime, no doubt from the coral reefs along the coast, as there is no limestone rock in the neighbourhood or along the course of the Kelani River, which debouches to the south of the reef. It is not known whence the magnetite and corundum have been derived, except that they have possibly come from the degradation of the gneiss rocks occurring along the coast. Although corundum is comparatively abundant in the interior of Ceylon, it has never been found in its matrix, but always either in pocket holes in streams, or in drift, intermixed with rounded pebbles of quartz. The character of the rivers in the neighbourhood of the coast apparently precludes the possibility of fragments of corundum being carried down to the sea.

A closer examination of the structure of the beach reveals the fact that the heavier particles are frequently deposited in extremely thin strata, transverse sections of which exhibit the most beautiful curves. Examples of this are seen in Figs. 1 and 2, which are half the natural size, the light parts representing quartz, the dark ones

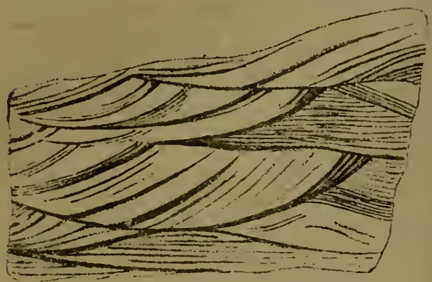

Fig. 1.—About one-fourth natural size.

magnetite. The explanation of this is apparently simple. When the quartz fragments of which the larger portion of the rock is formed have become consolidated, depressions will be formed by the heavy particles of magnetite under the influence of the waves, very much after the manner in which pocket holes are formed in the rocky beds of nearly all the mountain streams in the island. (It was in these pocket-holes that the earlier sapphires were nearly always found.) When once commenced this scouring process would go on as long as the water was sufficiently agitated to keep the fragments of magnetite in motion. Their superior weight would have a tendency to keep them in the hollows they had formed, and the carbonate of lime in the water would fix them in position as soon as they were left undisturbed by the waves. The succeeding waves

Fig. 2.—About one-fourth natural size.

hat reached the hollow would fill it chiefly with quartz fragments which would become cemented together, and the process of scouring would go on as before.

It may be noticed in explanation of the very beautiful skein-like appearance of Fig. 2, that when once a stratum of magnetite had become consolidated, it would be much less liable to be removed by the scouring process than the neighbouring quartz, on account of its superior hardness, and therefore the original shape of the basin has been retained, whilst other basins, represented by the dark lines, have been formed above it, differing only slightly in shape from the original one. Some portions of this beach are quarried for edging and coping stones which are sent to Colombo. R. Abbay

ON THE POTENTIAL DIMENSIONS OF DIFFERENTIATED ENERGY[1]

IN his great work, which appears to be but little known in England, "Ueber die stille Bewegung hypotetischer Körper," Prof. Hans points out that the dimensions of "ideal" matter may not only differ in degree, but also in kind. He deduces, by means of implicit reasoning from his three primitive "stations," that not only must there be space of 4, 5, 6, &c., dimensions, but also that there must be space of − 1, − 3, − 5, &c., dimensions, and that there may be space of − 2, − 4, − 6, &c., dimensions. Pursuing Hans's train of thought further, Lobwirmski has quite recently interpreted space of 1·1, 1·2, 1·3, &c., dimensions. Not only has fractional space been thus proved to exist, but the same philosopher has also conclusively shown that if space of $n . \sqrt{-1}$ exists, it has all the properties of angular magnitude; *e.g.* like all partly bounded infinities (*theilweise begränzte Unendlichkeiten*), it is unmagnifiable.

These speculations, which are really rather more hyperphysical than metaphysical, immediately suggest the analogous kinematic considerations, and have led me to examine the potential dimensions of differentiated energy. Before pointing out the main conclusion to which I have been led, let me make quite clear the meaning of the terms employed. "Differentiated energy" is that energy which would survive if all matter were destroyed, and simultaneously re-created in such a manner that all its properties were inverted. By "potential dimension" I mean the dimension which, by reason of the kinetic energy of all other dimensions, is only able to vary according to Lobwirmski's groove (*Kleise*).

Let us start from the idea of what is ordinarily conceived to be a Thing, and imagine the Thing itself (not its measure) to be saturated with the property *a*, after the manner in which the circle is saturated with the straight line in the spiral watch-spring (*spiralförmiger Haasesprung einer Wacht*). Further, let us suppose *a* to change in such a way that all previous values of any one attribute other than those dependent on its rate of variation can be arranged in a series, the functionally alternate terms of which, up to a certain number whose value will be given by taking each turn separately, and finding to what amount its *a* property may, under the influence of the given "groove" exceed the *a*-property of its immediately antecedent term, represent any convenient converging series. The vigour of this change being, as usual, measured by the degree of matter affected, and also by the index of change in a given time, we have at once the simple relationship

$$a = \left\{ \begin{matrix} \beta \\ \gamma \end{matrix} \right.$$

Accordingly, it is obvious as one of the simplest corollaries from the above, that if we know the present position, mass, direction of motion, and velocity of a given piece of matter, we should be able within certain limits to calculate its chemical composition.

As an example of the application of this let us suppose that the earth's satellite M has the mass C; let its direction of motion at *any* given time *q* be N. Let its rectangular co-ordinates, at the same time, measured from the absolute zero of position, be *m*, *n*, and *p*. Let O be its velocity, and H an arbitrary constant. We have, substituting in the above equation—

$$M = C_m N_n O_p H_q,$$

which has, at least, no closer resemblance to any other body than it has to caseine. A. V. Nudeln

[1] The correspondent who has received the above letter has forwarded it to us for publication. We are not aware that the general scientific opinion in Germany is in consonance with the results reached in the letter.

A TIDAL PROBLEM

THE so-called *seiches*, or alternate flux and reflux of water in the Lake of Geneva and other bodies of fresh water, have, as our readers know, formed the subject of an interesting study during the past decade by Dr. F. A. Forel, of Morges, near Geneva. Small local tides are constantly noticeable there, the difference between ebb and flow varying from a few centimetres to 2 metres. Their cause is to be traced to the wind, variations in atmospheric pressure at the extremities of the lake, &c. Dr. Forel, as the result of his investigations has established a formula by means of which the duration of a local ebb and flow can be determined—not only for the Lake of Geneva, but for any lake—when its average depth and its length are known. The following is the formula $T = 2\frac{2L}{\sqrt{gh}}$, in which L denotes the length of the lake, h its average depth, and g the acceleration of gravity. This formula gives for the Lake of Geneva, which has a length of 73 kilometres, a duration of tide of 13 minutes; a figure coinciding with the fact.

The law thus established by M. Forel has recently received an interesting application in solving a problem which has puzzled travellers and philosophers for over 2,000 years, viz., the explanation of the currents in the narrow straits of Euripus, where the famous five-arched bridge of Egripo joins the Island of Eubœa to the mainland of Greece. The currents sweeping below the bridge are so violent that mills are kept in operation by them, but they are noted for the changes in direction which occur from four to fourteen times daily. Tradition relates that Aristotle, in despair at his inability to explain this phenomenon, threw himself from the bridge into the water.

A comparison of the large number of observations made upon this strange tidal movement shows that there are two distinct periods: that in which there are but four changes of direction or two tides in a lunar day of 24 hours and 50 minutes, and that in which these tides number from eleven to fourteen daily. This latter phenomenon is observable invariably at the quadratures of the

moon. M. Forel, in his explanation, shows that the regular ebb and flow twice a day in the former period is due to the tidal movement of the Ægean Sea, which is then at its maximum. The increase in the number of tides daily becomes manifest, however, when the tidal force of the Ægean is at its minimum, viz., at the quadratures, and must be owing to some other force more powerful than the minimum but less powerful than the maximum force of the Ægean tide. This force is found in the local tides or *seiches* of the Gulf of Talanti to the north of the straits, which is so shut in by land that it can practically be regarded as subject to the same laws as the lakes of Switzerland and other countries. This basin is 115 kilometres long, and is from 100 to 200 metres in depth. Applying these figures to M. Forel's formula, the ebb and flow in the Gulf of Talanti would be for 100 metres, 122 minutes; for 150 metres, 100 minutes; for 200 metres, 86 minutes. The eleven to fourteen currents observable daily at Euripus during the quadratures last from 103 to 131 minutes. This shows so striking a conformity with the theory advanced by the Swiss *savant*, that we can but consider this problem, which so vexed the ancients, as fairly solved.

Dr. Forel asks intelligent visitors to the locality to verify his interpretation by attending especially to the following points:—1. Ascertain the exact duration of the flux and reflux of the Euripus, and determine its normal rhythm. 2. Ascertain if, as in the *seiches* of the Lake of Geneva, the amplitude of the flux and reflux of the irregular current is stronger in bad weather than when there are no atmospherical perturbations. 3. Ascertain if the connections between the direction of the current and the flow of the rising sea are, as he supposes, inverse, according as the current is regular or irregular.

NOTES

THE great osteological collection which Dr. Barnard Davis, F.R.S., has accumulated during a long life devoted to anthropological pursuits is well known, both in England and abroad, as the richest and most valuable ever formed by a private individual, exceeding, as it does, in variety and rarity of the specimens all the public collections of this country and most of those on the Continent. It contains about eighteen hundred specimens of skulls and skeletons of various races of men, the value of which is greatly increased by an excellent catalogue, called "Thesaurus Craniorum," in which each is fully described, and all known particulars of its history recorded. We believe that, at one time, Dr. Davis contemplated leaving the collection to the College of Surgeons; but considerations for the interests of his family do not appear to have justified this arrangement, and he has now offered it for the sum of 1,000*l.*—which, considering its extent, and the labour and time taken in its formation, must be considered very moderate. Upon this becoming known to the Council at their meeting on December 11, through a communication of Prof. Flower, we learn from the *British Medical Journal*, it was the unanimous feeling of all present that the opportunity of acquiring it upon the terms offered by Dr. Barnard Davis should not be lost. It was referred to the Museum Committee to consider and report whether the necessary sum could be provided out of the College funds, or whether it was desirable to seek for aid from other sources; for the latter alternative several liberal offers were at once made by individual members of the Council. We feel sure that all who are interested in the scientific progress of the country will have great satisfaction in knowing that the Council of the College have thus promptly stepped forward to save this noble collection from dispersion or expatriation; and that, if it should be thought that the College funds cannot judiciously be taxed at the present time, the country will as promptly respond to an appeal for such a truly national purpose. The Hunterian Museum, thus enriched, would more than ever become the great centre of osteological and anthropological research and instruction, and in the hands of Mr. Flower we may be sure that this collection would be so arranged, developed, and studied as to be rendered in the highest degree available for the advancement of knowledge. It is an opportunity which must not be let pass.

THE following translation of a Chinese placard regarding the highly immoral practice of consuming cow's milk is sent to the *Foochow Herald* for publication:—"Strictly refrain from eating cow's milk! Man should not rob the beasts of their food. Moreover of all beasts the cow is the most useful and meritorious. Men who do not discriminate between mankind and beasts are worse than senseless. Those who sell milk darken their consciences for gain, and those who eat cow's milk foolishly think they are benefiting their bodies. Men who take medicine should first carefully investigate and find out its nature. Why do not those who eat cow's milk consider and inquire into its origin? For instance, men beget children, and while the children are small they depend upon milk for their nourishment; so it is also with beasts. But when men buy milk to eat, do they not do injury to the life of the calf? And is there not bitter hatred and distress in the minds of both cow and calf? Beasts cannot speak: how then are they able to tell the man that, in eating the milk of beasts, his body becomes like that of birds and beasts? But if men wish to take strengthening medicine, there are numberless other articles in the world that are beneficial; and what necessity then is there for taking cow's milk? Besides this, the death and life of men have their fixed number and limit, and this cow's milk cannot lengthen out and continue the life of man. Since, then, all know the truth—that it cannot do this, all ought to act with loving and benevolent spirit. Especially all who receive this exhortation should keep from eating milk. The children of those who cause their families to refrain from eating milk will be preserved to grow up; they also will thus lengthen out their own lives, and will escape from evil in time of fatal epidemics. If such persons be able also to exhort others, who are ignorant of first principles, to leave off the eating of milk, their descendants shall surely prosper. Published by the Hall of Good Exhortations. The Xylographic blocks are deposited in the Ung Ling Kóh."

AN important discovery has just been made in the neighbourhood of Elbœuf, Seine-Inférieure, by M. Noury. He has found a multitude of pre-historic implements in the siliceous sands which form the sub-soil of the Seine valley, between Elbœuf and Rouen. In a single locality he collected more than 400 among bones of large quaternary mammals. These implements are said to belong to the palæolithic age; they consist of cut flints forming axes, cores, punches, and hammers of various dimensions.

WITH reference to the discovery of a jade scraper at Geneva, referred to in NATURE, vol. xxi. p. 163, Prof. Max Müller writes to the *Times*:—"Scrapers or cutting instruments made of real jade are very rare, in Switzerland and elsewhere, but I have myself seen several beautiful specimens—among the rest, one found by Dr. Uhlmann, of München-buchsee, whose collection of lacustrine antiquities, all taken out by his own hand from one and the same small lake, the Moossee-dorfsee, is perhaps the most authentic and most instructive collection in the whole of Switzerland." Prof. Müller does not see any difficulty in believing that the early "Aryan" immigrants into Europe brought with them and preserved, "from generation to generation, so handy and so valuable an instrument as a scraper or knife, made of a substance which is *ære perennius*." On the same subject Mr. B. M. Westropp sends the opinion of M. Desors, as follows:—"We cannot share the opinion which attributes extensive commercial relations to the tribes of the age of stone. In support of this opinion are cited the hatchets of nephrite (jade), of which numbers are found at Concise and other stations of that epoch; and as this stone now comes to us from the East, it has been inferred that the tribes of the remote period in question trafficked with Asia. But it should be remembered that the greater part of the hatchets which are assumed to be nephrite may very well be only varieties of indigenous rocks, proceeding from siliceous veins in the serpentine, and whose depository might be found, according to M. de Mortellet, in the higher Maurienne. It seems to us very difficult to admit that so distant a commerce should have been restricted to the exchange of certain stones, which, after all, are not very superior to common silex, while the East might have furnished objects of far greater utility, particularly metals."

ONCE more the New York correspondent of the *Daily News* telegraphs of Mr. Edison's success in electric lighting. "Mr. Edison," we are told, "has perfected an electric lamp of extraordinary simplicity, costing only 25 cents, with which he proposes a general illumination of the village of Menlo Park on New Year's Eve. He has discovered that a steady brilliant light is obtained by the incandescence of mere carbonised paper better than from any other known substance. Strips of drawing paper in horse-shoe form are placed in a mould and baked at a very high temperature. The charred residuum is then attached to the platinum wires and hermetically sealed in a glass globe from which the air has been exhausted. This attached to a wooden stand, or ordinary gas fixtures, is the whole lamp. No regulating apparatus is required, the flow of electricity being automatically increased and diminished at the central generating station. A single generating machine of simple construction, and applicable for domestic use, supplies about fifty lamps. The cost of the power is not stated. The quantity of electricity supplied to each householder is measured by the deposit of copper particles in an electrolytic cell."

M. A. GUYARD claims to have discovered another new metal of the platinum group which he names uralium, from the Ural Mountains, whence the ore is procured. There have been quite a flood of similar announcements lately. We have now gallium, davyum, mosandrum, neptunium, decipium, phillipium, norvegium, scandium, ytterbium, holmium, "X," thulium, and uralium. Chemists will have to keep as narrow a watch on these minor elements as our astronomers do upon the minor planets, or we shall not know where we are.

IN a paper on the destruction of obnoxious insects, by Prof. Hagen, of Harvard, in which he describes some experiments that had been made by Mr. J. H. Burns and others, he comes to the following conclusions:—1. That the common house-fly is often killed by a fungus, and that in epizootics a large number of insects which live in the same locality are killed by the same fungus. 2. That the fungus of the house-fly works as well as yeast for baking and brewing purposes. 3. That the application of yeast on insects produces in them a fungus which becomes fatal to the insects. 4. That, in the experiment made by Mr. J. H. Burns, all potato-beetles sprinkled with diluted yeast died from the eighth to the twelfth day, and that the fungus was found in the vessels of the wings. He admits that further experiments are necessary to find out the most convenient method of application.

WOOLWICH is taking a step ahead in the use of the electric light, a number of tradespeople in that suburb being now supplied by Messrs. Siemens, who have set up for that purpose three of their most powerful machines. Power is supplied from the steam-engines of Messrs. Rose and Mellish's establishment on the river bank, when the day's work is over. The lights are maintained from 6 P.M. till midnight.

A CORRESPONDENT sends us the following account of the recent severe weather at Mulhouse; it is contained in a letter from Mr. Alfred von Glehn:—"I must give you some description of the fearful weather we had last Friday (December 5). No one here ever remembers such a day. On Thursday night it began to rain, the thermometer being about 8° below freezing, then came lightning and thunder, and then the most terrible wind got up, with driving snow; it lasted all night and next day. It blew a hurricane, thermometer about 20° F. below freezing, and all the time the snow fell so thick that you could not see a yard before you. I really hardly know how I got to the works; one could hardly breathe, and at certain open places one could hardly stand, and I saw people have to turn back and take refuge in shops. No trains could run; one was stopped between here and Bâle, and the people had to come back as best they could on foot. A goods train was snowed up between here and Cernay, and was only got out on Sunday. Two factory chimneys were blown down, and numberless smaller accidents occurred. We had to allow the workmen who live in the country to start for their homes at three o'clock in the afternoon, as at night it would have been impossible for them to find their way. Everywhere in the streets stood carts abandoned by their owners, as the horses could not move them. One train was got ready for Strassburg, with four engines, but it stuck just outside the station, and could go no farther. The next day the weather was fine and cold. Sunday night the thermometer fell to 40° F. below freezing, and at 12 o'clock in the middle of the day with a bright sun stood at 0° F. This morning it went down to 51° F. below freezing, and when I went to the works it was only a few degrees less. The air is fortunately still, and as there has been bright sunshine everything is wonderfully beautiful. Skating is unfortunately out of the question, owing to the masses of snow. Sledges are to be seen on all sides, even the cabs are mostly sledges, and those who have horses are to be envied, as the roads are in a splendid state."

THE *Derry Journal* of the 10th inst. states that on the previous Saturday, at about 11.30 P.M., the inhabitants of Stranorlar, county Donegal, and for many miles around, were startled with a strange and unusual sound. It resembled the noise produced by the falling in of a large building, and in some cases the commotion was so powerful that chairs and other household articles were seen to move. The phenomenon is believed to be a slight convulsion of earthquake, and much resembled distant thunder. Mr. Thomas Watson, of Derry, writes that a similar disturbance was noticed at exactly the same hour at Barons Court, the seat of the Duke of Abercorn, in county Tyrone, and was sufficiently intense to cause the candelabrum in one of the large rooms to shake very perceptibly, the noise at the same time being very loud, and of a nature that puzzled those who heard it to explain. It seems to have been in some way connected with an earthquake wave which appears to have taken the direction almost east and west.

IN a recently-received report from Guayaquil, it seems that the bad season of 1878 had a most serious effect upon the produce of the soil in that country. The cocoa crop (*Theobroma cacao*) was the smallest on record, though the high prices obtained for this article in the European markets have in some degree compensated for the loss. The coffee crops gave even a worse result, as during the last months of the year it was found necessary to import coffee from Central America for home consumption. The quality of the coffee produced in Guayaquil during the year was very inferior. The rice plantations having been almost entirely under water, owing to the heavy rains, for a long period during 1877 and 1878, the production of this article of food (of which, in the coast provinces of the Republic alone, 5,000 quintals per month are consumed) was very limited. The cotton plantations were also destroyed by the same cause. The failure of the above-mentioned crops left a large number of men free to attend to the collection of india-rubber and ivory nuts. The export of the former during 1878 was a little below that of the preceding year, owing doubtless to the scarcity of the trees producing it, and the difficulties of bringing it down to the coast from the inland forests, where it is gathered, each year made more distant from the ports of embarkation owing to the continued wanton destruction of the trees. The quantity of ivory nuts gathered and exported by far surpassed all previous years.

THE *Pharmaceutical Journal* of December 20 contains a valuable report on the botany of the Kuram and Hariab districts, by Surgeon-Major J. E. T. Aitchison.

A NUMBER of papers on the hymenoptera and coleoptera of the United States, by Messrs. E. Norton, C. A. Blake, and Dr. Horn, are in course of publication in the *Transactions* of the American Entomological Society of Philadelphia.

FROM the *American Naturalist* we learn that Thos. G. Gentry is engaged in a work on the fertilisation of plants by insects, based on observations made in Pennsylvania and New Jersey, and that Prof. O. S. Jordan is preparing a work on the Fishes of North America.

A FAVOURABLE report was presented at the last meeting of the Eastbourne Natural History Society.

IN a recent volume of the *Ann. de l'Obs. Roy. de Bruxelles* (September, 1879, 84 pp.) M. Fievez gives a comprehensive bibliography of works, treatises, and notices on spectroscopy. An index facilitates the search for any particular point relating to the subject.

THE Russian Technical Society will hold an exhibition of the latest Russian and foreign technical machines, apparatus, instruments, and inventions, from December 15 until May 15 next, at St. Petersburg.

A PAPER of great value on the Geology of the Lower Amazons, by Mr. Orville A. Derby, read before the American Philosophical Society, has been issued in a separate form.

THE *Transactions* of the Cumberland Association for the Advancement of Literature and Science for 1878-9, is a volume of 340 pages, edited by the Rev. J. Clifton Ward. Among the numerous excellent papers contained in the volume are the following:—An ethnological paper by Mr. R. S. Ferguson, entitled "The Formation of Cumberland;" "Our Summer Visitors," a local natural history article, by Mr. T. Duckworth; an interesting paper on the Dipper (*Cinclus aquaticus*) by Mr. William Duckworth; "The Entomology of the District," by Mr. George Dawson; "The Great Lake, Lagoon or Bay of Triton," by Mr. B. A. Irving; "List of Cumberland Birds in the Carlisle and Keswick Museums," by Mr. George Dawson and the Rev. J. Clifton Ward.

PHYSICAL NOTES

SOME useful observations on the action of safety valves on boilers have been recently communicated to the Vienna Academy by Herr von Burg (November 13). Among other things it is proved that the authoritative directions given in different countries as to the size of safety valves are not at all adequate, and are based on erroneous conceptions. As to the cause of the small amount of lifting of the valve during escape of steam (seldom over ½ mm.), the author at first supposed a vibratory motion of the valve, but further study and experiment led him to the hypothesis that the steam jets, in lifting the valve, do not begin to move from its middle point, but from the periphery of a circle, ρ, out to the circumference of the valve of radius r; so that the pressure of steam on the under surface of the valve is composed of two parts, of which the inner, or *aërostatic*, is produced by the solid steam-cylinder of radius ρ, and the outer or weak *aërodynamic* part, by the external hollow cylinder of $r-\rho$ thickness of wall. The phases of development of steam tension, and other topics, are also investigated.

A SIMPLE method of perforating glass with the electric spark is described by M. Fages in a recent number of *La Nature*. The apparatus required consists (1) of a rectangular plate of ebonite, its size, for a coil giving 12 ctm. sparks, about 18 ctm. by 12; (2) of a brass wire passing under the plate and having its pointed end bent up and penetrating through the plate (not further). This wire is connected with one of the poles of the coil. A few drops of olive oil are placed on the ebonite plate about the point, and the piece of glass to be perforated is superposed, care being taken not to imprison any bubbles of air. The olive oil perfectly accomplishes the object of insulating the wire. One has then only to bring down a wire from the outer pole of the coil, on the piece of glass, above the point of the lower wire, and pass the spark. By displacing the glass laterally, for successive sparks, it is easy to make a close series of holes in a few seconds.

IT has often been queried what might be the reason of the high specific heat of water. Some light has been thrown upon this problem by the recent research of a Russian gentleman of the name of Beketoff, upon the specific heat of the hydrogenium-alloy of palladium, and upon that of the hydrogen in the alloy. The specimen examined by M. Beketoff contained about half per cent. of hydrogenium to ninety-nine and a half of palladium. On examination by careful calorimetric measurements the specific heat of hydrogenium was found to be not less than 5·88; which though probably requiring correction is certainly not greater than the true value. The value should be somewhere about 6·4 by the law of atomic heat of Dulong and Petit.

A VIBRATION micrometer for ascertaining with precision the amplitude of vibrations of tuning-forks and other sounding bodies was recently shown in Paris by M. Mercadier. It is an extremely simple device and can be applied to any vibrating bodies except such as possess very small mass. A small piece of thin white paper bearing one fine black line is affixed to the body whose vibrations are to be measured. If this line is upright, it will, when caused to vibrate, present the appearance of a pale grey parallelogram, the persistence of the visual impression being perfectly definite for the extreme positions of the vibration. To ascertain the amplitude of the vibration, all that is necessary is to measure the apparent width of this minute parallelogram in a direction at right angles to the axis of symmetry of the oscillations. To do this with still greater precision, M. Mercadier proposes to set the line not perpendicular to the direction of the movement, but inclined to it at a small angle, and marks also upon the paper a fine scale of lines parallel to the direction of the movement and distant from one another by equal distances of one millimetre. The width of the narrow parallelogram is thus read off along a straight line, which makes a small angle with its sides, thus giving the quotient of the amplitude sought by the tangent of a small angle. Using this method, M. Mercadier showed that the vibrations of a tuning-fork "interrupter," vibrating automatically under the influence of an electro-magnet, may be regulated so as to be greater or less at will by adjusting to a greater or less distance from the prongs of the fork the electro-magnet which maintains the vibrations.

PROF. TAIT has abandoned the enticing speculation that the thermal conductivity of metals is inversely proportional to their absolute temperature, a conclusion to which his earlier experiments on the conductivity of iron seemed to point. Many metals, indeed, present the opposite case, their conductivity increasing with the temperature.

A MEANS of comparing the intensities of lights of different colours has long been desired. Until quite lately there did not even exist a means of measuring the relative intensity of two lights of the same given colour. M. Gouy has been investigating the latter point by the aid of a particular photometer, and by flames of constant brilliancy produced by the combustion of a homogeneous mixture of coal-gas with air impregnated with saline powders. The photometer resembles in general appearance a two-prism spectroscope, having also an auxiliary collimator with a fixed lamp to serve as a standard light. In place of the usual eye-piece of the instrument a second slit is placed. By this means any one ray can be separately observed, and its intensity compared with the intensity of the same ray from the standard source. M. Gouy states that this slit eye-piece arrangement is capable of such accurate adjustment that each of the two D-lines can be separately examined and its intensity measured.

MARAT, the notorious hero of the first French revolution, the same who met his death at the hands of Charlotte Corday, was the author of several important essays on electricity. This fact, which is not generally known, was recently brought to notice by Mr. A. J. Frost, who is editing the catalogue of the Ronalds Library. Most of Marat's works were written between 1779 and 1785, and several of them were translated into German. Marat was not the only one of the prominent figures of the time who worked in physical science. Arago, though his fame does not rest upon his political achievements, once enacted the chief part in the crowning of the statue of Liberty. "Citizen" Charles was as famous amongst the revolutionists as for his scientific attainments. Robespierre wrote an article on the lightning-conductor for the *Journal des Savants*; and last, but not least, Napoleon Buonaparte on many occasions dabbled in scientific lore, and was the liberal patron of men of science.

EDISON'S telephone has, it is said, been successfully used over a line of 2,000 miles in length. A hunting party in Nebraska were thus enabled to converse with perfect distinctness with their friends in Pennsylvania, *viâ* Chicago and the Western Union Telegraph Company's line.

GEOGRAPHICAL NOTES

THE Neapolitans are preparing to *fête* Prof. Nordenskjöld, who intends staying a short time in Southern Italy before returning overland to Sweden. The *Vega* arrived at Galle on the 16th inst. We have received from Hongkong an account of the reception given to Prof. Nordenskjöld and the officers of the *Vega*, on arriving at that Eastern limit of the British Empire. At the close of an official banquet at Government House, Governor Hennessy congratulated Prof. Nordenskjöld and his staff in the warmest terms. "We behold," he said, "as it were in this remote outpost of Europe, the writing of the last words in the last chapter of heroic maritime discovery." Captain Palander brought down to the drawing-room the actual charts he had used during the voyage, and throughout the evening they were inspected by the Governor's guests with great interest. The charts were Russian ones, and one of the minor results of the expedition has been the establishment of the fact that they are not accurate, inasmuch as a great deal that was put down as land was actually sailed over by the *Vega*. The route was marked in red ink and pencil and showed these inaccuracies. Some specimens of the plants from the region where the *Vega* was so long bound up in the ice and photographs of the natives were also on the drawing-room tables. We understand

Prof. Nordenskjöld, before his departure, received from his Excellency, as a present to the *Vega* expedition, an herbarium of the plants of Hongkong and South China, prepared by Mr. Ford, the head of the Botanical Department of the Colony.

ZANZIBAR advices report that the Abbé Debaize, the French explorer, was on the 13th of June at Ujiji, on Lake Tanganyika. He was waiting for some boats to go to the north of the lake, and meanwhile was examining neighbouring rivers and some points on the lake. At the beginning of September he expected to start for the Uzige country, there to leave a depôt of merchandise under trustworthy men while he proceeded with the rest of his effects to Aruwimi or Stanley river, which joins the Congo, leaving there a second depôt, exploring with his best men the western slope of the Blue Mountains and the region between Lakes Albert and Tanganyika, and then returning to Uzige to despatch reports and explain his further plans.

THE enlarged edition of Whitaker's Almanack for 1880 contains an article on geographical discovery, written in a somewhat perfunctory manner. As instances of the want of proportion observable in it, we may mention the space given to the voyage of the *Isbjörn* to Novaya Zemlya, and Mr. McCarthy's journey across China, the former of which was admittedly unsuccessful, while the latter, which did not occur in the period under review, added nothing whatever to our geographical knowledge. Accuracy hardly appears to be the writer's *forte*, otherwise he would hardly discourse about Mr. E. Colborne Ba*k*er's journey in Western China, nor would he turn one of the Portuguese African explorers' names into Ives, not to mention his inability to make up his mind how to spell Thibet.

IN the course of their explorations last year in the unknown highlands of Eastern Perak, a party of Englishmen met with several small settlements of Sakis, presumably the aborigines of the peninsula, who still hold themselves aloof from the Malays. Few of these people have metal or earthenware cooking utensils, but roast their sago in large bamboos. The majority of them speak Malay, with an accent not unlike the Chinese; their own language is described as soft and guttural. Two specimens of these people—a man and a woman—on being measured, were found to be 4 feet 6 inches and 4 feet 1 inch in height, and these appeared to be about the average. The women are said to be not bad-looking, with thick lips and flat noses; their figures are good, though rather inclined to stoutness; and they have remarkably pretty little feet and hands. The dress of both sexes consists of a strip of bark about 9 feet long and 1 foot 6 inches wide, wound round the bodies. The bark used is that of a species of fig, and is very soft and pliable; there are two descriptions of it, obtained from different trees, one of a dirty white and the other of a reddish brown colour.

THE new number of the *Bulletin* of the Société Commerciale de Géographie of Bordeaux, contains an article on Cabul, and from its "Chronique Géographique" we learn that the French Minister of Marine has ordered the Governor of Senegal to send an expeditionary column to the country between the Upper Senegal and the Niger. The object of the column will be to explore the region in order to see by actual survey and examination whether the two rivers can be joined by a railway. The expedition will be accompanied by a skilled topographer.

MR. H. CONYBEARE, of the Bengal Civil Service, has published a carefully prepared report on the Pargana Dudhi, which extends from 25° 52′ 17″ to 24° 21′ 21″ N. lat., and from 82° 59′ 28″ to 83° 28′ 7″ E. long. The first portion deals almost entirely with geographical matters, and furnishes much interesting information respecting the various aboriginal tribes, their language, customs, and style of cultivation, &c.

THE *Hiogo News* states that the Japanese Government has decided upon at once going on with the construction of a railway between Shiwotsu, at the head of Lake Biwa, and Tsuruga, a town at the head of a large bay, which will probably before long become an open port. Some high officials connected with the Board of Works are to proceed to Tsuruga on this business without delay. It is expected that the opening of the line in question will have a most beneficial effect on the trade of the treaty port of Kobe. A large extent of rich country will be opened up to commerce, and it is probable that the whole of the produce of the silk districts to the north of Lake Biwa will be brought to Kobe for shipment to Europe.

ON THE NATURE OF THE ABSORPTION OF GASES

MORE than seventy years ago Dalton made the assertion that gases, when absorbed by liquids (*e.g.*, water), remain only mechanically included in the latter, without losing thereby any property which belongs to them as gases. This hypothesis of the nature of absorption is opposed by a still older one—the chemical—which considers the phenomenon as the consequence of an affinity between gases and liquids, and explains, for example, the absorption of CO_2 and N_2O by water by the formation of H_2CO_3 and HNO. Since the time when these two hypotheses were started, their proof has always been attempted with the aid of the statical method; *i.e.*, by the determination of the proportion in which the absorbed and absorbing bodies maintain their equilibrium under given conditions; or, in other words, by the determination of the coefficients of absorption. Mackenzie, who in this way has lately most thoroughly examined into the absorption of carbonic acid by means of a solution of salt in water, says that it would be presumptuous, on the basis of existing observations, to attempt yet to solve the problem whether absorption is a purely physical phenomenon or whether it belongs rather to the domain of the so-called chemical phenomena.

After these two hypotheses there comes yet a third, set forth by Graham, according to which gases are transformed into the liquid state in the case of their absorption by bodies such as liquids, caoutchouc, or by glowing metals. This hypothesis is supported on the one hand by the circumstance, already remarked by Mitchell, that membranes of caoutchouc are most easily penetrable for those gases which are most readily capable of being rendered liquid and are most soluble; on the other, by two assertions of Graham's—(1) That a body in the form of a liquid penetrates another body more easily than in the form of a gas; and (2) That liquids and such colloid substances as caoutchouc, have no pores at all, and, in point of fact, are, even in the thinnest film, impenetrable, to gases as such. According to Graham, then, it is impossible for a gas to penetrate such a substance without this conversion into a liquid state, which may or should be favoured in some measure by the chemical affinity between the gas and the absorbing substance.

My researches in the domain of diffusion gradually led me to the conviction that a much nearer approach will be made to a solution of the problem of absorption if conclusions are drawn, with reference to the state in which gases exist in these substances from the study of the phenomena of motion, which exhibit them in their diffusion through absorbing substances. Availing myself of the kind invitation of the editor of NATURE, I shall take the liberty of here briefly describing the results which I have in this way obtained. They refer to what takes place in the case of caoutchouc.

The application of the laws of the diffusion of gases through absorbing substances[1] to the phenomena which appear in caoutchouc shows that the quantity of gas which passes through a membrane of caoutchouc in a unit of time is, conditions being equal (*i.e.*, equal surfaces of diffusion, equal thickness of the membrane, and equal difference of saturation on both sides of the membrane) in proportion to the product $D\,S$. D is the *constant of diffusion* of a gas in caoutchouc, and corresponds to the thermometric conductivity of a body in the theory of the conduction of heat. S is the *coefficient of saturation*, and is expressed by the equation—

$$S = A_\theta \frac{p}{76},$$

in which A_θ denotes the coefficient of absorption of caoutchouc for the gas under consideration at the temperature θ, and p the pressure (in centimetres of mercury) under which the gas is. The coefficient, then, is that volume of gas reduced to 0° C. and under 76 cm. of mercury which can be contained in the unit or volume of caoutchouc at the given temperature and under the given pressure. It corresponds to the specific heat of the unit of volume of a substance in the theory of heat.

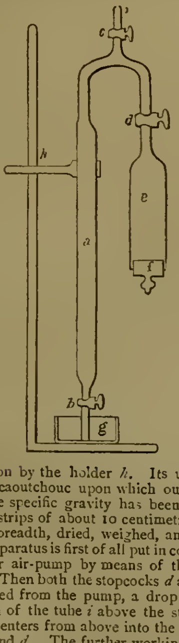
Mitchell and Graham, during their experiments with caoutchouc, have always measured the product $D\,S$ only, which can give us absolutely no explanation of the nature of the absorption of gases, and which has led Graham, as we shall see further on, to false inductions.

In order to determine the constant D, which shall form the basis of our examination, it is necessary to know the coefficient of absorption, by means of which the coefficient of saturation

[1] Wroblewski in Wiedemann's *Annalen*, ii., 481-513.

can then be ascertained. The determination of the coefficient of absorption presupposes, moreover, that the Henry-Dalton law of absorption holds good for caoutchouc as well. That this law is valid is proved by the experiments which I made several years ago on the passage of gases through membranes of caoutchouc,[1] and by means of which I have shown that, at the various differences of pressure between 74 cm. and 2 cm. mercury, the quantity of gas which passes through is proportional to the actual pressure of gas upon the membrane. This relation between the quantity of gas passing through and the pressure is only *possible* in the case of the coefficient of saturation being proportional to the pressure, or, in other words, when the Henry-Dalton law holds good for caoutchouc within the given limits.

The absorptiometer which I have constructed for the determination of the coefficients of absorption, consists of glass throughout. *a* is a tube which is divided into tenths of cubic centimetres, and from which even hundredths of cubic centimetres may be read off; *b*, *c*, and *d* are glass stopcocks; *e* is a space which serves as a receptacle for the caoutchouc, and is closed from beneath by a glass stopper which renders it air-tight when shut. The apparatus stands in a glass trough, *g*, of mercury, and is held



in a vertical position by the holder *h*. Its use is very simple. The membranes of caoutchouc upon which our experiment is to be made, and whose specific gravity has been previously ascertained, is cut into strips of about 10 centimetres in length, and 1·5 centimetres in breadth, dried, weighed, and introduced into the space *e*. The apparatus is first of all put in communication with the Jolly quicksilver air-pump by means of the stopcock *c*, and is pumped empty. Then both the stopcocks *d* and *e* are shut, the apparatus is separated from the pump, a drop of water is introduced at the bottom of the tube *i* above the stopcock *e*, and the gas to be examined enters from above into the space inclosed by the stopcocks *b*, *c*, and *d*. The further working of the apparatus explains itself. If the volume of gas which has been allowed to enter has been measured, and also the pressure under which it is, the stopcock *d* is opened, and after the lapse of from three to twelve hours, the volume of gas and the pressure is again ascertained. The calculation of the coefficients of absorption is made according to the known formula.

I will here remark that the pressure of the gas which remains in the caoutchouc after the apparatus has been pumped free therefrom can only be measured by the hundredth part of a millimetre of mercury, which at the same time is the limit of the power of action of the Jolly pump.

For the experiments, red vulcanised caoutchouc of about one-third of a millimetre in thickness was employed. Its specific gravity at 15° C. was 1·02685.

The coefficient of absorption of the four following gases was

[1] Wroblewski in *Poggendorff's Annalen*, clviii., 539-568.

ascertained: nitrous oxide (N_2O), carbonic acid (CO_2), hydrogen and atmospheric air.

It was shown that the coefficient of absorption of caoutchouc for gases, within the limits of the examination, are linear functions of the temperature, and that they diminish with an increase of temperature in the case of nitrous oxide and carbonic acid. The coefficient of absorption of hydrogen, on the other hand, grows larger with increase of temperature, and atmospheric air shows a similar tendency. The coefficient of absorption is as follows:—

	At 5° C.	At 10°.	At 15°.
For N_2O	1·8229	1·6896	1·5564
,, CO_2	1·1991	1·1203	1·0416
,, H	—	0·06121	0·08157
,, Air	—	0·09832	0·11710

With the assistance of these values the constant D can now be ascertained. For the description of the diffusiometer which I have constructed for that purpose and for the method of observation, I must refer the reader to my paper in Wiedemann's *Annalen*, vol. viii. pp. 29-52.

The experiments showed that the constant D amounted to—

	At 12° C.	At 14° C.	
For N_2O	56	62	$\times 10^{-8} \frac{cm^2}{sec}$
,, CO_2	54	61	

Nitrous oxide and carbonic acid have thus almost equal constants, a somewhat greater value being accorded to nitrous oxide (being the somewhat specifically lighter gas). The constant for these two gases increases with the temperature, and is at 10° 50 times smaller than D for carbonic acid in water,[1] and 300,000 times smaller than the constant of free diffusion for carbonic acid and air at the same temperature and the same pressure.

If the great difference in the coefficients of absorption of caoutchouc for both gases is taken into account, it is at once seen that the constant D depends neither upon the chemical nature of the gas nor upon the value of the coefficients of absorption. It can, in this case, depend only upon the physical properties of the gases, and since specific gravity is the principal property in which gases differ from each other in physical respects, the constant D must depend upon the specific gravity of the gases. Proof of this is afforded by the determination of the constant D for hydrogen gas: it comes to $353 \times 10^{-8} \frac{cm^2}{sec}$. The constants for these three gases is thus nearly in inverse ratio to the square root of the specific gravity of the gases.

If the behaviour of the nitrous oxide is held as normal, it is found that D is about 27 per cent. greater for hydrogen than it would be if the constant under consideration were exactly in inverse ratio to the square root of the specific gravity of the gas. The same variation here appears which Graham has observed in the diffusion of gases through plates of graphite. Hydrogen diffused itself through a plate of 0·05 centimetres in thickness—supposing the air to show its normal behaviour—about 9 per cent. quicker than is prescribed by the above relation. A similar variation was observed when hydrogen diffused itself in oxygen or carbonic acid instead of air. Granted that this deviation is in inverse ratio to the specific gravity of the gas, it would, in the case of the aforesaid graphite, amount to about 23 per cent. for hydrogen in comparison with nitrous oxide. The deviation is thus with such heterogeneous bodies as vulcanised caoutchouc and compressed graphite, not only of the same direction, but also of the same order, hence there is no ground for supposing that the gas, in its passage through a non-absorbent porous partition like a plate of graphite, should change its aggregate condition, and since the dependence of the constant D of a gas upon its specific gravity can only be considered a sign of the gaseous form of the aggregate condition of the diffusing body, it follows, then, that *gases cannot possibly exist in caoutchouc in a fluid form, and they retain also during their absorption by caoutchouc all the properties which belong to them as gases. Graham's hypothesis of the nature of absorption of gases must certainly, therefore, be regarded as false*, and a greater or less degree of penetrability of the layer for one or other of the gases

[1] The constant D for CO_2 in water is, according to my experiment, about $0·000025 \frac{cm^2}{sec}$. It depends neither upon the coefficient of absorption nor upon the coefficient of saturation. On the other hand it depends upon the viscosity of the fluid. If any body, *e.g.*, a crystalloid or a colloid, is dissolved in water, and a more viscous fluid is thereby obtained, the constant D decreases. This constant, however, as is shown by my experiments with glycerine in water, cannot be diminished at will by increasing progressively the viscosity of the medium in which the diffusion of the gas takes place. (See Wiedemann's *Annalen*, vol. iv. pp. 268-277, and vol. vii. pp. 11-23.)

has nothing—as Mitchell asserted—to do with its solubility or compressibility. *Just as little practicable is the chemical hypothesis upon what takes place in caoutchouc, and the absorption of gases such as nitrous oxide, carbonic acid, and hydrogen by caoutchouc must be considered as a purely physical phenomenon.* A layer of caoutchouc is, then, to be conceived as a *porous* substance, endowed with powers of condensing as well as of rarefying gases whose porosity is of the same order as the porosity of graphite. The motion of the gas takes place through the pores of the caoutchouc.

It is much to be regretted that Graham's experiments upon the passage of gases through metals were so conducted, that they cannot now be calculated with the help of the laws of the diffusion of gases in absorbent substances. I have been able to calculate only those numbers which, as they are not without interest, I will here communicate. They are the constant D for hydrogen in platinum at bright red heat, and D for carbonic oxide and hydrogen in iron at full red heat.

A platinum wire absorbed at red heat 0·17 volumes of hydrogen (taking the average of four experiments). A tube drawn out of the same mass of fused platinum, 0·11 centimetres in diameter, let 489·2 cubic centimetres of gas in the minute pass through a surface of 1 square metre; therefore

$$D = 0{\cdot}00053 \, \frac{\text{cm}^2}{\text{sec}}.$$

A tube of malleable iron, 0·17 centimetres in diameter, let 0·284 cubic centimetres of carbonic oxide and 76·5 cubic centimetres of hydrogen through the square metre in the minute. Since one volume of this metal can contain four volumes of carbonic oxide, so is for this gas

$$D = 0{\cdot}00000002 \, \frac{\text{cm}^2}{\text{sec}}.$$

Since the coefficient of absorption of this metal for hydrogen was less than four, so is the constant D for this gas greater than $0{\cdot}00000054 \, \frac{\text{cm}^2}{\text{sec}}$, whence it follows, if there can be any comparison between these two numbers, that in metals greater constants D belong to specifically lighter gases.

It has lately been asserted by Stefan that the constant D, in both water and alcohol, is greater for oxygen and nitrogen than for carbonic acid, and that the greatest constant pertains to hydrogen. It would be, however, premature to wish to draw from his experiments any conclusions with regard to the nature of absorption of gases in fluids.

Franz Exner has already shown, several years ago, that, on the passage of gases through a lamina consisting of a solution of soap in water, the interchanged volumes of two gases are directly proportional to their coefficients of absorption and in inverse ratio to the square root of their specific gravities. Hence Stefan has concluded that the constant D in fluids is in inverse ratio to the square root of the specific gravity of the gas, and that the gas molecules move by themselves and not in connection with the molecules of the fluid, which would correspond with Dalton's views on the nature of absorption in fluids. Meanwhile, these conclusions are contradicted by the experiments of Pranghe, who has shown that the above-mentioned relation in the case of the lamina is not at all borne out when pure unboiled linseed oil is used. We see from this, then, that what takes place in the case of fluids must be much more complicated, and that we must subject the matter to a much more searching and extended inquiry before we shall be in a position to say anything definite upon the nature of the absorption of gases in liquids.

S. WROBLEWSKI

NOTE ON PREHISTORIC STATIONS IN CARNIOLA [1]

THE most important of these prehistoric stations is the burial-field of Klenik, near Waatsch. During the year 1878 about 250 graves, covered with stone slabs, were opened at a depth of from ½ metre to 2½ metres. They contained skeletons, some remains of burnt corpses, and a great number of various objects. The bronze and other articles are very similar to those found in the well-known cemetery near Hallstadt, in Upper Austria. No Roman remains were met with. Thus there is no doubt of the pre-Roman age of these stations and cemeteries near Waatsch. They may be ascribed with great probability to the Taurisci, a Celtic tribe, known to have worked the salt at Hallstadt, and to have extended from Upper Austria, through Styria and Carinthia, as far as the Julian Alps. Strabo asserts explicitly that the very ancient landing-place Nauportus (now Ober-Laibach) was a settlement of this people, and, according to him, Italian merchandise was brought by carriage from Aquileja over Mount Okra (now Birnbaumer Wald), then by the River Savus to Siscia (now Sissek) and the Danubian districts. Thus it must be admitted that before the reign of Augustus a much-used water-communication existed on the Save and the Laibach between Siscia and Nauportus. The tradition ascribing the foundation of Emona to the Argonauts is an indication of the very remote beginning of this intercourse. Prof. Müllner, of Marburg, has lately offered some forcible arguments to the effect that Emona did not occupy the present position of Laibach, but was at the south end of the Laibach Moor, where Brundorf and Sonnegg now stand.

The graves, with skeletons, at Rojé, near Morants, contain objects referable to the Merovingian Period (fourth to seventh centuries); and a skull from one of them is of the type of those found in the successional sepultures.

GEOLOGY OF GREECE

1. *The Thessalian Olympus.*—In treating of the geology of Greece, as determined by a recent survey, Herr M. Neumayr, in the *Proceed.* Imper. Acad. Sciences, Vienna, July 17, 1879, describes this mountain-group as having a north and south direction, and consisting of a somewhat flattened dome of strata, with a subordinate syncline on the west. The limits on both sides are defined by lines of fracture. The constituent rocks are schists, of many kinds, with enormous intercalated limestones, at some places 3,000 metres thick. These latter are partly saccharoidal, partly semicrystalline, and sometimes nearly compact. In the last variety there are, in some localities numerous indeterminable organic remains.

2. M. Neumayr and L. Burgerstein state that the broad peninsular mass in South Roumelia, below Salonica, known as Chalkidiké (Chalcidica), is for the most part composed of micaceous and other schists, excepting its south-west portion and the Athos promontory. At some places considerable beds of marble are intercalated. The middle promontory of the three terminating the great peninsula is called Longos, and consists of gneiss, the oldest rock of the region.

3. The Island of Cos, according to Neumayr, consists for the most part of schists, marble, and Hippurite-limestone (with Rudistæ). The remainder is occupied by upper tertiary and diluvial deposits. Of the tertiaries the lower pliocene paludina beds strikingly resemble, in their fauna, the analogous Sclavonian deposits, and over them lie marine pliocene beds and rhyolitic tuffs; and eruptive rocks, trachytic in character, are also present. Being the extreme eastern member of the Cyclado-Sporadic series, traversing the Egean, and being connected with the neighbouring volcanic islands, Cos is well adapted to afford an insight into the nature of this submarine mountain-chain, and it yields an indication of the South-Egean basin being a depressed area of diluvial origin. The freshwater pliocene fauna offers interesting materials for the discussion of the upper tertiary freshwater deposits of the Egean region at present known, and of the evolution of the Eastern Mediterranean area. A number of passages have been collected by Prof. Hörnes from the Greek Classics, mentioning "giants' bones," which may point to places where remains of fossil mammals have been found.

NOTES FROM NEW ZEALAND

Wild Pigs and Wekas (*Ocydromus*).—Early in the spring of 1876 I spent several days in fern-collecting and botanising in the Malvern Hills district of Canterbury. Whilst so engaged, in many places I came across fresh pig-tracks and rootings, now and then sighting a boar. On one open hillside, bordered with fagus woods, I found three nests of that curious rail, the weka (*Ocydromus*); each of the nests contained eggs. It seemed remarkable that the nests should have remained unravaged by the wild pigs that were constantly roaming about the neighbourhood. It is highly improbable that the keen-scented swine were not aware of the weka's haunts. The trail of this bird is strong, readily followed by dogs; indeed, dogs take to this pursuit with so much of pleasure and relish that many good sheep-dogs become unreliable and almost worthless when they enter upon weka-hunting. It is a well-known fact that wekas usually abound in districts infested with wild pigs; they probably find their advantage in feeding on the varied forms of insect life disclosed in the soil upturned by the swine in rooting up ferns, spear-grass, &c.

The Kea (*Nestor notabilis*).—In NATURE, vol. iv. p. 489, I called attention to certain destructive habits developed in the Kea. Since the date when that notice was written the bird has become very much better known to sheep-farmers in the alpine districts. During the past winter sheep were attacked by the kea as far north as the Rangitata River; it is probable these birds came from the district known as the Mackenzie country, as they have been troublesome about Lake Ohou.

A New Zealand Gamekeeper's Return.—Naturalists may read with some interest perhaps the following return of animals killed by gun or trap, on a large estate in the Middle Island; the numbers given do not include animals that have been destroyed by means of poison, or "the bill of mortality" would have been very much heavier.

From January 12, 1879, *to August* 24, 1879

Wild pigs	108
,, cats	18
Rats	1,054
Falcons	10
Harriers (*Circus assimilis*)	790

SCIENTIFIC SERIALS

Journal of the Asiatic Society of Bengal, vol. 48, Part 2, No. 11, 1879, contains:—S. E. Peal, note on the old Burmese route over Patkai *via* Nongyang (viewed as the most feasible and direct route from India to China), with two maps and two plates.—Louis Schwendler, on a new standard of light, with a plate.—W. T. Blanford, a second note on mammalia collected by Major Biddulph in Gilgit.—Dr. J. Armstrong, Marine Survey Department, on some new species of hydroid zoophytes from the seas and coasts of India, with four plates.—Lieut. R. C. Temple, note on the formation of the country passed through by the 2nd column Tal Chotiali field force during its march from Kala Abdullah Khan, in the Khójak Pass to Lugári Bárkhan, in the spring of 1879, with a map.—W. T. Blanford, notes on a collection of frogs and reptiles from the neighbourhood of Ellore and Dumagudem.—J. Wood-Mason, preliminary notice of a new genus (Parectatosoma) of Phasmidæ, from Madagascar, with descriptions of its two species.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 11.—"On the Reversal of the Lines of Metallic Vapours," No. VII. By G. D. Liveing, M.A., F.R.S., Professor of Chemistry, and J. Dewar, M.A., F.R.S., Jacksonian Professor, University of Cambridge.

The experiments of which the results are here given were all made with the powerful electric current from the Siemens dynamo-electric machine in limestone crucibles.

With sodium carbonate the green pair wave-lengths 4983, 4982 were reversed, showing dark lines in the middle of the bright ones, the less refrangible of the two giving the stronger dark line. The sodium line given by Lecoq de Boisbaudran at wave-length 4670 showed as a diffuse blue band with a *pair* of fine dark lines in it, of which the stronger and more lasting was the less refrangible. The diffuse blue band resolved itself into *two* diffuse lines as the sodium carbonate evaporated, and the measurement of their positions in comparison with a conspicuous titanium line, which lies between them, and was made to show at the same time by introducing a fragment of titanic oxide into the crucible, gave for this sodium pair the wave-lengths 4667, 4664. The red pair, wave-lengths 6160, 6154, were also seen reversed in like manner, but the authors failed to detect any difference in the strength or continuance of the dark lines in this case. The reversals of the red pair first ceased to be visible, next those of the diffuse blue pair, then the dark lines in the green pair, and then those in the yellowish green (5687, 5681). In some cases when a large quantity of sodium carbonate was put into the crucible a curious double reversal occurred. In the middle of an enormous dark expansion of D a bright yellow band appeared, which in turn had a narrower dark band, or a pair of dark lines, in its middle. A similar double reversal of the lithium blue line occurred so far as to show a bright line in the middle of the dark one. Of the two violet lines of potassium the authors observed that the more refrangible remained reversed longer than the other.

In addition to the reversals of calcium lines before observed by them, the authors have noticed the reversal of all the more conspicuous calcium lines of the G group and some others. The finer lines, wave-lengths 4434·3, 4454·5, slightly less refrangible than the strong lines 4434, 4454, were reversed, but only when one of the poles was a bar of iron, instead of carbon. The strong lines just mentioned were expanded so as to cover their neighbours, and all four lines were seen black against the bright background in the positions and of the same relative strengths as when bright.

When strontium chloride was put into the crucible twelve lines besides those before noted were observed reversed. Besides these, many dark bands were observed in the less refrangible part of the spectrum, of which three appear to be identical with bright bands ascribed to strontia, and one with a bright line given by strontium chloride.

Manganese, introduced as sulphate, gave with facility the violet triplet, as dark lines on the continuous background. The bright blue lines of manganese were not, however, reversed until some metallic magnesium was introduced. This brought out the reversal of the lines, wave-lengths 4753, 4783, and 4823, the last being the most easily reversed of the three.

Lead introduced in the metallic state gave a reversal of the violet line, wave-length 4058, which Cornu had previously seen reversed, but this reversal was far better seen, becoming a wide black band when the lead was introduced as an alloy with zinc. Probably the lead vapour was not so rapidly oxidised when mixed with zinc, and a thicker, if less dense, stratum interposed between the arc and the spectroscope. When lead ferrocyanide was used, not only the line above mentioned was reversed, but also, much less strongly, a line near it, wave-length 4062.

With zinc, only the less refrangible two of the three bright blue lines were seen reversed. The very bright lines, wave-lengths 4924, 4911, seen in the spark between zinc poles, were not seen at all in the arc, resembling in this respect the magnesium line, wave-length 4481, and the cadmium lines, wave-lengths 5377, 5336.

When cadmium was put into the crucible the lines, wave-length 5085, 4799, and 4677 were reversed, not the line, wave-length 4415. With a large dose of cadmium the red line, wave-length 6438, was once seen reversed for an instant only.

With silver, besides the reversals before observed by the authors, the line, wave-length 4053, showed a dark line in the middle of its expansion as noticed by Mr. Lockyer, but they could see no reversal of the line, wave-length 4208. Instead of the reversal of this line they observed that a second bright line came out close to it, rather diffuse, and about midway between the line 4208 and the calcium line 4215. This second line coming out near the other silver line gave the appearance of a reversal in the middle of a diffuse line, but besides the measurements made with a micrometer the authors assured themselves of the fact by watching the fading of the second line as the silver evaporated. The use of an alloy of zinc with silver did not alter the appearance of these two lines, or bring out a reversal of either of them. The authors failed to see any line of silver either bright or reversed with wave-length about 4240, as noticed by Cornu. With the carbons arranged vertically and the light viewed through the upper, perforated carbon, silver gave a channelled spectrum as described by Lockyer and Roberts. As this channelled spectrum was not seen with silver in any other arrangement of the crucibles, the authors are led to attribute it to a comparatively cool condition of the silver vapour ascending the carbon tube, a condition of near approach to a state of liquefaction.

Having observed that lines frequently came out with mixtures which were not visible when the separate ingredients were used, they tried a few amalgams. None of these showed any reversals of the mercury lines. But an amalgam of bismuth gave readily the reversal of the bismuth line, wave-length 4722, and with more difficulty that of the line, wave-length 4119.

Antimony did not appear to give any lines, or none easily distinguishable, in the arc.

With copper the reversal of two lines only were observed, wave-length 5105, 5153.

Iron introduced as metal, or as chloride, in the usual way, gave no reversal; with an iron rod used as positive pole instead of one of the carbons, the authors succeeded in getting the reversal of one line, wave-length 4045, which expanded and showed a fine dark line in its middle; but by passing an iron wire into the arc through the positive carbon, which was perforated, and pushing in the wire slowly as the end burned away, several of the brightest of the iron lines were reversed. The three violet lines, wave-lengths 4045, 4063, 4071, were the first to be reversed. They all expanded before showing reversal, and the order of reversal was that of refrangibility. Besides these seven other of the brightest lines were reversed.

Nickel, whether put into the crucible in the old way, or fed into the arc in small fragments filling a platinum tube which was passed through a perforated carbon pole, gave no definite reversal of any of its lines; nor did cobalt, even when a bar of cobalt was used as the positive pole.

Tin, palladium, and platinum gave no reversals.

It is worthy of remark in regard to the difficulty of obtaining substances chemically pure that the authors found that carbon poles which had been for some hours ignited in a current of chlorine and further intensely heated in the arc, while a current of chlorine was passed through perforations down their axes, still showed in the arc, of course without any crucible being employed, a multitude of lines amongst which the so-called carbon lines and those of calcium and iron were conspicuous.

December 18.—"On the Capillary Electroscope," by G. Gore, LL.D., F.R.S.

This paper contains a description of a modified form of the "Capillary Electroscope," together with full details of its construction and of the circumstances which affect its successful action. Numerous forms of the apparatus were constructed and a variety of solutions employed with the hope of obtaining an instrument capable of being employed for accurate measurements of feeble electromotive forces, but without success. The author is now engaged in examining the behaviour of a variety of liquids in the apparatus, and in completing an investigation of the causes and conditions of the movements. During this examination he has discovered the singular circumstance that in certain cases the mercury moves in an opposite direction to the electric current.

Mathematical Society, December 11.—C. W. Merrifield, F.R.S., president, in the chair.—The following gentlemen were elected members:—Mr. W. Burnside, Mr. J. R. Harris, Dr. W. Jack, Mr. W. J. Curran Sharpe, and Prof. W. Woolsey Johnson, St. John's College, Annapolis, Maryland.—The following communications were made to the Society:—Note on a method of obtaining the q-formula for the sine-amplitude in elliptic functions, by Mr. J. W. L. Glaisher, F.R.S.—Note on a numerical theorem connected with the cubical division of space, by the President.—Notes on Curvature, by Mr. J. J. Walker.—A property of a linkage, by Mr. A. B. Kempe.—Mr. Merrifield's note arose thus:—it is known that if space be cubically divided by three systems of orthogonal and equidistant planes, there must be an infinite number of ways of selecting points of the system, which shall be the corners of cubes obliquely placed and the theorem (*infra*) shows that the edges of such cubes will be commensurable with the unit of the system. Take $OA = OB = OC$, orthogonal to one another, and the co-ordinates of A, B, C referred to rectangular axes, rational numbers, it is shown that the length $OA = OB = OC$ is also a rational number. If $l_1\, m_1\, n_1$; $l_2\, m_2\, n_2$; $l_3\, m_3\, n_3$ are the co-ordinates of A, B, C respectively, then we have—

$$l_2 l_3 + m_2 m_3 + n_2 n_3 = 0,$$

and two other like equations. Also if

$$r = \frac{m_2 n_3 - m_3 n_2}{l_1} = \ldots = \ldots$$

then $(l_2^2 + m_2^2 + n_2^2)(l_3^2 + m_3^2 + n_3^2) = r^2(l_1^2 + m_1^2 + n_1^2)$, or $OB^2 . OC^2 = r^2 OA^2$. Therefore if any two of the three lines OA, OB, OC are equal, the third is rational. A few numerical examples are given:—

$$r = 9, \left\{\begin{matrix} -8 & 4 & 1 \\ 4 & 7 & 4 \\ 1 & 4 & -8 \end{matrix}\right. \qquad r = 21, \left\{\begin{matrix} -19 & 8 & 4 \\ 8 & 11 & 16 \\ 4 & 16 & -13 \end{matrix}\right.$$

$$r = 11, \left\{\begin{matrix} -9 & 6 & 2 \\ 6 & 7 & 6 \\ 2 & 6 & -9 \end{matrix}\right. \qquad r = 25, \left\{\begin{matrix} 9 & 12 & -20 \\ 12 & 16 & 15 \\ -20 & 15 & 0 \end{matrix}\right.$$

Values were also given for $r = 19$, 23, other values proved refractory. If the above are read as determinants, the groups are all symmetrical, 9, 11, 19 being symmetrical about both diagonals. The value of the determinant is always $\pm r^3$ as it should be, being simply the volume of the cube of which r is an edge. Mr. Glaisher pointed out that the diagonal about which there is symmetry has the sum of its terms $= \pm r$. The reason for this and why there should be symmetry, is not so apparent.

Geological Society, December 3.—Henry Clifton Sorby, F.R.S., president, in the chair.—Syed Ali, Wynne Edwin Baxter, Arthur Robert Boyle, Rev. John Lowry Carrick, M.A., Prof. Edward Waller Claypole, Rev. T. Dowen, Rowland Gascoyne, George M. Henty, John Marshall, Josiah Martin, Charles Maxted, Edward Provis, Thomas William Rumble, Rev. John Reuben Taft, Octavius Albert Shrubsole, Samuel Richard Smyth, and William Neish Walter were elected Fellows of the Society.—The following communications were read:—The gneissic and granitoid rocks of Anglesey and the Malvern Hills, by C. Callaway, F.G.S., with an appendix on the microscopic structure of some of the rocks, by Prof. T. G. Bonney, F.R.S., Sec.G.S. The author described the results of his investigations into the stratigraphy and petrology of the above districts, which have led him to the following conclusions:—1. The granitoid (Dimetian) rocks of Anglesey pass down into an anticlinal of dark gneiss (above) and grey gneiss (below). 2. Associated with the granitoid series are bands of felsite, hälleflintas, and felspathic breccias. 3. The succession of gneissic and granitoid rocks in Anglesey resembles so closely the metamorphic series of Malvern as to justify the correlation of the two groups. 4. The pre-Cambrian rocks of Anglesey and the Malverns, from the highest known member down to the base of the gneiss, may be thus classified:—A. Pebidian (to be described hereafter); B. Malvernian; (*a*) Dimetian, with associated quartz-felsites and hälleflintas (Arvonian) passing down into (*b*) Lewisian.—Petrological notes on the neighbourhood of Loch Maree, by Prof. T. G. Bonney, F.R.S., Sec.G.S. The author described the microscopic structure of a typical series of the Hebridean gneiss, and gave reasons for considering the mass of rock on the right bank of Glen Laggan to be not an intrusive "syenite," as has usually been supposed, but a mass of the Hebridean gneiss faulted against the *newer* series. By examination of specimens, collected both in Glen Laggan and at other points along the northern escarpment of the *newer* series, the author showed that its rocks have been rightly called metamorphic; and then, by comparison of these with specimens collected in Glen Docherty, he concluded that the latter belonged to the *newer* series, and that no part of the Hebridean series reappeared here.—On some undescribed Comatulæ from the British secondary rocks, by P. Herbert Carpenter.

Zoological Society, December 16.—Prof. Flower, F.R.S., president, in the chair.—Mr. H. Seebohm exhibited and made remarks on a collection of birds made by Captain the Hon. G. C. Napier, in the valley of the Atreck, near the south-east corner of the Caspian Sea.—Mr. R. G. Wardlaw Ramsay exhibited a specimen of *Pericrocotus flammeus* in an abnormal state of plumage, obtained on the Neilgherry Hills in Southern India.—Mr. Sclater exhibited a small collection of birds from the Island of Montserrat, West Indies, received from Mr. J. E. Sturge, of that island. This collection, though small, was of much interest, as nothing was previously known of the ornithology of Montserrat.—Mr. T. J. Parker read a paper on the intestinal spiral valve in the genus *Raia*. Mr. Parker showed that there were four types of valve exhibited in individuals of that genus, differing from one another in morphological characters, in the extent of absorption surface presented to the food, and in the resistance offered to the passage of food.—A communication was read from the Marquis de Folin on the mollusca of the *Challenger* Expedition of the genera *Parastrophia*, *Watsonia*, and *Cæcum*.—Prof. W. H. Flower, F.R.S., read a communication on the cæcum of the Red Wolf (*Canis jubatus*), in which it was shown that that animal differed from the majority of the *Canidæ* in possessing a very short and perfectly straight cæcum.—A communication was read from Mr. Edward Bartlett containing a list of the mammals and birds collected by Mr. Thomas Waters in

South-East Betsileo, Madagascar. The collection contained a new species of rodent belonging to the genus *Nesomys*, and two new species of birds of the genera *Cypselus* and *Zapornia*.—Dr. A. Günther, F.R.S., read the description of a new species of Dwarf Antelope, obtained by Dr. Kirk near Brava in the South Somali country. Dr. Günther proposed for this new species the name of *Neotragus kirki*.—A communication was read from Mr. Martin Jacoby containing the descriptions of new species of phytophagous coleoptera.—A communication was read from Prof. J. Reay Greene, F.Z.S., on a remarkable Medusa (*Charybdæa haplonema*), from Santa Catharina, Brazil.—Mr. Edward R. Alston read a description of a skull of a chamois with four horns, which had been exhibited at a previous meeting of the Society.—Mr. Henry Seebohm read a paper on certain obscure species of Siberian, Indian, and Chinese thrushes.

Physical Society, December 1.—Prof. W. G. Adams in the chair.—New Members—Mr. J. H. Poynting, Mr. R. T. Glazewood, Dr. R. C. Shettle, Prof. Rowland, Mr. John Gray, D.Sc., Mr. H. R. Brook, Mr. E. B. Sargent, Mr. E. Paterson.—On the graduation of the sonometer, by M. J. H. Poynting, Trinity College. The author had endeavoured to reduce the present arbitrary readings of the sonometer of Prof. Hughes to absolute measure by adapting the formula given in Maxwell's "Electricity," vol. ii. chap. xiv., to the induction of two circular coils on the same axis, separated by a distance greater than the radii of the coil, on a third coil intermediate. By applying the formula thus obtained to the results of Prof. Hughes for different metals, he finds that either the specific resistances of metals as given in the tables are not the same as the resistances of the metals employed by Prof. Hughes, or that the induction effect of the balance or sonometer is not proportional to the conductivity of the metal.—Prof. Ayrton reminded the Society that at a former meeting he had shown mathematically that the effect was not proportional to the conductivity, but to an exponential function of the conductivity. Mr. Chandler Roberts, F.R.S., stated that Prof. Hughes did not profess that the metals used by him to obtain his results were pure. Prof. Adams mentioned that Prof. Hughes had shown that the effect was dependent on other conditions than the mere purity of the metal.—Dr. J. A. Fleming, St. John's College, Cambridge, exhibited and described a new form of Wheatstone balance, designed principally for comparing the B.A. units of resistance deposited in the Cavendish Laboratory. The divided resistance is a circular platinum-iridium wire and an arm fitted with a contact at its extremity revolves round after the manner of circular resistance coils, thus altering the ratios of the divided resistances. The contact is a knife-edge of platinum, and it is made and broken by hand like a key. A series of ingenious copper mercury cups are fitted to the balance so as to permit of two coils being compared at any temperature with great exactness by the method suggested by Prof. Foster and adopted by Prof. Crystal, of Cambridge. This consists in exchanging the positions of the units on the balance and observing the difference in the results. By Dr. Fleming's arrangement this exchange can be effected without removing the coils from the heating apparatus in which they are placed or otherwise altering their conditions. The mercury contact cups and the heating cans were also improved by Dr. Fleming for the purpose of facilitating accuracy of results.—Prof. Perry described a dispersion photometer devised by himself and Prof. Ayrton for the purpose of comparing intense lights such as the electric with a standard candle without taking up much room, in order to put the stronger light at a distance from the screen proper, to give an illumination equal to that of the candle. To reduce the distance of the stronger light from the screen, the authors had inserted a lens in the track of the beam, so as to disperse the beam to a degree which could be determined by an easy formula. Thus by artificially diluting the powerful beam they could compare it with the feebler beam from the standard light in a shorter space. For an electric light of 6,400 candles only eight feet need be required by the new plan instead of eighty feet by the unassisted method. Dr. John Hopkinson, F.R.S., stated that he had actually used the same method for some months past in his electric light experiments. He recommended a plano-convex lens as the best to use, and suggested that the focal length should be calculated. He thought that the error due to absorption could easily be obviated.—Prof. Ayrton then described a method by which Prof. Perry and he had determined the value of g, or the coefficient of gravity at the Imperial Engineering College, Tokio, Japan, by means of pendulums. Their result is 980·06, and calculation from the position of the places makes it 979·8.—An improved form of spherometer, designed by Mr. W. Goolden and made by Mr. Adam Hilgar, was exhibited to the meeting. The frame is of aluminium, combining lightness and rigidity; the legs and screws of hard steel. The screw carries a drum divided into 1,000 parts, and the instrument gives a reading to the $\frac{1}{100000}$th of an inch by the usual method of touch. Increased sensitiveness is got by employing a galvanometer to indicate the contact of the middle pointer with the surface. By this means it is made correct to the $\frac{1}{500000}$th of an inch.

Anthropological Institute, December 9.—Edward B. Tylor, F.R.S., president, in the chair.—The President read some communications from the Rev. L. Fison and Mr. J. Forrest, on Australian marriage customs, which will materially assist in clearing away the difficulties which surround this interesting subject. Mr. Morgan in his "Ancient Society," says that amongst the aborigines of Australia there exists a state of communal marriage not found elsewhere, viz., that any man in a given tribe or class A is the husband of every woman in another class B. This view, however, Mr. Fison states, is not quite accurate, and he explains that men belonging to a class A can marry women belonging to another class B and no others; and that if a man from class A visit a station occupied by class B, he is provided during his stay there with a temporary wife. The offspring belongs not to either the father's or the mother's class, but to a third class C which is in its turn provided with wives exclusively from a fourth class D.—In the absence of the author the Director read a paper on savage and civilised warfare, by Mr. J. A. Farrer. It is interesting to note the existence of certain laws of war among the lower races, because it is generally assumed that they are only the product of an advanced civilisation, and the glory of a so-called civilised warfare. Even amongst the Khonds, it is necessary, previous to an attack, to allow the enemy to complete the same fetichistic ceremony as the offensive tribe itself performs.—The Caffres consider it shameful to attack their enemy without a declaration of war, and when war has broken out they refrain from seeking to starve him out; they spare the lives of women and children, and restore them after the war. The Canarians held it to be base and mean to injure the women and children of the enemy. War between civilised nations might well become a moral impossibility irrespective of any international treaty of disarmament. All that is wanted is a certain amount of human opinion and human will; of opinion, that quarrels may and should be settled peaceably, of will, that they shall be settled in no other way. Not more will is required than sufficed to put down the slave trade; nor is any stronger opinion needed than was enough for the extinction of duelling and torture.—Mr. Worthington G. Smith exhibited a collection of sixty specimens of Palæolithic implements chiefly from the valley of the Axe, many of them unusually large and heavy and in an excellent state of preservation.—Four water-colour portraits of Tasmanians were exhibited taken about forty years ago, and showing clearly all the physiognomical peculiarities of that interesting race.

Royal Microscopical Society, December 10.—Dr. Beale, F.R.S., president, in the chair.—Ten new Fellows were elected, and ten proposed for election at the next meeting.—The following papers were read:—Mr. Dallinger on a series of experiments made to determine the thermal death-point of known monad germs when the heat is endured in a fluid.—Mr. Gulliver on the classificatory significance of rhaphides in *Hydrangia*.—Prof. M. Duncan on a part of the life-cycle of *Clathrocystis æruginosa*.—Mr. Washington Teesdale on a simple revolving object-holder.—Amongst the objects exhibited were annelid jaws by Mr. G. J. Hind, sections of plants by Mr. G. J. Ward, a revolving table microscope for thirty objects, a Schmidt's microscope with spiral focal adjustment, and various hose-pieces and stage plates, by Mr. Crisp.

Meteorological Society, December 17.—Mr. C. Greaves, president, in the chair.—T. Buckland and J. Wigner were balloted for and duly elected Fellows.—The following papers were read:—On a sand-storm at Aden, July 16, 1878, by Lieut. Herbert H. Russell, 8th Regiment.—On a new form of hygrometer, by G. Dines, F.M.S. This is a modification of the hygrometer which was first described at the British Association meeting in 1872. The outside dimensions of the instrument, inclusive of the wood casing, are about 10 inches in length, 3 inches in breadth, and 2 inches in depth. The upper part consists of a vessel of thin metal, 6 inches long, 2½ inches broad, and 1¼ inch deep. Beneath this, and detached from it, but connected by a pipe, is a small chamber 2¼ inches long and 1¼ inch deep from back to front, standing about ½ inch more forward than the vessel above, and with a piece of thin, black glass in front. Inside this chamber, parallel to the front, is a division which separates it into two parts. This division does not extend quite to the top of the chamber, and is slightly turned over towards the front, so as to allow water to pass over it, and to induce the latter to flow more directly to the centre of the front of the chamber. The upper vessel is connected with the bottom and back part of this chamber by a small pipe with a tap to it, which is turned from the outside. The front of the chamber has a pipe attached to the bottom, passing upward in an inclined direction, and terminating at the outside in a small lip or spout. A thermometer, with the bulb inside and over the front of the chamber, passes through an india-rubber collar at the top of it, and is protected by a groove sunk in the face of the wooden case. The action of the instrument is as follows:—Water, of a lower temperature than the dew-point, is placed in the upper vessel, and, on the tap being turned, flows into the back of the small chamber, and thence, passing over the top of the middle division, flows downwards, cooling in its passage the thermometer and black glass, and eventually escapes by the small spout on the right side of the instrument. As soon as dew appears on the glass, the flow of the water is stopped by means of the tap, and the temperature is read off by the thermometer. When ether is used it is poured into the small spout, passes down the inclined pipe, and remains in the front part of the chamber. A piece of metal tube, ground so as to fit tightly the inclined pipe, and with an aspirator attached, is then inserted, and the dew-point is ascertained in the same way as by Regnault's hygrometer.—The diurnal range of atmospheric pressure, by R. Strachan, F.M.S. The author has compiled a table of constants from thirty places in various parts of the globe, which support Sir John Herschel's remark that "the diurnal oscillation of the barometer is a phenomenon which invariably makes its appearance in every part of the world where the alternation of day and night exists, and that within the Arctic Circle the diurnal dies out, or rather merges in, the annual oscillation."—Note on a curious fracture of a solar radiation thermometer, by G. M. Whipple, B.Sc., F.R.A.S.—Mr. R. H. Scott, F.R.S., exhibited and described a new form of sunshine recorder, which is to be used during the coming year at a considerable number of stations distributed over England.

Society of Telegraph Engineers.—At the annual general meeting of the Society on the 10th inst., the following gentlemen were elected office-bearers for the year 1880:—President—W. H. Preece. Vice-president—Prof. Foster, F.R.S., Carl Siemens, Willoughby Smith, Major Webber, R.E. Council—Prof. Adams, F.R.S., W. A. Andrews, W. T. Ansell, Sir Charles Bright, H. G. Ericksen, Col. Glover, R.E., Charles Hockin, Prof. Hughes, Louis Loeffler, C. E. Spagnoletti, Augustus Stroh, C. F. Varley, F.R.S., Members, and Alexander J. S. Adams, Capt. Macgregor Green, R.E., and J. T. Hill, Associates. Hon. Treasurer—Edward Graves. Hon. Sec.—Lieut.-Col. Frank Bolton. Secretary—F. H. Webb.—The Annual Report of the Council stated that fifty-nine new Members and Associates had been elected during the year. Among the losses by death the Society had to deplore those of Sir William Fothergill Cooke, Prof. Clerk Maxwell, and Mr. R. S. Brough. Special mention was made of the International Telegraph Conference, held in London in the summer, many of the most distinguished delegates being foreign members of the Society. Many valuable and interesting papers have been read during the session. The printing of the "Ronalds Catalogue," containing upwards of 12,000 entries, is being rapidly proceeded with, nearly 400 pages have been set up in type, of which 360 have been finally corrected and struck off. The valuable library bequeathed to the Society by Sir Francis Ronalds, including some hundreds of rare pamphlets, and constituting the most important collection of works on electricity and magnetism in the world, is being bound, and will shortly be available for the use of the members of the Society, and all students of electrical science. It was stated that steps were being taken for the incorporation of the Society, and that arrangements were in contemplation for the further development of its proceedings in respect to the purely scientific branch of electricity. The Society would be duly represented in the deliberations, being held to give effect to the proposal for the erection of a central hall to accommodate all the societies established for the encouragement of the applied sciences, towards which scheme Dr. Siemens had offered the munificent contribution of 10,000*l*. The financial position of the Society is very satisfactory.—A paper was read by Mr. E. Marsh Webb on the operations connected with the laying of the new Algiers-Marseilles cable, which led to an interesting discussion.

MANCHESTER

Literary and Philosophical Society, November 10.—Charles Bailey, F.L.S., president, in the chair.—Additional note on hydra, by Marcus M. Hartog, F.L.S.—On some undescribed hairs in Copepoda, by the same.—On an undescribed Acinetan, by the same.

November 18.—J. P. Joule, F.R.S., president, in the chair.—Recording sunshine, by David Winstanley, F.R.A.S.—On some notices in classical authors of the action of sunlight on purple dye, by James Bottomley, F.C.S.—On the origin of the word chemistry, by Carl Schorlemmer, F.R.S.

December 2.—R. Angus Smith, F.R.S., in the chair.—On a peculiar feature in the water of the well in Carisbrooke Castle, Isle of Wight, by Harry Grimshaw, F.C.S.—Note on the identity of the spectra obtained from the different allotropic forms of carbon, by Arthur Schuster, F.R.S., and H. E. Roscoe, F.R.S.

BOSTON, U.S.A.

American Academy of Arts and Sciences, November 12.—The following papers were presented:—On the relative replacability of the bromine in the three brombenzyl bromides, by Prof. C. Loring Jackson.—On a new form of astronomical level, by Prof. W. A. Rogers. This consists of a mercury surface to which any surface can be brought parallel by means of electrical contacts.—On orthobrombenzyl compounds, by C. Loring Jackson and J. L. White.—On measurements of the satellites of Mars, by Prof. E. C. Pickering. Prof. Pickering described the measurements of the position angles of the satellites of Mars, now in progress at the Harvard College Observatory. Instead of spider lines, two glass threads of such a diameter that they are visible without illumination are used. The settings are made accurately and rapidly by placing the lines so that they shall cut off equal segments of the planet and that the satellites shall be midway between them. The light of the planet is reduced by a shade glass, so that it can be seen at the same time as the satellite. The improvement of the method more than compensates for the increased distance of Mars, so that the observations are much more accordant than those taken in 1877. When the outer satellite is well seen, the probable error of the separate settings, compared with their mean, is less than half a degree. 180 settings of Deimos and 33 of Phobos have already been obtained.—Prof. Hagen read a paper on the destruction of insect pests by dilute yeast.—Prof. Trowbridge read by title a paper on dynamical ideas in the calculus.

CONTENTS

THURSDAY, JANUARY 1, 1880

GEOLOGICAL SURVEY OF THE UNITED STATES

IT will be in the recollection of geological readers that the chronic feuds to which so many independent United States Government Surveys with rival objects and officers gave rise, were last year referred by Congress to the National Academy of Sciences, and that, acting on the Report submitted by the Academy, Congress determined to abolish all the separate geological and geographical surveys then in existence under different Departments, and to consolidate the work under one establishment, to be termed the United States Geological Survey. In order, however, that the work already in progress might not be wholly lost or indefinitely postponed it was enacted that for the preparation and completion of the reports, maps, and other work of the Geological and Geographical Survey of the Territories, of the Geographical and Geological Survey of the Rocky Mountain Region, and of the Geographical Surveys West of the 100th Meridian under the direction of the Secretary of War, the sum of twenty thousand dollars, to be immediately available, should be given to each of these three offices. It is to be hoped that these provisions will suffice for the publication of several valuable memoirs which are known to have been in progress for some years.

One of the recommendations made by the Academy of Sciences was that a separate organisation should be provided for the surveys of mensuration, including the purely geographical and topographical work such as had been carried on by the Coast and Geodetic Surveys and the Land Office. For this fundamentally important and indispensable branch of the scientific examination of the country no special provision was, however, made by Congress; which is all the more to be regretted seeing that by the terms of the Act, so far as we can make out, the Engineer bureau was to be relieved of the important geodetic work it had so long and so ably been conducting west of the 100th meridian. There are ways indeed of driving a carriage and four through an Act of Congress, and the Engineers have shown themselves so able to hold their own under many successive administrations, that we wait with some interest to learn how far exactly their operations will be curtailed or modified.

The Act which constituted the new organisation of the Geological Survey likewise made provision for a Commission on the codification of the laws relating to the Survey and disposition of the Public Domain. Of this Commission the Director of the United States Geological Survey was *ex officio* appointed a member. The Commission began its work last summer in the Western Territories, and made rapid progress. Besides Mr. Clarence King, it included among its members Major Powell and Capt. Dutton, who have so long been known for their geological labours among the great plateaux and Cañons of the West. Doubtless the objects of the Commission were of paramount importance, and these three geologists, from their long and intimate knowledge of the Territories, were probably better fitted than any other citizens for carrying out rapidly and exhaustively the special inquiries entrusted to them. Otherwise some natural regret might be expressed that the services of such men should have been removed for practically a year from the geological work for which they have proved themselves so eminently qualified.

It is an excellent custom in the United States to define the time within which a Commission appointed by Congress is to send in its Report. This inquiry into the Land Laws and the classification of public lands was required to be completed within a year from the organisation of the Commission. We hear that the work is now finished so far as collecting evidence goes, and that the Report on the whole subject may shortly be expected. How long would a Royal Commission of similar nature and scope have lasted here?

The cessation of the labours of the Commission will free the geologists for the work of the Geological Survey. Much interest is felt as to the distribution of their staff and the areas over which it will be extended. Certainly no corps of geologists ever had a more magnificent opportunity of adding to the temple of science. They have large funds at their disposal, boundless territory, ground of surpassing geological interest, and the enormous advantage of a previous experience of many years spent in the West. Their doings are watched with particular care and even with some anxiety in the eastern States, owing to a curious episode after the passing of the Act establishing the Geological Survey. Subsequent to the appointment of the Director of the new organisation, an extra Session of Congress was held, in which a resolution was passed in the House of Representatives to the effect "that the Director may extend his examinations into the States." As this resolution was adopted on June 29 and the Session closed next day, there was not time to bring it before the Senate.

It will be seen that the addition of these words enormously widens the area of the Director's jurisdiction. As Prof. Dana complains, this area is "suddenly enlarged to the dimensions of the whole country from the Atlantic to the Pacific," and he adds that this was the view of the director himself, who had personally informed him "that it was his purpose under the Act, to send a party into New England next spring." We can hardly suppose that any such vast extension of the original scope of the Geological Survey was present to the minds of the representatives who passed the resolution. The additional words were probably meant only to authorise the work of the Survey to be prolonged into States adjoining the Territories, to such an extent as the necessities or advantages of the service might require. And this was a very proper addition. Geological boundary lines have seldom any close relation to political ones, even when physical features are used as lines of demarcation. But in America, where the limits of States and Territories are defined by meridians and parallels, it would be absurd to arrest a geologist's work in the middle of a prairie, or a cañon, or a mountain-range, because he had reached the limiting but invisible boundary of his territory. The idea of sending a party into New England looks like a joke, and as such we shall believe it to have been intended until authentic news of the arrival of the Survey party actually reaches this country. That it is not so regarded in the United States, however, is manifest by the flutter into which the geologists of the Eastern States have been thrown. We hear of the scheme being stigmatised as another example of the infringement of State rights, of the illegal assumption of State responsibilities, and of the danger to private interests as well as public morality to be apprehended from the temptations which such a vastly extended supervision would put in the way of the central authority.

The area in the West yet to be explored is so vast, the problems offered by it so numerous and so tempting, the field so free from "vested interests" of any previous explorers, that we cannot for a moment imagine that Mr. Clarence King and his associates, who, having already cleared a way for themselves through that wide West, know better than any other men its infinite variety and attractiveness, will trouble themselves with the geology of the East, where for generations past the labourers have been so many, and where, comparatively speaking, the field is so small and already so well tilled. With the humour of their countrymen they may have made use of the rather indefinite language of a congressional resolution to scare their less adventurous brethren in the Eastern cities. We would, therefore, counsel the geologists of the East to treat the matter as a joke. They have nothing to fear. It would be as absurd to give the Director of the United States Geological Survey control over the geology of all the States, as to make the Chief Constable of New York comptroller of morals for the whole of the Union.

A. G.

SAHARA AND SUDAN

Saharâ und Sudan Ergebnisse sechsjähriger Reisen in Africa. Von Dr. Gustav Nachtigal. Erster Theil, mit 49 Holzschnitten und 2 Karten. (Berlin, 1879.)

DR. NACHTIGAL'S wanderings came to an end more than six years ago. Most of his results have been brought at various times before learned societies and otherwise published, and the most important parts of his route are laid down in published atlases. The present work contains a detailed account of his entire travels and observations. The book now under consideration is only an instalment extending over his journey up to the end of the year 1870; a second is to follow. The volume is a large octavo of 750 closely printed pages with an appendix containing meteorological observations.

Dr. Nachtigal undertook the duty of conveying to the Sultan of Bornu, the country surrounding Lake Tsad, a present sent by the Emperor of Germany in acknowledgment of the hospitality and assistance afforded by the Sultan to the German travellers, Barth and Overweg, Vogel, von Beurman, and Rohlfs. In his journey from Tripolis to Bornu the author passed along the caravan route traversed before by Denham and Clapperton in 1822-23-24, and by Barth and Vogel in 1849-55, and also by Rohlfs. During all this portion of his journey he was therefore on ground comparatively well-known from the writings of the above travellers. He made however three long excursions to the eastward, one into Tibesti or Tu, another to Borku, and a third into Bagirmi to the south of Lake Tsad; finally he made his way eastward from Lake Tsad across Wadai and Darfor, to Chartum.

Of the present volume more than two-thirds is occupied with the account of the journey along the direct route between Tripolis and Bornu, and an account of Fezzan, and of Bornu and its capital, Kuka. The remaining third of the book relates to the journey into the unexplored region of Tibesti and is thus the most interesting and important portion of the work.

Lake Tsad lies almost due south of Tripolis and the caravan route follows an almost straight line between the two points. Dr. Nachtigal left Tripolis on February 18, 1869, and after his wanderings in Tibesti and many mishaps reached Kuka in June 1870. At Tripolis, and also in Murzuq he frequently met with the well-known traveller, Miss Tinne, of whose history and deplorable murder by the Tuaric he gives a full account. Miss Tinne or "the King's Daughter," as she was called by the inhabitants of the country, excited the greatest curiosity and was believed to possess supernatural powers. One story circulated about her at Murzuq was to the effect that her large pet dog which travelled with her was a bewitched man and changed into the human form from time to time.

The fourth chapter deals with the natural characteristics of the district of Fezzan. So scarce and dear are mutton and goats' flesh in Fezzan that recourse is had to minute crustacea and the larvæ of diptera from lakes of brackish water as food. The Bahâr-el-Dûd, or "worm lake," is so full of the larvæ and of the crustacea, the cosmopolitan inhabitant of salt water lakes, Artemia, that the inhabitants collect these animals in masses and knead them up with dates and an alga which also grows in the lake to form a repast which is highly esteemed. An Artemia occurs in the Great Salt Lake in Utah; the species in the present case is *A. Oudneyi.*

A long chapter on the climate and diseases of Fezzan follows, in which the maladies are described with an amount and character of detail which, though highly valuable, is perhaps more befitting a strictly medical publication than a general book on travel with a more or less popular aim. Similar medical details are given throughout the book and sometimes seem very much out of place. The native notions of medical treatment are curious and primitive. Thus patients suffering from cancer of the breast must most carefully abstain from all food derived from animals provided with tails, even such as milk and butter. To promote fruitfulness in women young suckling hares are prescribed. No one in Fezzan doubts that it is possible for a child to remain dormant within the mother for years or even for ever and this theory is most conveniently made use of when mishap necessitates it by wives whose husbands have been absent on very long journeys. As an aphrodisiac the fat of a Manatee, *Manatus Vogellii,* is used. The drug is sold at a high price being brought from the River Binüe a tributary of the Kowara in which the animal is abundant. Diseases are believed to be caused either by evil spirits or by the action of the evil eye.

During his exploration of Tibesti Dr. Nachtigal experienced many dangers and difficulties, losing his way, and suffering from want of water and forced night marches. A very interesting account is given of the ceremonials observed by the Tubu people in greeting one another. A most elaborate performance is gone through when two strangers meet in this wild country. Each of the performers covers all his face but his eyes with his turban, seizes his spear and throwing iron (a curious boomerang-like weapon with a long projecting prong on the concave margin), and thus prepared the two approach one another. At a distance of about six steps from one another they squat on their heels with spear upright in one hand and iron in the other. The one then asks "How do you do?" about a dozen times by means of four different words having that meaning used alternately, the reply being varied of the use of two words Laha, or Killala.

Then one of the two loudly sings the word "Ihilla," which is returned by the other in a similar tone. The word is exchanged again and again, being commenced in a loud high pitched note and gradually run down the scale until it reaches a low bass murmur. When it has become so low as scarcely to be heard, on a sudden it is shouted again in high key and the gamut is run through as before. This goes on for a very long while, the performers going through it as a strict matter of ceremony, and taking no interest in one another all the while but looking round at the horizon or elsewhere during their vocal exertions. After a while various forms of the question "How are you?" and the answer "Well," are introduced, at last questions or other topics are brought forward, although now and again the "Ihilla" bursts out in the midst of them, but the series of notes in which it is shouted becomes shorter and shorter. At last the Ihilla is got rid of altogether and ordinary conversation becomes possible. Strangers do not shake hands, but acquaintances do. The covering of the face when greeting or meeting strangers is considered as a most important matter of etiquette.

In the Zuar Valley the large baboons (*Cynocephalus babuin*) were met with in great numbers climbing on the rocks and trees, and, on account of their greenish grey colour, hardly to be distinguished from the tree trunks and stones. They tumble about amongst trees beset thickly with thorns many inches long without hurt. The Tubu do not molest them, partly because they are afraid of their strength and partly from superstitious motives.

On the cliffs bounding the river Udêno, near Bardai, in the centre of Tibesti, the author found a series of rude drawings of the same kind as those discovered by Barth in the north-eastern Tuârik region. The drawings are incised on the stone and represent almost without exception oxen with the horns bent forwards, all of which have a rope attached to the horns and drawn forward as if they were being led by it; some have on their backs the pack-saddle now used for oxen in Sudan. That the drawings were not inspired by reminiscences of the pack cattle of Sudan is shown by the circumstance that the leading rope is attached to the nostrils of the oxen and by the absence of the hump in them. The drawings are probably very ancient and date back from a time when cattle were used as beasts of burden in the country, and camels as yet not introduced. Barth remarked on the entire absence of the camel from amongst the very numerous drawings examined by him, in the present instance one drawing of a camel does occur, but Dr. Nachtigal thinks it has been probably added by a later hand in imitation of the ancient drawings. There is one figure of a man, a warrior of life size, with a spear in one hand and in the other a shield of a different form from that now used in Tubu and curiously enough divided into four fields by a cross.

Dr. Nachtigal had a hard time of it in Bardai, being kept a prisoner in his camp and cruelly stoned by crowds of girls of 12 or 14 years of age, if he attempted to move out. The children evidently thought it good fun stoning him as well as their religious duty to do so. They watched him closely in case he should dare to steal out during quiet hours and rallied one another with the shout of "at the heathen." Sometimes a drunken man joined in the sport with his throwing-iron and made matters very serious indeed. It was of no avail for Dr. Nachtigal to give the children sugar, or other presents, or to attend the sick; as soon as the presents were secured or the visit to the patient completed, the volleys of stones came flying as before. It was just before his flight from Bardai that Dr. Nachtigal heard of the murder of Miss Tinne; the news hastened his departure, and he returned to Fezzan.

A chapter is devoted to the natural productions of Tu. The best camels of the Eastern part of the Great Desert are bred by the Tubu. They belong to that variety of the animal which is peculiar to the Central and Southern Sahara, and which is distinguished at first glance from the Northern or Arab camel. The latter has short limbs, stout body, heavy head and neck, and shaggy hair; the former is higher on the legs and lighter built with smooth hair. The Arab variety looks built for weight-carrying, the Tuarik animal for pace.

The fat-tailed sheep of the coast does not occur in Tibesti, the sheep of the region having long legs, a long thin tail and pretty long black shining hair instead of wool.

The throwing irons of the Teda are curious weapons of boomerang form beset with projecting prongs of various shapes. They are double-edged in parts and single-edged with a stout back in others. The handle is bound with leather to give a firm grip.

The weapon is thrown horizontally with great precision and terrible effect. Children practise with a piece of bent flattened wood sharpened on one edge in imitation of the throwing iron and carry also a wooden-tipped spear. Being thus accustomed to carry weapons in their hands all their lives, the full-grown men when they are about their dwelling-places where they are strictly forbidden by custom to carry actual arms, return to the weapons of their childhood and carry about the wooden spear and throwing weapon.

The illustration given by the author of his reception by the Sultan of Bornu may be compared with the similar reception accorded to Denham and Clapperton so many years ago, and with their illustration of the ceremony. The then Sultan when he received Denham and Clapperton was concealed behind a lattice which was dispensed with in Dr. Nachtigal's case. Amongst the presents conveyed by the present author were life-sized portraits of the King and Queen of Germany and of the Crown Prince.

We cannot follow Dr. Nachtigal further, or pick out more interesting matter. The book seems to us rather too long and somewhat spun out; it is most sumptuously got up, with two large maps, well bound, and is full of good illustrations. Of these latter no list is given nor any information as to the sources from which those which have appeared before are derived. The familiar figure in Denham and Clapperton's work of a mail-clad warrior and horse of Bornu is copied without any kind of acknowledgment. Very slight differences have been made in the present figure: thus in it the great toe only is placed in the stirrup instead of the whole foot, as in the original, and the spear-blade is double instead of single, whilst the helmet has a plume added, but all the rest is directly copied without any reason being given for the alterations. A most remarkable defect in the book, considering that it is German and scientific, is the almost entire absence of references to former works of all kinds. As far as we have been able to discover there are only two references to other books in the entire work, one to Fournel's "Les Berbes," the other to the publications of the German Geographical Society. Though Barth and Duveyrier are mentioned and their views are quoted, no references to their writings are given. And Denham and Clapperton are entirely ignored even in the account of Bornu. A serious drawback is that the book is published so long after the travels to which it relates were completed. We hope that the second volume may not be long in appearing. We understand that the book is shortly to be published in English. It is full of interesting and valuable matter and of scientific details.

THE SCIENCE OF AGRICULTURE

First Lessons in the Science of Agriculture; for Use in Indian Elementary Schools or Classes. Pp. 67. By J. B. Fuller. (Calcutta: Stanhope Press, 1879.)

THIS little primer is issued under the authority of the Department of Agriculture and Commerce, North-West Provinces and Oudh. If its teachings be accepted and followed by those for whom they are intended, increased and improved crops must be the consequence. Of course, within the narrow limits of some seventy small pages, we cannot expect to find the scientific basis of the art of agriculture fully developed; indeed, the explanations of the materials and processes with which Indian farming is concerned are neither numerous nor full. But to show clearly a few of the worst mistakes made by Eastern cultivators of the soil, and to indicate remedies and improved methods of procedure in but half-a-dozen cases, is a useful beginning of an important work. We note, in passing, a few examples of the recommendations, based upon scientific knowledge, which Mr. Fuller makes in these "First Lessons." On p. 7 the usefulness of a good tilth and of a feeding-ground deepened by thorough ploughing for crops during seasons of drought, is illustrated and enforced. We learn from pp. 26 and 27 that due importance is not generally attached to the selection and securing of the best varieties and qualities of seed for sowing the fields. Too often they sow any seed they have by them, the produce of their own fields, and often of inferior quality. Good kinds of grain, &c., are thus found to be confined to one village, though they might be grown successfully in many neighbouring places. Thus, the village of Jaláli in the Aligarh district is well known for its fine white wheat; Sánkni, in Bulandshahar, for its safflower; some districts north-west of Allahabad for indigo, and Hinganghát for cotton. The value of new plants to India is discussed on pp. 31 and 32, the cases cited being tea, the potato, reana, and Egyptian cotton. Passing over a chapter in which some elementary facts about plant-food are given, we find many useful remarks (pp. 37 to 44) on the fertility of the soil and the means of restoring or increasing it. Here we are introduced to *reh* and *usar*. The former term is applied to the saline efflorescence, which, in some seasons especially, appear in many tracts of land in the North-West Provinces and elsewhere in India. *Reh* consists mainly of sodium and calcium sulphates, with some common salt and nitrates. The *usar* plain is infected with *reh*, but I cannot agree with Mr. Fuller in condemning the usar soils as sterile through deficiency of plant-food (p. 38). My analyses of such soils gave in most cases no evidence of deficiencies in the mineral elements of plant-nutrition, they merely showed an excess of soluble salts. What Mr. Fuller says about the best way of getting rid of *reh* is very judicious, so are his remarks about the sad waste of animal and vegetable residues (including indigo waste, and the bones of bullocks and buffaloes, in India)—residues which, instead of being burnt or neglected, should certainly be much more largely than at present ploughed into the land. His contrast between the work of the Indian plough and the English, the latter doing in one ploughing what the former needs twelve ploughings to accomplish, should be of some real service, especially as the new English-pattern ploughs made at Cawnpore are very light, and do not cost more than eight rupees apiece. By the use of this improved implement the "pan," which has been formed two or three inches under so large a tract of Indian soil by the rubbing of the old ploughshares and the trampling of the bullocks, would be broken up, and the rains would penetrate and moisten a much greater depth of soil. Mr. Fuller illustrates the advantage of increasing by such deep ploughing the depth of water-holding soil. He says: "In Madras, in the year 1878, when there was a great famine from the failure of the rains, some land was ploughed with the European plough, and some with the native plough, on the Government farm. Neither was irrigated, and both had to depend for their water on the little rain that fell. The European-ploughed land gave a rice-crop of six maunds per acre; the native-ploughed land did not yield a single grain." The two last lessons in this useful little book contain some quite satisfactory explanations as to the respective merits of canal and well water, and of thin and thick seeding in India. A. H. C.

OUR BOOK SHELF

On the Crystallography of Calcite. By J. R. McD. Irby, B.Sc., of Lynchburg, U.S. (Bonn: Charles Georgi, 1878.)

ONE is pleased to find that, in an essay on the crystallography of calcite, by a gentleman who has received his training in America and Germany, the system of representation used by Prof. Miller has been adopted, and not the objectional modification employed by Professors Groth and Dana, jun. One regrets that the paper is unaccompanied by a stereographic projection, which would have much simplified the discussion of the distribution and position of the forms.

The original part of the essay consists of a criticism and redetermination of some forms involving very high indices on crystals examined by the late M. Hessenberg. The measurements were made with one of the goniometers devised by Prof. Groth, which gives definite results when the faces are good. The collimator and telescope are fixed, however, at right angles to one another, so that the determination of striated faces, such as many of those examined were, is difficult and uncertain. Much more reliable measurements would be obtained were the angle between collimator and telescope small, and it would be very easy to arrange the collimator so that the angle of incidence and reflection might be varied at will. Prof. Miller used to arrange his goniometer so that the angle between the incident and reflected ray was less than 20°, and was thus able to get rid of a good deal of the difficulty arising from striation.

Mr. Irby has guarded himself from error by the comparison of several independent observations of the angles made by a new face with those adjoining it, with the angles obtained by calculation, and has avoided employing the angles made with faces on more distant parts of the crystal, though the latter would be often better adapted for purposes of calculation. He criticises Prof. vom Rath's method of observation by taking the reflection of a window-bar as signal. The error which would thus arise would not exceed 1′ in the case of good faces, and I believe Prof. vom Rath only employs this method of observation with very good faces. Another source of error would be due to the proximity of the signal which would give a considerable error if the edge were not well-centred. Moreover, a goniometer with vertical plane of reflection is very difficult to get into or keep in good adjustment, and errors might arise in this way. None of these errors will, however, account for the impossibility of getting simpler indices for the form $\{35, 17, \bar{32}\}$, considering how definite were the angles obtained from the several faces of the scalenohedron. A careful criticism of this form at the time it was published, and of all the different ways in which errors might be piled up in the course of the analysis, failed to lead to any result but that of admitting the possibility of forms with these high indices. In the Cambridge collection is a crystal of quartz with an extremely well-developed face, which Prof. Miller has determined to be $\{50, \bar{19}, \bar{19}\}$. It is very slightly rounded on the edge of the prism face. Of course, when the faces are rounded or otherwise distorted, indices calculated from the observations are mere approximations. Seeing the great variations which occur in the angles of well-crystallised minerals, good work might be done in testing the constancy of the angle of the cleavage rhomb in the specimens from different localities. Breithaupt's determinations of this angle are unfortunately not sufficiently reliable.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Molecular Velocity of Gases

YOUR correspondent, M. Hajniš, asserts in a foot-note appended to his letter published in NATURE, vol. xxi. p. 176, that "the formula for the molecular velocity (of gases) was first given by Krönig," and not by Joule. I am at a loss to understand how this statement can be justified.

Krönig's paper appeared in 1856, while Joule's calculation, which is that now generally received, is of date 1848. In his discourse on molecules (*Phil. Mag.*, December, 1873), Prof. Maxwell says: "The further development of the theory is generally supposed to have begun with a paper by Krönig, which does not, however, so far as I can see, contain any improvement on what had gone before." R.

Weaver Birds and Fire-Flies

UNDER the heading "Natural History Notes from Burmah," in NATURE, vol. xx. p. 362 of the present series, Mr. R. Romanis asked if any of your readers have ever seen or heard of weaver birds sticking fire-flies to lumps of mud on the sides of their nest for the purpose of illumination.

The tradition that certain birds of the weaver family (*Ploceidæ*) and their allies do this, is prevalent over a large portion of the globe inhabited by these birds. I have traced it personally from China, all parts of India, Burmah, Ceylon, the Malayan Peninsula, Indian Archipelago, Southern, Eastern, and Western Africa, and South America. I have examined "weaver birds'" nests from all these countries, and have found lumps of mud sticking inside them, and "*therefore it must be true, you know!*"

But for what use are these lumps of mud stuck there?

Some years ago I wrote an article in the *Cape Monthly Magazine* on this very subject, entitled "Strange Stories and their probable Origin," and I started by saying "Where there is smoke there must be fire," quoting the old proverb.

My belief is that these lumps of mud are used as *scrapers* on which to clean the birds' bills, as I have frequently found the wing cases, and other *débris* of *Coleoptera*, &c., fixed to them. Hence the superstition that they stick fireflies thereon. I should remind your readers that all the "weavers" are grain feeders, and perhaps only occasionally partaking of insect-food, they are bothered by the bits sticking to their bills. I see my tamed birds are most careful in cleaning their beaks.

At the time I wrote my article above alluded to, I was not so conversant with the African "hang-nests" as I afterwards became, but I can affirm that in all the places I have named the superstition, *and the mud*, is to be found. E. L. LAYARD

British Consulate, Noumea, October 22, 1879

The Papau

PERMIT me to add to my friend the Rev. S. J. Whitmee's testimony of the papau being eaten by birds in the Samoan Islands, that it is here (New Caledonia) a favourite food of the "white eye" (*Zosterops*), and in the Loyalty Islands was used as the only bait to attract these birds, of which dozens were brought me—of the three known species of that genus which inhabit that group (see my letters to *Field* newspaper) all caught by the boys through its means. If my memory serves me rightly, I have seen the papau in Mauritius eaten by a species of *Zosterops*. E. L. LAYARD

October 22, 1879

Scale of Colours

IN NATURE, vol. xxi. p. 172, it is stated that at a meeting of the Zoological Society, December 2, 1879, "A letter was read from Mr. E. L. Layard, F.L.S., advocating the desirability of a fixed scale of colour for use among naturalists in describing the plumage and pelages of birds and other animals." Perhaps Mr. Layard is not aware that such a scale, in form of thin 8vo, was published by Patrick Syme in Edinburgh, in 1821, the tints being illustrated by carefully coloured examples. The exact title of the work, a copy of which is in my own library, is as follows:—"Werner's Nomenclature of Colours, with Additions, arranged so as to render it highly useful to the Arts and Sciences, particularly Zoology, Botany, Mineralogy, and Morbid Anatomy. Annexed to which are Examples selected from well-known Objects in the Animal, Vegetable, and Mineral Kingdoms." The date given above is that of the second edition, which was "Printed for William Blackwood, Edinburgh, and T. Cadells, Strand, London." L. BLOMEFIELD

Bath, December 22, 1879 (late JENYNS)

On the "Habitat" of Lophiomys

ON reading the review of "Cassell's Natural History," vol. iii., given in NATURE, vol. xxi. p. 136, I find that both the author and the reviewer do not appear to have been aware that the "habitat" of that most interesting rodent, *Lophiomys imhausi*, is well known. The rich and interesting Museo Civico di Storia Naturale, of Genoa, amongst its many rarities, contains a magnificent specimen of the *Lophiomys*, mounted skin and skeleton, which specimen was caught at Keren in the Bogos land, in June, 1870, and forms part of the fine collections made at that place by Dr. Beccari and Marquis Antinori. The native name of the *Lophiomys*, according to Antinori, is *Tzechiza*.

The reviewer cites M. Alphonse Milne-Edwards's impression of the resemblance of *Lophiomys* to certain opossums, a point in which I cannot completely agree; my impression is that this very remarkable rodent offers one of the best cases of "defensive mimicry," being strangely like a Viverrine carnivore in outward appearance. The granulation of the upper portion of the skull, which extends to the upper surface of the first cervical vertebra, is very peculiar; but it is not strictly correct to assert that nothing of the kind is met with in other mammals; in the very same order, Rodentia, we find a very similar structure in the cranium of the Paca (*Cœlogenys*), and I believe some allied forms.

HENRY HILLYER GIGLIOLI

Reale Istituto, Florence, December 17, 1879

On Haloporphyrus lepidion (Risso)

I HAVE recently had occasion to examine two specimens of this rare and remarkable gadoid fish of the Mediterranean, originally described as *Gadus lepidion* by Risso ("Ichthyologie de Nice," p. 118). The first was captured in my presence in the Gulf of Genoa, in July last, from a depth of about 900 metres, the second I received from Nice, where it was captured in deep waters on September 1 last, and I know of a third specimen taken at the latter place. All agree perfectly with Risso's description except in the general colour, a light brown, and not "*un beau rouge incarnat*," while Risso appears to have overlooked the presence of a small patch of vomerine teeth. But our Mediterranean specimens present notable differences from that described by Dr. Günther ("Catalogue of Fishes," iv. p. 358), and referred by him to this species; besides being considerably larger, the British Museum specimen, which is from Madeira, has a much smaller eye and much longer snout and barbel. Such differences *might* depend on age, but I am strongly inclined to consider them specific, and therefore beg to draw the attention of ichthyologists to the case; should my opinion prove correct, the Madeiran fish might go by the name of *Haloporphyrus güntheri*.

While rapidly completing the rich series of fishes belonging to the central collection of Italian vertebrata, formed by me in the Florence Zoological Museum, I have recently been able to add thereto a second very rare gadoid, the *Physiculus dalwigki*, Kaup, a new acquisition to the Mediterranean fauna. My specimen was captured at Nice on August 4 last, and strange to say was sent to me as *Uraleptus maraldi*.

Reale Istituto, Florence HENRY HILLYER GIGLIOLI

Edison's New Lamp

I OBSERVE in NATURE, vol. xxi. p. 187, a statement to the effect that Mr. Edison has adopted the use of carbon in his new electric lamp, and that the carbon he uses is charred paper or card of the shape of a horse-shoe.

Fifteen years ago I used charred paper and card in the construction of an electric lamp on the incandescent principle. I used it, too, of the shape of a horse-shoe, precisely as, you say, Mr. Edison is now using it. I did not then succeed in obtaining the durability which I was in search of, but I have since made many experiments on the subject, and within the last six months I have, I believe, completely conquered the difficulty which led to previous failure, and I am now able to produce a perfectly durable electric lamp by means of incandescent carbon.

JOSEPH W. SWAN

Underhill, Low Fell, Gateshead, December 29, 1879

Flow of Viscous Materials

MR. BOTTOMLEY, in his paper on this subject in NATURE, vol. xxi. p. 159, refers to experiments made four years ago, but if he refers to the *Philosophical Magazine*, vol. xxvi. 206, 1845, he will find a notice of an experiment made twenty-four years ago. It occurred thus:—A barrel of pitch, with one end partly knocked out, had been lying in the sun for some months, and a part of it had run out on the ground.

My late partner, Prof. L. Gordon, visited the wire-rope works one day in August, 1844, and I called his attention to the appearance of the pitch as being a good illustration of Prof. Forbes's theory of glaciers; thereupon he wrote the letter referred to; which is also quoted in Forbes's "Theory of Glaciers," p. 269.

Any sort of pitch, such as that obtained from gas tar, will answer the purpose. If the surface is rubbed over with some white material, the formation of crevasses will be well shown; and if a row of pins are stuck into the pitch about an inch and allowed to project they will soon lose their perpendicularity and thus indicate the movements in the model glacier. The rapidity of flow of course varies with the temperature.

I had a curious illustration of the power of plants in forcing their way through resisting materials. I had covered the ground with about two inches of asphalt, and a dandelion pushed its flower and leaves through this viscous mass.

Ferndene, December 28, 1879 R. S. NEWALL

Hungarian Earthquakes and the Kolumbács Flies

A NOTE in NATURE, vol. xxi. p. 89, speaking of the recent Hungarian earthquakes, contains, amongst others, the following passage:—"Near Weisskirchen, the old ruins of the Castle of Golubacz have fallen in completely, and in the vicinity several caves were rendered inaccessible. These caves were the *breeding places* of the dreaded Kolumbács mosquitos, and if this insect is thus exterminated the earthquake may, with all the damage it did, have yet been of some use."

This report is based on obvious error, for it is a well-known act that the small (3-4 millim. long) Kolumbács flies (*Simulia golumbacensis*, Fabr.), which, in the southern part of Hungary, especially in the old Banat and the county of Hunyad, cause considerable damage among the pasturing cattle (especially among horned cattle, horses, swine, and sheep), breed by no means in those caves which are to be found around the ancient Galambócz (known nowadays under the name of Golubácz or Kolumbács, on the Servian territory), but in the shallower parts of the waters extending in great quantities in that country. The course of life of the Kolumbács fly is, for the most part, in conformity with that of many families of the Nemocera, or Tipulariæ group, as are the Culicidæ, many species of flies (Brachycera), the Phryganidæ, &c. The mature and fecundated mother-fly lays her eggs upon the plants vegetating on the water-borders, whence they get on the stones under the water, and other objects, there living through their larva and nymph states until they arrive at their full development.

But, in the first years after 1850, under the rule of the Austrian military system of that time, there did occur the curious fact that —upon the advice of a military officer of the frontier-districts, who, as it was supposed, had made out that the breeding-nests of these flies are in the caves around Galambócz, Old Moldavia, and their environs—the Government of Vienna officially decreed the walling up of the openings of the caves. And actually they were walled up. But in the next mild spring, the conditions of development being favourable again, the Kolumbács fly appeared and ravaged once more. The Viennese Government, on learning this unpleasant and disappointing news, hastened to amend the blunder, and sent to the place a Hungarian *savant*, Vincent Kollár, and a German entomologist, Joseph Mann, to take the question under examination. These, in a brief space of time, succeeded in clearing up the true state of things, and in gathering such a series, as contained all the stages of the development of the Kolumbács fly in numerous specimens. This collection is to be seen now in the entomological section of the Naturalien Cabinet of Vienna, grouped in the best order.

The imputation, therefore, as if it were the Hungarians who had walled up the orifices of the caves in the vicinity of Galambócz, in order to exterminate the Kolumbács flies by that means—an opinion which, as I, this year, happened to hear at the lecture of an eminent German *savant*, is propagated even in Germany—is entirely erroneous and without any foundation.

Budapest, December 2 JULIUS LETHÖ

Unconscious Thought

RESUMING this subject, I again call attention to the circumstance that unconscious thought in children is more developed than conscious thought, though conscious thought or sensation lays the foundation of what becomes habitual or instinctive. In man, unconscious thought becoming habitual, it is the nursery again of conscious thought, the two conditions in the adult coexisting.

Turning to comparative psychology, a branch which has always appeared to me of particular importance, we find in intelligent animals, as the dog, either in community (commonly called wild) or in the domesticated state, the same nature of mind as in man and the like manifestations. In the young animal, however, there must have been the same precedent stage, though the conscious stage is of course produced earlier than in man.

This raises the question, on which we can speculate, but which we cannot as yet solve, whether some animals are not mostly in the state of unconscious thought, never attaining to that of conscious thought. Looking to the cases of degradation in man, it appears to me that in softening of the brain the man falls back to the unconscious stage, and in some instances remains for some time in it, so that here we get an example of prolongation, it may be called continuance, of the unconscious stage.

Such a state as that of habitual unconscious thought may be regarded as possible and probable, and we are justified in applying it to many animals of inferior nervous organisation. The condition of consciousness being absent, the degree of pain is less, as must be the case in infants. So far from the saying of the master painter of mankind being true that the worm feels as great a pang as when the giant dies, the worm must be less sensitive and less sensible. It is quite possible that the antivivisectionists may be in the wrong as to lower animals, whatever reason they may have as to those like the dog.

There will be at least the like gradations of mind as of form in the animal world, and the difference between an animalcule and a dog will be enormous, and still greater that between the animalcule and man. In the higher stages the differences will be vastly augmented by the agencies at work. Thus it must be that the conscious stage producing precision of action influences the habitual condition of the unconscious stage. Having applied this to man, we may better conceive it, and form some notion of its prodigious relative development by considering how man so constituted has his power of thought enhanced by the great instrument of speech.

These causes contribute to the great differences which I long since pointed out between the rapidity of thought of one man and another, or of the same man at different times of life or under various conditions. My paper "On the Geographical Distribution of Intellectual Faculties in England," following one at the British Association, being published in the *Journal* of the Statistical Society (June, 1871, p. 357), has escaped the notice of psychologists and physiologists, being esteemed statistical, whereas it is also psychological. At p. 357 I gave an account of an experiment, showing a fluctuation in conscious thought in one adult of from 1 to 4, or 100 to 400, denoting an enormous difference, and illustrative of the variations in mental power which exist in society. If, however, we were to estimate a child of 14 at 50, then the ratio would be as 1 to 8. If we take a child of 7 at the quarter of an adult, then we should have 1 to 16. These are not extreme measures, for in the babe we may find 1 to 100, 1 to 200, 1 to 400.

This is given as an illustration of what must exist in the animal world as to conscious thought, and that without reference to unconscious thought, which must be the condition of many classes. Physiologically the subject has been treated by many physiologists, and notably most admirably by Dr. Carpenter; but here the psychological aspect in the special forms indicated is alone brought into prominence.

The phenomena of unconscious thought, indeed, require much greater attention. Not only do they underlie the distinctions between animals and between animals and man, but they must be taken into consideration as explanatory of dreams and of many forms of mental disease. This has been partly dealt with by Dr. Carpenter.

While the later steps of dreams, the visible and pictorial stages, are greatly under the influence of conscious thought, the early stages are under the influence of unconscious thought. It appears to me quite possible that unconscious thought is not altogether latent in sleep. It is worthy of consideration what is the condition of a wakeful animal, say a dog—whether it is one succession of dreams or a form like delirium.

The recurrence of an error once implanted in the mind, notwithstanding our efforts to eliminate or counteract it, is probably due to the tenacious resistance of unconscious thought, storing up and reproducing the error.

Heredity of thought, whether as dealt with by Mr. Francis Galton or by myself in the paper quoted at p. 359, &c., may be assigned chiefly to the transmission of the habits of unconscious thought, if we consider more especially the condition of the lower animals.

As my last communication was mentioned in the *Daily Telegraph* of November 29, and with the assertion that Dr. Carpenter, Mr. C. T. Munro, and myself have provided in unconscious thought a new plea for unaccountability for criminal actions, it is well to remark that the phenomena discussed have no such bearing.

HYDE CLARKE

December 20, 1879

Stags' Horns

THE disappearance of the antlers of stags, in the Highlands and elsewhere, is to be accounted for by the fact that they are saleable articles; but although they do not assist as *entremets* at the animal's meal it may happen that they assist—in the form of knife-handles—in the distribution of his venison at our dinners.

When a lad I obtained many antlers of the Fallow Deer from a neighbouring park, the tines of which were sometimes broken but never gnawed or polished by licking.

It would scarcely be surprising that deer should crave for calcareous matter during the rapid development of their antlers, but neither are their tongues adapted for rasping nor their teeth for comminuting hard bones.

PAUL HENRY STOKOE

Beddington Park

No gillie that I know of has the honour of my acquaintance, and therefore no gillie can know, save indirectly, that I have picked up a horn of the red deer, in a park near Sheffield! I was told at the time by the gardener who accompanied me that these horns were eagerly sought after by the Sheffield knife-makers for the purpose of making bucks' horn knife-handles.

M. T. M.

A Query

I HAVE seen somewhere (but I am unable to say where) a statement to the effect that there is some evidence for the supposition that in the crystallising state of matter the forces between molecule and molecule are not directed in the right lines joining the molecules. Can any of your readers throw light on this subject, or give references to sources of information about any other case in which the mutual action of two molecules is not directed in the line joining them?

IGNORAMUS

THE ASSERTED ARTIFICIAL PRODUCTION OF THE DIAMOND

PROF. MASKELYNE sends us the following letter on this subject:—

I should be obliged if you would accord me space in one of your columns in order that I may answer a great number of letters and applications which have pursued me during the past few days on a subject of some little public interest, that subject being the asserted formation of diamonds by a gentleman at Glasgow.

Some ten days ago I had heard nothing whatever of the claim of Mr. Mactear, of the St. Rollox Works, Glasgow, to the artificial production of the diamond.

My name, however, was already in several newspapers as that of a person in whose hands the asserted diamonds had been placed for a decision as to their true nature. Ultimately a small watch-glass with a few microscopic crystalline particles came into my hands for this purpose from Mr. Warington Smyth, and subsequently a supply came to me direct from Mr. Mactear. I shall proceed to state the results I have obtained from the examination of these.

Out of the first supply I selected by far the largest particle, one about the $\frac{1}{50}$th of an inch in length, and it may be that I wasted some time in experimenting on this particle, as it might not have been an authentic example of the "manufactured diamond," since it differed in some respects from the specimens I have since received direct from Mr. Mactear.

The diamond excels all substances in hardness. Its crystals belong to the cubic system, and should not, therefore, present the property of doubly refracting light. Frequently, however, from the influence of strains within the crystal due to inclosed gas bubbles, or other causes, diamonds are not entirely without action on a ray of polarised light sent through them. Finally, the diamond is pure carbon, and, as such, burns entirely away when heated to a sufficiently high temperature in the air, and more vividly so burns, or rather glows away, when heated in oxygen gas.

The specimens I had to experiment upon were too light to possess appreciable weight, too small even to see unless by very good eyesight or with a lens, yet were, nevertheless, sufficiently large to answer the three questions suggested by the above properties.

A few grains of the dust, for such the substance must be termed, were placed between a plate of topaz—a cleavage-face with its fine natural polish—and a polished surface of sapphire, and the two surfaces were carefully "worked" over each other with a view to the production of lines of abrasion from the particles between them. There was no abrasion. Ultimately the particles became bruised into a powder but without scratching even the topaz. They are not diamond.

Secondly, some particles more crystalline in appearance than the rest were mounted on a glass microscope slide and examined in the microscope with polarised light. They acted each and all powerfully in the manner of a birefringent crystal. It seemed even in one or two of them that when they lay on their broadest surface (it can scarcely be called a "crystal-face") a principal section of the crystal was just slightly inclined to a flattish side of it in a manner that suggested its not being a crystal of any of the orthosymmetrical systems. Be that as it may, it is not a diamond.

Finally, I took two of these microscopic particles and exposed them to the intense heat of a table blow-pipe on a bit of platinum foil. They resisted this attempt to burn them. Then, for comparison, they were placed in contact with two little particles of diamond dust exceeding them in size, and the experiment was repeated. The result was that the diamond particles glowed and disappeared, while the little particle from Glasgow was as obstinate and as unacted on as before. I had previously treated the specimen I have alluded to as the first on which I experimented by making a similar attempt in a hard glass tube in a stream of oxygen, and the result was the same. Hence I conclude that the substance supposed to be artificially formed diamond is not diamond and is not carbon, and I feel as confident in the results thus obtained from a few infinitesimal particles that can barely be measured and could only be weighed by an assay balance of the most refined delicacy, as if the experiments had been performed on crystals of appreciable size.

Not content with merely proving what these crystalline particles are not, I made an experiment to determine something about what they are.

Heated on platinum foil several times with ammonium fluoride, they became visibly more minute, and a slight reddish white incrustation was seen on the foil. At the suggestion of Dr. Flight, assistant in this department, a master in the craft of the chemical analyst, these little particles were left for the night in hydrofluoric acid in a platinum capsule. This morning they have disappeared, having become dissolved in the acid.

I have, therefore, no hesitation in declaring Mr. Mactear's "diamonds" not only not to be diamonds at all, but to consist of some crystallised silicate, possibly one resembling an augite, though it would be very rash to assert anything beyond the fact that they consist of a compound of silica, and possibly of more than one such compound.

The problem of the permutation of carbon from its ordinary opaque black condition into that in which it occurs in nature, as the limpid crystal of diamond is still unsolved. That it will be solved no scientific mind can doubt, though the conditions necessary may prove to be very difficult to fulfil. It is possible that carbon, like metallic arsenic, passes directly into the condition of vapour from that of a solid, and that the condition for its sublimation in the form of crystals, or its cooling into crystal diamond from the liquid state, is one involving a combination of high temperature and high pressure present in the depths of the earth's crust, but very difficult to establish in a laboratory experiment.

NEVIL STORY-MASKELYNE

FURTHER NOTES UPON THE PAPUANS OF MACLAY COAST, NEW GUINEA

I.

HAVING recently received from my friend M. von Miklucho Maclay, by way of Singapore, some further notes upon the ethnology of the Papuans of Maclay Coast, in New Guinea, I herewith contribute the following abstract of them to the pages of NATURE, as the periodical in which they were published is not readily accessible to English readers.[1]

The Daily Life of the Papuans.—With regard to the application of pigment to the face and body, the Papuans paint the face with red and black colours, the red being such usually used by the young (those from fifteen to thirty years "malassi"), and the black by those of riper years. The young further use the colouring agents in the form of various devices. On ordinary days they are unpainted, or confine themselves to a ring round the eyes or a line along the nose, which goes to join another running from the temple to the vertex, over the shaved eyebrows. On formal occasions, however, the whole face is smeared with a pigment over which white and black are drawn. Sometimes half of the face is painted black, while the other half is red, which gives a very remarkable appearance. The Tamo, or men over thirty years old, almost never employ the real colour, but substitute black instead. On important occasions the whole head is covered with the pigment; in fact, in certain districts, *e.g.*, "Kar Kar," Dampier Island, where this is abundant, the inhabitants smear the whole body with it, and with such care that it would be readily taken for their natural colour.

The women of Maclay coast are seldom to be seen painted, and, when they are, in not so elaborate a mode as are the men. A description has been already given of the *coiffure*. Before the arrival of Maclay bamboo knives and fragments of flint were used for the removal of the hair; but during his stay sherds of glass collected in the neighbourhood of his hut were substituted. Another method was also employed for the removal of single hairs by means of a noose made with a stalk of grass, in which the hair was twisted out of its follicle. Although this operation would seem to be a painful one, a Papuan has been seen engaged for three or four hours on this occupation, without a shade of an expression of pain being seen to pass over his features. Although the Papuans of this region are not conversant with the art of tattooing, they are accustomed to burn rows of scars in lines upon the skin. The operation is thus performed:—The patient having been placed either upon his back or belly, a red-hot fragment of dry bark is laid

[1] "Ethnologische Bemerkungen über die Papuas der Maclay-Küste in Neu Guinea—Alltägiges Leben der Papuas" (Fortsetzung). Reprinted from the *Natuurkundig Tijdschrift voor Nederlandsch Indie*, Zevende Serie, Deel vi. p. 294. (Batavia, 1876.) This abstract may be regarded as a continuation of two articles by me upon the same subject, which were published in NATURE, vol. ix. p. 328, vol. xiv. pp. 107, 136.—J. C. G.

upon the skin until it is entirely consumed to ashes, and so on with each mark. This procedure, too, must demand great patience and self-control. The women, curiously enough, ornament their bodies much less than do the men, their costume being not infrequently reduced to a minimum. In Billi-Billi, Maclay saw a marriageable maiden in the most singular costume that could possibly be conceived, consisting, as it did, of a single large shell (a white *Cypræa*) upon the lower part of the *mons Veneris*.

The men employ four or five hours in the combing of their hair and in smearing it with a decoction of the fruit of the Súbari (*Calophyllum inophyllum*), also in adorning it with feathers and flowers, and in painting their faces and backs. The only decorations, on the other hand, in which the females indulge on festal occasions is in a little dye with which they smear their hair, cheeks, and forehead, and a number of necklaces composed of shells of various sizes and gaily-coloured fruit kernels.

With regard to the social position of the women. Although it can hardly be said that the Maclay Coast Papuans ill-treat their wives, or that these latter have no influence upon the men, it is nevertheless the case that the women in almost every particular play an inferior *rôle*; for even when they are not overworked they have always enough employment throughout the year, while the men, with the exception of a few weeks spent in heavy work—the laying-out of plantations and cultivation of the ground—can for three-fourths of the time enjoy a *dolce far niente*. The women, moreover, have a worse diet, and dare not take their meals in company with the men, and in comparison with the latter wear scarcely any ornaments, nor do they take any part in their feasts.

Neither the marriage nor the birth of children are celebrated with any particular festal observance. Circumcision, on the other hand, is a somewhat important rite. This is performed at the age of twelve years, in the forest, at a distance from the village, and, as Zipporah did it, with a sharp flint, and after the ceremony the neophyte is escorted with songs back to the village. He is now no longer regarded as a boy, but as having come to man's estate, and enjoys, accordingly, many privileges which are not accorded to mere children.

The mode of salutation is somewhat laconic. When a neighbour comes into a village he says to the children, "*E-Wau!*" "Hey, children!" while the men and women are greeted respectively with a "*E-Nangeli!*" and "*E-Mem!*" "Hey, you women!" and "Hey, fathers!" The greeting of the Tamo among themselves is "*E-Aba!*" "Hey, brothers!" Relations, however, and friends are not accustomed to greet one another. The Papuans reach out their hands one to another, with a kind of movement, but without any mutual pressure. On departure the guest says "*Adi-angarmem*," "I am going," to which the host and any others who may be present reply "*E-Aba*," or "*E-Mem*," and the guest answers in corresponding terms. Upon this the host says, "*Glembe*"—"Depart, then"—and escorts his guest as far as the entrance of the village, carrying with him the presents and the remnants of the feast. Hereupon the guest frequently remarks, "Stay you here, but I must be off." If the parting be of a particularly feeling character, one presses the other on the left side of the breast, embracing him at the same time with one arm, while with the other hand he pats him gently on the back. In the village Bogat, and in the Archipelago of Contentment, Maclay remarked that the people greeted a particularly honourable guest by squatting in a particular position on the ground.[1]

The custom of mutual exchange of names is pretty widely spread throughout the coast, and Maclay was frequently begged to change his name with that of one of the natives whom he might have distinguished in some way or other. In order, however, to avoid any misunderstanding, he always refused this request, and only as a particular favour allowed his name, "Maclay," to be borne by the newly-born boys, whose fathers regarded themselves as his special friends. He was, moreover, frequently requested to choose a name for newly-born boys and girls.

As regards the treatment of the dead, the news of the death of a man is announced to the surrounding villages by a fixed succession of strokes on the *barum*. On the same or the next day the whole male population assembles in complete war equipment in the neighbourhood of the village. To the sound of the *barum* the guests stream into the village, and are awaited in the neighbourhood of the hut of the deceased by a crowd likewise in warlike accoutrements. After a short palaver those present divide into two opposite camps, after which the performance of a sham fight takes place. They go to work, however, somewhat carefully in that they make no use of their spears; dozens of arrows, however, are shot off, so that not a few are somewhat seriously wounded in this make-believe encounter. The relations and friends of the deceased seem in particular to get excited and behave like madmen. After all are tired out, and all arrows have been shot away, the *quasi* enemies sit down in a circle and comport themselves merely as lookers-on. The nearest relations of the deceased then bring a pair of mats and the sheaths of the petioles of the fronds of the sago-palm, and lay them in the midst of the open space. Next they bring the corpse out of its hut, maintained in the stooping posture, with the chin resting upon the knees, and the arms embracing the legs, by means of strips of rattan. Close to the corpse are placed its property, gifts of its neighbours, and a couple of bowls (*tabir*) full of freshly-cooked food, while the men sit in a circle round the open space, the women, but only those nearest related to the deceased, merely look on at a distance. The corpse is then, with great neatness and art, wrapped in the mats and palm leaves, and tied up fast with a quantity of rattan and lianas, so that the whole finally resembles a well-made parcel. This, after being fastened to a strong stake, is brought into the hut and the stake is fastened under the roof; finally, after arranging all the property, presents, and food in the neighbourhood of the corpse, the guests leave the hut and return to to their respective villages.

Some days later, when the corpse has become very decomposed, it is buried in the hut itself, a proceeding which in no wise hinders the relations from continuing to use it as a dwelling-place. About a year afterwards the skull is dug up and separated from the body of the corpse; but it is not the whole skull, but only the lower jaw which is preserved, and that by the nearest relation of the deceased, being carried, not infrequently, in the *gun*, or worn as a kind of armlet.[1] This bone is most carefully preserved as a *souvenir* of the deceased, and it was only by the help of much persuasion, backed by numerous presents, that Dr. M. Maclay prevailed upon its possessor to part, under the seal of secresy, with this treasured memento. The burial of a child or of a woman is attended with much less ceremony, being heralded by the sound of no *barum*, and accompanied by no assembly of neighbours, nor martial pomp and circumstance.

[1] "Niederhocken." This position has been already described in the first paper on the Papuans of Maclay coast. NATURE, vol. ix. p. 329.

[1] This is not the only instance of the bones of the dead being worn by their surviving relatives. For instance, the Tasmanians (*vide* NATURE, vol. xiv. p. 211), according to Dr. Barnard Davis, carry as necklaces fragments of the bones of their relatives; and it is moreover stated by Prof. Allen Thomson, that the widows among the Andaman Islanders—the Mincopies according to Dr. B. Davis—actually wear the skulls of their late husbands upon their shoulders (NATURE, vol. xiv. p. 489). Prof. Flower, in a recent lecture on ethnology at the Royal College of Surgeons, showed the skull of an Andamanese man, to which was attached a very elegant webbed sling by which it had been suspended from the neck of the widow.—J. C. G.

With regard to the language and dialects. This study was attended with great difficulty because there was at hand no go-between who could play the part of a mutual interpreter, for the terms which were required could only be learnt either by pointing to the corresponding object, or through such signs as would be employed in barter. These two methods were, however, the source of many misunderstandings and mistakes, for the same object was variously named by different people, and for weeks Maclay was uncertain as to which term was the correct one. Here is an instance of what frequently happened. Dr. Maclay showed a leaf, hoping to arrive at its name, a native mentioned a name, which was forthwith written down; another Papuan gave another name on being shown the same thing; a third, fourth, and fifth, each gave a different word. Which out of all these was the proper name of the leaf in question?

After a time and by degrees it was discovered that the word first mentioned was the proper name of the plant to which the leaf belonged, the second betokened its colour, *e.g.*, *green*, the third *dirt* or *useless*, probably because the leaf had been picked up from the ground, or belonged to a tree not turned to account by the Papuans. And so it came to pass with many words with abstract expressions and such as could not be explained by signs. Maclay, too, had obviously greater difficulties, for instance, how to inquire the equivalent word for "friend," and that for "friendship," and it was only after the lapse of four months that the corresponding word to "seeing" was arrived at, but as to the equivalent of "hearing," this was never come upon. The writing down of words was involved in further difficulties; there were certain tones of the Papuan language which were absolutely impossible to imitate. This Maclay rightly attributes to fundamental differences in the anatomical structure of the larynx and the whole muscular system of the organ of speech in the two races. Not only the organ of speech but also that of hearing plays an important part, for the same word may be heard in a totally distinct manner by different individuals. There is, too, in the denotation of the words of such a tongue quite a series of sources of fallacy—(1) the aborigines have not the same pronunciation; (2) the translator hears the words with his individual organ of hearing; (3) previously to writing it down he pronounces it with his individual organ of speech; (4) and finally, after pronunciation, the foreign word must be expressed in the characters of a known language. Nearly every village on Maclay Coast has its peculiar dialect, and these vary so much, that when making an excursion of two or three days, M. Maclay required the assistance of two, and even three, interpreters. It is only the old who understand two or three dialects, and it not infrequently happens that young persons do not know words of their own dialect, in which case they resort for information to some old Papuan. From this it may come to pass that upon the death of elders new words must be brought out by the young and introduced into the vocabulary. On the other hand the Papuans are fairly quick at learning a new language, consequently there are now to be heard on Maclay Coast a number of Russian equivalents for such words as axe, knife, nail, &c. The names of various birds are founded upon the cry which they utter. There are, moreover, among the dialects of Maclay Coast a number of Malayo-Polynesian words. J. C. GALTON

(*To be continued.*)

JAMES R. NAPIER, F.R.S.

MANY cultivators of science, both at home and abroad, more especially those engaged in engineering and shipbuilding, will deeply regret to learn of the decease of Mr. James R. Napier, F.R.S., the eldest son of the late Mr. Robert Napier of Shandon, the eminent pioneer of the shipbuilding and marine engineering industries of the Clyde. The sad event occurred on Saturday, the 13th ult., at his house in Glasgow, after an illness which had confined him to his room for about three weeks. His health had been very unsatisfactory, however, for a number of years, and, with the view in a great measure of securing a better bodily condition, he had travelled a good deal—to Australia, twice to America, several times up the Mediterranean, wintering once at Malta, and on another occasion at Madeira, where he had the melancholy satisfaction of having as a brother invalid the late Prof. W. K. Clifford.

Born in the year 1821, and educated at the High School of Glasgow, Mr. Napier studied mathematics under Dr. James Thomson (Sir William Thomson's father), natural philosophy under Dr. W. Meikleham (Sir William's immediate predecessor), and practical astronomy under the late Prof. J. P. Nichol.

When quite a young man he was installed in his father's shipbuilding yard at Govan in a responsible position, having had, however, an excellent practical training in the workshop under the late David Elder, a man who did much to train the present race of mechanics who have since secured prominent positions in their profession. By and by the firm of Robert Napier and Sons was constituted, the sons being the deceased and his brother John; and the firm eventually attained a position in connection with marine engineering and naval architecture that has never been excelled in the annals of steam navigation. About twenty years ago Mr. James R. Napier retired from the firm, and for a time he conducted a shipbuilding business of his own, when he availed himself of the opportunity of putting into practice a number of his most advanced notions in ship construction. But it would seem as if he was not destined to shine as a man of business, being very unlike his father in this respect. During his subsequent career he occasionally executed a number of commissions in connection with matters in which his special knowledge could be profitably turned to account, and much of his time was devoted to scientific pursuits.

From time to time Mr. Napier communicated many interesting papers to learned societies with which he became connected. One of those bodies was the Philosophical Society of Glasgow, which he joined in the year 1850, when its presidential chair was filled by Dr. Thomas Thomson, F.R.S., the eminent chemist and mineralogist. In 1855 he became a life member of the British Association, on the occasion of its second meeting in Glasgow, and he long took a deep interest in its affairs, by serving on special committees, and otherwise. He was one of the founders, and subsequently president, of the Institution of Engineers in Scotland (now Institution of Engineers and Shipbuilders), the birth of which took place in 1857, with Prof. Rankine as the first president. When the Institution of Naval Architects was formed in the year 1860, he became a member, and was honoured by a seat in its first council.

Following the example of Prof. Roscoe in Manchester, a number of people of scientific proclivities, a few years ago, originated the Glasgow Science Lectures Association, the first lecture of which was, appropriately, delivered by Roscoe himself. The movement in Glasgow met with very hearty co-operation from the deceased. His sympathy with scientific progress was shown in a great variety of ways; and as an inventor who had often to apply to the Patent Office, he was leagued with Sir William Thomson and others in the recent movements for bringing about a comprehensive reform of the patent laws.

One of the leading features of Mr. Napier's career was the unbroken intercourse, personal and professional, which was maintained between him and Prof. Rankine. They had numerous joint undertakings in experimental investigation, and each was of very great service to his fellow, and in the end to science. As might well be understood, to no person was Rankine's too early decease a greater loss than to James R. Napier. JOHN MAYER

FERTILITY OF HYBRIDS FROM THE COMMON AND CHINESE GOOSE

IN the "Origin of Species" I have given the case, on the excellent authority of Mr. Eyton, of hybrids from the common and Chinese goose (*Anser cygnoides*) being quite fertile *inter se;* and this is the most remarkable fact as yet recorded with respect to the fertility of hybrids, for many persons feel sceptical about the hare and the rabbit. I was therefore glad to have the opportunity of repeating the trial, through the kindness of the Rev. Dr. Goodacre, who gave me a brother and sister hybrid from the same hatch. A union between these birds was therefore a shade closer than that made by Mr. Eyton, who coupled a brother and sister from different hatches. As there were tame geese at a neighbouring farm-house, and as my birds were apt to wander, they were confined in a large cage; but we found out after a time that a daily visit to a pond (during which time they were watched) was indispensable for the fertilisation of the eggs. The result was that three birds were hatched from the first set of eggs; two others were fully formed, but did not succeed in breaking through the shell; and the remaining first-laid eggs were unfertilised. From a second lot of eggs two birds were hatched. I should have thought that this small number of only five birds reared alive indicated some degree of infertility in the parents, had not Mr. Eyton reared eight hybrids from one set of eggs. My small success may perhaps be attributed in part to the confinement of the parents and their very close relationship. The five hybrids, grandchildren of the pure parents, were extremely fine birds, and resembled in every detail their hybrid parents. It appeared superfluous to test the fertility of these hybrids with either pure species, as this had been done by Dr. Goodacre; and every possible gradation between them may be commonly seen, according to Mr. Blyth and Capt. Hutton in India, and occasionally in England.

The fact of these two species of geese breeding so freely together is remarkable from their distinctness, which has led some ornithologists to place them in separate genera or sub-genera. The Chinese goose differs conspicuously from the common goose in the knob at the base of the beak, which affects the shape of the skull; in the very long neck with a stripe of dark feathers running down it; in the number of the sacral vertebræ; in the proportions of the sternum;[1] markedly in the voice or "resonant trumpeting," and, according to Mr. Dixon,[2] in the period of incubation, though this has been denied by others. In the wild state the two species inhabit different regions.[3] I am aware that Dr. Goodacre is inclined to believe that *Anser cygnoides* is only a variety of the common goose raised under domestication. He shows that in all the above indicated characters, parallel or almost parallel variations have arisen with other animals under domestication. But it would, I believe, be quite impossible to find so many *concurrent and constant* points of difference as the above, between any two domesticated varieties of the same species. If these two species are classed as varieties, so might the horse and ass, or the hare and rabbit.

The fertility of the hybrids in the present case probably depends to a limited degree (1) on the reproductive power of all the Anatidæ being very little affected by changed conditions, and (2) on both species having been long domesticated. For the view propounded by Pallas, that domestication tends to eliminate the almost universal sterility of species when intercrossed, becomes the more probable the more we learn about the history and multiple origin of most of our domesticated animals. This view, in so far as it can be trusted, removes a difficulty in the acceptance of the descent-theory, for it shows that mutual sterility is no safe and immutable criterion of specific difference. We have, however, much better evidence on this head, in the fact of two individuals of the same form of heterostyled plants, which belong to the same species as certainly as do two individuals of any species, yielding when crossed fewer seeds than the normal number, and the plants raised from such seeds being, in the case of *Lythrum salicaria,* as sterile as are the most sterile hybrids.

CLOUD CLASSIFICATION[1]

THE work of a meteorologist who has devoted himself with great diligence for many years to the study of the structure, forms, and movements of the clouds, possesses a strong claim on the attention of all who are interested in this difficult branch of science. Independently of the importance of the challenge which Prof. Poëy offers to an existing system of nomenclature, his book contains numerous facts and suggestions of very considerable scientific value. In the present enlarged and revised edition the author has endeavoured to satisfy the requirements of our advancing knowledge on the subject of which he treats; a task which ought, unfortunately, to be one of no great difficulty, owing to the small amount of progress which has been made in this, as compared with other departments of meteorology, since the appearance of the second edition.

The history of cloud-nomenclature has been to a great extent a record of wrecks and casualties, because classification has, by an unfortunate necessity, preceded the knowledge of the physical structure of the objects classified. Prof. Poëy was one of the first to appreciate the importance of the fact that the terminology of the clouds must, ultimately, be based not simply upon the varieties of the forms of clouds, but upon those physical conditions to which these varieties are related. But our knowledge of the physical conditions which determine the development of the modifications of cloud is at the present time so limited that no classification founded thereon can as yet be unreservedly adopted. A great deal of questionable hypothesis necessarily enters into the construction of Prof. Poëy's scheme, as he would, we believe, with the candour which distinguishes him, be the first to admit. There is of course a strong *prima facie* desirability that cloud observers should possess some definite system of nomenclature; and at present nearly all of them, not of the lazy class, complain that cloud-classification is still in a state of chaos. Yet it may be doubted whether, for some years to come, a Meteorological Congress will be able to establish an absolutely fixed system of classification which will be universally accepted. Of the ground on which such a system should be built science has hitherto explored but a small portion; and even where we have the materials for observational and experimental research in this direction, very inadequate use has been made of these materials. The immediately practical problem which is raised by the study of this book is this:—In the provisional adaptation of our cloud classification to the status of our knowledge, is it desirable that Prof. Poëy's terminology be adopted in lieu of that of Howard, or should the still prevailing nomenclature be retained, with such modifications as the observations of Poëy and of other students of the subject have as yet shown to be necessary? To this problem we shall venture in the present article to suggest an answer.

As might be expected from the condition of the subject the critical portion of Prof. Poëy's treatise is more successful than the constructive. Several of Howard's terms have had from the first an ill-fated career. To

[1] "Comment on observe les Nuages pour prevoir le Temps." Par André Poëy. Third Edition. (Paris: Gauthier-Villars, 1879.)

FIG. 1.—"Cumulus" with "Fracto-cumulus."

FIG. 2.—"Stratus" with "Fracto-stratus."

begin with, the name "stratus," which has ever been the object of Poëy's especial animadversion, was unluckily applied by Howard himself to ground fog. The result has been a curious condition of anarchy among the followers of Howard's system up to the present day. The predicament in which these observers have found themselves is this. One of the three primary cloud-names which Howard introduced is never, if his system be rigidly followed, to be applied to any object which most people call a cloud at all. It must be admitted that a fog and a cloud are, in structure, one and the same thing: a cloud is a fog viewed from without, and a fog is a cloud viewed from within. But it is precisely because a fog is, in this sense, a cloud, and not a particular kind of cloud, that it is objectionable in practice to apply to a fog a specific cloud name. An observer may be for hours together enveloped in a fog of the form of which he can discover nothing, except that the under surface necessarily follows the contour of the earth's surface. In a classification having reference to the shapes of clouds, it is undesirable to give to such a phenomenon a technical name distinctive of a special form of cloud. Prof. Poëy pertinently says "aucun observateur consciencieux ne voudra enregistrer sous le nom de 'stratus' un phénomène de brouillard." On the other hand, a very large class of clouds, occurring in every part of the globe, and in some parts actually the predominant type, have possessed in Howard's terminology no appellation at all, viz., the clouds, neither cumulus nor cirrus, which extend themselves in a bed or layer, whose vertical dimensions as compared with its horizontal are very small. A certain number of observers have freely applied the term "stratus" to this type of cloud. Others,

Fig. 3.—"Mammato-cumulus."

perhaps more conservative, have created endless confusion by bestowing the name "cirro-stratus" on all clouds of the description to which we refer, while others again have wrought similar havoc by a corresponding misapplication of another of Howard's compounds "cumulo-stratus." Finally, Prof. Hildebrandsson is driven to the revival of the "strato-cumulus" of Kaemtz, as the title for the prevailing winter-cloud of Northern Europe. Prof. Poëy's remedy for this state of things is to abolish the term "stratus," and to apply to all clouds which lie in beds the title "pallium." The effort has already proved partially successful, for, owing to the defect in Howard's system, "pallium" and its compounds have to some extent replaced, at least among American meteorologists, the "stratus" of Howard and its compounds. Ice-clouds disposed in a sheet or layer are to receive the name "pallio-cirrus"; water-clouds the name "pallio-cumulus." We think Prof. Poëy's objection to the word "stratus" as applied to a bed or layer of cloud somewhat ill-directed. The term (signifying "levelled," or "laid flat") is in itself quite as expressive as "pallium" (which does not so much involve the idea of the horizontal); and, however it may have been misapplied, we suspect that it will yet prove possessed of too much respectability to be summarily ejected. Prof. Poëy would retain, inconsistently as it appears to us, the compound name "cirro-stratus," but we have always found it extremely difficult to understand precisely what kind of cloud he means to describe under this name, or to recognise with any distinctness what is his idea of "nuage stratifié," the clouds which he terms "stratified" being rather what most persons would call "striated." Whenever cirrus becomes sufficiently extended to form a veil or sheet, it is to receive the name "pallio-cirrus." "Cirro-stratus" is something which floats at a higher level than "pallio-cirrus." Looking at one of the figures in which "cirro-stratus" is portrayed, we recognise only cirrus, tending slightly to the form cirro-cumulus (Plate 3, Fig. 1). Some of the other representations convey the idea of clouds which would certainly be at a lower level than the usual veil or bed of extensive sheet-cirrus. Some readers may however be more fortunate than we have been in recognising the form of cloud which the author intends to designate as "cirro-stratus." His theory of the formation of the varieties of clouds of the cirrus types is perhaps as clearly expressed in the following as in any passage in the book. "Voici exactement ce qui se passe dans la nature : lorsque les cirrus s'abaissent, ils se transforment en cirro-stratus. Les aiguilles glacées de ce dernier nuage inférieur sont plus compactes et abondantes, plus définies et mieux géométriquement distribuées que les particules moins abondantes et plus isolées des cirrus supérieurs. Quand les cirro-stratus s'abaissent à leur tour, ils se transforment en cirro-cumulus : la structure neigeuse remplace la structure glacée par l'effet de la hausse de la température. Les cirro-cumulus en s'abaissant eux-mêmes, se transforment en pallio-cirrus ou en une couche neigeuse" (p. 29).

The compound "cumulo-stratus" Prof. Poëy would get rid of. We believe that Howard had himself a clear idea of a distinct object when he employed this word; but up to the present time, owing to indistinctness of verbal description, to ill luck as to illustrations, and to other accidents, the word has had a desperately unfortunate history, and Prof. Poëy's objections to it consequently come with great force. It is no exaggeration to say that while we have seldom found two observers really agreed as to the object denoted by this word, we have known the word applied to every existing description of cloud, with the sole exception of unmistakable cirrus.

Poëy's word "tracto-cirrus," the use of which he advocates whenever the cirrus-clouds arrange themselves in parallel bands, is an expressive term. But it is often extremely difficult to decide whether the cirri are or are not arranged in bands. And in treating the "tracto-cirrus" as if it always occupied a lower level in the atmosphere than cirrus, and the "pallio-cirrus" as floating at a still lower level, the author appears to be straining physical fact in order to strengthen the basis of his classification. There is, so far as we are aware, no evidence to show that whenever cirrus adopts, as it does in a majority of cases in most regions of the globe, the band form, it sinks in the atmosphere, and that a further subsidence takes place whenever it spreads itself into a veil or sheet.

The word "nimbus" is to share the fate of stratus and cumulo-stratus. Here again we think the author would have been more successful if he had preferred reform to abolition. That two distinct beds of cloud, the one at a high, and the other at a low level, frequently exist when rain is falling, there is abundant evidence to show, and perhaps this is especially the case during extensive intra-tropical rains. But observers are at least equally agreed as to the fact that a bed of cirrus may coexist with a layer of low cloud, either with or without one or more intermediate layers, without the occurrence of rain or snow. And it is equally certain again that the majority of passing showers are produced in a single mass of cloud, not necessarily, and perhaps never, homogeneous in structure in the portions near the earth and in those which extend into the higher regions of the atmosphere, but certainly not divided into two ocularly distinguishable strata. These facts seem to be ignored by the author when he substitutes "pallium" for "nimbus," and then makes the rainy "pallium" to consist in all cases of "pallio-cirrus" superimposed upon "pallio-cumulus."

As regards the term "pallio-cumulus," we are again obliged to hesitate in accepting it as a thoroughly descriptive title for a layer of low cloud, which has little in common with cumulus except that it occupies much the same level in the atmosphere.

Another of the author's terms, "fracto-cumulus," which he employs for those fragments of low cloud, which, though not themselves hemispherical, are nascent or potential cumuli, seems a useful word (perhaps only open to the slight objection that the affix would be liable, if Poëy's system were adopted, to be confounded, especially in MS. reports, with his other affix tracto). His French equivalent "nuage venteux" is, however, not sufficiently comprehensive, and is open to the same objection as the English word "scud," which involves the idea of rapid motion. The low cloud-fragments are not necessarily either the concomitants or the precursors of wind.

A highly interesting section is devoted to the clouds which have been in England denominated "pocky clouds." The fact that this name has been applied to several distinct varieties of clouds is certainly not unduly pressed by the author; in truth he scarcely appears adequately to realize the amount of misapprehension which has existed on the subject of these clouds. A Latin affix would certainly have the desirable effect of obliging the observer to give attention to the generic form of cloud from which hang the characteristic bladder-like protuberances; thus clouds of the cirrus and of the cumulus type, presenting this peculiarity, would no longer be registered under a single title. But Poëy's proposed affix "globo" does not appear satisfactory, for there is reason to suspect that some observers would be likely to apply it to any spherical or apparently spherical masses of cloud. How easily, in cloud terminology, misapprehension arises from the mere sound of a name the author himself in this very section illustrates, when he mistakes the "roll-cumulus" of the English Meteorological Office for ill-developed pocky cloud.

Beset with difficulty as all questions of cloud classification must necessarily be, we yet believe that at the present time, and for the present, a useful and unobjectionable compromise might be made between the systems of Howard and of Poëy.

Stratus might, without dissolution, leave the surface of the earth, as it already has done in numerous meteorological records, and be applied to all clouds, not of the cirrus type, which arrange themselves in a horizontal bed. *Cirro-stratus* would then form the descriptive title of the ice-clouds of the higher regions whenever these are disposed in a bed, sheet, or veil. The terms *cumulus* and *cirro-cumulus* may remain undisturbed. If the title *cumulo-stratus* have not received mortal injury from abuse, it might be applied to those peculiar descriptions of "mackerel cloud" or "nuage pommelé," which are only at a moderate elevation, and are not in physical structure cirro-cumuli, a class of clouds which much need a distinctive title. If *nimbus* is to be retained, it might be subdivided into its two essentially distinct varieties, the massive local shower-cloud, and the extensive bank of composite rain-cloud; and for these varieties the titles *cumulo-nimbus* and *strato-nimbus*, or some equivalent expressions, might come into use. The expressive *fracto-cumulus* should have its place secured; and this affix of Poëy's may have further applications; detached pieces of those clouds which tend to arrange themselves in horizontal beds (pieces which are in no sense the nuclei of cumulus clouds), may conveniently be termed *fracto-stratus*, while to the little wavy or broken shreds of ice-cloud which Poëy seems to designate "cirro-strati," the term *fracto-cirrus* might perhaps be applied. For the bizarre "pocky clouds," which, though not nearly so rare as is usually suposed, are certainly not common, an affix, if descriptive, would be none the worse for being somewhat outlandish, and possibly "*mammato*," or even "papillato," might be acceptable. If the course suggested in the present article be adopted, no very serious changes will have to be made in the application of Howard's terminology, and no terms will have either to be coined or to be introduced from other systems of classification into that of Howard, with the exception of the affix "fracto," and the affix "mammato" (or one equivalent to it). We have thought it desirable to give illustrations of the types of cloud to be distinguished by these last names. In the first sketch "cumulus" is shown with "fracto-cumulus"; in the second "stratus" with "fracto-stratus"; in the third the characteristic base of "mammato-cumulus"; and in the fourth that of "mammato-cirrus."

We are not without hopes that Prof. Poëy will be induced to give his aid to proposals of moderate reform in the direction above indicated. We are convinced that he will find it easier to modify, by limitations and expansions, a long existing terminology, wherever the terms are essentially truthful and expressive, than to sweep it away and introduce another in its place.

To return to the book under notice. "How to classify the Clouds" would be a more descriptive title than that which it possesses. However, the reader who wishes to learn the art of cloud observation, with the view of learning to forecast the weather, will obtain valuable information from the descriptions which the author founds upon his own observations, as well as from those which he quotes from other observers, *e.g.* the exquisitely truthful description of cirrus quoted from Bravais (pp. 64 and 65). Some of the remarks on the azimuthal rotation of the clouds in Havanna, and on other phenomena, are well worthy of the attention of meteorologists. Here, *e.g.* is an observation, which, taken in conjunction with the inclination of the axes of cyclones and anti-cyclones in-

Fig. 4.—"Mammato-cirrus."

dicated by cloud-observations in Europe, and also with the recent conclusions of Prof. Loomis as to the sequence of winds at the American mountain observatories, may point to an important general law; "dans le plus grand nombre de cas, le vent anticipe sur les fracto-cumulus, ceux-ci sur les cirro-cumulus, et ces derniers sur les cirrus, c'est-à-dire de bas en haut, au lieu d'être de haut en bas. Ce fait paraît contredire l'hypothèse que les courants supérieurs déterminent, de proche en proche, le passage, sous le même parallèle, des courants inférieurs jusqu'aux vents de surface" (p. 127).

One who writes on a generally neglected subject, to which he has himself devoted much attention, is often tempted to accept too readily as grist anything that comes to his mill, and Prof. Poëy is not altogether free from this tendency, especially in those parts of his works in which he launches out into very questionable hypotheses both on the theory of winds, and on the action of heat and of electricity upon the clouds. Still more to be regretted is a certain looseness, not so much of language as of conception, which occasionally leads him to make some surprising statements, as well as to employ inaccurate expressions.

He usually speaks of the water-clouds as composed of aqueous vesicles, sometimes of vesicular vapour. In one passage, speaking of frozen clouds, he talks of the "vesicular vapour passing from the state of particles of ice to those of snow" (p. 77).

A protest is necessary against his often repeated definition of cumulus as a "cloud of the horizon." He says (p. 23), "Nous pouvons assurer que, sous toutes les latitudes du globe, les cumulus sont spécifiquement des nuages d'*été*, de *jour*, et de l'*horizon*." And again (p. 104), "Ils demeurent toujours confinés à l'horizon, et ne traversent jamais la région zénithale qu'ils n'atteignent même pas. Cette seule circonstance distingue profondément les cumulus des fracto-cumulus." Truly a profound distinction! We had supposed that in regard to clouds, as in some other matters, "one man's horizon is another man's zenith." Are cloud-classifiers really driven to such extremities? What would be thought of the botanist who appended to his description of the *Ulmaceæ* the statement that "the trees belonging to this family are objects seen upon the horizon," and then proceeded to meet the reasonable objection of the surprised reader by the remark that certainly the elm trees around his (the botanist's) residence, were all seen near the horizon? Yet this is how (p. 24) the author handles his descriptions of cumulus. (The fact of course is that the characteristic form of cumulus is not readily discernible when the cloud is near the zenith.) A somewhat similar remark, made by the author in explanation of the fact that a belt of cirrus, clearly visible towards opposite points of the horizon, is frequently invisible, or nearly so, overhead, a fact of which the optical explanation is obvious, is so strange that we must quote it. "Nous l'attribuons à l'extrême degré de froid que nous avons toujours observé dans la région zénithale, relativement aux autres azimuts. Sous cette basse température et cette extrême sécheresse, la vapeur d'eau se maintient à l'état élastique, et se précipite difficilement sous la forme de filaments extrêmement déliés. C'est pour cela que les cirrus sont plus rares, moins denses et passagers vers la région zénithale," (p. 69).

It is with reluctance that we notice statements of this kind in a work the general idea of which we admire, and in the aim of which we cordially sympathise.

W. CLEMENT LEY

THE PLANETS OF THE SEASON

MARS

IF the two great leaders of the planetary system have filled us with astonishment at their magnitude and velocity, and with perplexity in the contemplation of arrangements so incomprehensibly unlike our own, they have not exhausted all the resources of the season. There yet remains a much nearer and more intelligible neighbour, who possesses a peculiar interest for an opposite reason—his similarity to ourselves. This especial character of the ruddy planet has long been known to astronomers, and will naturally make him an object of careful study before we leave him too far behind; and though the opposition of this year does not diminish his distance so much as that of 1877, yet his almost startling brilliancy has been alone enough to prove it among the favourable ones; for English astronomers, at least, it is far more propitious than the last, from his greatly-increased elevation. Much had been expected at that last opposition from the broad expansion of his disk, but the indistinctness of detail was a general source of disappointment here, though the success of Schiaparelli at Milan and Green at Madeira showed that the fault lay chiefly—perhaps not exclusively—in the English sky. My own impression certainly then was that, besides the want of clear outline inseparable from so low an altitude, there was a deficiency in decidedness of form and strength of tone as compared with previous observations, the cause of which may have lain in the atmosphere of the planet, affected possibly by especial proximity to the sun in an orbit of considerable excentricity. At any rate, we may reasonably hope to find the present season more favourable for exploration than the last; for though at nearest approach we have only had 23″ of disk instead of 29″·4 in 1877, success depends, with equal instrumental sharpness, much more upon altitude and steadiness of air than on increase of visible surface. Schiaparelli was enabled to obtain his most valuable results after opposition, when the diameter had decreased to 20″ or even 16″, and he asserts that he was able to continue his researches with advantage even till it came down to less than 6″.

We have alluded to the special interest of this planet arising from its supposed close correspondence with the earth, and it may not be out of place on this occasion if we bestow a little pains in examining the ground of that supposition. This we may conveniently do by imagining what would be the telescopic aspect of our own globe at a distance not equal to that of Mars, as we should then appear about twice as large, but such as to reduce our apparent diameter to equality with his in a favourable opposition.

There is every reason to believe that our surface would then appear mapped out by a distinct separation into oceans and continents, the fluid being darker than the solid masses, and preserving their bluish-green tinge but little affected by distance. Except in very shallow parts, their darkness would be uniform from the rapid absorption of incident light, and their contour would be sharply defined. The general hue of the land would be lighter; and at a distance where its variegated patches of colour would be separately undistinguishable, the result would be a grey resulting from the mixture of many tints, except where tracts such as the great deserts or prairies might subtend a sufficient angle to preserve their natural hue, or where extensive forests might rival seas in depth of tone. In many places, too, brilliant streaks and patches would show where mountain masses were capped with dense clouds, or surpassed the level of perpetual snow; but our largest rivers, except possibly at some great *embouchure*, would be totally imperceptible.

Such, in its general lineaments, would be the distant aspect of our globe, if the whole lay at once distinctly before the eye. But this would never be the case. The formation and transference of masses of vapour would produce incessant and most uncertain changes. In some regions and at certain times of year there would be unbroken clearness; in other tracts the outlines and colouring of land and sea would be indistinct, or concealed, at times for short, but occasionally for very lengthened, periods. And the interposition would doubtless be always of a white aspect, since such is the character of our clouds wherever they are illuminated by the sun. Towards our polar regions this whiteness would be permanent in the form of great spots, excentric as regards the axis of rotation, increasing through and after the winter, with a corresponding diminution after the summer solstice. There would always be, however, a large unmelted area, even at the warmest period, and its outlines would probably be often irregular and extended from the presence of great masses of frozen clouds. Now, if these would be the probable features of the earth, presented to us at a distance of seventy or eighty millions of miles, in what respects shall we be able to trace the resemblance on Mars? We are soon brought to the conclusion that, according to the general rule already referred to, there is more analogical than identical correspondence: the inclination of axis, the excentricity of orbit, the duration of day and night, the respective length of the seasons—from the relative similarity but not identity in these particulars, we are prepared to meet with the same kind of proportion throughout. As far as aspect goes, a solid and fluid condition may be thought to divide each superficies; but if so, the land there is in a much larger ratio to the water; and if the colour of our oceans is repeated on Mars, we have little to correspond with the orange-yellow tinge which, since it leaves unaffected the polar snows, cannot arise from atmospheric absorption. The so-called seas, too, though in some places apparently deep and dark, frequently shoal off and show subaqueous markings in a way that perhaps would be scarcely paralleled in our own.

In atmospheric conditions, indeed, we find great approach to identity; yet even here there are discrepancies; the polar snows of the earth would probably not be distinguishable from the upper surfaces of terrestrial clouds floating in any latitude, while on Mars such peculiar whiteness, though sometimes vividly brought out in certain localities, is by no means universally concurrent with the local indistinctness and confusion that so often puzzle the areographer. The action of solar heat on the polar deposits seems identical, and yet it may be a question whether our Arctic snows are marked out by as regular a contour as those of Mars, and still less would they show what has often been observed there—a strongly-marked border of darkness. And however striking and suggestive may be the fact that in either globe the thermal axis is not that of rotation, we have the discrepancy that on Mars the glaciation is reduced in a much greater ratio, so that the pole, according to Schiaparelli, was, in 1877, entirely free. This observer, who is fully impressed with the terrestrial theory, admits that the vertical sunlight, instead of producing clouds, as on the earth, appears to clear the sky of Mars, and thinks the atmospheric changes there of a more simple nature. That the southern hemisphere would be subject to greater extremes of temperature than the opposite, as shown by the variation in size of the white caps, might have been expected as a direct consequence of the elliptical form of its orbit greatly surpassing our own.

A passing reference will be sufficient to the brighter zone, which, according to some observers, distinguishes the edge of the disk, but which others, including myself, have never detected; or to the bluish or greenish patches sometimes noticed on the limb. Such appearances may be mere results of contrast; at any rate they may be left on one side as not directly affecting our present comparison. But there is one consideration which cannot be thus disposed of, and which, obvious as it is, seems to have been taken little into account—the very different amount of solar radiation on the two planets. The heat derived from the sun on Mars is only from $\frac{1}{3}$ to $\frac{1}{2}$ of that received by ourselves. And thus we seem reduced to the alternative of either abandoning to a considerable extent the supposed closeness of resemblance in material and constitution, or of maintaining it by the hypothesis of a supply of heat on Mars derived in some other way. No ice such as ours would be so reduced by the unaided action of that distant sun—no terrestrial continents could remain so long unclothed with snow. The dilemma is a curious one. It may not be incapable of explanation, but it certainly requires more special and careful consideration than it has yet received.

We have been looking at the subject much as though a supposed view of the earth at a suitable distance might be fairly paralleled with a corresponding representation of Mars as drawn by the best observers. But it must be added, with much regret, that such is not yet the case. As to certain main features of that planet, there is indeed a very satisfactory agreement; but with regard to others, and as to details in general, we feel, as a first impression, some extent of disappointment. It may be fairly admitted that the disk is after all not large, and its markings often feeble; and there is great diversity in instruments, and eyes, and hands, and aptitude for the work. Yet still an exhaustive survey, of which we cannot even indicate the materials in this place, but which we trust will be carried on, as it has been most ably commenced, by Dr. Terby of Louvain, would show much unexplained, and some things unsatisfactory. Mädler laid the foundation of definite areography; but his successors, while enlarging, have not always confirmed his results, and, to say nothing of others who have bestowed much pains upon the subject with more or less mutual agreement, our own keen-eyed and accomplished Dawes—at least as represented by Proctor—is found to differ in some parts materially from Lockyer, Kaiser, and Secchi. At the last opposition in 1877, the subject was taken in hand with especial zeal and perseverance by Schiaparelli at Milan with an exquisitely sharp Merz object-glass of 7·15 inches aperture and 10 feet 8 inches focus, and by Green, who went out purposely to Madeira with a 13-inch mirror by With, the perfect polish and critical definition of which are sufficiently guaranteed by the maker's name. Each did his best; each was far in advance of the other observers of the season; and yet at first sight there is more apparent difference in their results than might have been expected. It is not surprising that in the case of minute details each should have caught something peculiarly his own; but there is a general want of resemblance not easily explained, till, on careful comparison, we find that much may be due to the different mode of viewing the same objects, to the different training of the observers, and to the different principles on which the delineation was undertaken. Green, an accomplished master of form and colour, has given a portraiture, the resemblance of which as a whole, commends itself to every eye familiar with the original. The Italian professor, on the other hand, inconvenienced by colour-blindness, but of micrometric vision, commenced by actual measurement of sixty-two fundamental points, and carrying on his work with most commendable pertinacity, has plotted a sharply-outlined chart, which, whatever may be its fidelity, no one would at first imagine to be intended as a representation of Mars. His style is as unpleasantly conventional as that of Green indicates the pencil of an artist; the one has produced a picture, the other a plan. The discordance arising from such opposite modes of treatment would naturally be less real than apparent; still, a good deal remains that it is not easy to harmonise. Let us hope that during the present favourable opportunity, much may be effected towards clearing up the obscurities that still rest upon the study of Mars. Every contribution may prove of use, provided it is the result of that conscientious spirit that will show only what it sees, and take care to show it well.

A suggestion may be permitted that observations in the twilight might obviate the unpleasant glare arising from the vivid light of the disk, or that a screen-glass might be advantageously employed for the same purpose at a later hour.

Meanwhile the nomenclature of the spots—a point of increasing importance for identification—is in a state of pitiable confusion. This ought to be remedied at once; and its revision could be more suitably intrusted to no one than to Dr. Terby, who so thoroughly knows its difficulties, and is so competent to decide upon some system that may be adopted with the general concurrence of observers.

With regard to the satellites, we have entered into so much detail about the primary, that little space remains for them. Yet we must express our hope that, once discovered, they may be more easily caught in our larger instruments, and that the magnificent reflector of Mr. Common may, as is very possible, increase their recognised number. Those already discovered are certainly among the most wonderful objects in the whole solar system. So disproportionally minute, according to our limited ideas of proportion; so speedy in their revolution that the innermost rises in the west and sets in the east, and compasses the whole heavens more than three times in a Martial day; so close that the same attendant ranges at less than 4,000 miles from the surface of his primary; so much of their time invisible in total eclipse; so powerless to influence any fluid mass beneath them; one might call them exceptions, while yet they are among the strongest illustrations of the great principle of identity of character combined with the extremest variety in detail, in the inscrutable work of the Creator.

T. W. WEBB

RECORDING SUNSHINE[1]

SO far as I have seen there is in use at present but one form of apparatus which effects an automatic registration of the duration and the times of sunshine, and that is the instrument of Campbell, in which a sphere of glass is so disposed as to burn a piece of wood or paper by the concentration of his rays when the sun may chance to shine. During the past few years I have devoted some attention to this matter and devised a number of appliances having the same object for their end but differing materially both in their construction and in the manner of their use from the apparatus I have named.

One of these, with your permission, I will now describe. It is an arrangement which places a lead pencil on a sheet of paper and writes down therewith when and for how long the sunshine lasts.

It consists essentially of a differential thermometer with a long horizontal stem, in which latter is contained throughout the greater portion of its length some fluid intended to operate by its weight. This thermometer is attached to a scale beam or some equivalent device which also carries the pencil by means of which the record shall be made.

The whole is so arranged that in its normal state it rests gently—upon that side to which the pencil is *not* attached—on an embankment provided for that end.

Close beneath the pencil point a disk of metal rotated at the proper speed carries a paper dial whereon marks and figures are engraved corresponding with the hours at which the sun may shine.

When using this instrument I have it inclosed within a box which permits one bulb only of the thermometer—that most distant from the clock—to be affected by the radiance of the sun, which when it shines expands the air contained therein, forces the fluid along the tube and by altering the equilibrium of the beam brings some portion of its weight to bear upon the pencil point, and so the record is commenced.

When the sun becomes obscured, the air expanded by his rays contracts, the fluid in the tube returns, the normal equilibrium is restored, and the pencil ceases to produce its mark.

In the instance of the instrument I use the stem of the thermometer is 18 inches long and the eighth of an inch or thereabouts in bore.

Mercury in consideration of its weight is the fluid I employ, and in conjunction with it some sulphuric acid is inclosed, because of the mobility which is thereby gained. I am aware that in these circumstances mercuric sulphate is very slowly formed, but after two years' lapse of time no inconvenience has been caused thereby and the mobility of the mercury remains.

The bulbs of the thermometer are 2 inches in diameter or thereabouts, and that they may be more rapidly affected the glass thereof is thin. Both are blacked, and the one intended to receive the radiance of the sun projects above the box in which the apparatus is contained into a dome of glass.

[1] Paper read at the Literary and Philosophical Society of Manchester by David Winstanley, F.R.A.S., November 18, 1879.

NOTES

W. HEPWORTH DIXON died very suddenly early on Saturday morning. He was best known to us as a brilliant writer and speaker, and but comparatively few knew how profoundly, and with what patient determination he would sift the truth, alike of even the most well attested, as of the most apparently trivial fact, before making use of it in his work. Only those within the circle of his more intimate friends were aware how well he followed and how easily he grasped the progress of scientific thought. In this circle were several with whom and about whose labours he delighted to converse, and none could listen without benefiting by the practical views his vigorous intellect suggested, the more so as they were possibly induced by quite other claims of thought. These columns have called attention to the ethnological value of his researches in America. His travels, especially those in the Far West, in the wilder parts of Russia, in the Holy Land, and in Cyprus, attended at times with personal risk, are full of suggestive interest to the scientific mind, and we may shortly to call attention to some of the salient facts connected with natural science which they contain. In his early days he studied astronomy and kindred subjects, and it almost seemed at one period of his life that his bent would have led him more deeply into these researches. That this early inclination never forsook him, even those who knew him least, may gather from his attendance at the meetings of the British Association, his unremitting labours as chairman of the Palestine Exploration Fund, and his presence at numerous anniversary meetings of our learned societies. His surviving son, Harold, is already known as a teacher of natural science at Oxford University.

THE death, on December 18, is announced of Prof. Franz Boll, who has filled the Chair of Physiology and Comparative Anatomy in the Roman University; he was only thirty years of age. Born at New Brandenburg in February, 1849, he studied at Berlin and took his Doctor's degree in medicine and surgery in 1869. When little more than twenty years old, he became assistant to Dubois-Reymond in his physiological laboratory at Berlin. Having been obliged on account of his health to seek the warmer climate of Italy, he was in 1873 offered an appointment in the Roman University, and in 1877 was, by the unanimous decision of the Commission of Examiners, elected to the chair he has since held. His researches regarding the arterial circulation of the retina are recognised as a most valuable contribution to physiological science.

GENERAL surprise is naturally expressed that Dr. William Farr has not been appointed to succeed Major Graham as Registrar-General. Dr. Farr's qualifications for the post are known to all the world; but it has been conferred upon Sir Brydges Henniker, Bart., for what reason we have failed to discover. It must be regarded as an almost national misfortune, though it will surprise no one, that Dr. Farr has resigned his post as head of the statistical department.

THE *Hannoversche Courier* announces that Leibnitz's long-lost calculating machine has been recovered. Leibnitz invented and constructed this machine in 1672, during his stay in Paris. It can add, subtract, divide, and multiply, and was the wonder of the time. This machine became the property of the Hanover public library, but long ago disappeared from among its treasures. All that was known about its disappearance was that it had once been sent to an instrument maker at Göttingen to be repaired. It has now turned up again in the Göttingen library, and through the efforts of Dr. Bodemann, the librarian of the Hanover public library, has again come into the possession of the institution.

IT is only about a year since we gave some account (NATURE, vol. xviii. p. 361) of the railway bridge which spans the Firth of Tay at Dundee, and on Sunday it was the scene of one of the most terrible railway accidents on record. With the details of this sad occurrence our readers are no doubt familiar; for accurate information as to the prime cause we must await the searching inquiry which will no doubt be instituted. The structure appears to have been subjected to the most rigid tests before being opened to traffic, but we fear there must have been more than one screw loose somewhere. Upwards of 3,000 feet of the high girders are reported to have been swept away. One conjecture is that the train had got well upon the girders when a gust of greater strength had caught the structure. There would thus be, in addition to the ordinary vibration of the train, an enormous lateral pressure from the wind. The carriages of the train would also, of course, feel the full force of the blast, and once the weakest part yielded the whole would go with a sudden crash. In a letter to the *Glasgow Herald*, Prof. Grant states that the storm of Sunday was the most violent in Scotland for thirty years, and that the rate of the wind about 7 P.M. was upwards of seventy miles per hour, equal to a pressure of forty-two pounds per square foot. No doubt there were frequent sudden gusts reaching a rate of ninety miles per hour. A Commission of Investigation has already been appointed.

THE *Times* correspondent describes a visit he made to inspect Mr. Edison's new electric light at Menlo Park. Two of the lights had been burning continuously for ten days without injury to the baked cardboard horseshoe in the little glass globe which furnishes the light. Cardboard, he states, seems sufficiently durable, successfully resisting quite rough usage, such as dropping, shaking, turning the current on and off thousands of times, and raising the intensity of light to that of 400 candles. All the arrangements are simple. Mr. Edison will put about 800 lights at Menlo Park, while the inventions immediately go into practical operation in New York city. The globe containing the horseshoe is exhausted to one-millionth of an atmosphere by the Sprengel pump, measured by the M'Leod gauge. By successfully dividing the electric current Mr. Edison gets individual lamps of 16-candle power, each lamp having 100 ohms resistance. Light is turned on or off, and the current regulated with the same ease as gas is, while the current can be transmitted on wire as small as No. 36. The central regulator contains an even current, while the meters accurately measure the supply furnished to each consumer. Mr. Edison finds that the best generators are of five to seven horse power, each one-horse power maintaining eight lamps. Each lamp costs about one shilling to manufacture, while a supply equivalent to 10,000 feet of gas can be produced for tenpence or less. Mr. Edison calculates the cost of furnishing light thus:—the consumption of 3 lb. of coal in a steam engine will maintain eight to ten lamps one hour. Mr. Edison's system also furnishes electric power for small industries, such as running sewing machines. Mr. Edison's light is bright, clear, mellow, regular, free from flickering or pulsations, while the observer gets more satisfaction from it than from gas. Mr. Edison lights at Menlo Park, dwellings, offices, desks, street-lamps, also laboratory and workshop, making it available for every lighting purpose for which gas is used.

PROFESSORS C. A. F. PETERS (director of Kiel Observatory) and Albert von Kölliker (Würzburg) have been decorated by the King of Bavaria with the Maximilian Order for Art and Science.

THE death is announced of Dr. Alexander Sadebeck, of Kiel, professor of mineralogy and geology at Kiel University, on December 9, 1879, at the early age of thirty-six years.

THE Emperor of Austria has presented the Austrian Gold Medal for Arts and Sciences to Herr Wilhelm Hoffmann, of Dresden, in recognition of his merits in advancing the art of photography.

ON January 2, 1882, the University of Würzburg will celebrate the 300th anniversary of its foundation. The Bavarian Government had intended to set aside a sum of 2,000*l*. to defray the expenses of the celebration. The Finance Committee of the Bavarian House of Deputies have, however, declined to allow the sum in question.

THE two first parts of an interesting work, "Bibliotheca Belgica: Bibliographie générale des Pays Bas," have just been published. The editor is M. Ferd. van der Haeghen, librarian of Ghent University. The work will contain (1) the description of all works printed in the Netherlands during the fifteenth and sixteenth centuries, as well as of the principal ones printed between 1600 and 1879; (2) a description of all works whose authors are born Netherlanders, as well as of all works printed abroad which refer to the Netherlands; (3) a list of all the works printed by Netherlanders who settled abroad.

A HIGHLY interesting discovery has recently been made on the Russian peninsula of Kertch. The director of the Kertch Museum discovered a tomb dating from the third century B.C., and from the reign of Persidas II., King of the Bosphorus. The tomb is situated on the road from Temruk and near the Sennaja Station. In it were found (1) a thick gold necklace, with a lion's head at each end; (2) a gold crown of about one inch in breadth, the exterior part being formed of intertwisted rings, and ornamented with fine stones; (3) several pairs of gold earrings; (4) two gold chains, of which one is ornamented with figures; (5) two gold bracelets; (6) a round gold brooch, and a gold pin representing Venus and Cupid; (7) four gold leaves; (8) a pearl necklace, some amulets, and three small gold rings; (9) a phial, an urn, a vase, a spoon, &c.—all these of silver.

THE opening meeting of the Epping Forest and County of Essex Naturalists' Field Club will be held on Saturday evening, January 10, at the rooms of the Buckhurst Hill Art Classes, 3, St. John's Terrace, at seven o'clock. The objects of the club, as set forth in the proposed rules, are as follows:—"The investigation of the natural history, geology, and archæology of the County of Essex (special attention being given to the fauna, flora, geology, and antiquities of Epping Forest), the publication of the results of such investigations, the formation of a library of works of local interest and other publications, and the dissemination amongst its members of information on natural science and antiquities." Excursions, under skilful direction, to various localities of interest to the naturalist and antiquary, will also be a main object of the Club. The Club will strongly discourage the practice of removing rare plants from the localities where they are to be found or of which they are characteristic, and of risking the extermination of rare birds and other animals by wanton persecution; it will also endeavour to use its influence with landowners and others for the protection of the same, and to dispel the prejudices which are leading to their destruction. In like manner the club will endeavour to cultivate a fuller knowledge of local antiquities, historical, popular, and idiomatic, and to promote a taste for carefully preserving the monuments of the past from wanton injury. Considering the fine field offered to the biologist in Epping Forest and the surrounding country, it is certainly a matter of surprise that a society similar to that now in process of formation was not long since founded. We trust the club will meet ample support.

THE latest news from the St. Gothard Tunnel states that the thickness of the soft strata recently encountered was only ten metres, and that the boring machines are again at work on solid and firm rock.

AN earthquake is reported from Agram. It occurred during the night of December 8, 1879, and lasted three seconds. Another phenomenon of the same nature was observed at Seisenberg (Carniola) on December 4, at 6.45 A.M., lasting two seconds. The direction of the shock was from north to south. Ten minutes later a second shock was felt. The intensity of the shocks was alarming. A smart shock was felt at Geneva on December 30, at 12.15 P.M. Several shocks were felt on December 26, at Lyons, where the winter has been exceptionally severe.

THE *Times* correspondent describes an eruption of Vesuvius on the night of December 18, 1879. The mountain has been in an uneasy state for several years, and slight eruptions have constantly taken place; but the climax seemed to have been arrived at on the 17th, when Vesuvius changed its mantle of snow for one of fire. As the wind blew furiously from the north-east, the lava descended in the direction of Portici, covering a large portion of the cone and presenting a magnificent spectacle. On the 18th there was less disturbance; but even in its state of greatest activity the mountain made none of those awful efforts which form a grand eruption. There were some local shocks, and a heavy breathing from the furnace, but there was no tremendous explosion. The cup was full, and it flowed over. This flowing over, however, if continued to great excess, may produce far greater disasters than a roaring discharge which finishes the whole business. Prof. Palmieri's reports of Mount Vesuvius state that the present modest eruption has lasted since 1875. It commenced at the bottom of the vast and deep crater left after the eruption of 1872, and was therefore only visible to those who ascended to the summit of the mountain. But now this crater is filled up by the new lava which flowed at successive periods, and therefore the fresh streams which issue from the eruptive cone flow down the external parts of the mountain, generally on the side towards Naples. The new eruptive cone has gradually increased in height until it now protrudes about fifty feet above the edge of the old crater.

WRITING to the *Western Daily Press* under the date of December 22, 1879, Prof. Silvanus Thompson says:—I had the opportunity about half-past ten this morning of witnessing from Clifton Down a phenomenon which enjoys the repute of being very rare. The entire gorge of the Avon was filled with mist, so that the river in the bottom and the Leigh Woods opposite were quite obscured. Standing on the western extremity of the Observatory Hill, I observed a dim gigantic figure apparently standing out through the mist upon one of the lower slopes of Clifton Down, where it runs down in undulating ridges from the promenade towards the river. A moment's glance sufficed to show me that it was my own shadow on the mist, and as I waved my arms about the gaunt spectre followed every movement. A gentleman who stood beside me likewise saw his spectre, but not mine, as we ascertained by the movements executed; nor could I see his, unless we stood so close together that the spectres seemed combined into one. The analogy presented by these spectres with the famous *Spectre of the Brocken*, seen by travellers in the level rays of the morning sun from the summit of that celebrated mountain, and described by Sir David Brewster in his "Letters on Natural Magic," is very striking.

A PRIZE of 200*l.* has been offered by the Rev. E. Wyatt Edgell, through the Sanitary Institute of Great Britain, for the best essay that may be sent in by August 1 next, on "The Cause of Hereditary Tendencies in Health and Disease." The subject is of first importance in its bearings not only on personal but on natural health, and the Council of the Institute expects to receive many valuable contributions in competition. It only regrets that the generous donor, who for a long time has filled the office of Honorary Treasurer of the Institute, is obliged to resign office owing to a state of impaired health, which demands for a time residence abroad. The Chairman of Council of the Institute, Dr. Benjamin W. Richardson, F.R.S., and Dr. W. Farr, F.R.S., are appointed adjudicators of the prize.

PROF. F. W. HUTTON, of Dunedin, New Zealand, has been appointed to fill the new Chair of Biology in the Canterbury College at Christchurch. In consequence of this move the Chair of Natural Science in the Otago University is vacant. We have not heard what steps are being taken to fill it.

A REMARKABLE anthropological discovery has recently been made at Sypniewo, near Marienwerder (Prussia), by Herr Wilckens. In a bronze cauldron which was imbedded in the ground several feet deep, were found calcined human bones (apparently both male and female), a golden hoop, an open necklace with hook and eye, two square sticks of greenish glass with marks on them, similar to the eyes of dice, twenty button-like ball segments without holes, four bronze plates, and fragments of some metal implements evidently burnt with the bodies. The articles seem to be of old Etruscan or Phœnician workmanship, and are now in the hands of the Historical Society of Marienwerder.

"WATER ANALYSIS," by Prof. Frankland, a long-promised contribution to an important question, will be published during January, by Mr. Van Voorst.

IN reporting the reception of Prof. Nordenskjöld and the staff of the *Vega* at Nagasáki, the correspondent of the *North China Herald* notes that there was not a single case of scurvy during the whole voyage. This, he learns, was owing to the free use of a curious little berry that springs out of the eternal ice and snow during the short summer; it bears profusely, and has a taste like the raspberry, but more acid. The fruit is dried, and then mixed with the milk of the reindeer, and it can be carried in a frozen state for thousands of miles. There was also used a curious kind of food made from the whale's hide, which is pickled and eaten freely during the winter.

THE additions to the Zoological Society's Gardens during the past week include a Yellow Conure (*Conurus solstitialis*) from Guiana, received in exchange; a Vulpine Phalanger (*Phalangista vulpina*), a Geoffroy's Dove (*Peristera geoffroii*), bred in the Gardens.

GEOGRAPHICAL NOTES

THE eminent Russo-German traveller, Dr. Wilhelm Junker, well known by his successful tours in the Nile districts, left Cairo for Chartum on December 1. He travels *viâ* Suez and Suakin, and hopes during the present winter to reach the Upper Nile districts beyond Chartum. This time the Monbuttu land will form the basis of his operations, and he intends to penetrate into the interior in the direction of the Congo or the Schari rivers.

DR. GERHARD ROHLFS has arrived at Rome on his return from North Africa.

THE expedition charged with the investigation of the question whether it is possible to conduct the waters of the Amu Daria into the Caspian Sea has started from St. Petersburg. General A. J. Gluchowski is commander of the Expedition, and M. Holmstrem acts as chief engineer. MM. Bole, Svichtchoff, and Macsimovich are assistant engineers. Prince Gedroitz takes part in the expedition in the capacity of geologist. These gentlemen will be joined by Capt. Roop, from Turkestan, and by Engineer Hellmann, from the Caucasus. The company will first proceed to the delta of the Amu Daria, and then begin the investigation of the river's course and of the surrounding territory, with regard to elevation, geology, &c., &c. It is considered that two or three years will be necessary for collecting the materials to finally decide the question.

PROF. BASTIAN has arrived at Batavia. He has made important ethnological and anthropological researches in Assam, and has also brought together a valuable collection of illustrative specimens. He then continued his studies in the Padang Islands, and will now do the same on the island of Java.

THE Geographical Society of Hamburg has elected the well-known author of numerous descriptions of travels, cities, and countries, Herr Ernst von Hesse Wartegg, as a corresponding member.

THE Archbishop of Algiers has received from Zanzibar favourable reports of the eighteen missionaries who left Algeria last June and had reached Ugogo, as also of the missionaries sent out last year for Tanganyika. The latter had lost their superior, Père Pascal, but had arrived at Ujiji and had been well received there by the English mission and the Arab chiefs. They had explored Urundi, a rich region, which they depict in altogether different colours from Stanley, and by invitation of the Sultan of Bikari they had established a station, commencing operations by rescuing abandoned infants. The Abbé Debaize, on the other hand, had been twice deserted by his porters, had been plundered of a great part of his outfit, and had returned sick and discouraged to Ujiji, where the Algerian and English missions were nursing him. It was not known whether he would recommence the exploration intrusted to him by the French Government.

THE death is announced of Prof. Wappæus, of Göttingen, an industrious German geographer.

THE newly-established Geographical Society of Rochefort has just issued the first number of their *Bulletin*, the more noteworthy contents of which are a paper by M. L. Delavaud on the Portuguese in Central Africa before the seventeenth century, and another by M. Silvestre on Indo-China.

ON THE HETEROSTYLISM OF "MELOCHIA PARVIFOLIA"

MELOCHIA PARVIFOLIA, H.B.K. (nova gen. et spec., pl. v., 325) is a very common plant on the dry plains in the neighbourhood of Carácas, where it flowers nearly all the year round, and not only in the month of January, as Kunth says in his description, which in all other respects is a very complete and good one. I was led to notice the heterostylism of this plant when comparing carefully Kunth's words with a specimen I had brought home. Humboldt's specimen belonged to the long-styled form, for Kunth says:—*Stamina petalis dimidio breviora, Styli longitudine petalorum.* Mine was short-styled, so that I found these proportions to be inverse. I searched immediately our *sabanas* (or plains) for long-styled plants, and came at once across a considerable number of both forms. A comparison of their flowers gives the following result:—

Short-styled Flowers.	*Long-styled Flowers.*
1. Stamens as long as the petals.	1. Stamens half as long as the petals.
2. Styles scarcely half as long as the stamens.	2. Styles as long as the petals.
3. Stigmata with few and short papillæ.	3. Stigmata with many and rather long papillæ.
4. Styles without stellate hairs.	4. Styles with stellate hairs.
5. Pollen grains:—	5. Pollen grains:—
a. Dry, globular, diam. 0·044 mm.	*a*. Dry, elliptical, obtusely triangular in cross-section, diam. 0·044 × 0·024 mm.
b. In water, globular, diam. 0·060 mm.	*b*. In water, globular, diam. 0·052 mm.
c. In alc. abs., globular, diam. 0·036 mm.	*c*. In alc. abs., elliptical, diam. 0·040 × 0·028 mm.

(My measurements were made with a glass micrometer by Oberhäuser, five divisions of which are equal to 0·02 millimetres for the enlargement I used.)

It would appear that the protoplasm of the pollen-grains of the short-styled form contains a larger percentage of water, their size shrinking more in alcohol than that of the pollen-grains of the long-styled form.

Although the heterostylism of *Melochia parvifolia* might be fairly admitted from the stated morphological differences, I was desirous to try by experiments whether there was also a functional difference, as Darwin and Hildebrand have done in the case of other heterostyled plants.

Both forms of *Melochia parvifolia* seem to be equally common in our flora. This I ascertained in the following manner:—On the *Sabana de San Lázaro*, where this plant constitutes all the higher vegetation, together with *Turnera ulmifolia*, *Pavonia cancellata*, and *Hyptis suaveolens*, all the plants of *Melochia* were examined in a square, the side of which was 100 steps. There were altogether forty-two plants, twenty with long-styled flowers, and twenty-two with short-styled ones. In one single plant of the former two short-styled flowers were discovered, in all the rest each plant had only one kind of flower. I collected seeds from both forms, and began last year my experiments by sowing them in cases placed in one of the yards of my house in town. This circumstance was perhaps of some consequence, the yard being surrounded by walls 12 feet high, so that there could be next to nothing of the influence of the wind, just the reverse as in the open field.

Ten seeds taken from plants with long-styled flowers produced eight plants, which this year flowered, all the flowers being long-styled ones.

Ten seeds of the short-styled form gave nine plants; two of these perished before setting flowers; the remainder produced in due time a large number of short-styled blossoms.

The last summer was very rainy, thus not at all favourable to experimental research connected with artificial fecundation. However, I tried my best, and obtained the results given in the following table, which is constructed according to Darwin's models in his "Forms of Flowers":—

Nature of union.	Number of flowers fertilised.	Number of capsules produced.	Average number of seeds per capsule.	Percentage of capsules in reference to flowers.
a. Long-styled form by pollen of short-styled	12	12	5[1]	100
b. Long-styled form by own-form pollen, from a distinct plant	10	8	3·5	80
c. Long-styled form by pollen from the same flower[2] ...	6	1	5	16·6
d. Short-styled form by pollen of long-styled	12	12	5	100
e. Short-styled form by own-form pollen from a distinct plant	10	9	3·3	90
f. Short-styled form by pollen from the same flower[3] ...	8	6	4	75
Cases *a* and *d* together (legitimate unions)	24	24	5	100
Cases *b* and *e* together (illegitimate unions)	20	17	3·4	85
Cases *c* and *f* together (illegitimate unions)	14	7	3·6	50

I think the favourable influence of cross-fertilisation is evident, as in no other case the *average* number of seeds per capsule reached the *normal* number, although there were some few capsules in the other crops which also contained five seeds.

In the open field the flowers of *Melochia parvifolia* are visited by large numbers of small hymenoptera, which fly about during the hottest hours of the day, when these flowers are open. They have no particular smell, and fade very soon; on cloudy or rainy days they do not open at all, so that not a few wither before getting fertilised, which accounts for the considerable number of seedless capsules to be found on nearly every plant.

The seeds of my crop appeared to be of good quality (their specific weight being greater than that of water). I have sown them already in separate lots, in order to find out how far they will germinate and produce strong and healthy plants, and which forms of flowers these latter will have. A. ERNST

Carácas, November 2

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Next term, at Cambridge, practical anatomy in the dissecting-room will commence on January 17. The professor of anatomy is to be assigned (as to his fellowship) to King's College, and not to Caius, as originally proposed; it was thought more advisable not to assign two professorial fellowships in medical science to Caius, but rather to divide the association. Prof. Paget is especially fitted to receive further honour from Caius College, and we trust he will ultimately attain the mastership.

Prof. Newton announces that his lectures will recommence on February 2; and the demonstrator will take an advanced class on Sauropsida, beginning on the same day.

[1] Normal number of seeds in *Melochia parvifolia*.

[2] The plant was left to itself, foreign pollen being excluded by a fine muslin-bag tied around it. The numbers show that self-fertilisation was difficult in this case; though in the open field, where the wind has its full sway, it may be much easier, and perhaps more frequent.

[3] The plant was treated as stated in the foregoing note. Self-fertilisation is no doubt easier in this case, but the result of the crop was not very good.

Candidates for the natural science scholarship at Clare College are to be examined in chemistry and chemical physics, without restrictions in age.

At King's College any candidates for honours are now received, a great improvement on the old exclusiveness. The Vintner exhibition for natural science is worth 90*l*. a year, but only candidates under twenty, and British subjects, may compete, also undergraduates of the College in their first or second year. The scholarships are to be held till M.A. standing, or until election to a fellowship. Candidates in natural science must notify before March 1 in what branches of natural science they wish to be examined.

Every encouragement is now offered to selected candidates for the Indian Civil Service.

It having been decided that there should be a memorial to Prof. Clerk Maxwell, it might be suggested that a Maxwell university scholarship in experimental and molecular physics would be a great benefit, as there are scarcely any mathematical or natural science competitions open to the University. Let it be given for a specified research, rather than spend it on a posthumous bust or portrait.

MANCHESTER.—Mr. J. E. A. Steggall, B.A., scholar of Trinity College, Cambridge, mathematical master at Clifton College, Bristol, has been appointed to the Fielden lectureship in mathematics in the Owens College, vacant by the appointment of Mr. A. T. Bentley, M.A., to the principalship of the Firth College, Sheffield. Mr. Steggall graduated as second wrangler in January, 1878, and subsequently gained the First Smith's Prize. There were twenty candidates.

WE have received a very favourable report from the Liverpool School of Science, which now numbers 800 students. Before long it is hoped that a central college may be established in Liverpool, from which all existing branches with extensions may be worked.

THE Kaiser Wilhelm University at Strassburg is seemingly becoming popular in Germany. During the last term the number of students rose to 810, this being the largest number reached since the University was inaugurated.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 11, 1879.—This opens with a valuable contribution by Herr Hagenbach in support of Stokes's law, the validity of which has been somewhat controverted recently. The author regards Lommel's division of fluorescent bodies as based on no essentially different behaviour of them.—Some curious experiments on electric perforation of glass are described in papers by Herren Mach and Doubrava, and Herr Waltenhofen; the latter considers the phenomenon as "a mechanical work taking place at cost of the *vis viva* of the colliding air-molecules at the part perforated, and this transformation of energy is evidently more easily effected the stronger the molecular motions; which, when they meet an obstacle, are suddenly checked." Herr Doubrava also writes on the motion of plates between the electrodes of the Holtz machine.—A series of experiments, by Herr L. Weber, with electricity of high tension used in the telephone, seem to clear up some sources of error in like observations by other physicists, to give new proof of the availability of the telephone for observing weak periodic discharges of a conductor, and to illustrate the conception of Helmholtz and others as to electric movements in an induction circuit and electrolytes inserted in it.—The relations between velocity of rotation, resistance, current strength, and electromotive force, in the Gramme machine, are set forth by Herr Meyer and Herr Auerbach.—Other papers:—On the true theory of Fresnel's interference phenomena, by Herr F. Weber.—On the relation between galvanic resistance and specific heat, by Herr Auerbach.—On extra currents in iron wires, by Herr Herwig.—Experimental researches in determination of the indices of refraction of liquefied gases, by Herr Bleekrode.—Influence of temperature on tuning-forks, by Herr Kayser.—On galvanic conduction of metallic alloys, by Herr Elsässer.—On phosphorescence-phenomena, by Herr Stürtz.

Gazetta Chimica Italiana, fasc. x. 1879.—Researches on cobalt and nickel, and methods for distinguishing them when mixed, by Dr. Papasogli.—On the constitution of ellagic acid, by S. Schiff.—On determination of acetyl by means of magnesia, by the same.—Ozone with some noble metals, by Prof. Volta.—On paraoxymethylphenyl-cinnamic acid, and on oxymethylstilbene, by Dr. Oglialoro.—On the action of perchloride of phosphorus on molybdic anhydrides, by S. Piutti.—On some derivatives of naphtols, by S. Marchetti.—Researches on the diffusion of copper in the animal kingdom, by Dr. Giunti.—On amines corresponding to a toluic alcohol, by Dr. Spica.—On the preparation of hydroxylamine, by Dr. Bertoni.—Transformation of hydroxylamine into nitrous and nitric acid, by Dr. Bertoni.—On an easy and rapid process for determining at any time the nitrogen, sulphur and chlorine, in organic substances, by Dr. Spica.

Bulletin de l'Académie Royale des Sciences de Belgique, Nos. 9 and 10.—M. Montigny here describes a case of supernumerary rainbows which were only visible at the lower extremities of the principal bow (a phenomenon overlooked in works on meteorology).—M. van Mensbrugghe shows how the ventral and nodal appearances of liquid veins may be explained on principles he lately enunciated.—Dr. Jorissen contributes a note on the employment of chloride of zinc as reagent for certain alkaloids, glucosides, &c.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 18, 1879.—"Chemico-Electric Relations of Metals in Solutions of Salts of Potassium," by G. Gore, LL.D., F.R.S.

In this investigation the author has determined the chemico-electric positions of about twenty-four elementary substances in a number of solutions, of various degrees of strength, and both cold and hot, of chloride, bromide, iodide, and cyanide of potassium, and has drawn from the results of the experiments various general conclusions. The results are exhibited in a series of tables. The experiments were made with the intention of also determining by means of a capillary electrometer the quantitative differences of electromotive force between each two consecutive elementary substances of the entire series; but after making many attempts the author was unable to construct such a form of that instrument as might be relied upon for accurately measuring such differences.

Chemical Society, December 18, 1879.—Mr. Warren De La Rue, president, in the chair.—The following papers were read:—On the specific volume of water of crystallisation, by T. E. Thorpe and J. J. Watts. Some years ago Playfair and Joule pointed out that the volumes of certain highly hydrated salts, for example, sodium carbonate with ten molecules of water, are equal to that of the water, considered as ice, which they respectively contain. This law does not hold good for salts less highly hydrated. The authors of the present paper have determined the precise relations between the specific volumes of various sulphates of copper, magnesium, zinc, nickel, cobalt, iron, and manganese, and their respective degrees of hydration. They conclude that in the case, at least of the so-called magnesian sulphates, the volume occupied by the several molecules of water varies with the degree of hydration. The first molecule occupies less bulk than any other, its mean relative value is 10·7, the value of the second molecule being 13·3, of the third 14·5, the fourth 15·4, the fifth 15·6, the sixth 15·7, the seventh 16·2. These results accord with the fact that the different molecules of water in a hydrated salt are held with various degrees of tenacity. The authors point out the importance of estimating the amounts of heat resulting from the combination of successive molecules of water.—Note on the formation of ozone during the slow oxidation of phosphorus, by H. McLeod. The active substance formed during the slow oxidation of phosphorus is probably either ozone or peroxide of hydrogen. Air in which phosphorus is slowly oxidising, was drawn through a U-tube 9½ inches long (filled with fragments of glass containing in succession sodic carbonate, a mixture of potassic bichromate and sulphuric acid, and potassic permanganate), the U-tube was at the temperature of the air or at 100° C., in both cases the gas which passed through rendered blue a solution of potassic iodide and starch, hydroxyl under these circumstances would be completely decomposed. In another series of experiments the gas was passed through a narrow U-tube heated to 150° to 200° C., but no water was formed. It is extremely improbable that ozone and hydroxyl are simultaneously formed, as these substances decompose each other. The author therefore concludes that the gas obtained during the slow oxidation of phosphorus possesses the properties of ozone and not those of hydroxyl, the only known peroxide of hydrogen.—On the analysis of organic bodies containing nitrogen, by W. H. Perkin. The author proposes to substitute for the freshly reduced metallic copper, which has severa disadvantages (such as being hygroscopic, occluding iron, &c.), roughly powdered or granulated potassic chromate. About 4 to 7 inches of this substance are placed in the front of the combustion tube and maintained at a low red heat. All nitrous fumes are completely absorbed, whilst no effect is produced on the carbonic acid determination. The salt can be readily dried. It also absorbs sulphurous acid completely.

Linnean Society, December 18, 1879.—Prof. Allman, F.R.S., president, in the chair.—Mr. B. Daydon Jackson exhibited series of the various editions of Dillenius's "Historia Muscorum," Oxford, 1741, and its reprint, Edinburgh, 1811, in illustration of the following communication.—The Rev. J. M. Crombie read a paper on the lichens of Dillenius's "Historia Muscorum," as illustrated by his herbarium. This latter collection is preserved in the Botanic Gardens at Oxford, and the specimens, though well nigh 150 years old, are still in a fair state of preservation. The intrinsic value of Dillenius's material rests in the fact of the earlier writers on cryptogamic botany referring constantly, in their synonomy and nomenclature, to his descriptions; hence the importance of an accurate knowledge of the collection, to judge from a present standard, in how far his descriptions and figures agree with the specimens themselves. No systematic examination has hitherto been made, though some old writers have compared certain of the forms. While the Dillenian lichens identified are, as a whole, now found to bear considerable accuracy with his descriptions and figures, yet serious mistakes have crept in. Mr. Crombie gives technical data and details of the series, and adds a conspectus for reference to workers on lichens who have not Dillenius's volumes and figures at hand.—Prof. Allman then gave a description of what appears to be true sense-organs in the hydroids. In one form the organ in question is a bulb, with rod-like structures and a series of radiating filaments. These latter terminate in conical bodies containing filaments which resemble thread-cells, though differing physiologically. Another form is met with in a Medusa (*Gemmellaria*), where free, club-topped filaments constantly in motion are attached to the tentacles, and possess sacs with thread-cells, but incapable of being exserted. Prof. Allman suggests the term *Podocysts* for these, and says, from his observations in *Myriothela* and other genera, they have a wide extension among the hydroids.—Mr. H. Seebohm was elected a Fellow of the Society, and Messrs. A. D. Bartlett (Zool. Gard.), N. E. Brown (Kew Herb.), and F. H. Waterhouse (Librarian, Z.S.) were balloted for and elected Associates.

Entomological Society, December 3, 1879.—J. W. Dunning, F.L.S., vice-president, in the chair.—Mr. Howard Vaughan exhibited a series of extreme varieties of *Lycæna corydon* which had been taken at Dover.—Mr. W. L. Distant exhibited a hitherto unrecorded variety of *Danais plexippus* (commonly known as *D. archippus*) received from Antigua.—Mr. T. R. Billups exhibited some rare British beetles, and a specimen of *Carabus auratus* taken in the Borough Market.—Mr. C. O. Waterhouse communicated some interesting details as to tenacity of life in *Curculio cleonus*.—The Rev. H. S. Gorham read a paper entitled "Materials for a Revision of the Lampyridæ." Mr. Bates, in connection with the light-emitting power of this family, remarked that certain species of Longicorns mimicked Lampyrids with great exactness, the light-giving segments of the latter being perfectly represented in the Longicorns, although destitute of phosphorescent power.—Mr. J. W. Slater communicated a paper on certain minute characters of insects with reference to the theory of evolution.—A communication was received from Mr. P. H. Gosse, on *Papilia homerus*, its ovum and larva, and a paper from Mr. Roland Trimen, on some hitherto undetermined butterflies inhabiting Southern Africa.

Geological Society, December 17, 1879.—Henry Clifton Sorby, F.R.S., president, in the chair.—James Booth, Edgar S. Cobbold, D. M. Ford Gaskin, John Farran Penrose, Stephen Seal, Thomas Tate, and Richard Taylor were elected Fellows of the Society.—The following communications were read:—A contribution to the physical history of the cretaceous flints, by Surgeon-Major G. C. Wallich, M.D. The author described the origin, the mode of formation, and the cause of the stratification of the chalk flints. Taking as the basis of his conclusions the fact brought to notice by him in 1860, namely, that the whole of the protozoan life at the sea-bed is strictly limited to the immediate surface-layer of the muddy deposits, he pointed out in detail the successive stages of the flint-formation, from the period when the chief portion of the silica of which they are composed, was eliminated from the ocean-water by the deep-sea sponges to the period when it became consolidated in layers or sheets conforming to the stratification of the chalk. In relation to this subject the author claimed to have sustained the following conclusions:—1. That the silica of the flints is derived mainly from the sponge-beds and sponge-fields, which exist in immense profusion over the areas occupied by the globigerine or calcareous "ooze." 2. That the deep-sea sponges, with their environment of protoplasmic matter, constitute by far the most important and essential factors in the production and stratification of the flints. 3. That whereas nearly the whole of the carbonate of lime, derived partly from foraminifera and other organisms that have lived and died at the bottom, and partly from such as have subsided to the bottom only after death, goes to build up the calcareous stratum, nearly the whole of the silica, whether derived from the deep sea sponges or from surface protozoa, goes to form the flints. 4. That the sponges are the only really important contributors to the flint-formation that live and die at the sea-bed. 5. That the flints are just as much an organic product as the chalk itself. 6. That the stratification of the flint is the immediate result of all sessile protozoan life being confined to the superficial layer of the muddy deposits. 7. That the substance which received the name of "*Bathybius*," and was declared to be an independent living Moneron, is, in reality, sponge-protoplasm. 8. That no valid *lithological* distinction exists between the chalk and the calcareous mud of the Atlantic, and *pro tanto*, therefore, the calcareous mud may be, and in all probability is, "a continuation of *the* chalk-formation."—Undescribed fossil carnivora from the Sivalik Hills, in the collection of the British Museum, by P. N. Bose. This communication contained descriptions of nine species of carnivora from the ossiferous Sivaliks, together with an introduction, in which the age of the Sivalik fauna, and several matters of general interest, were briefly discussed. The species described were: *Machærodus sivalensis*, *M. palæindicus*, *Felis grandicristata*, *Hyæna sivalensis*, *H. felina*, *Viverra bakerii*, *Lutra palæindica*, *Canis curvipalatus*, and *C. cautleyi*. *Canis curvipalatus* is so named on account of the curvation of the palate. *C. cautleyi* is closely allied to the wolf, as is *Viverra bakerii* to the civet. The form of the forehead is peculiar in *Lutra palæindica*. In the form of the skull, the dimensions of the upper tubercular, &c., *Hyæna sivalensis* approximates to the living Indian hyæna (*H. striata*); but, in the absence or extremely rudimentary character of the postero-internal cusp in the lower carnassial, as well as in the entire absence of the anterior accessory cusps in the upper and the first two lower premolars, the Sivalik species comes closer to *H. crocuta*. *H. felina* differs from all other species of hyæna, living or extinct, in the absence of the upper premolar 1. *Felis grandicristata*, which was of about the same size as some of the larger varieties of the Royal Tiger, had the sagittal crest even more prominent than the *F. cristata* of Falconer and Cautley. *Machærodus sivalensis* was of about the same size as the jaguar. One of the specimens, on which this species is based, shows two molars in the deciduous dentition instead of three (as in the genus *Felis*). *M. palæindicus* was considerably larger than *M. sivalensis*. Both differ from all other known species of *Machærodus* in the form of the lower jaw, &c.

PARIS

Academy of Sciences, December 15, 1879.—M. Daubrée in the chair.—The following papers were read:—On some applications of elliptic functions, by M. Hermite.—Researches on the substance designated hydride of copper, by M. Berthelot. The amorphous substance precipitated in the reaction of hypophosphorous acid with sulphate of copper is not a true hydride; it contains constitutional water, oxygen, and phosphorus in considerable quantity.—On the cold of December and its influence on the temperature of the snow-covered ground, by MM. Becquerel. Snow alone does not preserve the bodies it covers from frost. It acts, indeed, as a screen, preventing radiation, and gives water at 0°, which filters through the ground; but under 0° it undergoes, like other bodies, by its conductivity, variations of temperature, and may transmit them, attenuated much, however, by reason of its thickness. But the presence of straw or the like under the snow may preserve organic bodies in the ground.—M. Pasteur stated that the bacteridium of anthrax, and the organism which produces the cholera of fowls, could both resist a temperature of 40° below zero.—On the variations of the vertical, by M. D'Abbadie. In his observatory near the Pyrenees he has found the place of the vertical vary in only six hours, from 7″·4 to 2″·4, and he thinks the changes there do not depend on temperature (as M. Plantamour explains the phenomena he noted). The desirability of all astronomers publishing their observations on this subject is referred to.—Craniology of Australian races, by MM. Quatrefages and Hamy. The eighth volume of their "Crania Ethnica" completes the study of the Australians, and treats partly of the African negro races. The Australian continent seems to contain only two indigenous races, one forming the Australian race proper, the other distinguished as *neanderthaloid*, and represented by a small number of homogeneous and disappearing tribes. The craniological characters are indicated. The male natives of the interior have considerably larger cranial capacity than those of the coast, but the women have slightly less.—Observations during a voyage in Equatorial America, by M. Crévaux. The River Iça (one of the affluents of the Amazon) is navigable for 800 geographical miles, as far as the outliers of the Andes.—New æroplane, moved by a compressed air-engine; experimental determination of the work necessary to make it fly, by M. Tatin. The apparatus resembled that of Henson's (1843), except in dimensions, a sort of kite moved by screw propellers. It rises and describes a curve in the air, coming to the ground again. The horse-power was about 1 per 50 kg.—Reply to M. Balbiani, on the presence of the winter egg of phylloxera in the ground, by M. Boiteau.—A head of jacquez grafted on a French vine, by M. de Lafitte.—On a class of functions connected with the functions of M. Heine, by M. Appell.—On measurement of the intensity of absorption lines and dark lines of the solar spectrum, by M. Gouy. The problem is reduced to making a pure spectrum, and measuring the intensity of different portions of it.—On a curare of the unstriped muscles, by MM. Couty and De Lacerda. This kills by lowering the arterial tension, and consequent cessation of the circulation. The effects were got with preparations from *Strychnos gardnerii* and *S. triplinervia*.—Alterations of the cutaneous nerves in a case of vitiligo, by MM. Leloir and Chabrier.—Researches on vaso-dilator nerves contained in various branches of the fifth pair, by MM. Jolyet and Laffont.—On the chemical composition of bones in arthropathy of the ataxic, by M. Regnard. Fat becomes abundant, and phosphate of lime is greatly diminished.—Researches on the mode of formation of the spinal fissure, by M. Dareste.—On a new form of vesicular worm found in a jerboa, by M. Mégnin.—New remarks on the Orthonectida, by M. Giard.—On the reproduction of marine algæ (Bryopsis), by M. Cornu.—On the influence of forests on rain-currents traversing them, and the affinity of pines for vapours, by M. Fautrat. On an average the weight of aqueous vapour contained in 1 cub. metre above pines is 8·66 gr., and on bare ground at the same height 7·39 gr.; showing 1·27 gr. in favour of the pines. Above leafy trees the corresponding numbers are 8·46 gr. and 8·04 gr.; difference in favour of leafy trees 0·42 gr.—On a very intense hoar-frost observed at Angers on December 12 and 13, by M. Decharme. The temperature was − 8°·8 to − 6°·4; pressure 779 mm.; wind weak. The numerous long opaque needles of ice were all placed on one side of the branches, that opposite to the direction of the wind.—M. Jobert proposed a large celestial reflector, giving, in a dark chamber which might hold as many as a hundred observers, an enlarged image of heavenly bodies.

December 22, 1879.—M. Daubrée in the chair.—M. Faye presented his "Cours d'Astronomie nautique." His method is to bring all questions to two or three fundamental equations (which ever recur). The study of chronometers is treated with special care. The graphic solutions of Douwes's problem are expounded from a new standpoint.—Reply to M. St. Claire Deville's remarks on the temperature of decomposition of vapours, by M. Wurtz.—Observations on M. Berthelot's note entitled "Researches on the Substance named Hydride of Copper," by M. Wurtz. He adheres to his formula, Cu_2H_2. The presence of a small quantity of copper and phosphate of copper in the product explains at once the existence of small quantities of oxygen and phosphorus, and the deficit in hydrogen.—On a new hydride of silicium, by M. Ogier. He submitted some siliciuretted hydrogen to the electric *effluve*. After some time the gas is wholly destroyed; a yellow coat forms on the walls of the tube, and the gaseous volume (pure hydrogen) increases to a sensibly constant limit. The composition of the deposited matter (arrived at from comparing the volume of the siliciuretted hydrogen and the resulting hydrogen), appeared to be Si_2H_3. The body is thus a sub-hydride of silicium corresponding to sub-oxide of carbon, or to crotonylene. (Its properties are specified.) Similar effects are got with the *effluve* acting on arseniuretted hydrogen; a solid hydride As_2H is formed, corresponding to solid phosphide of hydrogen, P_2H.—Comparative studies on ptyaline and diastase, by M. Defresne. These two bodies are not identical physiologically. Ptyaline saccharifies starch in the mixed gastric juice as well as in the mouth; it is only paralysed an instant in pure gastric juice, and recovers its action in the mixed juice and in the duodenum. Diastase or maltine is destroyed immediately in chlorhydic solutions or in pure gastric juice, and after having passed into the mixed juice, it is profoundly altered, for, if again dissolved with starch, it no longer saccharifies it.—M. Debrun submitted a new capillary electrometer, a modification of Lippmann's, a microscope being dispensed with, and the mercury surface whose displacements are observed being in a graduated tube inclined at an angle of 10° to the horizon. The change of level is about 75 mm. for a variation of one volt (giving, with a Vernier, a sensibility of at least $\frac{1}{150}$ of a volt).—On the determination of the elements of a vibratory movement; measurement of periods, by M. Mercadier. Two very fine styles are fixed (parallel, and one behind the other, and very near it, in a horizontal plane) to the two vibrating bodies; and their shadows with light coincide on a vertical screen. When the bodies vibrate vertically, a certain number of lines result in the projection, some of which are broader than others, and seem fixed. (These effects are investigated).—Researches on nitrification, by MM. Schlœsing and Muntz. The conditions affecting the production of nitrates are set forth; temperature, access of oxygen, humidity, weak alkalinity, presence of various organic matters, &c. *Nitrites* are formed in general when the conditions of temperature and aëration are not advantageous.—On dioxyethylmethylene, and on the preparation of chloride of methylene, by M. Greene.—On two substances, palmelline and characine, extracted from fresh-water algæ, by Mr. Phipson. It is characine that gives plants of the *chara* genus their marshy odour; it is formed by the plant during life, and is not a product of decomposition. It is lighter than water, and is a species of camphor, forming very thin pellicles on the water surface, but dissolving very little in it.—Habits and parthenogenesis of *Halictus*, by M. Fabre. These animals have two generations annually, one in spring, and sexual, from mothers which, fecundated in autumn, have passed the winter in their cells; the other in summer, and due to parthenogenesis.—On tubercular inflammation of the internal coat of the vessels in tubercular meningitis, by M. Cornil.—On the structure of the bark and wood of *strychnos*, by M. Planchon.

THURSDAY, JANUARY 8, 1880

THE TECHNICAL UNIVERSITY QUESTION

THE correspondence which has appeared during the month of December in the columns of the *Times* concerning the question of a Metropolitan Technical University, has revived a question upon which we have more than once spoken in these columns, and of which we shall hear more hereafter. It is quite evident that the promoters of the City and Guilds of London Institute for the Advancement of Technical Education meet with many great and unforeseen difficulties in the way of pushing into execution their laudable project for applying some of the vast funds they have inherited from the Trade Guilds of the past to the purpose of promoting the elevation of trade by science. It is equally evident that they will not abandon their projects without a very considerable effort, especially now that the pressure of public opinion is beginning to bear upon the question and to aid them in their demand. No one probably denies or doubts the legal right of the City Companies to the funds which have thus come down to them. Probably also no one denies or doubts that the law-making power which gave them these legal rights can take them away and can force them to hand over, if need be, to the advancement of Technical Education at large, the wealth which they have ceased to apply to the advancement of Technical Education within their own borders. Two years ago a very definite scheme in this direction was launched by the provisional Committee appointed by some of the Guilds. Recognising the moral obligation upon them to use their funds for the advancement of their respective industries, some dozen out of the eighty City Companies agreed to devote a certain yearly sum for this purpose. They even went so far as to invite a number of distinguished men of science to write reports on the best way of attaining the ends in view, and eventually they embodied their suggestions in a report which was characterised by two main propositions: firstly, to establish local technical schools which should be accessible to artisans; secondly, to found a central institution, chiefly for training technical teachers and scholars of exceptional promise. This was two years ago; and in the mean time so little has been done, that some of those who have taken an active part in the earlier stages, begin to be impatient at the little substantial progress made.

A note of dissatisfaction of this nature was heard at the beginning of the month of December, and gave rise to the discussion in the *Times*, to which we have alluded. To understand the merits of the controversy it will be necessary to go back to the beginning. The correspondence arose out of some remarks made by Prof. Huxley when presiding at the meeting of the Society of Arts on December 3, at which a paper on apprenticeship was read by Prof. Silvanus Thompson, of Bristol, and to which a paragraph was devoted in NATURE, vol. xxi. p. 139. Prof. Thompson's paper, which appeared in the *Journal* of the Society of Arts for December 5, and which has been reprinted in pamphlet form, was devoted to a discussion of the relation between apprenticeship and technical education; and after laying down the general principles of a scientific and rational system of apprentice training, pointed out that the "lower technical," or "industrial" training which is needed for the forming of good workmen, cannot exist in any effective degree until there is some provision made for the higher technical training analogous to that of the great technical schools of Germany and France, which would qualify a superior class to become on the one hand foremen and masters, and on the other teachers in technical schools. In short, Prof. Thompson's argument was that there could be no growth of technical schools for the artisan without a central technical university to train teachers for such schools.

In the discussion which ensued Prof. Huxley made some pungent remarks upon the delays which had arisen over the project of the Guilds and Companies of the City of London, who had consulted him some time back concerning their proposal to found a Central Institution or Technical College, and who, two years ago had empowered him to make known their good intentions. It was time, he thought, that those good intentions bore fruit. It would be an utter scandal if one shilling were asked for out of the general revenue for this purpose, at least so far as London was concerned, for the Livery Companies were in possession of the enormous funds inherited along with the ancient traditions of the crafts from the old Guilds of London, which were established to aid their respective trades—funds which they were morally, if not legally, bound to apply to the advancement of Technical Education.

Prof. Huxley's remarks were not, however, suffered to pass unchallenged. In the *Times* of December 9 Mr. J. H. Crossman condemned Prof. Huxley and those who act with him as somewhat impatient and hasty in their proposals.

To this letter Prof. Huxley replied a few days later in a most admirably conceived and no less successfully worded letter. What had been proposed was simply the establishment of local technical schools accessible to the artisans, and a Central Institution chiefly for the training of teachers and of scholars of exceptional capacity; and he added the very pertinent query: "Do the Livery Companies of London intend to carry out any general scheme of Technical Education such as that adopted by their own Committee, or do they not?"

Mr. Owen Roberts, one of the Honorary Secretaries of the City and Guilds Institute, replied to the point raised by Prof. Huxley's letter, asking whether he was aware of the negotiations which had been going on between the City and Guilds Institute, and the Lords Commissioners of the Exhibition of 1851, for a piece of land on the South Kensington estate as a site for a central institution, and stating that the only reason why these negotiations had not been definitely concluded, was that lately the Commissioners had put forward certain requirements, as a condition of their grant of a site, which the Livery Companies have not considered to be consistent with their independence of action. Hence the repeated delays, which had not, however, debarred the Institute from proceeding with one very important section of its work, namely, the promotion of local schools for artisans.

Following hard on Mr. Roberts's letter, there appeared in the *Times* of December 27 a communicated article giving a careful and detailed history of the various schemes considered by the City and Guilds Institute, which may be broadly stated as being three in number. The first of these schemes, proposing to build a central institution upon a site on the Corporation lands on the Thames Embankment, has been dismissed as essentially too costly. The second, the proposal to obtain a site from the Commissioners of the South Kensington Estate, is in abeyance since the ancient free "spirit" of the Companies leads them to regard as distasteful either that the Commissioners should be directly represented on the managing body of the Central Institution, or that, as an alternative, the chief scientific bodies of the nation should have the right of being represented on it. The third scheme, which apparently does not stand a much better chance of success than its predecessors, though having many points in its favour, was a proposal to buy the palatial mansion built by Baron Grant at Kensington, with its seven acres of ground, and convert it into a building for a Central Institution by slight but suitable alterations in its interior arrangements, thus obtaining capital laboratories and lecture theatres. But the unreasoning outcry raised against the site simply because it was in the west, and not in some equally inaccessible situation in the north or in the east, has been so loud in its tones that we believe the project has virtually been abandoned. At least so the semi-official article in the *Times* would lead us to imagine. Prof. Huxley has, however, had a last word on the matter. He cannot quite agree in the view that the guarantees asked by the Lords Commissioners are so unreasonable as the Livery Companies think them. In his second letter of the 29th ult. he says that if he is rightly informed, they amount to being guarantees firstly of sufficiency and permanency of endowment, and secondly of proper government; the desire of the Commissioners in reserving the right of nominating two or three members of the governing body being merely that they may insure the presence amongst the representatives of the city magnates that small number of "educational experts." To which Mr. Roberts quietly rejoined that educational experts differed considerably in the advice they tendered, and that the principal point of objection lay in the proposal that the two or three persons nominated by an exterior authority should be the only permanent members of a governing body the majority of whom were continually going off by rotation.

It is not our place to pronounce judgment upon the conflicting views which have been maintained concerning the conditions imposed by the Commissioners in their offer of a site. If Prof. Huxley's information is correct, it is hard to see how or why the independence of the Guilds, or of the Institute they have founded, should be impaired by the presence on the governing body of such men as, say, Mr. Lyon Playfair, or Mr. Mundella, or perhaps even Prof. Huxley himself. If, on the other hand, the Livery Companies have some further knowledge or insight than Prof. Huxley has, it would certainly be well if they would explain what it is that is incompatible with their ancient liberties, and would suggest some alternative course, which, while reserving them all reasonable liberty of action, should attain the ends for which guarantees are desired.

The most painful aspect of the whole controversy is one which does not come to the surface in this correspondence, but which is nevertheless a very real one. There is a large section of the outside public who take a deep and increasing interest in the question of technical education, and who have watched the present scheme from its first inception with something more than curiosity. They cannot understand that any body of men really intending to carry out a project such as that which was made public two years ago could permit such endless delays, such interminable cross-purposes, such haggling over different schemes, as have been lately witnessed. They begin to fear that all these things are done with a purpose, and that the delays are interested, and the rival schemes manufactured to serve some less noble end. Whether such persons are right or wrong, all these whispers would be at once silenced by a few unmistakable signs of real progress, such as we have looked for in vain. The public knows well enough that the organisation of the City Guilds *as they are* is a blot upon an intelligent community; that they have ceased in all but name to represent the trades for the sake of which and out of which they arose. It knows full well that their unfathomed funds are not applied to the purpose of elevating and improving their respective crafts, whatever else they may be applied to. And it is quite prepared to say with emphasis when the moment arrives that if reform does not come from within it must come from without. The first step, if such measures must come, will doubtless be the appointment of a Royal Commission of Inquiry. What the second might be he must be bold who would predict.

The announcements made two years ago were hailed as a note of progress, indicating the probability that wiser counsels would prevail, and that the needed reform was to be brought about quietly and harmoniously from within. But the project for founding a Central Technical College is as far from realisation as ever, and the hopes raised have been sorely disappointed. Men of scientific habits and of business aptitudes are alike getting tired of the endless delays and fruitless negotiations that have taken place. And there are, we suspect, many who, on learning how one scheme after another has fallen through for want of unanimity of purpose to carry it out, will be quite ready to think that it was not without good cause that Prof. Huxley asked: *Do the Livery Companies of London intend to carry out any general scheme of Technical Education such as that adopted by their own Committee, or do they not?*

OSTEOLOGY OF MAN

Catalogue of the Specimens Illustrating the Osteology and Dentition of Vertebrated Animals, Recent and Extinct, contained in the Museum of the Royal College of Surgeons of England. By William Henry Flower, Conservator of the Museum. Part I. *Man.* (London: David Bogue, 1879.)

IT is now twenty-five years ago since Prof. Owen, the then Conservator of the Museum of the Royal College of Surgeons, completed the last volume of the catalogue of the osteological collection. Since that time the additions to the Museum have been so numerous and valuable that the original catalogue has ceased to fulfil the requirements of the collection, and the preparation of a new catalogue has become necessary.

Prof. Flower, the present Conservator, has undertaken this task, and the first fruit of his labours is now before us. In this volume he has catalogued the specimens, 1,312 in number, which illustrate the development of the human skeleton, the osteology of adult man, the dentition of man, and the crania and other parts of the skeleton illustrating the osteological characters of the various races of men. This volume is, therefore, from the extent and variety of the collection, and from the methodical way in which the numerous measurements are recorded, an important contribution to physical anthropology.

In the introductory chapter Prof. Flower describes the method he has pursued in obtaining the measurements of the crania, and he explains the meaning of a number of terms, mostly introduced by Paul Broca, into craniology. The measurements which he records are taken with especial reference to the determination of the circumference of the cranium, its length, breadth, and height and the relations of these to each other; the length from the anterior margin of the foramen magnum, on the one hand to the fronto-nasal suture, and on the other to the most projecting part of the upper alveolar arch, from which the alveolar index is deduced; the height and width of the nose; the height and width of the orbit; and the cubic capacity of the cranium. The capacity is expressed in cubic centimetres and the other measurements in millimetres.

In measuring the length of a skull craniologists are in the habit of taking the longitudinal diameter between the prominence at the root of the nose called the glabella, and the most projecting part of the occiput behind, a measurement which has the advantage of giving the absolute length of the cranium between its two most extreme points. Prof. Flower, however, does not follow this method, but prefers to take the length from the most projecting part of the occiput behind, to a point situated immediately above the projection of the glabella, to which Broca has given the name ophryon. This point is in the centre of a line drawn across the narrowest part of the forehead, which separates the face from the cranium. He has selected this point anteriorly, in preference to the glabella, on the ground that the glabella is properly a part of the face, and that it may vary much in development, without occasioning any alteration in the essential form of the cranium. Similarly in taking the horizontal circumference of the cranium he passes the tape line, not over the prominence of the glabella, as is customary with craniologists, but above it, around the supra-orbital line. Mr. Flower therefore entirely excludes this well-known prominence from his measurement of the cranium.

But in excluding the glabella from the cranium, on the ground that it belongs to the face, he does not appear in his measurements of the face, to have made provision for including th glabella, so that in these measurements a feature which gives a very decided character to the anterior region of the head is left out of consideration. This seems to us to be a defect, for if such a mode of mensuration were generally adopted, skulls possessing great projections in the glabellar and supraciliary regions, such as the well-known Neanderthal skull and the crania of the generality of the Australian aborigines would not have, what undoubtedly constitutes one of their most salient and characteristic features, represented in a table of their dimensions, and the relations of their extreme length and breadth to each other, as expressed by the latitudinal cephalic index, would not be fully brought out.

It may, however, be argued that, by including the glabella in the longitudinal diameter and in the horizontal circumference, a portion of the cranial wall which lies superficial and owes its extent of projection to a subjacent air-containing space—the frontal sinus—and not to the brain cavity, is made to appear as if it were an essential part of the box containing the brain, and that the size of the cavity of that box is made to seem therefore to be greater than it really is. But to this it may be replied that the capacity of the cranial box, as capable of being deduced from external measurements, is affected, even when the glabella and supraciliary ridges are left out of consideration, by other causes, such as variations in the thickness of the diplöe and the development of ridges for muscular attachment.

The only reliable mode of ascertaining the capacity of the cranium is by actual measurement of what it can contain, and not by calculations based on the external dimensions of its walls. The longitudinal diameter of the cranium ought in our judgment to express the actual length of the skull between its two extreme anterior and posterior points, to whatever cause it may be due. The special mode of taking the length of the cranium, adopted in this Catalogue, is to be kept in mind in comparing, not only the length of the crania but their latitudinal and altitudinal indices, with the corresponding measurements recorded by those craniologists who take the length of the skull between its two most extreme points.

The several measurements have been made and recorded with that care and precision which characterises all the anatomical work done by Prof. Flower. To obtain reliable evidence of the cubic capacity, one of the most difficult and important measurements to procure, many thousands of experiments have been made to ascertain the best process, and some of the crania have been gauged several times over. The material used has been mustard seed, with which the brain cavity has been filled to its maximum and the quantity of the seed has then been taken with the choremometer designed and constructed by Mr. Busk.

In addition to the measurements recorded of the individual crania, the author has given a valuable table in which he summarises the general results that have been obtained from the examination of the skulls of the different races. This table shows clearly that after making allowance for variations in individual skulls, yet that the different races of mankind possess in the configuration and dimensions of their skulls certain tangible characters which may be expressed by distinctive terms. Thus, to select a few examples adduced by the author, from the races which are probably unmixed. The Veddah race of Ceylon is dolichocephalic, orthognathous, with the orbital and nasal apertures moderately wide in proportion to the height (*mesoseme* and *mesorhine*), and with the capacity of the cranium small (microcephalic). The Australian race, again, whilst dolichocephalic, and microcephalic as regards the dimensions of the cranium, is prognathous, platyrhine, and microseme in the measurements of the face. The now extinct Tasmanian race was, like the Australian, prognathous, platyrhine, microseme, microcephalic, but in the relations of the length to the breadth of the cranium not dolichocephalic but mesaticephalic, *i.e.*, between dolichocephalic and brachycephalic. The Bushmen, whilst mesaticephalic, platyrhine, microseme, microcephalic, are, as regards the upper jaw, not prognathous, but orthognathous. The Bush crania differ in an important manner from their near geographical neighbours the Kaffirs and Zulus, which, though platyrhine in their nasal relations, are dolichocephalic and megacephalic in their cranial dimensions, mesognathous as regards the projection of the upper jaw and mesoseme in their orbital dimensions. The skulls of the African Negroes are dolichocephalic, mesocephalic, prognathous, platyrhine, and mesoseme; whilst the Andamanese, of which the Museum possesses a remarkably good series, are brachycephalic, microcephalic, mesognathous, mesorhine, and megaseme. As regards the Australian and the dark races with frizzly hair dolichocephalism and prognathism, with small or moderate cranial capacities prevail, except in the Bushmen and the Andamanese. The prevailing characteristics of the races inhabiting Europe, North Africa, and South-West Asia are a moderate latitudinal index, a moderate orbital index, a low alveolar index, a low nasal index, and a high cerebral capacity. In the Mongoloid races again the orbital index is usually high, the cranial capacity variable, whilst in its dimensions the skull ranges from brachycephalism in the Siberians and Peruvians to extreme dolichocephalism in the Eskimo. The jaw may be either orthognathous or prognathous.

The study of this Catalogue is essential to all who are interested in physical anthropology, but more especially to those who may be engaged in working with the craniological collection in the Museum of the Royal College of Surgeons of England.

OUR BOOK SHELF

The Village Life. (Glasgow: Maclehose, 1879.)

THIS is a volume of poems intended to picture various phases of Scottish village life. It is beyond our province to criticise the quality of the poetry, but it deserves some notice at our hands for the prominence given throughout to the most recent scientific doctrines, especially that of evolution. With the latest teachings of science in this direction the author appears to be thoroughly acquainted, as is evidenced especially in the two poems on "The Schoolmaster" and "The Doctor." It seems to us a noteworthy fact in the progress of science that its latest developments should form so prominent a feature in a work so purely literary, as a series of poems. The author himself, while he has evidently a tenderness for the old beliefs and bygone customs, still, cannot help showing how strong is his leaning to the revelations of the science of to-day. We venture to think that the anonymous author's presentation of the latest results of scientific investigation ought to reassure those who dread that science and poetry cannot co-exist, that the spread of science and the increase of scientific knowledge will leave no room for the exercise of the poet's fancy. If ignorance is a necessary condition for the exercise of this function, it is quite safe to predict that there is no chance of the poet's occupation ever being gone. Let us suggest to the author of the "Village Life," as a subject to try the mettle of his fancy and the extent of his knowledge, the "Lake Dwellers." We think the present volume is likely to afford a quiet pleasure to many readers, and as a specimen of the versification and to show how clearly and musically the author can put a puzzling problem, we give the following quotation from the poem on "The Doctor":—

"Search as we may, no trace is found
Of how the man-ape was transformed
Into the man with speech and creed;
We know not how he shed his hair,
Or shortened his fore limbs and rose
On back-bone straight, with head thrown back,
With archèd foot, and supple knee;
Or by what process came the hue
Of his now soft and hairless skin,
Its brown, its red, its jetty black,
Its yellow, and the tints between;
Or how the straight and flattened nose,
Developed from the monkey's face,
The jaw prognathous, square or thin;
And above all how speech began—
How first the inarticulate,
Long-armed, broad-chested, roaring clan
Of men-apes, out of shouts and cries,
Formed syllables and meaning words;
How, from the jarring harsh discords
Of brutal sounds there broke instead,
Liquid utterances, replies,
Sweet conversation, grave debate?—
A vast development, so great
And splendid that the tail-less ape
At once became the planet's lord,
A god in reason, as in shape.

The Doctor hoped that searchers keen,
Might find before the glacial age
Some traces of an earlier stage—
Man Pliocene or Miocene—
A skull, or skeleton that showed,
The type improving from the ape;
Some form revealing how a broad
Divergence intellectual,
May come from trifling change of shape;
That showed complete, a reason why
The glorious art of speech arose;
How shortened arm, and thickened thigh,
Deepened the chest, enlarged the lung;
The larynx and the mouth and nose
Transforming with the breast and brain,
Became sonorous, and the tongue
Shaped simple words, they grew amain
To language musical, and song.
But though the search is deep and long,
And evolutionists await
With eager hope, the early 'brave'
Emerging from the brutal state;
He comes not from his ancient grave;
His grave is lost; his fossil bones
No geologic era owns."

Artificial Diamonds

THE fate of the Glasgow diamonds, as recorded in NATURE, vol. xxi. p. 203, reminds me of an adventure of my own that happened about ten years ago, and is likely to be repeated by others. For showing the popular class-room experiment of burning phosphorus in oxygen, I was in the habit of using a little cup of chalk made deeper and with smaller rim than the brass cups usually made for the purpose. The object of this was to limit the too rapid outburst of combustion. I noticed that a cup which had been used several times was coated on the inside with a hard, glassy enamel, which I supposed to be phosphate of lime. To test this, the cup was thrown into some hydrochloric acid and dissolved bodily, but I found at the bottom of the beaker an insoluble residue of crystalline particles. What were these? Could it be possible that the carbonic acid driven off by heating the chalk had, on reaching the heated phosphorus, become dissociated, its oxygen combining with the phosphorus, and its carbon thrown down as veritable diamond? To test this startling theory, I collected the particles and rubbed them between a glass pestle and mortar. They appeared hard enough to scratch the glass, but were too small for further examination. To obtain a better supply, I dissolved some phosphorus in bisulphide of carbon, pounded some chalk and made it into a paste with the solution, then filled a porcelain crucible with this and fired the mass by heating it over a Bunsen burner. It blazed magnificently, throwing out eruptive jets of flame. Here, in the absence of surrounding oxygen, the carbonic acid had every opportunity of becoming dissociated or reduced by the heated phosphorus. The residue was treated with hydrochloric acid, and this time I found at the bottom of the beaker quite a respectable quantity of crystalline grains. These left unmistakable scratches on the glass pestle and mortar, and seemed to make some fine scratches on an agate pestle and mortar. I next examined them under a microscope, and found that they were more like pebbles than crystals, so much so as to suggest another theory of their composition and origin, viz., that they were miniature chalk flints formed by the fusion and aggregation of the siliceous cuticles of fossil diatoms, or such-like organisms of which chalk appears to be in some degree made up.

To test this, I precipitated some pure carbonate of lime, soaked it with the solution of phosphorus and fired as before, then treated with hydrochloric acid; when, alas! my *Eldorado* of dissociated carbonic dioxide melted into thin air as the effervescent liquid gradually cleared itself and showed no traces of crystalline residue. Solar Phenomenon

ON the afternoon of the 18th ult., in company with Herr Lohse, of this observatory, I was occupied in adjusting a spectroscope attached to the 15-inch refractor. The sun was disappearing behind the ridge of the hill of Fare, about five miles distant. To utilise the last rays of the sun, I was directing the telescope on the gradually lessening segment of the sun's disk, while Herr Lohse was looking through the spectroscope. Under these circumstances it will be understood that we were both standing near the inner vertical surface of the drum-shaped dome, close to where it was lit up by the sunlight coming through the opposite vertical opening, which is 40 inches wide. It may be well to add that the dome is made of corrugated iron, painted slate-colour, the corrugations of the wall being vertical.

Under the impression that the sun had wholly disappeared, I looked at the inner wall of the dome to see if it was actually shaded by the distant hill.

To my great surprise, the still illuminated surface was crossed by a number of distinct, horizontal, black lines, which ascended at a uniform pace about a foot and a half in a second. The lines were, on an average, about $\frac{1}{4}$ inch thick, while the intervals may have been mostly some $2\frac{1}{2}$ inches, but I do not think that the intervals were uniform. Herr Lohse, on turning from the spectroscope, also saw the lines; but while he feels sure that some of them terminated in points, I am under the impression that all the lines crossed the entire illuminated space.

The lines had a distinct quivering motion, which, combined with their uniform ascent, gave the whole phenomenon a most beautiful appearance. We both independently estimated the number of lines seen at about thirty, and the duration of the phenomenon at half a minute from the time when we first saw it. It was, however, certainly fully developed when first caught sight of. These lines seem to be closely allied to those repeatedly seen at the beginning or end of the total phase of a solar eclipse. See particularly *Astronomische Nachrichten*, Nos. 1,921 and 1,922, and "Le Soleil" (German edition), p. 301, *et seq.*

Some of the observers referred to speak of the lines as undulating; in this case it is difficult to say if the lines were quite straight or not, because of the corrugations of the surface on which they were thrown. My own impression is that they were straight except in so far as they were affected by the quivering before mentioned.

It would be remarkable indeed if this is the first time they have been seen at the daily disappearance or reappearance of the sun. RALPH COPELAND

The Observatory, Dunecht, Aberdeen, December 23, 1879

Carbon and Water Figures

THE separation of clear water from a uniformly diffused mixture with soot is so remarkable that it seems worth attention, especially in connection with the behaviour of charcoal powder in water, which is always streaky after any amount of shaking.

For some months I have observed and recorded these figures, as shown in a large white basin of sooty rain water, which is left undisturbed for twelve to twenty-four hours; they only appear occasionally, perhaps once in a week, are not constant when formed, and are entirely destroyed by stirring or mixing the water. They always consist of lines, planes, or patches of *clearer* water, sometimes not containing certainly more than a quarter of the proportion of soot around them; no aggregation of sooty water, or soot, has ever been seen. These quasi-vertical planes are very thin, sometimes the clearest part as little as $\frac{1}{50}$th inch wide, and the extreme thickness $\frac{1}{20}$th, the other dimensions being $\frac{1}{2}$ to 1 inch deep, and 1 to 5 long. Most usually only one plane appears, the azimuth of which is quite irregular; occasionally it is curved; sometimes a row of quasi-parallel planes or lines appear—once as many as six, at irregular intervals averaging ·8 inch; once a clear circular spot about $1\frac{1}{2}$ inch across appeared.

The last form I found was by far the most complex, and is here given from a careful sketch.

The lines were not as thin as usual, only one or two being as little as $\frac{1}{30}$ inch wide. They were very bright, probably not containing $\frac{1}{4}$ of the average soot around them; the water was unusually dark. The central semicircular space was 3·6 inches long × 1·7 inch; when first seen this space was uniformly grey, but in a few minutes, after slightly disturbing the water, the bright sharp plane across it appeared, inclined at about 5° to vertical. Some of the other planes were inclined 15°. The most striking point was the sharp definition of the central space, all the lines ending abruptly at its regular outline.

The depth of these figures bears strongly on their cause. They are never at the surface, but usually on the bottom. The water is about 2 inches deep, and the upper limit of these planes is $\frac{1}{4}$ to $1\frac{1}{2}$ inch from the top. In the above figure the lines or planes appeared to lie on the bottom, and to turn upwards at the edge of the central space, leaving it untouched, thus forming a bright edge to it. I have also, on disturbing water, seen apparently that a clear layer existed below a uniformly sooty surface.

The conclusions are, that water tends to separate from the finely divided carbon, in a clear bottom layer (or lines) of uncertain thickness (though lamp-black sinks if diffused in water), and that parts of this layer are (by convection?) turned upward and form quasi-vertical planes. The points still to be settled are:—1. Why these layers when turned up should not re-mix with the general mass, if their separation is due only to gravity, especially when as thin as $\frac{1}{50}$ inch, or $\frac{1}{100}$ of their length? 2. Why a particular sharply-defined space in the above figure should be avoided by the lines? 3. Are the causes the same as those preventing the uniform diffusion of charcoal dust in water?

These figures are not due to any form of caustic curves, though mistaken for such at first sight, and therefore neglected.

W. M. FLINDERS PETRIE

Velocity of Light

IF you can spare the space please state that the corrected result for the velocity of light (NATURE, vol. xxi. p. 94) is—

299944 ± 50 kilometres,
or 186380 ± 33 miles per second.

The Word "Telegraph"

I HAVE recently had occasion to ascertain the period when the word "Telegraph" first came into use; the following may be of interest to your readers:—

It is not mentioned in Johnson's Dictionary, 1810, but it occurs in the edition of 1818. In that valuable work, Rees's "Encyclopædia," 1819, vol. xxxv., we find:—"The word telegraph, which is derived from two Greek words, τῆλε, at a distance, and γράφω, to write, was brought into use about 1793 or 1794, when the French Directory established machines of this kind for communicating intelligence between Paris and all the principal towns in France. The British Government soon after adopted the same measure, and it has since become very general." So that telegraph and semaphore are both of French origin.

In the grand French "Encyclopédie" of Diderot—1778—the word telegraph does not occur.

The Lophiomys

As the oft-repeated statement (which originated with M. Alphonse Milne-Edwards) *that the roofed-in temporal fossa of the Lophiomys finds its parallel in certain reptiles alone* reappears in the pages of Messrs. Cassell's excellent "Popular Natural History" (see NATURE, vol. xxi. p. 137), it is high time that it should be modified in accordance with more recent anatomical investigations, which show that two *amphibian* genera, Pelobates and Calyptocephalus, participate in this singular abnormality.

Beddington Park PAUL HENRY STOKOE

Scorpion Suicide?

MR. F. GILLMAN'S note (vol. xx. p. 629) in favour of scorpion suicide carries with it its own refutation, as will be seen by examining the details of his cruel experiment. Given the "circle of glowing charcoal embers a foot or so in diameter," and the inference is that the central temperature of that circle would be well nigh "glowing" too; dropped into this fire-bound ring, the poor scorpion would at once be scorched nigh unto death, and to escape the ensuing agony, why does it not, then and there, commit suicide? No, "after vain attempts to get away," in each of which it is more and more scorched, if not absolutely burned in its head, its vital powers fail, and its last instinctive throe is to gather its limbs together as much as possible, away from the heat. The heat has killed it, and I defy Mr. Gillman, or any one else to prove that, in this experiment, the scorpion "pierces its head with its sting and dies" in consequence.

As our winter has set in, and the crickets had gone into winter quarters, I determined upon giving my scorpions an opportunity of doing the same, so, taking them into the garden, I emptied them into a hole. I only mention this to illustrate my remarks on change of colour in lizards, for, taking my scorpions into the sun, out of a comparatively dark room, each individual distinctly assumed a lighter hue on the way to the hole.

Peshawar R. F. HUTCHINSON

Strange Incubation in Fishes

Apropos of my note on strange incubation in fishes, I send you, *quantum valeat*, an extract from Mrs. Yelverton's *olla podrida* of travels, "Teresina Peregrina," vol. ii. pp. 15, 16: "His Highness (the Tumangong of Johore) had a splendid collection of orchids, which it seemed to gratify him to point out to me. I recognised many of them as my old friends, the acanthus-shaped denizens of the Cambogian forests, from whose urn-like leaves my people used to bring me down the little fish. This *bouleversement* of natural history may sound like a traveller's tale, but the explanation is simple.

"The aquatic birds often drop the spawn of the fish into the calixes (*sic*) of these beautiful parasites, which the next shower of rain turns into basins or pools of water, wherein the little fish first opens his eyes and receives its consciousness, probably believing firmly that it is the proper thing for a fish to live in a tree (so strong are early impressions), while all the rest of the world, fish, flesh, and fowl, view him with amazement.

"Many of our beliefs have not one whit more solid foundation than this fish's belief in the cornucopia of the orchid being a real fish-pond, because a few accidental fish got there through the slavering of some ill-mannered water-fowl." ! ! !

Peshawar, December 2, 1879 R. F. HUTCHINSON

FURTHER NOTES UPON THE PAPUANS OF MACLAY COAST, NEW GUINEA[1]

II.

OBJECTS *of Art.*—Specimens down to the simplest and commonest ornament were collected, or, at any rate accurately copied by M. Maclay, for the reason that the natives of Maclay Coast were still in the "Stone age"—a period which will soon belong to the past, and of which the relics are yearly becoming rarer and rarer. The implements as yet discovered by the Papuans, and upon which artistic skill has been expended come under two categories. 1. Fragments of flint, shells, and bones. 2. Chipped stones in the form of axes. The ornaments themselves may be divided into three classes. (*a*) Ornaments properly speaking, engraved, or drawn on their own account solely, and serving none other than a decorative purpose. (*b*) Ornaments and drawings demonstrating the first beginning of the figurative or ideal style of writing. (*c*) Ornaments, sketches, and carvings, which stand in relation to the superstitions and dark stage of religious ideas among the Papuans.

1. *Ornaments in the strict Sense of the Word.*—The salient character of most Papuan ornaments is that they are for the most part rectilinear, and for the reason that bamboo and reed, from which the majority of their utensils are made, are best adapted for such style of decoration, for it is, as Maclay has practically convinced himself, difficult to draw or scratch round and circular designs upon the substance, while straight lines, on the contrary, can be made with ease, the tools being sharp fragments of flint or shell. It is upon the bamboo receptacles for lime for betel chewing, but more especially upon the large comb which is worn by all men that their decorative skill is principally expended. That style of ornament which of necessity was adopted for articles of bamboo, is also applied to such as are of other material, *e.g.*, wood or clay, for the Papuan, in general with the rest of mankind, is influenced by laziness, for he lacks the energy to make trial of such designs as would be more suitable for the latter kind of material. Some of the designs, however, upon wood are of a curved and circular character, but these are difficult to make with such primitive tools as the Papuan possesses. A slight scratch with a piece of flint suffices to mark a line upon the epidermis of bamboo, while in the case of wood, strong pressure and tedious scraping or scratching are necessary to produce a superficial design. More trouble, moreover, is expended upon things made of wood, such as drums and canoes (*praus*).

That the want of variety in subjects of decoration does not proceed from lack of inventive power and skill is shown by the fact that directly after use was made of the

[1] Continued from p. 206.

sherds of glass bottles collected near Maclay's hut new refinements and variations were introduced into their wood ornamentation. As regards the pottery ware, since this is made by the women, and as the latter are wanting in artistic sense or in interest in their work, it is quite devoid of ornament.

2. *The Origin of the Development of Symbolic Characters.*—M. Maclay believes that he discovered by accident the use of an ideograph ("Ideenschrift") by the Papuans in a very rudimentary form. He noticed upon the façade of the *buambramra* of a neighbouring village a row of shields formed from the leaf-bladders of the sago-palm, on which rude figures, *e.g.*, fish, snakes, suns, and stars were painted in various combinations. Their meaning puzzled him for a long time, and from insufficient knowledge of the language he was for a long period unable to inquire about it. In the forests, too, he remarked similar enigmatical symbols carved upon the bark of the trees; also upon the sides of the praus which came from the Islands of Contentment. The riddle remained unsolved until the occasion of a feast, several months later, given in celebration of the launch of two large canoes on which the natives had been working for a long time, when a solution suddenly presented itself. Towards the end of the feast one of the younger guests jumped up, took a coal, and began to sketch a row of primitive figures upon a plank which lay near. These symbols had a great resemblance to those which Maclay had previously remarked upon the trees, canoes, &c., and were sketched in the following order. First came a representation of the two newly launched *praus*, drawn as though half upon the shore and half in the water; then followed a drawing of men carrying two pigs tied fast to a stake, victims doomed to be sacrificed for the feast. After these were represented, a row of large *tabir*, equivalent in number to the "covers" which had been served at the banquet, while the rear was brought up by a drawing of Maclay's canoe, conspicuous by its large flag, two large sailing canoes from the Archipelago of Contentment, and a number of smaller ones without sails, from the neighbourhood of Bili-bili. This group, which symbolised the various guests present at the feast, was drawn as a *souvenir* of the banquet, and Maclay saw it several months afterwards. Further observations have led M. Maclay to the conclusion that representations such as that just mentioned, are not to be regarded in the light of pictures or sketches, but as rudiments of a primitive ideograph — "primitive Ideenschrift" — a conclusion which has been borne out by later observations. M. Maclay was impressed with the variety in the representation of the commonest objects, which implies a very limited comprehension of drawing and renders it an utter impossibility for any other [than the artist?] to understand this primitive writing, or pictorial mnemonic medium. A man, for example, was actually represented by the same artist (1) as a rough human shape; (2) as a face with eyes and a large mouth; (3) as a comb[1] with a plume of feathers, and, lastly, as the "membrum virile," and it is very probable that there are many other symbols besides having an analogous signification. Besides the pictorial representations, the Papuans of Maclay Coast employ several mnemonic appliances to aid in remembering important events; for in every village may be seen suspended "in memoriam," various objects, such as bones, as a *souvenir* of a great feast, cocoa-nut shells, of a less important feast—no animal having been slaughtered on the occasion—a dry bunch of leaves or an empty basket, the former hung up by some friend in remembrance of a visit, the latter in which some present had been brought, being left behind as a hint for some gift in return. In every *buambramra* hang rows of the lower jaws of pigs and dogs, skulls of fish and of various marsupial animals, in remembrance of feasts, successful fishing and hunting parties, and visits of friends; serving thus as a veritable calendar of the events of past months and years.

1 "Kamm," a comb or crest.

3. *Sculpture in Wood.*—To this category belongs principally the fairly numerous quantity of carvings which, if not precisely as idols, may nevertheless be regarded as objects standing in a very intimate relation to the religious ideas of the Papuans. Such, under the common term, *Telum*, were seen by M. Maclay in nearly every village, and accurate drawings were made of no less than twenty-one of them, interesting as they were not only as specimens of the art of the stone age, but as affording many a guide to the relationship of the Melanesian races. A *Telum* consists of a human figure, of either sex, fashioned out of wood, or, more rarely, from clay. Nearly all wear peculiar head-dresses, and those of the male sex have the genitals of an enormous size. In a mountain village a *Telum* was discovered with the body of a man, but the head of a crocodile, for which a turtle served as a kind of cap, and in the same village another human figure was found which held with both hands a tablet covered with various symbols. In all figures the nose, as is the custom among the Papuans, is bored through, and every *Telum*, moreover, of which several may be found in each village, has its own special name. As for the significance of these wood-carvings, M. Maclay is not quite certain upon this point, although he is sure that they stand in some relation to the rudimentary religious conceptions (*Vorstellungen*) of the Papuans, for in some of the hill villages large stones even were seen to be honoured as *Telums*. If, on the other hand, we regard these representations from an æsthetic point of view, we shall be again forced to admit the artistic capabilities of the Papuans, their great perseverance, as well as the way in which simple decorations become transformed into bas-relief, and again from *alto relievo* into the complete figure; for in Papuan art of the "stone age," such a series of progressive steps is demonstrated in the completest manner.

Superstitions and their Resulting Customs.—With regard to "Tabu,"[1] this custom exists in New Guinea, but M. Maclay did not succeed in finding out any equivalent term for it in the Papuan tongue, though frequent examples of it could be recognised in the various restrictions put upon the actions of women in their relation to the men. For example they are forbidden to set foot within the *buambramra*, they are excluded from all feasts, and every dainty which they prepare for the latter, especially the principal drink, *Keu*, is forbidden to them as well as the children. The meeting places of the men, music, musical instruments, and even the mere hearing of the same is strict *Tabu* for the women, for as soon as the sound of one is heard in the neighbourhood, they and the children must instantly flee. To the repeated inquiry of Maclay as to the reason of the above exclusion of the women, the answer was invariably returned—"It would never do, for the women and children would fall ill and die."

Music and Song.—The performance on all instruments of music, which are collectively included under the term "*Ai*," is allowed to the men alone. They are as follows:—

The "*Ai-Kabrai*."—This consists of a bamboo, about two yards and more in length, and about fifty millimetres in diameter, from which all the septa between the internodes have been removed so that the whole consists of a single long tube. This instrument is put into the mouth, and through its large orifice the performer blows, shrieks, or howls, the sound being audible in still weather at a distance of from two to three miles. The word "*Kabrai*"

1 Accounts of "*Tabu*" will be found in "Tylor's Researches into the Early History of Mankind." London. 1865, and in Captain Cook's "Voyage to the Pacific Ocean," Vol. i.i., p. 163. London. 1784. "This word" (*loc. cit.* p. 164) "is used to express anything sacred, or eminent, or devoted. Thus the King of Owhyhee was called *Eree-taboo*; a human victim, *Tangata-taboo*; and in the same manner, among the Friendly Islanders, Tonga, the island where the king resides, is named *Tonga-taboo*."—J. C. G.

is (in the Papuan dialect), the name of a species of parrot, with a loud screaming voice.

"*Munki-Ai.*"—This equally simple and ear-splitting instrument is made out of the shell of one of the smaller kinds of cocoa-nut (*Munki*), in which a hole is bored both in the side and in the upper end; a shrill piping tone being produced by blowing through the upper hole, and alternately stopping and leaving free the side one by means of a finger. This instrument is often elaborately and artistically ornamented.

"*Hol'-Ai.*"—This is a curved or straight wind-instrument, of the character of a trumpet, made out of the root of a kind of *Lagenaria.*[1]

The three just described are not strictly wind-instruments, as compared with those of a European model, but are rather of the character of a ship's speaking-trumpet, in that they are only used for strengthening the human voice, though the tunes produced are of extreme variety.

"*Orban-Ai.*"—This consists of a handle from which a number of perforated Orban-nut shells hang, each at the end of a cord. When this is shaken the shells strike against one another, producing a kind of rattling sound, which at times resembles the rustling of foliage caused by a breeze.

"*Okam.*"—This is a kind of drum made from a hollowed tree stem, over the upper end of which the skin of a Monitor lizard is stretched, while the lower end remains open.

For purposes of signalling, a triton-shell perforated at the side is used, and by this means the arrival or departure of the *praus* which come from Bili-Bili or the "Archipelago of Contentment" is made known.

All the above-mentioned instruments of music are *Tabu* to the women and children, being, like the wooden carvings, regarded as something sacred, and this to such a degree that M. Maclay had great difficulty in obtaining from their owners specimens for his collection.

The songs of the Papuans of Maclay Coast are of the very simplest, being confined to a few words which are perpetually repeated, sometimes in solo, sometimes in chorus. They are almost always improvised, the composition being prompted by the advent of guests, some occupation or other, or the most trifling events.

Under the common term "*Ai*" are included the feasts which are celebrated by the Papuans from time to time. The guests are summoned from the surrounding villages by a number of beats on the *Barum*, repeated at prescribed intervals, while the *Malassi* bring out the various utensils and instruments of music from the *Buamramra*. Baskets full of the root of the Colocasia (*Bau*), and the fruit of the Dioscorea (*Ajan*) are brought, of which a certain quantity is contributed by each male guest, and added to the general heap, each fresh arrival being greeted with applause. At length there arrives, bound to a stake carried by two men, and greeted with cries of joy, the principal object of the feast, a pig, richly decked out with the red flowers of the *Hibiscus*. The victim is laid on the ground, and, after a long oration from one of the Tamos, is despatched by a thrust of a spear in the armpit. As for dogs, which are not unfrequently eaten at feasts, they are slaughtered by being swung round by the hind legs and the head dashed against a tree trunk. Fowls, rats, the cuscus, and smaller marsupials are killed in the same manner. After the pig has been killed and the hair singed off over a large fire, it is placed on a number of banana leaves spread on the ground. In all the details of preparation for the feasts the Papuans show a remarkable appreciation of division of labour, for everything is done without noise or confusion. While the cooking of the various portions of food is taking place, the guests set about the brewing of their two favourite drinks, the *Munki-la* and the *Keu*. In order to make the first, green cocoa-nuts, after they have been stripped of their fibrous outer coating, are split down the middle by a single blow from a long stone implement, and the watery contents collected in a *Tabir*. The halves of the nuts having been distributed, each guest sets to work to shred the kernel with his *Jarur* into the bowl until the latter is filled to the brim with a whitish, gruelly mess. The second drink is thus made:—The fresh leaves of the *Keu*[2] plant, together with the young twigs, are chewed without further preparation, while the old and hard roots are previously softened by bruising with a stone. For this end all the young men play the part of living masticatory machines, their teeth fulfilling the function of millstones set in motion by the action of the "masseter" muscles. If one of them is tired out before the mass is soft enough, he forthwith spits it out into his hand, rolls it into a ball, and hands it over to a neighbour to finish the process. After having been duly masticated, the *Keu* is filtered by means of an apparatus consisting of two halves of a cocoa-nut shell, the upper of which, having an aperture in the middle, covered with some finely crushed grass, serves for a filter, while the lower receives the filtrate. To this latter, which is of a greyish-green colour, some water is added, and it is then left standing. Every *Keu* drinker has his own bowl reserved for this purpose alone, and carefully kept in his pouch, or *gun*. It consists of the shell of a small cocoa-nut, the inner surface of which is of a uniform greenish-grey colour, a result probably of the custom forbidding all cleaning of the interior, while the outer is decorated with various devices and coloured with a black pigment.

At length there rings over from the village, two or three short *Barum* tones, as a signal that the banquet is ready, and the *Keu* drinkers assemble, surrounded by the younger men. Each then rests his bowl in a shallow hole made by a lance in an area of ground previously cleared for the purpose, and into it the thick fluid is poured from the large *Keu* bowl. After a preliminary coughing and spitting, in order to clear out the mouth, each, in the order of seniority, or social standing, drinks his portion with many a grimace, as the infusion is very bitter; and in some instances, passes urine at the same moment. After this the guests proceed to eat, and when their hunger is appeased, the grated cocoa-nut infusion, *Munki-la*, is served round. If the pig is too small for all to partake of, only the men are allowed to eat of it, it being *Tabu* to the "Malassi," or youths, who will then on no account touch it, as they have the firm belief that if this rule be violated either illness or some calamity will inevitably overtake them. The feast is brought to a close by smoking and the chewing of Betel nut, and the "Siri" leaf. If, as is sometimes the case, there are not enough eatables for the feast, a supplementary banquet is held, the materials for which have to be first procured by an improvised fishing party. In order to keep the women and children from disturbing the guests when feasting, the musical instruments are brought into play, which, as before stated, is an infallible means of keeping them at a distance. Finally, as a *memento* of the feast, the lower jaw of the pig or dog which has figured on the principal dish is hung up in the *Buamramra*.

During the month of November and December, when the Papuans are less occupied in the plantations, certain other kinds of feast take place, of which at the first, called "*Ai-mun*," only the men are allowed to be present, while at the second, the "*Sel'-mun*," held in the villages, the presence both of women and children is permitted. At the *Ai-mun* very curious masked processions are formed, and here the *Aidogan*, a kind of *telum* consisting of numerous figures carved one over the other out of one

[1] A genus belonging to the order *Cucurbitaceæ*.

[2] According to Dr. Scheffer, director of the Botanic Garden at Buitenzorg, near Batavia, to whom they were submitted, the *Keu* plants brought by M. Maclay from Papua belong to two distinct species of the genus *Piper*, but neither of the two is identical with the *Kava* plant of Samoa. It is, moreover, doubtful even if this latter is really the *Piper methysticum*.

tree stem, play a conspicuous part, after having been brought, fresh painted, from the village to the feasting place. Sometimes there is even a migration of the revellers into another village, which generally results in a kind of sham fight between the two parties.

With regard to Betel chewing and tobacco-smoking, both these habits are very prevalent, and freely indulged in by the people inhabiting Maclay coast. Nevertheless, the *Areca* palm[1] is by no means abundant on the coast, being, with the exception of the "Archipelago of Contentment" and a few other spots, but seldom found in the villages. The process of Betel-chewing is as follows: The Areca nut having been first partly masticated, is then mixed with a little powdered lime, which is carried in a special box formed from bamboo or a calabash gourd, and, after being rolled in a Betel[2] leaf or two, is placed between the teeth and chewed. Although the tobacco plant, here called *Kas'*, is much cultivated, and flourishes well along the whole coast, the American tobacco, pressed flat into cakes, which Maclay had brought with him, was so much liked and prized, that he contributed a portion at almost every *Ai* feast. This, after being separated into its component leaves, was dried over a fire, torn into little shreds, and then rolled into cigarettes in green leaves, also previously dried at the fire. A single cigarette makes the round of a number of smokers. In smoking the Papuans swallow the smoke, and blow the rest through the nose.

As the *Keu* has soporific qualities, the Papuans have devised a means of keeping any one who has succumbed to its influence in a wakeful condition. The victim to its power betakes himself to a friend, who with a stalk of grass tickles the cornea and conjunctiva of his eyes until they become full of tears. This is repeated until the patient declares that he feels no longer sleepy. This operation is regarded as a very pleasant one, but "whether it always succeeds," remarks M. Maclay, "is another question."

J. C. GALTON

EPIDEMICS[3]

WE are now entering on our thirtieth session, and, I trust, with reason to believe that our progress is satisfactory, and our work such as to prove that the Society is fulfilling the main object for which it was founded. Though not one of the largest, it is certainly not one of the least active or important among the medical societies of the metropolis, whilst the cosmopolitan range of subjects embraced within the scope of its inquiry renders its proceedings of far more than mere local interest.

The *raison d'être* of this Society is the investigation and development of our knowledge of disease in motion. It involves much, for any disease where it spreads, whether among the people of a house, a ship, a village, a city, a province, or a continent, is an epidemic, and comes within the scope of our inquiry. Dysentery and malarious fevers are typically *endemic* diseases, but in India they may and do at times assume a dangerously epidemic character. But it is not meant that our inquiries should be restricted to mere epidemicity alone; we cannot advantageously study one phase of the natural history of disease and exclude others. There is so much in etiology, semeiology, and pathology both human and comparative that concerns our department of research that we may not ignore the means by which we gain the most important of all information to the epidemiologist—namely, the means of discriminating one form of disease from another. Therefore, though our proceedings will naturally refer mainly to epidemic disease, we shall thankfully receive and carefully consider all information that may tend in any way to throw light on the causal relations, and on the influences exercised by climate, season, locality, food, and occupation on the genesis and dissemination of all diseases, not excluding those of the lower animals, nor even of plant life. I might illustrate this by referring to the importance of discriminating between the different forms of fever that occur in India. It is well known that the greatest proportion of mortality in India is ascribed to fevers. The highest death-rate[1] was registered in Bombay, where it equalled 20·82 per 1000; in Madras the deaths of 469,241 persons gave a death-rate of 10·08 per 1,000. Both here and at Bombay, however, the mortality recorded was greatly aggravated by famine.

There is no doubt that, under the heading Fever, many deaths from other causes are recorded, and we may probably refer a large proportion of them to diseases of an inflammatory character affecting the thoraic or other viscera, or to complications involving inflammatory action elsewhere. In a vast country like India, where the population is so extensive, and the means of registration of necessity limited, often not under medical supervision at all, it is not to be expected that greater accuracy can be ensured; but, were it possible to discriminate among the various forms of disease returned as causing the mortality by fever, we should have a very different result from the present. One can hardly refer to this subject without expressing admiration at the great progress that has been made of late years in registration under the direction of the sanitary authorities of India, and confidence that it will continue to improve, and render the statistics more valuable even than they are now. Of course, where the registration of death is not subject to medical definition discrimination between the various forms of fever or other death-causes could hardly be expected; and therefore the example I have just given is hardly so good an illustration of what I refer to as typhoid, for which we have accurate medical statistics of our European troops in India. It is within my recollection that attention was first called to the existence of this form of fever in India, and yet there can be, I suppose, no doubt that it has always been there. It soon became generally recognised as a new discovery in India, and people wondered how it had escaped observation hitherto, whilst some perchance regarded it as a new disease. But it was just this power of discriminating observation that is so rare and so valuable that had been wanting; it was this that, exercised by Budd, Jenner, Stewart, Murchison, and others after them, established a new era in the nosology of fevers in England; and it was this, that, a little later, in India, discriminated between certain forms of remittent and enteric (*i.e.*, between malarious and specific) fevers, and that will, I hope, ere long further discriminate and rearrange the nosology of fevers in India and the tropics.

Now typhoid or enteric fever is an important cause of mortality among our young European soldiers in India; and it raises or suggests questions of great importance in regard to them—such, for example, as the right age, time, and seasons for sending them to India; to say nothing of the hygienic questions as to sanitary measures arising out of its causal relations. The Sanitary Commissioner's Report of 1877 says that out of 233 cases of typhoid, 92, or 39 per cent., proved fatal; the admission rate being 4·1 per 1,000 of strength. It moreover appears that 2·45 per cent. occurred at or under twenty-four years of age; 1·55 at twenty-five to twenty-nine; 0·99 at thirty to thirty-four; and a few or none above that age; showing that the disease tells most severely on the younger men—in this respect resembling typhoid in England. Again, Bryden, in his Report of the Statistical History of the European Army in India up to 1876 (published 1878)

[1] *Pinang* in the Malay language.
[2] *Siri* in Malay.
[3] Abstract of Presidential Address at the Epidemiological Society, delivered on November 5, 1879, by Sir Joseph Fayrer, K.C.S.I., LL.D., M.D., F.R.S.

[1] *Vide* Report of Sanitary Commission of the Government of India for 1877.

says: "It has no geography; and it is a matter of popular observation that no regiment or battery escapes enteric fever *in the first year*, whatever cantonment of India may be selected." "Out of seventy-three bodies of men two regiments and seven batteries only returned no case of enteric fever in the first year." And he gives the following analysis of 368 deaths that occurred between 1823 and 1876:—

Ages.	Total deaths.
24 and under	255
25 to 29	90
30 to 34	17
35 to 39	4
40 and upwards	2

Seventy-five of these deaths occurred within three years after landing in India, and 94 per cent. of the total were among men under thirty years of age. In a memorandum received only a few days ago Bryden says, out of 132 deaths from enteric fever in 1878, 90 occurred in men who had been under twenty-two months in India. All this shows that youth and the first year of service in India are the great predisposing causes.

Now is this the same disease as that which might be contracted in London, Dublin, Windsor, or elsewhere in a town or barrack? from a watercloset, drain, sewer, well, or, it may be, from a milk-can? I have little doubt that very frequently it is exactly identical; but I believe also that perhaps as frequently, or more so, it is not; and this, I believe, not in regard to young European soldiers only, but of the whole population of India. In short, I am, and long have been, of opinion that a form of fever exactly like European typhoid, except in its etiology, exists in India and other hot and malarious countries; and that it is due to climatic causes, not to filth or specific causes such as give rise to it in England and elsewhere, and recent reports from India and other parts of the world seem to show that this view is gaining ground.

Be it clearly understood, however, that I do not for a moment dispute the existence of genuine *filth* typhoid in India. The official returns, which cannot be gainsaid, and my own experience alike leave me in no doubt about it. But I do believe that many cases now recorded, and rightly recorded, as typhoid in India, are not caused by the same specific agency as that which gives rise to typhoid here, and also in India, where the necessary conditions are present. There are, in fact, two, perhaps more, forms of typhoid, or perhaps, I should say, different causes for a disease presenting the same phenomena, one being specific, the other climatic; if so, it is obviously very desirable to discriminate between them —not merely as a matter of nosological or pathological interest, but in regard to the hygienic measures that are necessary in either case. This question is of great interest to epidemiologists, and is just one of those subjects that should come within the scope of our inquiry. A remarkable instance occurred near London lately, where an *epidemic* of typhoid was traced to its origin along the track of a particular water-supply by a distinguished member of our Society. Our lamented colleague, Murchison, also traced a similar outbreak to contamination of milk by polluted water. The explanations of these outbreaks were exactly in accordance with these views, no doubt rightly held in Europe. Typhoid in India, however, would not always be similarly explained.

We know but little of the nature of the causes of epidemics such as cholera, or of malarious diseases, but we know something of what may be expected in regard to them, when and how they will appear, and how sanitary work may be made most effectually to avert, prevent, control, mitigate, or remove them; nor is it too much to say that we hope, if not to banish or stamp out, at all events still further to mitigate their ravages. This, I think, is warranted by experience, for certainly the past twenty years have witnessed great progress, and we already see that not only is the value of life increasing, but that the virulence of, and mortality caused by, epidemic disease are being controlled, whilst the vexatious and purposeless restrictions and restraints of quarantine are diminished if not altogether removed, in our dominions at least. Science that has enabled us to reduce the death rate among our troops from 17·9 to 8·56 per 1,000 in Europe, and from 69 to 17·62 per 1,000 in India, speaks for itself, and were there no other result this alone is a triumph such as has been achieved by no other department of knowledge. Pray do not suppose that I claim all this for Indian workers. We all know that these great steps in social and sanitary progress began here, but I do say that the torch then lighted has since been worthily and firmly borne in Indian hands.

This Society, young as it is, can remember the commencement of systematic sanitary work in the East, and may claim some share in the origination of the good work; for among its earlier members were some who advocated the study of epidemiology and hygiene in India. I cannot now stay to dwell on this, but I may say briefly in regard to its progress and work that until the sanitary department was formed, less than twenty years ago, comparative, I might almost say complete, ignorance on the subject of epidemics, and of the diseases that prevailed among the people, existed. An epidemic might carry off thousands, but we knew not where it commenced, where it ended, or what area it occupied. Now, thanks to the continued and careful statistics, we know all that and more, with fair accuracy, and are gradually collecting facts which make the study of epidemiology possible. Before organised sanitary work in India began our knowledge of the general population—nay, even of the European troops and prisoners—was most imperfect. Now, thanks to that department, and especially to Bryden, whose name cannot be too prominently mentioned in connection with the subject, we have, in his most elaborate and valuable statistical reports, facts and figures, as well as deductions, which deserve the closest attention. We have, in short, the most complete details of sickness and mortality in all classes over the whole of India. It is impossible, however much any one may differ from his conclusions, not to recognise the great value of his work, for these reports contain a vast and continued array of authenticated facts which will serve as a mine of information to epidemiologists; and there is every reason for believing that it is but an earnest of more, for if, as Bedford said, the circumstances of India were such as to favour the acquisition of knowledge in 1850, when the precise conditions of life of the population generally, and even of our troops and prisoners were imperfectly known, what must it be now when a system of observation, carried out by a body of trained observers under a head such as he contemplated, is in full and daily improving operation? One can only wish that, considering the magnitude of the work, it were more extensive still, and that observations, already of the greatest value, could be rendered still more so by being concentrated on certain limited areas so as to enable the inquiry to extend to details with a precision that at present can hardly be practicable. The results of epidemiological knowledge and sanitary work are seen in the effect already produced in reducing the mortality from cholera and other epidemics, and from malarial fevers. For instance, among our European troops, the circumstances of which are well known, there has been the following alteration in the general death-rate:—

1861 to 1865	9·02 per 1,000.
1865 to 1870	6·98 ,,
1870 to 1875	3·23 ,,
1875 to 1876	2·3 ,,
1876 to 1877	·84 ,,

And it can be shown from the same source (Bryden) that there is a similar reduction in the death-rate among native troops; and that, during the great cholera epidemic that prevailed in 1876, the death-rate among the civil population being 12·12 per 1,000 (it was the famine year), that of the European troops was 1·75 and of the native army 2·2 per 1,000. Also that in the death-rate of that great scourge of India—fever—there has been an equally happy result, as shown by the death-rate of a period of nine years—from 1868 to 1877—in the Bengal and N.W. Provinces gaols, as against a mean, in nine years ending 1867, of 22·41.[1]

	Per 1,000.		Per 1,000.
1859	13·76	1868	2·84
1860	49·19	1869	4·57
1861	38·14	1870	6·20
1862	30·81	1871	5·81
1863	25·44	1872	1·92
1864	29·96	1873	1·56
1865	7·65	1874	2·67
1866	5·23	1875	3·50
1867	3·12	1876	1·26
Mean ...	22·41	Mean ...	3·29

In India, as elsewhere, the purpose of epidemiological study is to observe accurately and to interpret the import of the facts—*i.e.* if possible, to elucidate the laws of which they are the expression,—and thus to form a scientific basis on which to direct sanitary work, which itself is the practical outcome of such observation, and concerns itself but little with theories. Those who have to do with it know how difficult it sometimes is to obtain *reliable* observations, such is the difficulty of excluding the bias of preconceived theory of the nature of the subject under investigation. Our Society, however, must hold the balance, and deal with theories as well as facts. No doubt the explanations sometimes are conflicting. Happily, in the practical mode of dealing with the question, there is not much conflict, and it is remarkable how little different is the action of those who hold opposite opinions on the causation of disease. As to the different views that are held in regard to fundamental questions regarding the genesis and diffusion of disease let us hope that we may, perhaps, here contribute something towards their adjustment.

In illustration of the state and progress of epidemiology in India I might select the history of any of the great epidemics that have occurred of late years, but it would be impossible, in the short space of time at my disposal, to do this completely. I shall, therefore, confine myself to a few remarks on cholera, as it, though far from being the most destructive, is the epidemic to which most interest attaches.

The theory that cholera is purely of Indian origin, and that wherever it may appear it is to be traced back ultimately to the delta of the Ganges, is disputed by some who see in history evidence that it had long been existing in other parts of the world, and that it was described by the earliest writers—Sanscrit, Greek, and Arabian. I may here just remark that the name "haida," or "haiza," used by Rhazes nearly 1000 years ago in describing the symptoms of cholera, is the same as that applied to it now by every Hindustanee-speaking native of India. As to its presence in India, from earlier periods we have descriptions by Correa, d'Orta, Bontius, and others, beginning from 1503. An epidemic of it in and about Goa in 1543, for example, is described by d'Orta, giving all the characteristics that distinguish an epidemic now. He calls it "moryxy" and also "haiza." It is described by a continuous chain of writers as occurring in various parts of India, in the interior as well as on the coast, up to the seventeenth century, when, after being quiescent during the later part of the eighteenth and early part of the nineteenth century, it broke out with great virulence in Bengal, and has remained there ever since, in what Bryden calls its endemic area, whence it spreads according to certain laws, which are being worked out with admirable patience and intelligence by this distinguished statistician. I cannot now trace the history of cholera in either East or West, nor refer even to the numerous authors who have described it. For full particulars on this subject I refer you to Inspector-General Dr. J. Macpherson's learned work, "The Annals of Cholera."

I need hardly insist that cholera is not a new disease, or that it did not, as by some supposed, make its first appearance as an epidemic in Jessore, in Bengal, in 1813; though no doubt since that period it has been more closely investigated and described. All seems to show that it is the same now as formerly, and that though we have gained much knowledge of its natural history of late years, yet we are as ignorant as our predecessors of its real nature. We have, thanks to sanitary measures, disarmed it of some of its terrors, and have diminished the mortality it caused; but as to treatment we have gained but little, though the empiricism of to-day is more scientific than it was in former days. We do not now burn our patients on the soles of the feet, tie ligatures round their limbs, or have recourse to other senseless barbarities; for we find that simpler and more rational methods are of greater avail, more or less according to the period of the epidemic at, and the promptitude with, which the remedies are applied. But we have learned that local causes have a potent influence, and that cleanliness, good air, *pure water*, and free ventilation are all powerful opponents of cholera; that we can predict its appearance and avoid it in certain places; and that it is not to be controlled by quarantine or sanitary cordons. And from the earnestness and intelligence with which the subject of its etiology is pursued, it is not improbable that sooner or later it too will be made out. We shall then be in a position to say, not only what it does or will do, but what it *is*. Meanwhile we must go on observing and investigating. It is satisfactory to know that we are daily learning, practically, better how to deal with it, and how to modify its cyclical intensity and avoid its ravages. For my own part, until I know something more of the *nature* of the cause—be it a material poison, aërial or telluric, a miasm, or a dynamic agency that so perturbs the vital energy, I cannot see my way to formulate a definite theory either of the nature of its origin or the method of its diffusion. I find the highest authorities at complete variance on the subject, and reposing faith in theories diametrically opposed to each other. Some explain all the phenomena by contagion—*i.e.*, communicability in some way of a *materies* or germ from one person to another. Cholera, they say, is the result of infection by a poison derived from the intestines, and water or air, but especially water, is the channel through, by, or in which the infective material is intensified and conveyed. These arguments are supported by an abundant array of facts, and have been maintained by men whose very names carry conviction. Others reject altogether this explanation; they insist that local influences are all-important, and deny that the spread of cholera is due to human intercourse, that there is any poison transmitted by the excreta, or that the disease is in any way communicable from one person to another. They admit the existence of a poison of some sort—a miasm or an influence, though of its nature they are ignorant. It is a subtle thing that travels in certain directions in obedience to certain laws, is influenced by atmospheric and telluric conditions, and where it finds certain local conditions, and the people prepared by them to submit to it, there cholera will prevail. They deny the efficacy of any enteric or specific poison in the water to produce it, though they attach the greatest importance to the purity of water from *all* organic contamination, impure water being one

[1] Bryden's Report (1876), p. 157.

of the local conditions which, if added to crowding, filth, or other insanitary conditions and want of proper ventilation, is that *of all others* which favours cholera. Such are the principal theories of the disease as they are supported by fact and argument which appear convincing. Europeans, Americans, and some authorities in India maintain the contagious view, whilst high authorities in India adhere to the opposite theory, and declare roundly that the facts of cholera, in India at least, are altogether opposed to the contagion theory.

On the question of importation of cholera in the Punjab epidemic (1875-6) and its spread by human agency, Dr. Bryden, in his report, p. 308 (1876, published 1878), says:—"The assertion amounts to this. The Punjab is divided into thirty-two districts. Cholera was introduced into seventeen of these in 1875, and therefore it spread. Cholera was *not* introduced into fifteen districts, and therefore did not appear, or, if it was introduced, influences of which we know nothing stopped its propagation in these districts. Unknown causes prevailing in the one-half of the area are presumed to influence the human system so that it is capable of receiving cholera, and in the other to act universally as an antidote even to a cholera poison when introduced. This is what is offered as antagonistic to the theory which asserts that cholera is air-borne and is as far-flying as are the limits of natural areas. Primarily, these theories cannot be reconciled; the one or the other is false. If cholera is spread only by the human being, the theory which shows it to be air-conveyed is untrue; if cholera is spread solely as an aërial miasm, then the theory which recognises only the effects of human intercourse is unfounded. The most that is admitted by the advocates of the human theory is, that the subjection of cholera to meteorological agencies is absolute, and that these influences can, and do operate so as to do away altogether with the effects of the poison, although imported. They do not recognise the entity *minus* the human being. The antagonistic theory, while holding, as opposed to demonstrable fact, the statement that cholera moves only by human agency, may, if necessary, be extended in its scope so as to embrace the other; that is to say, the inquiry is left open as to whether or not the cholera entity, after being aërially distributed, may be subsequently propagated or spread by man. In the theory which connects cholera solely with man there is no such extensibility. Human intercourse must explain every fact of spread and propagation, and nothing is left to the play of natural agencies. Human intercourse, giving the widest scope to the signification of the term, cannot pretend to account for any fundamental phenomenon displayed during the progress of epidemic cholera; and, therefore, I assert the theory to be radically untrue as applied to the behaviour of cholera in India. I do not say that the above statement will hold true all over the world; and, even as applied to India, the theory does not preclude the possibility that cholera may be conveyed by the human being. Naturally the recoil is to the opposite extreme. The bold statement that cholera is never spread over an area unless human agency intervenes, is apt to be met by the equally dogmatic statement that cholera is as pure a miasm as malaria, and as little amenable to the control of man.

In the present state of our knowledge we can only be guided by the inferences from well-ascertained facts and such laws as we have ascertained to be in constant operation, watching and carefully observing until we may, were it only by a process of exclusion, arrive at some deeper knowledge still. "So far," says the chief sanitary authority in India, "the history of cholera is full of enigmas and seeming contradictions, and though we have of late years collected many valuable data, and understood the importance of studying them on a broad basis, we know no more of the exact cause of the disease than our grandfathers did. We know that, whatever the cause may be, it flourishes in the midst of insanitary conditions of dirt and overcrowding, and especially of impure water, impure from whatever cause; we know that it is liable to occur under certain conditions, and at certain times and seasons, and we should endeavour to extend that knowledge, and hope, as we do so, to arrive at the precise nature of the disease itself." But it may be well to remember that "expenditure of public money must take place only on observed facts and experience," not in accordance with theories. "It would be prejudicial to real sanitary work if opinions which have been promulgated in some parts of India, as to the cause of cholera being due *solely* to the state of the water-supply, were to take root."

It is most important that we should arrive at some definite conclusion as to the real nature of the disease, for it is impossible but that our conceptions on this subject must influence the sanitary measures that deal with it, and I believe the question must find its final solution in India, where the disease is always present in its endemic and seldom absent from the epidemic areas. The highest authorities—for both I have the greatest respect—differ *toto cœlo* on this subject. Is it that they are both right, though seemingly so opposed in their views? Like the knights who fought about the silver and golden sides of the shield, will they not change places, and find why they differed?

I would venture to suggest that in India the inquiry might be pushed with more detail in regard to individual cases and outbreaks in certain limited areas; and that, on the other hand, one or more epidemiologists of European fame should be deputed to visit India and study cholera with the eminent men who have devoted so many years of close attention to it there. It might be, I believe it would be, that mutually they would gain from each other, and that those who went out would find their own views confirmed as to the disease in Europe—modified as to what they deemed it to be in India. Of one thing I am convinced, that simple truth is the object of their search; and I feel sure that from such combined action the greatest benefit would result.

POPULAR NATURAL HISTORY[1]

JUDGING by the continuous stream of popular "Natural Histories," the demand for such books must be great. Messrs. Cassell have already published many volumes of the kind, some dealing with the whole animal kingdom, some with a single class; they are now bringing out a series of volumes under the editorship of Dr. Martin Duncan, and in the mean time they present us with a single volume of a still more popular character by Dr. Perceval Wright. This book, as we are told in the preface, is intended for that large class of readers who, while they take an intelligent interest in the study of natural history, have but little taste for the technical details which would naturally form the bulk of a scientific manual on the subject. For this reason the space devoted to the several orders is roughly proportioned to the amount of interest generally felt in them. The mammalia occupy more than a third of the volume, the remaining orders of the vertebrata about an equal space, while the whole of the invertebrates are compressed into the space that remains—about one-fourth of that occupied by the vertebrates. The author tells us that his aim has been "to compile a story-book about animals, and at the same time in some degree to write a scientific manual." This is undoubtedly a difficult thing to do, and to do it thoroughly and in the best style would be a fitting life-work for a great naturalist. It would have to be done as a labour of love, not to the order of a publisher; and the

[1] Animal Life: being a Series of Descriptions of the Various Sub-kingdoms of the Animal Kingdom. By Perceval E. Wright, M.A., M.D., &c., Professor of Botany in the University of Dublin. With Illustrations. (Cassell, Petter, Galpin, and Co., London, Paris, and New York.)

illustrations should be of the very best kind, so as fully to exhibit the beauty, the variety, and the intricacy of nature.

The present volume lays no claim to such completeness; yet it is far superior to the mere popular natural history, inasmuch as it gives a considerable amount of accurate information both on the anatomy and physiology of the chief types of the animal kingdom, and on the geographical distribution of the chief families and genera of the higher animals. It also deserves great credit for the completeness of its review of the vertebrata, every well-established family group being referred to, and its more prominent characteristics usually described; so that, so far as this sub-kingdom is concerned, the book is a compendium of information well worthy of a place in the library of every natural history student. With the invertebrata a very different plan has had to be followed, only the more important orders being noticed, and a few typical forms selected for description and illustration; yet even here we are glad to meet with some account of the most recent discoveries among marine animals, and some illustrations which offer a welcome relief from the usual stereotyped forms of most popular works.

We shall best exhibit the character of Dr. Wright's volume by laying before our readers a few passages with their accompanying illustrations.

Under the mouse family (Muridæ) we have twenty species described or noticed, and these are illustrated by eight excellent figures. The beautiful illustration of the harvest-mouse nest building accompanies the following descriptive passage:—

FIG. 1. Harvest Mouse and Nest.

"The Harvest Mouse (*Mus minutus*) is found probably all over Europe. It is not common in England, and is more frequent in Belgium. White, of Selborne, in writing to Pennant, says: 'They build their nests amidst the straws of the corn above the ground, and sometimes in thistles. They breed as many as eight at a litter, in a little round nest composed of the blades of grass or wheat. One of these I procured this autumn, most artificially platted, and composed of the blades of grass or wheat, perfectly round, and about the size of a cricket-ball, with the aperture so ingeniously closed that there was no discovering to what part it belonged. It was so compact and well-filled that it would roll across the table without being discomposed, though it contained eight little mice that were naked and blind. As this nest was perfectly full, how could the dam come at her litter so as to administer respectively a teat to each? Perhaps she opens different places for that purpose, adjusting them again when the business is over, but she could not possibly be contained herself in the ball with her young, which, moreover, would be daily increasing in bulk. This wonderful procreant cradle—an elegant instance of the efforts of instinct—was found in a wheat-field suspended in the head of a thistle.' The food of this little mouse consists of corn and grass seeds, insects, and earth-worms. Of insects it is very fond."

Of the ravages of another British species we have the following interesting account:—

"The Short-tailed Field Mouse (*Arvicola arvalis*) is found throughout Europe to Siberia. Small and insignificant as this animal appears to be, there is scarcely a species among the rodents more destructive to our fields, gardens, and woods. In the corn-field, the rick-yard, the granary, and in extensive plantations, its depredations are often severe, and even calamitous. Of the damage effected by a multitude of these animals we give a single instance. In the year 1814 the whole, both of Dean and New Forest, appeared to be largely stocked with mice; at least wherever the large furze-brakes in the open parts had been burnt their holes and runs covered the surface. Hayward Hill, a new plantation of about 500 acres in the Forest of Dean, was particularly infested. This inclosure, after being properly fenced, was planted with acorns in 1810, and in the following spring about one-third came up, the rest of the seed having been destroyed principally by mice. The young shoots of the natural hollies of the district, which had been cut down to favour the plantation, were not attacked by the mice in the following winter, though their runs were numerous. In the autumn of the succeeding year a large quantity of five years old oaks and chestnuts, with ash, larch, and fir, were planted in the inclosure. In the winter the destruction began, and numbers of the hollies, then two, three, or more feet in height, were barked round from the ground to four or five inches upwards, and died. In the succeeding spring a number of the oaks and chestnuts were found dead; and when they were pulled up it appeared that the roots had been gnawed through two or three inches below the surface of the ground; many were also barked round and killed, like the holly-shoots, whilst others, which had been begun upon, were sickly. The evil now extended to the other inclosures, and becoming very serious both in Dean Forest and the New Forest, cats were turned out, the bushes, ferns, rough grass, and other plants were cleared off to expose the mice to beasts and birds of prey; poisons in great variety were laid, and seven or eight different sorts of traps were set for them, some of which succeeded very well. These were, however, superseded by the plan of a ratcatcher, who, having been employed to capture the mice, had observed, on going to work in the morning, that some of them had fallen into wells or pits accidentally formed, and could not get out again, many of them dying from hunger or fatigue in endeavouring to climb up the sides. Such pits were therefore tried on his recommendation. They were at first made three feet deep, three long, and two wide; but these were found to be unnecessarily large, and after various experiments it appeared that they answered best when from eighteen to twenty inches deep, about two feet in length, and a foot and a half in width at the bottom, and only eighteen inches long and nine wide at the top, or so wide as would allow of the earth being got out of a hole of that depth, for the wider they were below and the narrower above the better they answered their purpose.[1] They were made about twenty yards asunder, or, where the mice were less numerous, thirty yards apart. Nearly 30,000 mice were speedily caught by this method in Dean Forest, and in the New Forest about 10,000 more. It was believed that a far greater number had been taken out of the holes either alive or dead by stoats and weasels, or by kites, owls, crows, jays, and magpies."

The following account of the Angler (*Lophius piscatorius*), a curious large-headed fish belonging to the family of the Lophiidæ, or fishing-frogs, and a native of our seas, is short, but clear and instructive:—"This curious fish has the head wide, and the mouth nearly as wide as the head; the eyes are large; the lower jaw, which is the longer, is bearded or fringed all round the edge, and both jaws are armed with numerous teeth; the body is narrow compared with the breadth of the head, and tapers gradually to the tail. The colour of the upper surface of the body is uniform brown, the under surface white, and the tail almost black. On the top of the head are three long filaments; of these, two are seated just above the muzzle, the other rises from the back of the head. These filaments are movable in all directions, especially the first, which, tapering like the finest fishing-rod, ends in broad, flattened, silvery tips.

"The angler is insatiably voracious, but it is a slow swimmer; it is formed, in fact, for taking its prey in ambush. It reposes on the soft mud or sand, in some favourable lurking-place, and, stirring up the mud with its pectoral fins, thus obscures itself in a murky cloud, beyond which appear its long filaments, and, especially the first, with its glittering tip, offering an attractive bait to other fish. Thus stationed, the creature quietly expects its victim. On rove the shoals of fish, eager in quest of food. They pass one after another in succession, till at length one espies the bait. Forward the fish darts, either to examine or seize the expected prize; but at that instant, aided by its broad, feet-like pectoral fins, the watchful angler springs up and captures its prey."

FIG. 2.—Angler (*Lophius piscatorius*).

The fishes are generally very well illustrated, and a large number of interesting species are described.

Passing on to the invertebrates, we come first to the insects, which form the weakest part of the volume; but this is perhaps of less importance as none but specialists feel any interest in the bulk of the forms; while their immense numbers and endless variety, their strange habits, and marvellous instincts can only be adequately set forth where ample space can be afforded them. We pass on therefore to the lower marine animals, and select as an example of the way they are treated a rare British species allied to the sea cucumbers, and named *Synapta duvernea*. It was discovered in the English Channel by M. Quatrefages, who thus describes it:—

"Imagine a cylinder of rose-coloured crystal as much as eighteen inches long and more than an inch in diameter, traversed in all its length by five narrow ribbands of white silk, and its head surmounted by a living flower whose twelve tentacles of purest white fall behind in a graceful curve. In the centre of these tissues, which rival in their delicacy the most refined products of the loom, imagine an intestine of the thinnest gauze, gorged from one end to the other with coarse grains of granite, the rugged points and sharp edges of which are perfectly perceptible

[1] This is the form adopted for the tiger-pits made by the Chinese in Singapore.

to the naked eye. But what most struck me at first in this animal was that it seemed literally to have no other nourishment than the coarse sand by which it was surrounded. And then when, armed with scalpel and microscope, I ascertained something of its organisation, what unheard-of marvels were revealed! In this body, the walls of which scarcely reach the sixteenth part of an inch in thickness, I could distinguish seven distinct layers of tissue, with a skin, muscles, and membranes. Upon the petaloid tentacles I could trace terminal suckers, which enabled the Synapta to crawl up the side of a highly-polished vase. In short this creature, denuded to all appearance of every means of attack or defence, showed itself to be protected by a species of mosaic, formed of small, calcareous, shield-like defences, bristling with double hooks, the points of which, dentated like the arrows of the Carribeans, had taken hold of my hands. If one of these Synapta is preserved alive in sea-water for a short time, and subjected to a forced fast, a very strange phenomenon will be observed. The animal, being unable

FIG. 3.—*Synapta duvernea.*

to feed itself, successively detaches various parts of its own body, which it amputates spontaneously."

Although most of the illustrations in this volume are very good, and some are good works of art, there are also several which are very poor, and quite unworthy of the text. This is especially the case among the smaller birds, several of which are unrecognisable. A few also have been wrongly named, representing very different creatures from those they are said to be. The most prominent defects of this kind are the figure of the Leucoryx antelope, which is named *Saiga tartarica*, and that of two humming-birds, which do duty for sun-birds. These oversights, which no doubt occurred in the London office, since they are far too gross to be imputed to the author of the book, should be corrected in another edition; and if the publishers will substitute better figures for those of the stone-chat, hedge-sparrow, dipper, Java-sparrows and some others which are barely recognisable, the work will be one of permanent use and interest, both as an illustrated manual of the families of the vertebrata and a popular introduction to general natural history.

A. R. W.

ON THE SECULAR CHANGES IN THE ELEMENTS OF THE ORBIT OF A SATELLITE REVOLVING ABOUT A PLANET DISTORTED BY TIDES[1]

THE investigation which forms the subject of this paper is entirely mathematical, and is therefore not of a kind to be easily condensed into a short account.

This paper is the fifth of a series (of which notices have from time to time appeared in NATURE) in which I have endeavoured to trace the various effects on the configuration of a planet and satellite, which must result from tidal friction—the tides in the planet being either a bodily distortion or oceanic. The investigations are, I think, not without interest as a branch of pure dynamics, but this side of the subject is too complicated to be made intelligible without mathematical notation, and it would occupy too much space to explain the methods of treatment.

There is, however, another side of the subject, which must, I think, attract notice, or at least criticism, and this is the applicability of the results of analysis to the history of the earth and of the other planets.

[1] An account of a paper by G. H. Darwin, F.R.S., read before the Royal Society, on December 18.

We know that no solids are either perfectly rigid or perfectly elastic, and that no fluids are devoid of internal friction, and therefore the tides raised in any planet, whether consisting of oceanic tides or of a bodily distortion of the planet, must be subject to friction. From this it follows that the dynamical investigation must be applicable to some extent to actual planets and satellites. For myself, I believe that it gives the clue to the history of the system, but of course an ample field for criticism is here opened.

The investigation is intended to be more especially applicable to the case of the earth and moon, and therefore, instead of planet and satellite, the expressions earth and moon are used.

The effect of tidal friction upon the eccentricity and inclination of the lunar orbit here affords the principal topic. The obliquity of the ecliptic, the diurnal rotation of the earth, and the moon's periodic time were considered in a paper read before the Royal Society on December 19, 1878, and which will appear in the *Philosophical Transactions* for 1879.

The present paper completes (as far as I now see) the main investigation for the case of the earth and moon, and therefore it is now possible to bring the various results to a focus.

It appears then that, when we trace backwards in time the changes induced in the system of the earth and moon by tidal friction, we are led to an initial state which is defined as follows:—

The earth and moon are found to be initially nearly in contact; the moon always opposite the same face of the earth, or moving very slowly relatively to the earth's surface; the whole system rotating in from two to four hours, about an axis inclined to the normal to the ecliptic at an angle of 11° 45′, or somewhat less; and the moon moving in a circular orbit, the plane of which is nearly coincident with the earth's equator.

This initial configuration suggests that the moon was produced by the rupture, in consequence of rapid rotation or other causes, of a primeval planet, whose mass was made up of the present earth and moon. The coincidence is noted in the paper, that the shortest period of revolution of a fluid mass of the same mean density as the earth, which is consistent with an ellipsoidal form of equilibrium, is two hours twenty-four minutes; and that if the moon were to revolve about the earth with this periodic time, the surfaces of the two bodies would be almost in contact with one another.

The rupture of the primeval planet into two parts is a matter of speculation, but if a planet and satellite be given in the initial configuration above described, then a system bearing a close resemblance to our own, would necessarily be evolved under the influence of tidal friction.

The theory postulates that there is not sufficient diffused matter to materially resist the motions of the moon and earth through space. Sufficient lapse of time is also required. In a previous paper I showed that the minimum time in which the system could have degraded from the initial state, just after the rupture into two bodies, down to the present state, is fifty-four million years. The time actually occupied by the changes would certainly be much longer.

It appears to me that a theory, reposing on a *vera causa*, which brings into quantitative correlation the lengths of the present day and month, the obliquity of the ecliptic and the inclination and eccentricity of the lunar orbit, must have considerable claims to acceptance.

It was stated that the periodic times of revolution and rotation of the moon and earth might be traced back to a common period of from two to four hours. In a previous paper the common period was found to be a little over five hours in length; but that result was avowedly based on a partial neglect of the sun's attraction. In this paper certain further considerations are adduced, which show that, while the general principle remains intact, yet the common period of revolution of the earth and moon must initially have been shorter than five hours to an amount which is uncertain, but is probably large. The period of from two to four hours is here assigned, because it is mechanically impossible for the moon to revolve about the earth in less than two hours, and it is uncertain how the rupture of the primeval planet took place.

But if tidal friction has been the agent by which the earth and moon have been brought into their present configuration, then similar changes must have been going on in the other bodies which make up the solar system. I will therefore make a few remarks on the other satellites and planets.

In the first place it is in strict accordance with the theory, that the moon should always present the same face towards the earth. Helmholtz, was, I believe, the first who suggested tidal friction as the cause of the reduction of the moon's axial rotation to identity with her orbital motion. It is interesting to note in this connection that the telescope seems to show that the satellites of Jupiter, and one at least of the satellites of Saturn, also have the same peculiarity.

The process by which tidal friction brings about the changes in the configuration of a planet and satellite is a destruction of energy (or rather its partial conversion into heat within the planet, and partial redistribution), and a transference of angular momentum from that of planetary rotation to that of orbital revolution of the two bodies about their common centre of inertia.

Now a large planet has both more energy of rotation and more angular momentum; hence it is to be expected that large planets should proceed in their changes more slowly than small ones.

Mars is the smallest of the planets, which are attended by satellites, and it is here alone that we find a satellite revolving faster than the planet rotates. This will also be the ultimate fate of our moon, because after the joint lunar and solar tidal friction has reduced the earth's rotation to an identity with the moon's orbital motion, the solar tidal friction will continue to reduce it still further, so that the earth will rotate faster than the moon revolves.

Before, however, this can take place with us, the moon must recede to an enormous distance from the earth, and the earth must rotate in forty or fifty days instead of in twenty-four hours. But the satellites of Mars are so small, that they would only recede a very short way from the planet, before the solar tidal friction reduced the planet's rotation below the satellite's revolution. The rapid revolution of the inner satellite of Mars may then, in a sense, be considered as a memorial of the primitive rotation of the planet round its axis.

The planets Jupiter and Saturn are very much larger than the earth, and here we find the planets rotating with great speed, and the satellites revolving with short periodic times. The inclinations of the orbits of Jupiter's satellites to their "proper planes" are very interesting from the point of view of the present theory.

The Saturnian system is much more complex than that of Jupiter, and it seems partially in an early stage of development and partially far advanced.

The details of the motions of the satellites are scarcely well enough known to afford strong arguments either for or against the theory.

I have not as yet investigated the case of a planet or star attended by several satellites, but perhaps future investigations may throw further light both on the case of Saturn, and on the whole solar system itself.

The celebrated nebular hypothesis of Laplace and Kant supposes that a revolving nebula detached a ring, which ultimately became consolidated into a planet or satellite, and that the central portion of the nebula continued to contract, and formed the nucleus of the sun or planet.

The theory now proposed is a considerable modification of this view, for it supposes that the rupture of the central body did not take place until it was partially consolidated, and had attained nearly its present dimensions.

I do not pretend, in these remarks, to have thoroughly discussed the cases of the other planets, and have only drawn attention to a few salient features; in the paper itself the subject is considered at greater length. It will, however, I think, be admitted that the theory agrees with some remarkable facts in the solar system.

G. H. DARWIN

THE SEXUAL COLOURS OF CERTAIN BUTTERFLIES

DR. SCHULTE, of Fürstenwalde, has called my attention to the beautiful colours which appear on all four wings of a butterfly, the *Diadema bolina*, when looked at from one point of view. The two sexes of this butterfly differ widely in colour. The wings of the male, when viewed from behind, are black with six marks of pure white, and they present an elegant appearance; but when viewed in front, in which position, as Dr. Schulte remarks, the male would be seen by the female when approaching her, the white marks are surrounded by a halo of beautiful blue. Mr. Butler, also showed me in the British Museum an analogous and more striking case in the genus Apatura, in which the sexes likewise differ in colour, and in the males the most magnificent green and blue tints are visible only to a person standing in front. Again with Ornithoptera the hind wings of the male are in several species of a fine golden yellow, but only when viewed in front; this holds good with *O. magellanus* but here we have a partial exception, as was pointed out to me by Mr. Butler, for the hind wings when viewed from behind change from a golden tint into a pale iridescent blue. Whether this latter colour has any special meaning could be discovered only by some one observing the behaviour of the male in its native home. Butterflies when at rest close their wings, and their lower surfaces, which are often obscurely tinted, can then alone be seen; and this it is generally admitted, serves as a protection. But the males, when courting the females, alternately depress and raise their wings, thus displaying the brilliantly coloured upper surface; and it seems the natural inference that they act in this manner in order to charm or excite the females. In the cases above described this inference is rendered much more probable, as the full beauty of the male can be seen by the female only when he advances towards her. We are thus reminded of the elaborate and diversified manner in which the males of many birds, for instance the peacock, argus pheasant, &c., display their wonderful plumage to the greatest advantage before their unadorned friends.

The consideration of these cases leads me to add a few remarks on how far consciousness necessarily comes into play in the first acquirement of certain instincts, including sexual display; for as all the males of the same species behave in the same manner whilst courting the female, we may infer that the display is at least now instinctive. Most naturalists appear to believe that every instinct was at first consciously performed; but this seems to me an erroneous conclusion in many cases, though true in others. Birds, when variously excited, assume strange attitudes and ruffle their feathers; and if the erection of the feathers in some particular manner were advantageous to a male whilst courting the female, there does not seem to be any improbability in the offspring which inherited this action being favoured; and we know that odd tricks and new gestures performed unconsciously are often inherited by man. We may take a different case (which I believe has been already advanced by some one), that of young ground birds which squat and hide themselves when in danger immediately after emerging from the egg; and here it seems hardly possible that the habit could have been consciously acquired just after birth without any experience. But if those young birds which remained motionless when frightened, were oftener preserved from beasts of prey than those which tried to escape, the habit of squatting might have been acquired without any consciousness on the part of the young birds. This reasoning applies with special force to some young wading and water birds, the old of which do not conceal themselves when in danger. Again a hen partridge when there is danger flies a short distance from her young ones and leaves them closely squatted; she then flutters along the ground as if crippled, in the wonderful manner which is familiar to almost every one; but differently from a really wounded bird, she makes herself conspicuous. Now i is more than doubtful whether any bird ever existed with sufficient intellect to think that if she imitated the actions of an injured bird she would draw away a dog or other enemy from her young ones; for this presupposes that she had observed such actions in an injured comrade and knew that they would tempt an enemy to pursuit. Many naturalists now admit that, for instance, the hinge of a shell has been formed by the preservation and inheritance of successive useful variations, the individuals with a somewhat better constructed shell being preserved in greater numbers than those with a less well constructed one; and why should not beneficial variations in the inherited actions of a partridge be preserved in like manner, without any thought or conscious intention on her part any more than on the part of the mullusc, the hinge of whose shell has been modified and improved independently of consciousness. CHARLES DARWIN

Down, December 16, 1879

NOTES

WE are much pleased to be able to announce that the Committee of the British Association for the Exploration of Socotra have secured the services of Dr. I. B. Balfour, Professor of Botany at Glasgow, as naturalist. Besides many other qualifications for the post Dr. Balfour has recently taken part in the execution of a similar piece of work as one of the naturalists attached to the station for the observation of the Transit of Venus at Rodriguez. Dr. Balfour will leave for Aden on the 9th inst., and proceed thence to Socotra.

M. PERRIER, the head of the French Survey, has been appointed a Member of the Academy of Sciences. It may be remembered that M. Perrier is a commander on the staff, and has just accomplished one of the greatest geodetic feats on record, the connection of the South of Spain with the Algerian province of Oran. M. Perrier is a supporter of M. Roudaire's scheme, and his appointment is considered likely to accelerate the work of the survey for the great Saharan Railway.

WE are pleased to see that a movement is on foot to erect an educational natural history museum in Perth, as a memorial to the late Sir Thomas Moncrieffe, president of the Perthshire Natural History Society. From a statement sent us by Dr. Buchanan White, we notice that the organisers have a rational idea of what such an institution should be, and their scheme is a comprehensive one, having in view the education of the citizens of the ancient burgh, as well as the collection of objects of natural history connected with the county. A generous citizen of Perth, Mr. Robert Pullar, offers 500*l*. of the 2,000*l*. which it is estimated the building will cost.

M. E. LEVASSEUR, a well-known French geographer, has invented an amusing and instructive geographical game, to which he gives the name of "Tour du Monde." It is played on a large terrestrial globe divided into 232 spherical rectangles, each of which has a number, corresponding to a number on a list, indicating gains or losses, in accordance with the nature of the rectangle to which it belongs. The game is played with eighteen flags corresponding to the principal States of the world, from China, the most populous, down to Holland, the least populous. A brass slip, from pole to pole, contains eighteen holes, into which the flags are successively placed by the players at each revolution, commencing at the south pole and moving northwards. The gains and losses correspond with the nature of the facts indicated in the space above which a flag may stand when the globe stops revolving. Thus London counts thirty, Paris twenty, and so on, according to population. A coal-mine, a Manchester cotton factory, a grain centre, all count for gains; while meeting a Zulu or a lion in Africa, a storm in Atlantic or Pacific, a crocodile in the Nile, being caught in the Polar ice, &c., count for losses. Thus it will be seen, the new game is calculated to afford considerable excitement as well as instruction.

DR. B. W. RICHARDSON has been re-elected Assessor of the University Council of St. Andrew's University. This will be Dr. Richardson's third term of office.

WE last week referred to the new appointment to the Registrar-Generalship and the resignation of Dr. Farr. The following is Dr. Farr's dignified and temperate letter to Major Graham, the retiring Registrar-General:—"December 23.—Sir,—Having now heard from you that Sir Brydges Henniker is to be the new Registrar-General, and thus having lost all chance of being your successor, I shall be glad if the Lords of Her Majesty's Treasury will allow me to resign my appointment, and will grant me superannuation allowance to the extent of my full pay. I have served under you nearly forty years, I have taken with you three censuses, and I feel confident that I can leave my case in your hands.—(Signed) William Farr." The Government has possibly a complete justification to give for the appointment of Sir Brydges Henniker; if so, they should lose no time in making it public, as their treatment of Dr. Farr has roused universal indignation.

MR. EDISON publishes through the columns of the *New York Herald*, an elaborate and detailed account of his labours with his new form of electric lighting. Minutely describing the course of his studies, Mr. Edison says that he has made the discovery that the carbon framework of a small piece of paper is the best substance for incandescent lighting. A piece of cardboard, known in the trade as "Bristol," is cut, with a suitable punch, into strips in the form of miniature horseshoes, about 2 inches long, and one-eighth wide. A number of these strips are placed in a wrought-iron mould, separated from each other by tissue paper. The mould, after being well covered, is placed in an oven, where it is gradually exposed to a temperature of about 600° F., so as to allow the volatile portions of the paper to pass away. The mould is then removed to a furnace, kept there till it retains almost a white heat, and subsequently allowed gradually to cool down. On opening the mould, the charred remains of the cardboard must be taken out with great care, in order to prevent them from falling to pieces. They are placed in a small globe and attached to the wires connecting the generating machine. The next thing is to extract the air, by means of the pump, from the globe; that being accomplished, the globe is sealed, and the lamp is ready for use. It should be observed that the new lamp requires no complex regulating apparatus, such as characterised the earlier efforts. In fact, Mr. Edison finds that all previous labour in regard to regulators was practically wasted, and furthermore, that electricity can be regulated with absolute reliability in a manner precisely similar to that in which the pressure of gas is now produced. The system now adopted by Mr. Edison in connecting the wires admits of a given number of lights being extinguished without affecting those of other burners. In the same way as we would shut a certain number of gas burners and permit others to draw a supply from the meter, the electric light can be obtained or shut out. From the description now given it appears that the apparatus primarily used by Mr. Edison was in the shape of a large tuning-fork, constructed in a manner that both ends would vibrate when placed near the poles of the great magnet. Experience has demonstrated the impracticability of that apparatus, and it became necessary to search for other means. One experiment was made after another, which had the tendency to lead gradually to the adoption of the system now employed in the generating machine, and which Mr. Edison terms the Faradaic machine. It is briefly described thus:—Two upright iron columns 3 feet in height, and 8 inches in diameter, covered with coarse wire and resting upon a base, form the magnetic poles. Fixed on an angle, so as to admit a free revolution between the poles, is a cylindrical armature of wood, wound parallel to its axes with fine iron wire. This cylinder is made to revolve rapidly between the magnetic poles, and by means of a belt, driven by an engine, strong currents of electricity are generated in the wire surrounding the armature, and these currents are carried along the wires to the electric lamp.

A CHANGE has taken place in the French Ministry, and M. Freycinet, the Minister of Public Works, has been created Prime Minister by the President of the Republic. M. Varoy and General Farre, two pupils of the Polytechnic School, have been appointed to the Department of Public Works and War Office. It is known that M. Freycinet was educated in the same institution, which has never, since it was created in 1798, given at once so many Ministers to France.

IN the Annual Report of the Royal Botanical Garden at Calcutta for the year 1878–79, Dr. King confirms the opinion he has expressed in former reports regarding the unsuitability of the Para rubber plants for acclimatisation in some parts of India. He acknowledges that plants may be coaxed into growing in conservatories, but considers the species far too thoroughly tropical to withstand without protection the vicissitudes of the climate of Northern India. He says, "I believe it is useless to try it anywhere in India except in the south of Burmah or the Andamans, or perhaps in Malabar. Contrary to the experience with Para rubber, the Ceara Kina (*Manihot glaziovii*) promises well, and if the quality of rubber yielded by it in India proves to be good, its introduction will no doubt turn out of much importance. Seeds of a species of *Landolphia* yielding African rubber have been received at Calcutta from Zanzibar. Dr. King reports upon them as not looking very promising, but thought possibly some of them might grow. Seeds of the mahogany tree have been received at Calcutta in large quantities, and a large number of seedlings have been distributed. The cultivation of this valuable timber tree has been taken up by the Forest Department in the Government Plantation near Chittagong. Large quantities, also, of the seed and seedlings of the *Pithecolobium saman*, or rain-tree, have been distributed; and as the plant grows rapidly and seems to flower and seed freely, it may prove a valuable introduction to India.

THE annual prize of 25,000 francs (1,000*l*.), given by the King of the Belgians for works of a scientific character, is now offered for the year 1881. It will be awarded to the author of the best work on the means of improving sea-ports situated upon low and sandy coasts, such as the Belgian ports. Foreigners as well as Belgian subjects may compete, as the competition is an international one. The works must be sent to the "Ministère de l'Intérieur," at Brussels, before January 1 next. The prize will be awarded by a jury composed of four foreigners and three Belgians, all of whom are nominated by his Majesty.

A PRIZE is offered by the Governor of the Prussian province of Saxony for the best text-book of natural science and agriculture. The exact title is as follows: "Lehrbuch der Naturwissenschaften und der Landwirthschaft zum Gebrauch beim Unterricht in den Ackerbauschulen und landwirthschaftlichen Winterschulen in Sachsen." The competing works must be sent to Dr. Julius Kühne, Professor at the University of Halle. The extent of the book is to be moderate, and should not exceed thirty sheets.

ON December 10, 1878, the first cremation was executed at Gotha. We announced the fact at the time. News from that town now states that during 1879 fifteen other cremations were performed. This is looked upon as an extremely satisfactory result for the first year in which the process may be chosen by and for anybody. The time for the complete incineration of the bodies was between one and a half and two and a half hours, therefore about two hours on the average. Besides Gotha, other German towns furnished subjects for cremation, such as Langensalza, Naumburg, Neustadt on the Orla, Leipzig, Dresden, Bamberg, Hanover, Breslau, and Vienna.

ONE of the *desiderata* of M. Leverrier has been fulfilled. A lectureship of astronomy has been created in Marseilles, and M. Stephan, Director of the Observatory, appointed as lecturer.

M. C. DETAILLE, of Paris, is organising in France, at the request of Lord Lindsay, a system of astronomical exchanges similar to that suggested in these columns by his lordship for England.

THE thaw set in in Paris about 4 P.M. on December 28, just when the partial eclipse of the moon was beginning. The temperature has been increasing almost without interruption. 14° Cent. in the sun has been reached, and 9° Cent. in the shade. The breaking up of the ice in the Seine took place on the 2nd, and was so sudden that it took the engineers by surprise. An immense number of boats have been wrecked, and have created obstacles to the flow of water and ice under the arches of the bridges. The consequence has been the total wreck of the wooden foot-bridge of the Invalides and the destruction of two arches of the stone bridge now building at a distance of a few paces down the river. So serious were the fears entertained by the authorities for the safety of the iron bridges that the traffic was prohibited during the whole of Saturday. The news from the mountainous parts of the Seine basin announce that an immense quantity of water is travelling towards the sea.

WHILE Paris and the whole of France have been recently covered with snow, in a period of exceptional cold, the weather has been comparatively very clement on the summit of the Pic-du-Midi and the snow rare. General Nansouty telegraphed privately as follows to M. Tissandier on December 24:—"We are in distress; we shall presently be unable to find enough snow to make water for the tea and the soup. Send us some snow if Paris has enough."

SINCE December 13 the temperature of Algiers has been that of spring, the temperature in the shade varying from 6° to 17°, and in the sun of 32° Centigrade; almost no cloud in the sky, and a magnificent sun shining all the day long.

M. W. DE FONVIELLE has just published a novel under the title of "Neridah" (Hachette and Co.), in which, with considerable ingenuity, he brings the tricks of spiritualistic mediums and the facts of electrical science to bear upon the development of the plot. The scene of the story is in England and India.

PROF. SCHÄFER will, on Tuesday next, January 13, begin a course of ten lectures on the Physiology of Muscle at the Royal Institution; and Mr. H. H. Statham will, on Thursday next, January 15, give the first of two lectures on Modern Architecture since the Renaissance; at the first Friday evening meeting of the season, January 16, Prof. Dewar will describe his "Investigations at High Temperatures." On Saturday, the 17th, Prof. T. Rupert Jones will give the first of three lectures on Coal.

THE officers and engineers appointed to proceed to Algeria for the survey of the Transaharan railway, are leaving Paris by batches. They take with them a number of aneroid barometers specially constructed, which will be verified frequently by boiling water with a hypsometer of verysimple construction.

THE earthquake in Switzerland on December 30, 1879, is exciting great interest in scientific circles, and arrangements are being made for accurately measuring the duration of future shocks. The occurrence of a shock at the beginning of the late phenomenal frost and of another at its close is too remarkable to escape notice. The oscillation of Tuesday, though felt at places so far asunder as Chambery and Berne, seems to have been most marked at Geneva, Lausanne, and in the mountains of Bex. At Grion, in Vaud, 3,500 feet above the sea-level, the oscillation lasted five seconds, and was accompanied by a rumbling sound as of subterranean thunder.

THE subject of the Wyatt Edgell Prize Essay of the Sanitary Institute is "The *Range* of Hereditary Tendencies in Health and Disease," not the *Cause*.

THE programme for the meetings after Christmas of the Society of Arts has just been issued. Among papers to be read at the ordinary meetings between Christmas and Easter are:—January 21, "Dome tic Poisons," by Henry Carr; January 28, "The Future of Epping Forest," by William Paul, F.L.S.; February 4, "Trade and Commerce with Siberia, *viâ* the Kara Sea," by Henry Seebohm; February 11, "The History of the Art of Bookbinding," by Henry B. Wheatley, F.S.A.; February 18, "The Euphrates Valley Railway," by W. P. Andrew; February 25, "The Art of the Silversmith," by W. Herbert Singer; March 3, "The History of Musical Pitch," by Alexander J. Ellis, F.R.S.; March 10, "Recent Advances in the Production of Lambeth Art Pottery," by John Sparkes; March 17, "Buildings for Secondary Educational Purposes," by E. C. Robins, F.S.A. In the Indian Section, Prof. Vambéry, the great Eastern traveller, has undertaken to read a paper on "Russia's Influence over the Inhabitants of Central Asia during the last Ten Years," and he has promised to come over from Buda-Pesth expressly for the purpose. The other papers to be read in this section, for which dates are fixed, are:—January 30, "Herat," by Col. G. B. Malleson. C.S.I.; April 2, "The Best Route for a Line of Railway to India," by Mr. B. Haughton, C.E.; May 7, "Agriculture in India," by Mr. Robertson, Superintendent of the Government Farm, Madras. In the Chemical Sections, Prof. Perry will read a paper on "The Teaching of Physics," on January 22. On February 12 there will be a paper on "Gas Furnaces and Kilns for Burning Pottery," by Herbert Guthrie, C.E. The course of Cantor Lectures during this part of the year will be on the "Manufacture of India-rubber and Gutta-percha," by Thomas Bolas, F.C.S. It will consist of six lectures, the first of which will be given on February 2.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. L. C. Piggott; a Common Ocelot (*Felis pardalis*), a Harpy Eagle (*Thrasaëtus harpygia*) from Central America, a Black-tailed Parrakeet (*Polytelis melanurus*) from Australia, purchased; a Tamandua Ant-eater (*Tamandua tetradactyla*), two Naked-throated Bell Birds (*Chasmorhynchus nudicollis*) from Brazil, a Tuberculated Iguana (*Iguana tuberculata*) from South America, two Giant Toads (*Bufo agua*) from Savauilla, deposited.

OUR ASTRONOMICAL COLUMN

Minor Planets.—The number of discoveries in the group of minor planets during the year 1879 is *twenty*, against *twelve* in the preceding year, so that there is no present indication that we are getting to the end of them. Elements more or less approximate have been calculated for seventeen out of the twenty new ones, but no one of the orbits has any peculiarity. We subjoin their ordinal numbers, names so far as published, discoverers and dates of discovery, with their magnitudes at the time.

192	Nausikaa	Palisa	Feb. 17	11
193	Ambrosia	Coggia	Feb. 28	12
194	Procne	Peters	March 22	10·5
195	Euryclea	Palisa	April 28	12
196	Philomela	Peters	May 17	10
197	Arete	Palisa	May 21	12
198	Ampella	Borrelly	June 13	11
199	Byblis	Peters	July 9	11
200	Dynamene	Peters	July 27	11
201	Penelope	Palisa	Aug. 7	10·5
202	Chryseis	Peters	Sept. 23	11
203	Pompeia	Peters	Sept. 27	11
204	Callisto	Palisa	Oct. 8	12
205	...	Palisa	Oct. 13	12
206	Hersilia	Peters	Oct. 15	11
207	...	Palisa	Oct. 17	12
208	...	Palisa	Oct. 21	13
209	Dido	Peters	Oct. 22	11
210	...	Palisa	Nov. 12	11
211	...	Palisa	Dec. 10	10·5

The elements will be found in Nos. 109-127 of the *Circular zum Berliner Astronomisches Jahrbuch*.

The Melbourne Observatory.—The fourteenth Report of the Board of Visitors to the Observatory, presented to the Governor of Victoria, with the Report of the Government astronomer for the year ending June 30, 1879, has been received. The great reflector is stated to be in capital working order, but unexpected difficulties have been met with in placing the results of work with it before the astronomical public, this work consisting mainly of drawings of nebulæ in Sir John Herschel's catalogue. Fifty-four of the smaller nebulæ and clusters contained in it have been observed and compared, and the great majority found to agree well with the Cape descriptions. "Some, however, have considerably changed, whilst others are completely altered in appearance." Five nebulæ described by Herschel have not been found after careful search. The drawing of the great nebula around η Argus made in March, 1875, still accurately represents its appearance. Observations of the trifid nebula No. 4355 were made on ten nights for comparison of those by Holden and Trouvelot with the Washington refractor. Stress is laid upon the need of a transit-circle of increased capacity, and it is understood that the Government propose a vote for this purpose.

The Biela Comet Meteors.—Contrary to what had been anticipated by more than one astronomer who has given special attention to the subject, from present information it would appear that the earth passed the descending node of Biela's comet at the end of November last, without encountering any portion of the meteoric swarm, which, in November, 1872, was moving in its orbit. The earth would reach the node on the morning of November 28, or perhaps earlier; the comet attains its least distance from our track thirty-two hours after its nodal passage, or, with Michez's orbit of 1866, in about heliocentric longitude, 67° 19′.

Uranometria Argentina.—Within the last week we have received this very important work from the Director of the Cordoba Observatory, Dr. B. A. Gould. Some account of it was lately given in this column from an article in the Buenos Ayres *Standard*, but we shall revert to it at an early date. Its publication will form an epoch in southern sidereal astronomy.

The Close Binary 85 Pegasi.—We learn from Mr. Burnham that his recent measures fully establish the physical connection of the close components of this star. A mean of five nights' measures gives:

1879·46 ... Position 284°·6 ... Distance 0″·75.

The earlier mean result being:

1878·7 ... Position 274°·0 ... Distance 0″·67.

For the stars A and C Mr. Burnham finds:

1879·9 ... Position 28°·7 ... Distance 15″·40.

BIOLOGICAL NOTES

A Blind Isopod.—For some years past, Prof. Forel, of the Academy of Lausanne, has been engaged in investigating the animal forms to be met with in the great depths of the Lake Leman. These researches have been published from time to time since 1869 in the *Journal* of the Vaudois Society of Natural History, and the series is apparently brought to a close in the recently published number of the journal in which he sums up the general results, and enumerates no less than seventy-six species of animals described as discovered in the Lake at depths of from 100 to 300 metres. Among these is one new blind form, closely related to our own very common fresh-water Isopod called *Asellus aquaticus*. When drawn up from the water it is found constantly associated with *Niphargus puteanus*. It is of a whitish colour, through which the brownish-coloured alimentary canal is easily perceptible. When placed in an aquarium it lives but a short time. The organs of vision are only rudimentary. The species comes near to *A. cavaticus*, and has been named by H. Blanc *A. forellii*.

Notes on Crustacea.—Dr. P. P. C. Hoek of Leiden has published some very interesting results of his investigations among the smaller crustacean forms made at the Netherlands Zoological Station. One series of notes are devoted to the anatomy and systematic descriptions of the species of Caprellidæ met with, viz., *Podalirius typicus*, Kröyer, *Caprella linearis*, Lin., and *Leptomera pedata*, Abilgaard. Another series treats of several species of Corophidæ. Those met with were: *Corophium crassicorne* (Hoek confirms Norman's statement that the *C. Bonellii* of Bate and Westwood is the female of this species); *C. longicorne*, *Cerapus difformis*, *Podocerus falcatus*, *Orthopalame Terschellingi*, nov. gen., nov. sp. (this new genus belongs to the sub-family Podocerinæ), and *Amphitoe littorina*. A third series is devoted to an account of *Orchestia cavimana*, Heller, found by Dr. Noman at Zalt-Bommel, a town in the province of Gelderland. It is more than 80 kilometres from the sea; the water is not brackish, but the amphipods were not even found in the neighbourhood of a stream, but in a walled-in garden some slight distance therefrom, in a corner of which, under some flower-pots, and while in search for onisci, the species was taken. It would appear to be the same as the one described by Heller as found on Olympus by Dr. Kotschy, at a height of some 4,000 feet, in moist spots in the neighbourhood of a spring. Mr. Noman found the species in the same locality again in August last (1879). The listribution of some of the other species of *Orchestia* is also referred to. Series four treats of some insufficiently-known Gammaridæ, such as *Atylus swammerdammi*, *Calliopius læviusculus*, *Melita obtusata*, *Cheirocratus brevicornis*, n. sp., *Ampelisca æquicornis*. Series five gives some short anatomical remarks on Gammaridæ. These researches are illustrated by six plates, and form portion of the *Reports* of the Netherlands Zoological Station.

Ptyaline and Diastase.—Physiologists have differed in opinion as to the action of the gastric juice on ptyaline and on diastase. While some hold that the saliva is destroyed in the gastric juice, others maintain that it continues, in the stomach, its action on starch. Recent researches by M. Defresne (*Comptes rendus*) appear to throw light on the subject; they prove, on the one hand, that the saliva is paralysed in pure gastric juice, whereas with mixed gastric juice, containing only organic acids, saccharification proceeds as well as in the mouth. Ptyaline, then, like pancreatine, is an excellent reagent for demonstrating the difference between mixed and pure gastric juice. The latter, as M. Defresne has proved, owes its acidity to hydrochloric acid, combined doubtless with leucine; the former to organic acids, probably combined also with azotised matters. Ptyaline and diastase, therefore, are not two identical substances, from a physiological point of view. Ptyaline saccharifies the starch in mixed gastric juice, as well as in the mouth; it is only paralysed an instant in pure gastric juice, and then recovers its action in the mixed gastric juice and in the duodenum. Diastase or maltine is irrecoverably destroyed in hydrochloric solutions or in pure gastric juice, and after having passed into the mixed juice it is profoundly altered; for, if it still dissolves starch, it no longer saccharifies it.

Existence of the Chamois in the Abruzzi.—A recent communication of Mr. C. J. Forsyth-Major to the *Bulletin* of the Club Alpino Italiano, records the occurrence of the Chamois (*Rupicapra tragus*) on the Gran Sasso d'Italia in the Northern

Abruzzi. Mr. Forsyth-Major made an expedition into this district with the object of identifying the so-called "Chamozzo" of the inhabitants, and ascertained that this animal, now nearly extinct, was either the chamois of the Alps or a closely allied form. At Isola del Gran Sasso he was shown the horns and skin of an example shot in 1878. The present existence of the chamois so far south in Italy, although mentioned in several works, has not been previously authenticated.

MOVEMENT IN THE LEAVES OF CONIFERS.—Dr. Maxwell Masters (Linnean Society, December 4) has called attention to the contrasts to be drawn between the leaves of the spruce firs (*Picea*) and those of the silver firs (*Abies*) as regards their arrangement, relative position, form, relative size, and internal structure, as described by Bertrand, MacNab, Chatin, and others. The leaves of the silver firs are endowed with a power of motion in virtue of which they are raised or depressed. On the other hand, the leaves of the spruces are comparatively motionless. In those cases where the leaves have the power of movement there is usually a well-marked layer of "palisade cells" which are absent in the motionless leaves. This circumstance has led Dr. Masters to correlate the differences before alluded to with varying degrees of functional activity, and with the adaptations manifested to secure as far as possible to each leaf an equally favourable amount of exposure to light, &c. The very remarkable movements of revolving nutation observable in the "leader shoots" of many conifers during their season of active growth were mentioned as having been investigated by him and the rotation duly registered on a disk.

GEOLOGICAL NOTES

CRUSTACEA IN THE OLD RED SANDSTONE.—The occurrence of eurypterid crustaceans of the genus *Pterygotus* in the Tilestones of Herefordshire and Worcestershire, and in the Old Red Sandstone of Forfarshire, has long been well known. These organisms have been regarded as characteristic of that section of geological time in the British area represented by the Ludlow and Lower Old Red Sandstone formations. Murchison used their presence in the Arbroath flagstones as an argument for placing these strata in his "Lower" division of the Old Red Sandstone, while on the other hand he argued from their absence in the Caithness flagstones and from the dissimilarity of the fishes, that these northern deposits must be of later age. He therefore classed the great flagstone series of Caithness and the Orkney Islands as "Middle" Old Red Sandstone, thus bringing this series of formations into correspondence with his favourite threefold classification of the Devonian system. Recently, however, in the first part of his memoir "On the Old Red Sandstone of Western Europe," published in the *Transactions of the Royal Society of Edinburgh*, Prof. Geikie has pointed out that the contrast between the fish fauna of the Arbroath flagstones, or the ancient basin which he terms "Lake Caledonia" and that of the northern basin or "Lake Orcadie," is by no means so marked as Murchison believed, and that the characteristic *Pterygotus*, on which the author of "Siluria" laid so much stress as an Upper Silurian and Lower Old Red Sandstone type, occurs on several horizons and at different localities in the Caithness and Orkney basin. An important discovery confirmatory of the extension of these crustacea into the northern area has recently been made by Mr. James Linn in the course of the Geological Survey of Elginshire, now in progress. From the valley of the Spey he has obtained numerous fragments of what must have been a remarkably large *Pterygotus*, though the specimens so far found hardly admit of specific identification with the *P. anglicus* of Forfarshire. *Pterygotus* has thus been discovered in Orkney, Caithness, and on the Moray Firth, not only over an extensive geographical area, but throughout a wide vertical range of strata. These crustaceans must evidently have had a considerable and prolonged development in the waters of the northern basin of the Lower Old Red Sandstone period.

SALSES OF MOUNT ETNA.—As the result of his recent observations among the mud volcanoes of Paternò on Etna, Dr. A. von Lasaulx gives the following conclusions:—1. The Salses arise from the association of gaseous volcanic emanations with spring-water traversing easily soluble strata in which common salt, gypsum, lime, and other salts occur. 2. The carburetted hydrogen escaping in connection with the salses is produced by the same volcanic emanations with the co-operation of these strata. 3. The so-called eruptions of the mud-volcanoes are merely the squeezing out under pressure of the dissolved and loosened parts of strata, that are disturbed and dislocated by underground movements.

NEW JURASSIC REPTILES.—Prof. Marsh announces in the *American Journal of Science* the arrival at Yale of numerous remains of reptiles from the Jurassic deposits of the Rocky Mountains. He finds that they belong to several distinct groups and throw considerable light on forms already described from the same horizon. Among them he briefly describes a new genus under the name of *Camptonotus*, most nearly allied to *Laosaurus*, and forming with it a distinct family, the *Laosauridæ*. The name of the genus is taken from the fact that, as in *Laosaurus*, the sacral vertebræ are not co-ossified, while some of the other vertebræ even in the same specimen have their neural arches so completely united to the centra that the suture is nearly or quite obliterated. The known remains of *C. dispar* indicate, according to Prof. Marsh, a herbivorous animal about eight or ten feet high. Another species, about three times as large, is named *C. amplus*. One of the largest reptiles yet known (*Brontosaurus*) has recently been brought to light from the same region. It probably belongs to the *Sauropoda*, but has a sacrum composed of five thoroughly co-ossified vertebræ. Fresh specimens have been obtained throwing much new light on the structure of *Stegosaurus*. This dinosaur was covered with huge dermal plates, some of which ranged from two to three feet in diameter. The remains of a much smaller reptile, about the size of a wolf, apparently also a Dinosaur, and probably carnivorous, are included in a new genus, *Cælurus*.

GEOGRAPHICAL NOTES

NEWS has been received of Herr Carl Boch, on his return to the coast after his travels in the centre of Borneo. He has been up the Klintjouw River as far as Longwai, and thirty miles beyond where no European has yet penetrated. There is, however, but little to see, and the dead silence of an almost uninhabited forest prevails beyond Longwai. The birds of this district, with five or six exceptions, are the same as those found in the highlands of Sumatra. Herr Boch has made some very interesting observations on the inhabitants of those districts, of which he is preparing an account. The Dyaks of the interior are far more wild and savage than those of the coast, and are not, as a rule, partial to seeing strangers, but appear to offer them no harm in times of peace. They are, however, veritable "head hunters," and talk about it in a very free and easy manner. The Rajah, with whom Herr Boch had dealings, had a collection of six, taken from Dyaks of another tribe, not in open fight, but by treachery when they were asleep. A more interesting race, also head hunters, however, and still further removed from civilisation, are the Orang Poonan, or forest people. With these strange border-beings, who construct no houses, but live in the open forest, Herr Boch seems to have made himself quite friends, and regards them as good and honest people—always excepting the little eccentricity in the matter of heads. They are not dark, but fair, and of a yellowish complexion, and as they have allowed Herr Boch to take sketches of both sexes, these will doubtless afford much further interesting information. He proposes now to cross the island from east to west, coming out at Band-jermassing.

A CORRESPONDENT supplies us with the following translation of a letter from Dr. Gerhard Rohlfs, concerning his recent journey in Africa, which may interest our readers. The letter addressed to a German friend, is dated Benghasi, November 10: "When you receive these lines I shall no doubt be in Italy, and, therefore, back in Europe. Your last letter of July 9 I received at Kufra, when I was free again, and already on my return journey. . . . I hope that Stecker, my young companion, will again take up the expedition. The Sueya have partly returned our property, part they are still going to return, and part the Turkish Government will compensate us. If Stecker proceeds by way of Sella and Mursuk, he will probably not encounter too many difficulties. I may communicate to you the statistical fact that the distance between Battifal and Taiserbo is about 400 kilometres. We travelled over this distance in exactly 100 *consecutive* hours, certainly a great feat. Thus we cleared more than 90 kilometres per day. It must be remembered that this was done on foot and on camels, then it will be appreciated. We hardly slept at all, only in the evenings and mornings we rested for awhile. But then who would have thought that Kufra lies $1\frac{1}{2}^{\circ}$ more to the south than is indicated on the maps? that Kufra is the largest oasis but one of the Sahara? that of all oases Kufra contains the largest *uninterrupted* areas of arable land. Are there *uninterrupted* areas at Fesan extending over 200 kilometres? Or at Tuat, or at Tafilet? No! And everywhere the finest water. There may be about 1,000,000 palm trees in the oasis, and if Kufra is otherwise poor as regards variety of species of plants, it is all the richer in numbers of plants of one and the same species. I have not reached Wadai on my tour. Thus I have not even been able to reach the basis upon which my operations were really to begin. But it is not my fault. I have the consciousness of having fully done my duty."

THE King of Sweden has expressed his wish that after the *Vega* has reached Naples Prof. Nordenskjöld and Lieut. Palander should, on their trip overland, visit several geographical societies on the continent. At Copenhagen they are to rejoin their ship, and with it proceed to Stockholm.

AT the last meeting of the Halle Geographical Society, the President, Dr. Kirchhoff, announced the formation of a geographical union amongst the students at that University, this being the first union of the kind. It is hoped that the students at other universities will imitate this commendable example. Later on at the same meeting Dr. Lilienfeld read a highly interesting paper on the South African diamond fields which he visited last year.

DR. OSCAR LENZ writes from Tetuan, under date of November 27, as follows:—"I arrived at Tangiers in excellent health. After having made excursions from this place in all directions, I travelled to Tetuan, which is highly interesting and situated most beautifully, and which was particularly attractive to me in a geological sense. For several days past I have been trying to start in a southerly direction for the Shishuaun district, which has never before been visited by a Christian, but I have not yet obtained permission from the Caliph; it is stated that the inhabitants are in open revolt against the Sultan, also that the Kabyl tribes are extremely fanatical and will not tolerate any Christians in their country. Between December 4 and 8 I expect again to be at Tangiers, from which place I shall send a detailed report of my interesting journey to the African Society. Then I shall prepare for a prolonged sojourn in the interior. About New Year's Day I hope to be at Fez."

THE January number of *Petermann's Mittheilungen* contains a detailed account, by Prof. Veth, of the Dutch expedition to Sumatra. He gives a statement of the literature relating to Sumatra previous to the expedition, a sketch of its programme, the results of Schouw Santvoort's expedition, and those of his own and Hassel's journeys in Rawas, Lebong, and Lemun, concluding with a sketch of the important Balang Hari river. A fine large map of part of Sumatra accompanies the paper. This is followed by a paper on the Sanpu river of Tibet, with a map from English sources. There is also a narrative of the recent voyage of the Dutch vessel, *Willem Barents* to the Barents Sea, also with a map, which is followed by one of Dr. Emin Bey's valuable narratives, describing his journeys between the Victoria and Albert Nyanza in 1878. We are glad to see from the monthly summary that the publication of the narrative of Baron von Der Decken's travels in East Africa, 1859-65, has at last been concluded.

A GRANT of 4,000*l.* has been made by the Minister of Public Instruction at Paris, to the French Committee of the International African Association, in order to enable them to establish two stations similar to those which the Belgian expeditions are about to found in Eastern Africa. One of these will be placed in the Ogowé region, and will probably be under the command of M. Savorgnan de Brazza, already well known for his explorations in that quarter. It is expected that the other station will be established in Usagara, on the eastern side of the continent. It had previously been proposed that M. de Brazza should lead an expedition from the Gaboon towards Lake Chad, and it is not impossible that there may be some further modification of the present projects.

IN the letters which, after long delays, have at length reached the London Missionary Society from Ujiji, Mr. Hore gives some account of his explorations on Lake Tanganyika and its adjacent rivers. In March apparently he explored the coasts of Ujiji, Ukaranga, and Ukawendi, and the Malagarasi and Kibwe rivers. At the end of April he started on another voyage, during which he visited Uguhha and explored the mouth of the Lukuga River; this he declares is the veritable outlet of the lake. Mr. Hore descended the river in a canoe as far as where the Mitwanse—now swept away—used to be, and landed at Stanley's farthest. He then walked for six hours, and mounted the Kijanka ridge, which is farther down the river than Stanley places it. He slept there, getting the latitude by stars and good bearings; and from above where he landed he had a glorious bird's-eye view of the river far into Urua. He states that the so-called Lukuga Creek is a wide and very swift river. With regard to Uguhha, Mr. Hore says that, by general consent, it is the gateway from Lake Tanganyika to the west.

THE new number of the Geographical Society's periodical contains only one paper, Capt. A. H. Markham's account of his Arctic cruise of 1879, in the Barents Sea; it has been rendered inordinately long by the introduction of many pages of irrelevant matter. It has, however, a redeeming feature, in that it is illustrated by two useful maps.

THE new *Bulletin* of the Belgian Geographical Society furnishes some interesting information in its "Chronique Géographique," more particularly in regard to the various expeditions of the International African Association, from which we gather that another expedition will before long leave Zanzibar for the interior. It is especially worthy of note, however, that no information is allowed to leak out respecting Mr. H. M. Stanley's proceedings on the Lower Congo, on which subject and his plans the Central Committee maintains a discreet silence.

WE have received Parts 9, 10, and 11 of the new edition of Stieler's Hand Atlas.

PHYSICAL NOTES

WE learn that Mr. Edison is attempting to construct a portable electric lamp which shall, including the constant battery employed to generate the current, be no larger than an ordinary moderator lamp.

THE *Scientific American* states that the story of Edison's telephone having been used over 2,000 miles of line is incorrect; the messages were transmitted over the greater part of the line by telegraph, and only over the last few miles in Pennsylvania by telephone.

A MEASURING polariscope, specially adapted for examining the angles between the optic axes of crystals upon the plan suggested a few months ago by Prof. W. G. Adams, has been constructed by Herr E. Schneider, and is described in Carl's *Repertorium*.

THE study of the spirit level has been continued by M. Plantamour. He has shown that the bubble of very accurately adjusted levels is continually moving; indicating a continual gently rising and falling of the earth's crust.

A SINGULAR phenomenon of atmospheric electricity during a snow storm was observed at Cherbourg on November 20, by M. Delamare. At about half-past five in the evening the snow-flakes fell so quickly that it was perfectly dark. M. Delamare, walking along under the shelter of his umbrella, heard a faint buzzing sound as of insects flying around, and at the same moment observed a pale luminous "brush" proceeding from the extremity of each of the ribs of his umbrella. On extending his finger towards one rib the brush-discharges ceased, and he received a continuous stream of faint sparks. It would be interesting to learn whether the handle of the umbrella was of ivory or any material of specially good insulating properties.

M. GUÉBHARD has recently shown an elegant method of procuring iridescent rings in a permanent form. These rings, which are, like Newton's rings, due to interference giving rise to the "colours of thin plates," differ however from Newton's rings in reversing the order of the colours, that corresponding to greatest thickness being at the centre. M. Guébhard drops a little collodion on to the surface of mercury. It is drawn out on all sides into a thin film of iridescent hue, which when hard may be floated off on to paper. Ten years ago the writer of this note similarly fixed on paper iridescent films obtained by dropping mastic varnish on to the surface of water. M. Guébhard produces similar rings, though of no permanency, with drops of volatile mineral oil on the surface of mercury, or even by the film of moisture condensed from the breath. At the meeting of the *Société de Physique* of Paris, on December 5, these experiments were shown by projection upon the screen; and M. Guébhard awakened a lively interest when he proceeded to show that such films, especially the fleeting films condensed from the breath, may exhibit phoneidoscopic properties. The various vowels being pronounced so that the breath impinges on the surface of the cooled mercury, rings are obtained having certain forms more or less strongly characteristic of their different qualities of tone.

THE influence of temperature on tuning-forks (which are now such valuable aids to research), has been lately investigated by Herr Kayser (*Ann. de Phys.* No. 11), and by the method of observing the alteration of the difference of phase of two forks with the temperature. The forks were furnished with mirrors and the Lissajous figures observed with a telescope. These results were arrived at: 1. The vibration number of a tuning-fork is, between 0° and 30°, a linear function of the temperature. 2. The influence of temperature is greater, the higher the tone of the fork, and with similarly arranged forks, the variation of the vibration number is about proportional to the square root of that number. 3. With moderate variations of temperature, such as occur in a room, the temperature affects the vibration number in the second place of decimals. 4. The co-efficient of elasticity of steel increases between 0° and 30° with the temperature.

OBACH proved, a few years since, that alloys of the metals proper, such as lead and tin, potassium and sodium, and sodium amalgam, conduct a current, without being decomposed. Herr Elsässer has recently (*Ann. der Phys.* No. 11) experimented with combinations of metals with the half-metallic elements antimony and bismuth, passing a current through the fused alloy in a glass tube with electrodes of gas carbon. There was here also no decomposition. The author notes that the transition from these compound conductors of the first class to the electrolytes, is no sudden one. Between the two groups are substances, which at a low temperature conduct without decomposition, but at a higher one, and even partly before they melt, are electrolysed, *e.g.* copper and silver sulphides, and the sulphides of lead, nickel, iron, bismuth, tin, and antimony. To this middle class, also, may be added a number of compounds, which have not hitherto been electrolysed, probably because they are so difficult to fuse (such as the oxides of tin, iron, and chromium); the electrolytes proper do not conduct without being electrolysed; and to this class belong especially the haloid compounds of the metals, which are not decomposed in the solid state because they are insulators; whenever they begin to conduct, being fused, they are decomposed. Lastly there is a fourth class of compounds, which in general do not conduct, either with or without decomposition.

AN experimental determination of the indices of refraction of some liquefied gases has been lately made by Herr Bleekrode (*Ann. der Phys.* No. 11). He used the method of Faraday's tubes, but observed the liquefied gas with a microscope in a small vessel with plane parallel sides having mirror plates. Only cyanogen, carbonic acid, and ammonia, were thus successfully examined, and the average numbers obtained for these were, severally 1·320, 1·163, and 1·314. The method is also useful for compounds which are liquid at ordinary temperature, but difficult to examine on account of their inflammability. Thus, the author applied it to zinc-ethyl, obtaining the number 1·489. *A propos* of the index of carbonic acid, Herr Bleekrode has some interesting remarks on liquid inclosures in certain minerals. In another paper he hopes shortly to give the indices of most of the other liquefied gases, his experiments on which were, in part, accomplished with Cailletet's compression apparatus.

THE somewhat doubtful name *Audiphone* has been given by Mr. Rhodes of Chicago to an instrument to improve the hearing powers of the partially deaf. We understand that it consists essentially of a flat flexible disk of resonant metal furnished with a handle, like a palm leaf fan and capable of being adjusted in curvature by means of a cord and a tightening clamp. The edge of the disk is to be pressed against the upper front teeth while its concave surface is presented towards the speaker to receive the sounds. The vibrations thus taken up by the disk are transmitted through the teeth and bones of the skull to the auditory nerves. This would appear to be a more practical instrument than the megaphone of Mr. Edison, of which nothing has been heard of late, or the apparatus recently explained by M. Paul Bert to the *Académie des Sciences*. Mr. J. Samuelson of Liverpool, exhibited the Audiphone at the late *soirée* of the associated scientific societies held in the St. George's Hall.

PROF. C. S. HASTINGS of the Johns Hopkins University has contributed to the current number of *Silliman's Journal* an important paper on "Triple Objectives with Complete Colour Correction." He controverts the opinion of Prof. Harkness expressed in a preceding number of the journal that the focal plane of a system of lenses does not correspond to the minimum focal distance.

IT is stated that a new photographic process has just been discovered in Japan by an inventor whose name is not given. One of the substances employed in the manufacture of Japanese lacquer has the property of becoming almost as hard as stone under the action of light. A slab covered with this material and duly exposed behind a photographic "negative" for some twelve hours, was afterwards scraped, and rubbed with spatula and brush, leaving the hardened portions raised in low relief, and capable of being used as a block for printing.

OUR contemporary, the *Electrician*, announces the startling discovery of an electric divining-rod, "whereby paying deposits of gold, silver, and copper can be positively indicated, and their exact location pointed out." This "discovery" is of course a trans-Atlantic one, but, "strange to say, it does not emanate this time from Menlo Park, though Mr. Edison may of course have pre-invented it many years ago!"

IN the *Institutes of Akbar*, whose reign over a considerable part of India extended from 1560 to 1600, are found the following directions for the artificial freezing of water. Into two parts of water is thrown one part of dry powdered nitre. In this mixture a small stoppered silvered jug containing pure water is stirred about briskly for a quarter of an hour, when its contents will be found to be wholly or partially frozen.

SCIENTIFIC SERIALS

Journal of the Royal Microscopical Society, vol. ii. Nos. 7 and 7*a*, contains:—Transactions of the Society.—W. H. Gilburt, On the morphology of vegetable tissues (Plates 22 and 23).—J. Beck, On the structure of the scale of a species of the genus Mormo.—Prof. E. Abbe, On new methods for improving spherical correction, applied to the construction of wide-angled object-glasses.—H. E. Forrest, On the anatomy of *Leptodora hyalina* (Plates 24 and 25).—Dr. H. Stolterfoth, On a new species of Eucampia.—John Mayall, jun., On an immersion stage illuminator, and on aperture measurements of immersion objectives expressed as "numerical aperture."—J. W. Stephenson, On a table of numerical apertures showing the equivalent angles of aperture of dry, water immersion, and homogeneous immersion objectives, with their respective resolving powers, taking the wave-length of line E as the basis; $a = n$ sin. w, n = refractive index, and $w = \frac{1}{2}$ angle of aperture.—The record of current researches relating to zoology, botany, and microscopy.—Bibliography.—Proceedings of the Society.—The editor announces that the Society has obtained the assistance of Mr. T. Jeffery Parker, Mr. A. W. Bennett, and Prof. F. Jeffrey Bell in the production of the journal.—No. 7*a* is a supplementary number containing the index to vol. ii., List of Fellows of the Society, &c.

Proceedings of the Boston Society of Natural History, vol. xx. part 2, November, 1878, to April, 1879.—Dr. H. A. Hagen, Larvæ of insects discharged through the urethra, and On birds swarming after white ants.—Dr. S. Kneeland, Traces of the Mediterranean nations in the Northern Ocean.—Dr. H. A. Hagen, Remarks on white ants.—President Bouvé, Remarks on the death of Dr. J. B. S. Jackson.—Prof. N. S. Shaler, Evidences of a gradual passage from sedimentary to volcanic rocks in the Brighton district.—Dr. H. A. Hagen, Flies from a petroleum lake.—W. O. Crosby, Occurrence of fossiliferous boulders in the drift of Truro, Cape Cod.—Dr. S. Hunt, On the pre-Cambrian rocks of Great Britain.—W. H. Patton, Synopsis of the New England species of Colletes.—J. S. Kingsley, Notes of North American Decapoda.—W. P. Crosby, A possible origin of petro-silicious rocks.—B. D. Halsted, The American species of Characeæ. The author enumerates eight species of Nitella, one of Tolypella, and nine of Chara, one of which, *C. robbinsii*, from Rhode Island, is described as new.—Dr. C. S. Minot, Growth as a function of cells, and On certain laws of histological differentiation.—Rev. G. F. Wright, The kames and moraines of New England.—Mr. W. Upham, Glacial drift of Boston and vicinity.

SOCIETIES AND ACADEMIES

London

Royal Society, December 18, 1879.—"On the Histology of *Hydra fusca*." By T. Jeffery Parker, B.Sc., Lecturer on Biology in Bedford College, London, and Demonstrator in the Royal School of Mines. Communicated by Prof. Huxley, Sec.R.S. (From the Biological Laboratory of the Royal School of Mines.)

The following is an abstract of the paper:—The correctness of Kleinenberg's view of the relations of the muscular fibres was proved by longitudinal sections of ammonic bichromate specimens, in which the fibres were obtained *in situ* in direct connection with the attenuated inner ends of the ecdoderm cells.

No interstitial tissue could be made out in the thinnest sections of the tentacles; this tissue, therefore, cannot be the exclusive source of the nematocysts.

A distinct supporting lamella was clearly made out between the muscular layer and the endoderm.

The endoderm is shown to be, in all probability, ciliated throughout. Sections of osmic acid specimens showed each cell to bear one, two, or three, long, flagelliform cilia.

The active amœboid movements of the endoderm cells during life is strongly insisted on, the pseudopodial processes given off from them sometimes almost or entirely obliterating the digestive cavity.

It is suggested that the dark irregular granules found in the endoderm cells are food particles derived from the alimentary canals of the Entomostraca devoured. In one instance a diatom frustule was seen to be imbedded in a cell. Hydra thus, unlike most Metazoa, exhibits what Metschnikoff calls a "parenchymatous" mode of digestion.

Nematocysts are proved to occur here and there in the endoderm.

Paris

Academy of Sciences, December 29, 1879.—M. Daubrée in the chair.—M. Faye presented the *Annuaire du Bureau des Longitudes* for 1880, which contains, *inter alia*, tables of refractive indices, densities of minerals, dilatations of metals and crystalline bodies, all known gases, with formulæ, &c., data of thermochemistry, a map of lines of equal magnetic declination for France and neighbouring localities, and a work on statistical geography.—Note on the different branches of kinematics, by M. Resal. M. Mannheim has recently introduced the expression *kinematic geometry;* this branch dealing with motion independently of forces and times. It is not simply the geometrical part of kinematics as studied hitherto.—On some applications of elliptic functions, by M. Hermite.—On hydride of copper; reply to M. Wurtz, by M. Berthelot.—On the heat of formation of gaseous hydrate of chloral; reply to M. Wurtz, by M. Berthelot.—On the butyric ferment (*Bacillus amylobacter*) in the coal epoch, by M. van Tieghem. Examining numerous silicified rootlets of coniferæ from the coal strata, he finds signs of the same process in destruction of tissues as now; development of *Bac. am.* in the organs, either in the form of slender jointed filaments, or inflated rods each with a terminal spore, or innumerable free spores, amid homogeneous silica or ranged against the cuticle or vessels.—On the oxidation of alcohol by ammoniacal bioxide of copper, by M. Letellier. He heated the mixture at 180° in a sealed tube; the blue liquor becomes colourless, and the alcohol is changed into acetic acid.—On a property of certain functions similar to algebraic functions, by M. Picard.—On the impossibility of the algebraic relation $X^n + Y^n + Z^n = 0$, by M. Lionville.—On the determination of the elements of a vibratory movement; measurement of the phase, by M. Mercadier.—On a new electric burner, by M. Perruche. The "candle" part consists of three carbons, two being cylindrical (0·004 m. diameter) and applied to each other, the other of square section (0·005 m. a side), and placed in the angle formed by the first two. The cylinders are in pivoted brass holders, between brass plates, brought together by a spring. The holder of the square carbon is also capable of oscillation, and this carbon is held by a spring in contact with the others, while no current passes, but, when the current begins, takes its separate position. It is regulated by an iron lever and electro-magnet in circuit.—On a new phoneidoscopic process by coloured rings, by M. Guébhard. A development of his experiment of producing coloured rings by breathing on a surface of impure mercury. He shows the characteristic figures of the principal vowel sounds. They prove that the vocal emission in uttering these sounds does not present merely the longitudinal vibratory state of a cylindrical column (as indicated by manometric flames, &c.), but a very complex vibratory state at right angles to the direction of propagation, and whose influence cannot be negligible in the final wave. This has an obvious bearing on the sensibility of telephonic plates, which are affected by multiple centres of percussion.—Action of permanganate of potash on cyanide of potassium, by M. Baudrimont. This generates much nitrite and little urea in an alkaline medium, while much urea is formed if the medium tend to acidity by addition of SO_3HO. The greatest proportion of urea results from mixture of cameleon and cyanide in equal equivalents in presence of an excess of sulphuric acid.—Action of hydracids on isoprene; reproduction of caoutchouc, by M. Bouchardat. Isoprene behaves to hydracids like valerylene, fixing one or two molecules of acid and giving identical or isomeric compounds, with very similar properties; only isoprene (unlike valerylene) furnishes with dissolved acids an elastic polymer.—On the structure of sudoriparous glands, by M. Ranvier.—Alterations of cutaneous nerves in a case of congenital ichthyosis, by M. Leloir.—On the locomotion of insects and of arachnida, by M. Carlet. Insects of slow pace, and with equidistant legs, rest on a sustaining triangle formed of the two extreme legs on one side and the middle leg on the other, while they move the three other legs. In arachnida the polygon of sustentation is formed by the first and third leg on one side and the second and fourth on the other.—On the presence of diamond in an ophitic rock of South Africa, by MM. Fouqué and Lenz.

Vienna

Imperial Academy of Sciences, October 16, 1879.—The following among other papers were read:—On the physiological regeneration of the ciliated epithelium of the trachea, by Dr. Drasch.—On the solubility of mixtures of chloride of sodium and chloride of calcium at different temperatures, by Herr Schönach.—On a species of configuration in the plane and in space, by Herr Kantor.—On the causes of severe winters in Europe, by Herr Wolz.—Researches on the rain-conditions of Austria-Hungary, by Herr Hann.—Contributions to a monography of the genus Megalodus, with special reference to the mesozoic forms, by Prof. Hörnes.—A new chemical photometer by means of mercury oxalate, for determining the intensity of ultra-violet rays, and contributions to the photo-chemistry of mercury chloride, by Dr. Eden.

ERASMUS DARWIN

Erasmus Darwin. By Ernst Krause. Translated from the German by W. S. Dallas. With a Preliminary Notice by Charles Darwin. Portrait and Woodcuts. (London: Murray, 1879.)

THE memory of this great man has suffered from the florid and spiteful biography written by Miss Seward. That she was animated by a feeling of bitterness towards Erasmus Darwin, engendered by disappointment, is clearly shown in these pages; she was an unsuccessful candidate for the post of his second wife, and she seems never to have forgiven him for his blindness towards her merits. A trustworthy life of the author of the "Botanic Garden" was therefore much wanted, and no one could have been better qualified for the task than his grandson, Charles Darwin. He has done his work so well and completely as to leave no room for any subsequent biography; further criticism there may well be, but the facts of the life of Erasmus Darwin can never be better put together, and they are as fully given as there is any need for. The critical essay by Herr Krause forms only little more than one-third of the modest volume, and is really an appendix to the life by Mr. Darwin.

Erasmus Darwin was born of a good family at Elston Hall, Notts, on December 12, 1731. He was educated at a school at Chesterfield, from which he went to St. John's College, Cambridge, and subsequently to Edinburgh to study medicine. In 1756 he settled at Lichfield as a physician, and married in 1757, his wife dying in 1770. He married a second time in 1781, when he settled at Derby, where he died in 1802. From his earliest years he seems to have had a taste for versifying and mechanics, and when very young he made experiments in electricity with a rude apparatus of his own invention. Mr. Darwin gives a most amusing letter addressed to his grandfather when at Chesterfield, by Susannah, the sister of the latter, in which she sets down in a very incongruous fashion the details of four days' fasting in Lent. The reply of Erasmus (ætat 16) was characteristic:—

> "I fancy you forget in Yours to inform me y^t your Cheek was quite settled by your Temperance, but however I can easily suppose it. For y^e temperate enjoy an ever-blooming Health free from all y^e Infections and disorders luxurious mortals are subject to, the whimsical Tribe of Phisitians cheated of their fees may sit down in penury and Want, they may curse mankind and imprecate the Gods and call down y^t parent of all Deseases, luxury, to infest Mankind, luxury more destructive than y^e Sharpest Famine; tho' all the Distempers that ever Satan inflicted upon Job hover over y^e intemperate; they would play harmless round our Heads, nor dare to touch a single Hair. We should not meet those pale thin and haggard countenances which every day present themselves to us. No doubt men would still live their Hunderd, and Methusalem would lose his Character; fever banished from our Streets, limping Gout would fly y^e land, and Sedentary Stone would vanish into oblivion and death himself be slain."

Even at this early age is seen his leaning towards vegetarianism and abstinence from alcoholic drinks, which he subsequently carried into almost regular practice. This was not the only respect in which Erasmus Darwin was far ahead of his own time and even of ours. In sanitary matters he could read a lesson even to our advanced age, and with his mechanical genius he carried out his ideas in this respect into practice as far as the circumstances of the time would permit. He advocated the abolition of intra-mural interments, a rational treatment of the insane, radical reform in female education, and the abolition of slavery at a time when all the world, including the Society for the Propagation of the Gospel, regarded it as a divine institution. His little work on female education was translated into German, where it was regarded as an authority, and he carried out his ideas on the subject in the case of his own daughters, whom, for example, he taught to swim. He was a radical in politics, and a theist in religion, as his works amply testify, though his indiscriminating and bigoted contemporaries stamped him as an atheist. His friendship was wide, both in England and on the Continent, and included many of the most eminent men of his time. He was a man of great influence among his neighbours, and was specially beloved by the poor and needy, a common epithet coupled with his name being that of Benevolent. He was slightly irascible in temper, his massive face pitted from smallpox, he walked with a limp, and although he stammered in speech, he was one of the best conversationalists of his time. He soon acquired a good practice in Lichfield, and as a physician his fame reached George III., who wanted him to settle in London; but Darwin's desires in regard both to fame and income were moderate, and he preferred the quiet of Lichfield. His chief recreation was in tending eight acres of land near the city, which he converted into a botanic garden. Apart altogether from his position in the history of science, it will thus be seen that Erasmus Darwin was a man of unusual originality and independence of mind, who could rise far above the beliefs and customs of his time. But for us he is mainly interesting for the position his works hold in the history of the doctrine of evolution. We are inclined to think that had Erasmus Darwin not chosen to throw his ideas on this and other scientific matters into the form of verse, the theory itself and his claim to be the originator of it in its modern form would have been much sooner recognised. The works in which he embodied his speculations and theories are "The Botanic Garden," in its two parts, "The Loves of the Plants," and "The Economy of Vegetation," the latter, although the first part, having been published last; the former probably first appeared in 1788. Then followed the "Zoonomia" in 1794, soon after translated into German, French, and Italian; the "Phytologia" was published in 1800, and "The Temple of Nature, or the Origin of Society," the year after the author's death. In England, at least, where these works first appeared, they were treated mainly as poems, the scientific speculations which they contained, if referred to at all, being generally regarded as the mere fancies of a poet, or the dreams of a rhapsodist. As poems they had a reputation which must seem to the readers of to-day wonderful. Such men as Walpole and Edgeworth spoke of them with rapture, though the parody of the "Loves of the Plants," known as the "Loves of the Triangles," seems to have done much to destroy the reputation of the original.

Coleridge invented the term "Darwinising" to express his contempt for the speculations of the elder Darwin, and the *Edinburgh Review* treated his poems in its well-known "this-will-never-do" style. Still Darwin's poems contain many brilliant passages, yet we fear no reader of the present day would care to read them through merely as literary productions. Any one, however, who desires to master the history of the progress of scientific theory, must study them carefully; and this is what Herr Krause has done in order to be able to write the critical essay appended to the biography by Mr. Darwin, an essay which Mr. Dallas has turned into excellent English.

Herr Krause, then, claims for Erasmus Darwin that he is the real father of the doctrine of evolution in its modern form, and that much of the credit which has been ascribed to Lamarck is really due to his predecessor. No one can read Herr Krause's careful paper, fortified as it is with numerous extracts from the elder Darwin's works, without being convinced that the claim he upholds is just. True, Darwin often saw as in a glass darkly, what his greater grandson has been able to see and to show us face to face. But when we remember the state of scientific theory in his time, and the scanty store of data at his command, we cannot but be struck with the real penetrative genius of the man, and wonder that he was able to see so much. His powerful and thoroughly scientific imagination helped him to leap over many difficulties, which the Darwin of to-day has been able to bridge by an abundance of fresh facts. As might be expected, the elder Darwin's ideas are sometimes crude and undeveloped; when he seems in a fair way to arrive at the full-blown ideas connected with the doctrine of evolution such as we have it now, he sometimes turns aside ere the goal is reached, and concludes with something that is only half the truth. Here is how Herr Krause speaks of him:—

"I was speedily convinced that this man, equally eminent as philanthropist, physician, naturalist, philosopher, and poet, is far less known and valued by posterity than he deserves, in comparison with other persons who occupy a similar rank. It is true that what is perhaps the most important of his many-sided endowments, namely, his broad view of the philosophy of nature, was not intelligible to his contemporaries; it is only now, after the lapse of a hundred years, that by the labours of one of his descendants we are in a position to estimate at its true value the wonderful perceptivity, amounting almost to divination, that he displayed in the domain of biology. For in him we find the same indefatigable spirit of research, and almost the same biological tendency, as in his grandson; and we might, not without justice, assert that the latter has succeeded to an intellectual inheritance, and carried out a programme sketched forth and left behind by his grandfather.

"Almost every single work of the younger Darwin may be paralleled by at least a chapter in the works of his ancestor; the mystery of heredity, adaptation, the protective arrangements of animals and plants, sexual selection, insectivorous plants, and the analysis of the emotions and sociological impulses; nay, even the studies on infants are to be found already discussed in the writings of the elder Darwin. But at the same time we remark a material difference in their interpretation of nature. The elder Darwin was a Lamarckian, or, more properly, Jean Lamarck was a Darwinian of the older school, for he has only carried out further the ideas of Erasmus Darwin, although with great acumen; and it is to Darwin, therefore, that the credit is due of having first established a complete system of the theory of evolution."

Herr Krause then proceeds to analyse "The Botanic Garden" and other works, in order to produce evidence of the claim he maintains on behalf of Erasmus Darwin. It is interesting to read in a note appended by Darwin to a verse in "The Botanic Garden," the following idea and first scheme of the theory of evolution:—

"'From having observed the gradual evolution of the young animal or plant from its egg or seed; and afterwards its successive advances to its more perfect state, or maturity; philosophers of all ages seem to have imagined that the great world itself had likewise its infancy and its gradual progress to maturity; this seems to have given origin to the very antient and sublime allegory of Eros, or Divine love, producing the world from the egg of Night, as it floated in chaos.'"

It is in the "Economy of Vegetation" that the well-known prophetic lines on the power of steam occur:—

"'Soon shall thy arm, Unconquer'd Steam, afar
Drag the slow barge, or drive the rapid car;
Or on wide-waving wings expanded bear
The flying-chariot through the fields of air.
—— Fair crews, triumphant, leaning from above,
Shall wave their flutt'ring kerchiefs as they move;
Or warrior-bands alarm the gaping crowd,
And armies shrink beneath the shadowy cloud.'"

Darwin goes on then to describe the formation of the earth, which he maintains was shot forth from a volcano in the sun, the formation of a nucleus, the precipitation of water, the formation of clouds, &c.:—

"In this connection the fossil marine animals also come under discussion; and after mentioning the singular circumstance that most fossil marine animals as, for example, the ammonites, are no longer found living, whilst the living animals do not occur in the fossil state, the author raises the questions, 'Were all the ammoniæ destroyed when the continents were raised? Or do some genera of animals perish by the increasing power of their enemies? Or do they still reside at inaccessible depths in the sea? Or do some animals change their forms gradually and become new genera?'"

How very near the now accepted truth is this! While he divined the principle of mimicry in plants, and speculated on the interesting subject of their fertilisation and their relation to insects, he here just missed the truth from his want of knowledge of facts; had he had as much power of patient observation as his grandson, he would have come nearer the truth in this matter. While he held even bold speculation to be of value to science, he distinctly recognised observation and experiment as the only true bases of scientific progress, as will be seen in his admirable address to the Philosophical Society of Derby, of which he was one of the founders; he defined a fool as "A man who never tried an experiment in his life." The fundamental idea of Darwin's "Zoonomia," it seems to Herr Krause—

"Is that in plants and animals a living force is at work, which, endowed in both with sensibility, is enabled *spontaneously* to adapt them to the circumstances of the outer world, so that the assumption of innate ideas, of divinely implanted impulses and instincts is rendered unnecessary, and even the process of thought appears attainable as the legitimate activity of a mechanical analysis and combination. All kinds of human knowledge originate from the senses, the action of which is regarded as the chief source of knowledge, and is accordingly first of all investigated.

"As regards the apparently inborn faculties which young animals bring with them into the world, the author explains them by repeated exertions of the muscles under the guidance of the sensations and stimuli.

"The author very carefully studied this subject, which has been elaborated by his grandson with so much success, and deduces his formulæ especially from the *first* impressions of new-born creatures. The trembling of fear may perhaps be referred back to the cold shivering of the new-born infant; and weeping to the first irritation of the lachrymal glands by cold air, as well as by pleasant and disagreeable odours. That anger and rage are universally expressed by animals taking the position of attack, is immediately intelligible. As regards smiling and the expression of the agreeable sensations, the author refers them, as well as the feeling of the beauty of undulating lines and of rounded surfaces, to the pleasure of the first nourishment derived from the soft and gently rounded maternal breast."

Here also is a remarkable passage in which the principle of heredity is distinctly recognised:—

"'The ingenious Dr. Hartley in his work on man, and some other philosophers,' says Darwin, 'have been of opinion, that our immortal part acquires during this life certain habits of action or of sentiment, which become for ever indissoluble, continuing after death in a future state of existence; and add, that if these habits are of the malevolent kind, they must render the possessor miserable even in heaven. *I would apply this ingenious idea to the generation, or production of the embryon, or new animal which partakes so much of the form and propensities of the parent.*' And he continues as follows: 'Owing to the imperfection of language the offspring is termed a *new* animal, but is in truth a branch or elongation of the parent; since a part of the embryon-animal is, or was, a part of the parent; and therefore in strict language it cannot be said to be entirely *new* at the time of its production; and therefore it may retain some of the habits of the parent-system.'"

In the "Zoonomia" there are many passages we should like to quote, in which many of the doctrines associated at the present day with the name of the younger Darwin, are enunciated with wonderful clearness, even to sexual selection, the struggle for existence, and the survival of the fittest. Speaking of the weapons with which the males of animals are armed, and their contest for the possession of the female, he says:—

"'*The final cause of this contest amongst the males seems to be, that the strongest and most active animal should propagate the species, which should thence become improved.*'"

He concludes as follows the long passage in which this idea occurs:—

"'From thus meditating on the great similarity of the structure of the warm-blooded animals, and at the same time of the great changes they undergo both before and after their nativity; and by considering in how minute a portion of time many of the changes of animals above described have been produced; would it be too bold to imagine, that in the great length of time, since the earth began to exist, perhaps millions of ages before the commencement of the history of mankind, would it be too bold to imagine that all warm-blooded animals have arisen from one living filament which THE GREAT FIRST CAUSE endued with animality, with the power of acquiring new parts, attended with new propensities, directed by irritations, sensations, volitions, and associations; and thus possessing the faculty of continuing to improve by its own inherent activity, and of delivering down those improvements by generation to its posterity, world without end!'"

In his "Temple of Nature":—

"About the first hundred verses are devoted to a description of the pitiless struggle for existence which rages in the air, on the earth, and in the water, making the earth, with its incessantly warring inhabitants, like a vast slaughter-house:—

"'Air, earth, and ocean, to astonish'd day
One scene of blood, one mighty tomb display!
From Hunger's arm the shafts of Death are hurl'd,
And one great Slaughter-house the warring world!'"

Many more passages might be quoted all tending to prove what a really wonderful grasp the elder Darwin had of these doctrines, to which, through his grandson, his name is now so justly attached. But enough has been given to show that he deserves one of the highest places among those who have contributed to the progress of true science, and that the verdict of Herr Krause is amply borne out:—

"*That he was the first who proposed and consistently carried out, a well-rounded theory with regard to the development of the living world,* a merit which shines forth most brilliantly when we compare with it the vacillating and confused attempts of Buffon, Linnæus, and Göthe. It is the idea of a power working from within the organisms, to improve their natural position; and thus, out of the impulses of individual needs, to work towards the perfection of Nature as a whole."

Erasmus Darwin's system was in itself, as Herr Krause puts it, a most magnificent first step in the path of knowledge which his grandson has opened up for us. We ought to be grateful to Herr Krause for taking the pains he has done to show the true place of Erasmus Darwin in the history of science. There are many points in Mr. Darwin's intensely interesting, simple, and characteristic memoir we should have liked to notice, did space permit. The memoir is eminently candid and free from bias or anything like strong language, even when rebutting calumnies. Mr. Charles Darwin, we may say, is the son of Robert Waring Darwin, the third son of Erasmus by his first wife. A genealogy of the family is given which is of great interest in connection with the subject of hereditary genius, so well treated by Mr. Francis Galton, himself a descendant of the elder Darwin.

NORTH AMERICAN ETHNOLOGY

Contributions to North American Ethnology. Vol. iii. *Tribes of California.* By Stephen Powers. (Washington, 1877.)

"IT has been the melancholy fate of the Californian Indians to be more vilified and less understood than any other of the American aborigines. They were once probably the most contented and happy race on the continent, in proportion to their capacities of enjoyment, and they have been more miserably corrupted and destroyed than any other tribes within the union. They were certainly the most populous, and dwelt beneath the most genial heavens and amidst the most abundant natural productions, and they were swept away with the most swift and cruel extermination." Words such as these are now only too familiar to the ethnologist, and do not refer alone to the Californian Indians. As the ethnographic facts are slowly accumulated upon which general anthropology is founded, there comes the conviction in many cases that we are dealing with customs and beliefs that have already reached the twilight of their existence. The crania in our museums will soon be the only physical relics of many races that can just be said to still exist. The desire has therefore long been expressed for the immediate production of faithful and exhaustive monographs, by competent observers, of many of these fast-fading anthropological shadows. To this demand America is now contributing largely; the present volume relates to the habits, customs, legends, religious beliefs, and geographical distribution of the Californian Indians, information collected by Mr. Powers during three years' residence and travel among those tribes.

This work being the result of personal experiences, and as such of the greatest value, other authorities are necessarily not much quoted, but the reader who would desire a more exhaustive treatment of the subject, can supplement his perusal of this volume by that of the fourth chapter of the first volume of Bancroft's "Native Races of the Pacific States," and it is possible that little more in the way of general Californian ethnological information can be desired. In the introduction it is acknowledged that there is a difficulty in drawing a fine distinction between the Californian Indians and their neighbours, and although there are some customs which appear to differentiate them, these alone are not sufficient, and Mr. Powers considers the "crucial test is that of language." Twenty-eight principal tribes and some smaller ones related thereto are recognised and receive separate treatment.

La Pérouse compared these Californians from their dark colour to the negroes in the West Indies, and Prichard, generalising from the accounts of Rollin and Kotzebue, boldly compared the shape of their heads and features to those of the "Negroes of Guinea, New Guinea, and the New Hebrides." Without however ourselves attaching importance to these assumed or superficial resemblances, the above writers might have adduced another fact for the supposed negroid type from Mr. Powers, who tells us that "all Californian Indians emit an odour peculiar to themselves."

The women of the Kā-rok tribes are described as having, apart from tattooed chins, "a piquant and splendid beauty," which has resulted in much intermarriage with the whites, many pioneers, "including four county officers and the only editor in Klamath County, having taken them to wives." This is another illustration of the pregnant fact, pointed out by many writers during the last few years, that with the Indian tribes in North America there has in many cases been much assimilation, and not only extermination. It is stated, however, that among "half-breed" children a decided majority are girls. "Often I have seen whole families of half-breed girls, but never one composed entirely of boys, and seldom one where they were more numerous." It would be interesting to know the proportion of male to female births among the Californians themselves. Franz Mayer has stated that there are more boys than girls in Upper California. Among the Nozi tribe, whose stature is short, the children "often remain mere dwarfs until they are ten or fifteen years old, when they start and shoot up suddenly eighteen inches or so."

These Californian Indians have a considerable power of botanical discrimination. Of the Patawat tribe it is stated, "there is not the smallest moss or lichen, not a blossoming shrub, or tree, or root, not a flower or vine, no forest parasite, bulrush, or unsightly weed, growing in the water or out, or any sea-weed or kelp, for which they have not a specific name;" and Mr. Powers asserts without hesitation that an average intelligent Indian, even if not a shaman, has at command a much greater catalogue of names than is possessed by nine-tenths of Americans. It is, however, incorrect to say, at p. 419, that savages have no systematic classification of botanical knowledge —"there are no genera, no species." The same remark has been made by Dr. Peschel in his "Races of Man." Dr. Hector, on the contrary, has informed us that the Maoris of New Zealand have not only distinct names for nearly all their plants, but generic names, by which they group plants according to their affinities, in a way impossible to most people who were not educated botanists. These Californians sometimes exhibit morbid anticipations of death. Amongst the Pomo, the authority of Robt. White is given for the fact that aged men and women in early expectation of their demise, frequently dig their own burial-place, and then repair thither daily for months together, eating their repast at the mouth of the grave; whilst amongst the Wintun, Mr. Powers relates that sometimes an aged woman will wear around her for months, the rope wherewith she is to be wrapped when a corpse.

Mr. Powers also contributes a most valuable addition to Californian folk-lore in the numerous legends that have been exhaustively collected and excellently narrated. It becomes a question, however, whether some of these are truly aboriginal, and uninfluenced by the teachings of the early Spanish missionaries; the "Legend of Gard," p. 80, seems to have had a very possible inspiration from Eastern sources.

This work is more intended for the careful study of the ethnologist than to afford extracts for a reviewer; and though naturally a great part of the information has been previously collated, there is not only much that is decidedly new to science, but the whole forms an excellent example of what can be observed and collected by an ethnologist for ethnology. It is likewise another token of "American Progress;" published by the "Department of the Interior," it is distributed to European students, without barter and without price. It is well illustrated, many patterns of facial tattoo marks being shown. A good map also accompanies the volume, the value of which is farther enhanced by an appendix on Linguistics, edited by J. W. Powell, in which a number of vocabularies are given.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Sunshine Cycles

In Nature, vol. xxi. p. 81, your correspondent, Mr. B. G. Jenkins, with the best intentions, yet does me too much honour in quoting my name from a former volume of NATURE in 1872, as having then announced a cold wave of climate temperature being due to commence in 1878·8; or, as he is kind enough to say, the very day on which the severe winter of the years 1878 and 1879 did begin.

I must decline, at all events, the full honour, for these two reasons: *firstly*, the quoted datum was intended by me to signify the middle, not the beginning, of that cold wave; and as that lasted thirteen months, my date was between six and seven months too soon. *Secondly*, when I published again on the subject in the *Edinburgh Astr. Observations* of 1877, I indicated not 1878·8, but 1877·8 as the probable date of the then coming, now past, wave of cold, or erred much more than in 1872.

I have recently been looking into the reason of that latter calamitous failure, and find it clearly enough now on the plates of projections in that volume in this fact—that the then expected minimum of solar spots was inserted for 1877·5, or nearly two years sooner than sun observations have since then shown it to be. Rectifying, therefore, now that quantity, and in the then absence of our rock thermometers (which had first indicated the remarkable cycles of temperature in striking connection with the whole period, though not the details, of the sun-spots) using merely air-temperatures and re-drawing the curves, the middle epoch of the late cold wave comes out 1879·1, and of the next hot wave 1880·8.

Now these hot waves, I have always maintained, are more important, more regular, and more directly of solar origin, than the cold waves which are rather due to some indirect earthly effects of watery vapour and its transformations. It may be worth while, therefore, when we are now, as I believe, on the threshold of one of the heat-waves, to mention shortly the data on which the expectation is founded.

These are mainly the actual observations of no less than five occasions of such maxima of temperature occurring in a peculiar kind of dependence on successive sun-spot minima; or rather on the beginning, in each case, of the forces of a new spot cycle. The last such heat-wave was in 1868·8, or 1·8 year after the then last sun-spot minimum. Next before that in 1857·9, or 1·9 years after its previous sun-spot minimum. Before that, in 1846·4, or 2·4 years after the same solar test. Before that again, but then depending only on old atmospheric temperature observations, as our rock thermometers were not then existent, in 1834·5, or 1 year after; and still further back, in 1826·5, or also about 1 year after the then last sun-spot minimum.

These intervals from one to the other of the hot waves are by no means arithmetically equal, being 10·9, 11·5, 11·9, and 8·0. This last (really the earliest of the series) is a frightful inequality, but is borne out, *first*, by the sun-spot period of that cycle as given by M. Schwabe, having been also anomalously short; and *second*, by this remarkable testimony, which I have only just become acquainted with, in a pamphlet of most independent character by Sir Robert Christison, Bart., M.D., on tree-growth, read before the Botanical Society in Edinburgh:—

"The wonderful season of 1826, when warmth and sunshine, commencing with March, ended only with September, and when the summer was continuously such as to change in some respects the habits of the people."

The year 1826 was therefore a crucial case, not only for a maximum of temperature and sunshine in Scotland, but for its keeping such remarkable pace with the then anomalously shortened period of sun-spots. While the presently coming case of 1880 will equally prove, by what I have detailed above, that no certain success in weather predictions for several years beforehand can be hoped for, unless the dates of sun-spot minima can be also announced by authority beforehand to a very much smaller quantity than two years of error; and that no *mean* duration of the sun-spot cycle comes close enough to the fact of the large variations between one cycle and another. We must have therefore each cycle of sun-spots fixed by its own dates alone, and not smoothed away and improved out of creation by being made apparently conformable to others.

I have not yet seen, by those able men who believe they have traced sun-spots to planetary influences of position on the sun, any attempt, from the planetary places in almanacs, to compute the dates of all the solar minima of spots, say from 1825 to 1900. But something of that kind appears now to be necessary for the next steps of the science of the future.

Cranial Measurements

IN the notice of my catalogue of crania which you have been good enough to insert in NATURE, vol. xxi. p. 222, your reviewer has given me credit for originality of method, to which I have no wish to lay claim.

1. In reference to the mode of taking the horizontal circumference, it is said that I pass "the tape line, not over the prominence of the glabella, as is customary with craniologists, but above it, around the supra-orbital line." The fact is, that the method which I have adopted, so far from being a deviation from what is customary, is that recommended in the valuable "Instructions Craniologiques," drawn up by Broca and published by the French Anthropological Society, and which is used, certainly by the large majority, if not by all the craniologists with whose writings I am acquainted.

2. With regard to the more important measurement of the antero-posterior diameter of the cranium, more important on account of its influence on some of the most characteristic indices, there are, unfortunately, still considerable differences of method, and it was only after very full consideration of the subject that I decided not to follow the French instructions, but to adopt the plan used by Rolleston in "British Barrows," by Barnard Davis in his "Thesaurus Craniorum," and by the majority of German anthropologists. So fully was I convinced of the expediency of the latter, that after having already measured the whole of the crania in the collection, and calculated the indices by the method which included the prominence of the glabella in the cranial length, I took the trouble to remeasure them, with the results given in the catalogue. The object being to obtain, as near as may be, an idea of the form of the brain case, it appears desirable to exclude all extraneous projections which have no relation to this form. The impossibility of eliminating every source of fallacy, such as those occasioned by the varying thickness of bone or of diploë, is no argument against endeavouring to reduce them, as far as we can, to a minimum. The projection caused by the development of the frontal sinuses should certainly not be omitted in a complete description of a skull, but it no more affects the form of the cranium proper, than the prominence of the nasal bones or of the maxilla, which, important and instructive as they are from other points of view, are usually ignored in giving what is called the maximum length of the skull, although if the term is to be taken in its literal sense, they have as much claim to be included as the glabella or supra-orbital ridges.

Many other arguments might be adduced and authorities given for the usage I have adopted, but I will bear in mind your request for brevity.

Royal College of Surgeons, January 11

"Why the Air at the Equator is not Hotter in January than in July"—Freezing of the Neva

IN NATURE, vol. xxi. p. 129, Mr. Croll gives his reasons why the equator is not much warmer in January than in July, notwithstanding the greater nearness of the sun at the former season. To state the case briefly, he, having recalled the fact that the whole earth is colder in January than in July, because in the former the cold winter of the northern (or principally land) hemisphere coincides with the mild winter of the southern (or principally water) hemisphere, he continues: "Consequently the air which the equatorial regions receive from the trades must have a higher temperature in July than in January. The northern is the dominant hemisphere; it pours in hot air in July and cold air in January, and this effect is not counterbalanced by the air from the opposite hemisphere. The mean temperature of the air passing into the equatorial regions ought therefore to be much higher in July than in January, and this it no doubt would be were it not for the counteracting effects of eccentricity." And further: "There is another case which must also tend to lower the January and raise the July temperature of the equator: the northern trades pass farther south, and consequently cool the equatorial regions more during the former than the latter season."

I maintain that there is no such influence of the northern trades on the temperature of the equator, because they scarcely anywhere reach it, and then because the lower latitudes of the northern hemisphere are not colder in January than those of the southern hemisphere in July. *In the Atlantic the northern trades do not reach the equator at all in January*, but only in February, March, and April, and this but in the western part of the ocean.

The same may be said of the Pacific in its eastern part, where alone the trades are regular. In the Western Pacific, as well as in the Western Indian Ocean, I admit that air from the northern hemisphere reaches to the equator and somewhat beyond in January, but not that this tends to give the equator a lower temperature in this month than in July. According to Dove, the mean temperature of 10° N. in January is 77°·2; of 10° S. in July, 76°·1.

So far as the temperature of the equator is concerned, the southern is the dominant hemisphere, and the equator is certainly cooled by winds coming from the south. If the equator is not everywhere warmer in January than in July, this is caused by the rainy season, which on the equator, and even a few degrees north of it, generally coincides with the southern summer. Where the rains are not very heavy, as, for example, on the Isle of St. Thomas, West Africa, we have: January, 78°·3; July, 75°·7; at Padang, Sumatra, where the rains are exceedingly heavy all the year, there is scarcely any difference at all between the months. Somewhat to the south of the equator, where to the difference in the nearness of the sun is added a much greater height above the horizon in January, we have—

	Jan.	July.	Rainy Season.
Amboina, Molucca Islands, 4° S.	80·9	77·4	May to August.
Batavia, Java, 6° S.	77·7	78·8	December to February.
Pernambuco, Brazil, 8° S.	80·6	75·0	April to July.

so, by the first-rate observations of Batavia, it is established that, so far as 6° S., January is 1°·1 colder than July, because the former is very rainy, while the latter has little rain. Even to 9° lat. N., July is colder than January, if the former has much more rain, so for example—

Island of Fernando Po, W. Africa, 4° N.	79·9	76·5	March to November.
Gondokoro, Upper Nile, 5° N.	81·3	75·7	April to August.
Freetown, W. Africa, 8½° N.	80·4	77·0	June to October.

Thus, in the lowest latitudes of the northern hemisphere, we find differences amounting to 5°·6, while in the southern greater differences than 1°·1 are not known, which may, to a certain degree, be ascribed to the nearness of the sun in January.

I think I have proved that, as to what we call the temperature of the air (really that of the lowest stratum), it is, on the equator and a few degrees north and south from it, far more influenced by the yearly distribution of clouds and rain than by the different amount of heat received from the sun. The result would be different if we knew the temperature of the whole stratum of air. The heating of the upper surface of the clouds by the sun, and especially the heat liberated in the condensation of water must give to the higher strata a superior temperature than that they had in the dry season; in other words, the decrease of temperature with elevation is much slower during the rains than in the dry season, as was shown for India by Mr. Blanford. This is true for other regions, and where the sky is cloudy and rains abundant in the greater part of the year, the temperature of the whole air may yet be higher than in drier climates, where the soil and the lower stratum of air are hotter.

I do not agree with Mr. Croll in what he states at the end of his letter as to the effect of winds in cooling the equatorial regions and rendering them habitable, as they would be too hot for man without the cool air brought from the temperate regions. I think Mr. Croll has enormously over-stated the effects of winds on the temperature of the equator. The extent of the tropical zone is so great, its temperature so very near to that of the equator, the winds which blow across it so gentle, that I consider the effect of the winds from the temperate regions in directly cooling the temperature of the equator to be nearly imperceptible. The following is a good illustration:—Nowhere is the winter temperature so low near the tropics as in Southern China, for example, in January, Canton, 55°·6, Victoria, Hong-Kong, 59°·2. Yet Saigon, in Cochin China, but 11° to the south of Hong-Kong, and subjected to the full force of the north-east monsoon from the China seas, has a January temperature above 77°. Clearly the thermal effect even of the cold winter monsoon is scarcely perceptible farther south.

I consider water to be the only direct cause of the mildness and uniformity of equatorial temperatures, and this in three ways—(1) by the great heat-capacity of water; (2) by the clouds which interpose a screen between the sun and the surface of the earth; (3) by the evaporation of rain-water by the soil and plants.

The first cause is especially powerful on the ocean, while the two latter act especially on land, even very far from the sea. If it was not for the clouds and evaporation, how could we explain, for example, the absence of great heat (hottest month, 78°·6) at Iquitos, on the Amazons, 4° S., and more than 1,000 miles from the Atlantic, where the winds are generally weak?

As to the winds, I admit of their effect in this case; but (1) in causing ocean-currents, and thus removing the heated water from the equator; (2) in spreading the cold air from over the cold currents over a greater distance. The latter is the cause of the low temperature in the equatorial regions of the Eastern Atlantic and Eastern Pacific.

Where the sky is clear and humidity and rains deficient, very high temperatures of the air are attained, even at a great distance from the equator (10°–30°) and this notwithstanding winds of considerable force blowing from cooler regions. So, for example, the north winds blowing in the summer in the Sahara, and coming from the cooler Mediterranean, are certainly stronger than the trades of the ocean and yet do not prevent the desert from attaining a higher temperature than known in any equatorial region.

In the same number of NATURE you committed an error by giving the dates of freezing of the Neva in *old style*. The dates in *new style* are: Mean day of freezing, November 25, earliest October 28 (1805), latest (not quite certain), January 9 (1711), next latest December 26 (1826); mean day of opening, April 21, earliest, March 18 (1822), latest, May 12 (1810); number of days open, 218, least, 172 (1852), greatest, 279 (1822).

Sekpaleruaya 8, St. Petersburg, December 5-17, 1879

Hearing through the Mouth

THE principle of the so called "Audiphone," described in NATURE, vol. xxi. p. 243, is by no means a new discovery, although the application of it may be novel. It has long been known that sounds may be conveyed to the auditory nerves through the mouth when the drum of the ear is defective in its action, although the principle has, perhaps, been little acted upon by aurists. Mr. Rhodes's system is to press the edge of a vibrating metal disk against the upper teeth, and "the vibrations thus taken up by the disk are transmitted through the teeth and bones of the skull to the auditory nerve." (?) Such a remedy will, in many cases, be thought more inconvenient than the defect, and it is by no means necessary thus to jar the teeth and the bones. Although I am not deaf, some years ago I practised the listening to very feeble sounds through the mouth instead of by the outward ear, at the recommendation of the late Sir Charles Wheatstone. The inducing cause was to verify by experiment the true character and the notes of resultant tones, or Tartini's tones, about which no two authors had agreed. Sir Charles lent me one of his symphoniums—little instruments made like his concertinas, except that they were blown by the mouth directly upon the metal springs instead of by bellows. According to his directions I stopped my ears lightly with cotton, but pressed it into the *concha* with a thumb upon the lip of each ear. The little instrument was supported by my third and fourth fingers, leaving the notes to be touched by the first and second fingers of each hand. By thus excluding external sounds I could hear the deep and soft resultant tones to perfection; the instrument should not be tempered because they result from coincident vibrations of the notes sounded above. In these experiments I touched the symphonium as lightly as possible with elongated lips, the cavity of the mouth receiving the sounds. The teeth were covered by the lips.

WM. CHAPPELL

Strafford Lodge, Oatlands Park

Intellect in Brutes

THE numbers of NATURE containing the interesting discussion on this subject have only lately reached us, and it is late to bring forward anything on the question, yet the readers of NATURE will be interested in two instances of "calculation" on the part of wild birds that I have noticed. Some years ago I was overlooking a penguin "rookery" as it is called, at the Falklands, and watching the goings on of the numerous colony below me. It was breeding season, and the birds were sitting on their eggs on the bare earth, crowded together with hardly walking room between them. Amongst the birds stepped a pretty Sheath-bill (*Chionis alba*) with a quiet jaunty stride, picking what he could, and apparently perfectly indifferent to the motions of the penguins, who drove at him with their beaks as he passed, but never struck him. I saw him pass and repass one bird always just out of reach, till the bird could stand it no longer, but reached off her nest about an inch to strike him; he was still just out of reach and busy with something, apparently not noticing the penguin; she reached further, he crossed her again, still just out of reach, and this went on till he had drawn her about two feet from the nest, then in one stride he was beside the egg, had punched a hole, and was sipping the contents before the slow penguin could turn and hop back to save it; he again led her away by the same manœuvre and increased the hole and got a greater part; a third time he led her off and was eating the egg when he was driven right away by another penguin, who was wandering at liberty, the mate, I suppose, being on turn on the egg. The proceeding on the part of the sheath-bill was a perfect trap for the poor foolish old penguin.

The other instance I will give occurred in the Pacific, where some albatross were circling about, and frequently settling on the water in flocks; some sharks were about, and I watched to see if any albatross would be pulled down; then I noticed a cordon of sentries round the flock, who were relieved at times from the flock, a single bird going out and sitting near the sentry who flew in. Whenever a shark's fin approached the sentry he flew in, and the whole flock took up new position. Here was distinct organisation. The ship was going very slowly through the water, and I was able to study the whole carefully. J. P. MACLEAR

H.M.S. *Alert*, Straits of Magellan, November 5, 1879

THE following account of an incident in the early life of a South African baboon may not be out of place in your journal The person who witnessed it was a very trustworthy native attached to Bishopstowe, Natal, and who is employed from time to time to get game for the house. He used to find it an agreeable addition to this duty to collect objects of natural history for the cabinet as well as for the table. He was fully alive to, and took a keen interest in, what went on among the animals of all kinds, and was much struck with what he saw take place one day at the bottom of a little *iDonga*, or dry watercourse, over the brink of which he peeped, on the slope of a table-mountain, the grand object that lies in the front of Bishopstowe, some twelve miles distant.

It was a hot day, and a number of baboons were sunning themselves along the bottom of the *iDonga*. They lay upon their backs, with half-closed eyes, rubbing their stomachs in a state of placid enjoyment. Two or three young baboons had wandered to a little distance down the *iDonga*, searching for scorpions from stone to stone just below them. They were not very successful, and it did not appear that their movements were of much concern to their elders. Presently, however, one of the young ones, turning up a stone, lit upon a particularly fine and fat scorpion, which, with a furtive glance round at his elders, he seized and popped into his mouth, having first pinched off the sting. He at once proceeded to turn the stone over again with great assiduity, as though in further unsuccessful search for scorpions. He had not escaped notice, however, for down the gully in a sluggish roll came a great baboon, who seized the young one by the scruff of the neck, shaking him vigorously until the plump morsel dropped from his pouch. Having gobbled this up, the elder baboon at once regained his lounge, and all went on as before in the sleepy hollow.

London, January 8 FRANCIS E. COLENSO

Notes on the Papuans of Maclay Coast, New Guinea

THE articles on the above subject which have appeared in NATURE, vol. xxi. pp. 204, 226, have been read by me with great interest in consequence of the resemblance which certain of the customs therein described have to some which have come under my observation among the inhabitants of the Andaman and Nicobar Islands.

With regard to the custom of the relatives of deceased persons in the Andamans ornamenting and carrying about the skulls of the departed, which is alluded to in a note on p. 205, I believe I may claim to have first described and figured such a skull. My paper entitled "On a Visit to the Andamanese Home, Port Blair, Andaman Islands" (of which I inclose a copy), was published in the *Proceedings* of the Royal Irish Academy for 1871. In it I mentioned, together with some other facts, that I had witnessed the process of making flakes from a piece of bottle-glass which I saw subsequently employed for shaving.

An Andamanese necklace made of human clavicles and turtles' ribs is now in my possession, and I believe human finger and toe bones are also sometimes strung together and worn round the neck. In reference to the ideograph discovered by Mr. Maclay among the Papuans I would refer to a paper "On Nicobarese Hieroglyphics or Picture Writing," which I communicated to the pages of the *Indian Antiquary* (Bombay) in the year 1875.

The screen which is figured is one out of many which I saw in the Nicobar Islands. It consists of the spathe of a palm and is covered with representations, done in vermilion, of men (in various attitudes), pigs, fish, houses, canoes, weapons, &c., &c. It would take up too much space to give details of it here, but I may state that my conclusion regarding it was that it was the pictorial record of some past event. Both skull and screen are described, but unfortunately not figured, in my recently-published work, "Jungle Life in India."

To any of your readers who may be specially interested in the matter I shall be happy to forward, on application, copies of the papers above mentioned and photographs of the screen so far as the numbers available for the purpose will go. V. BALL

37, Northumberland Road, Dublin, January 9

The Word "Telegraph"

THE word "telegraph" appears to have been naturalised in our language at a much earlier date than that given by Mr. Warren de la Rue in his letter in NATURE, vol. xxi. p. 226. There are several references to the apparatus in the *Gentleman's Magazine* for July, December, 1794, and the next three volumes. At first the word appears in its French form with the final "e," but the sign of its foreign origin soon disappears. Under the date January 28, 1796, we find amongst "Domestic Occurrences" a paragraph stating that "a telegraph was this day erected over the Admiralty." This, I think, was removed about thirty years ago. In case your correspondent should wish to verify the references in the indexes to the *Gentleman's Magazine*, I may point out that there are two pages numbered 106 in the volume for January to June, 1795, and that there is an article at p. 1176 of that for July to December, 1794, not mentioned in the index.

Watt, in his "Bibliotheca Britannica," gives a still earlier reference to the word in R. H. Gower's "Theory and Practice of Seamanship," but there is no mention of a telegraph in the first edition of that work, published in 1793.

The word occurs many times in Dr. Thos. Young's "Lectures on Natural Philosophy," 1807, and some interesting information on the subject may be found in Gregory's "Treatise of Mechanics" (2nd ed.), vol. ii. p. 434 (London, 1807), where several sorts of telegraphs are described.

H.M. Patent Office, January 12 RICHARD B. PROSSER

Stags' Horns

THOUGH, no doubt, as Mr. Stokoe suggests, many antlers are picked up and sold to knife-handle makers, or, if they happen to be good ones, used for "making up" deers' heads, yet many, I believe, are really eaten by the deer themselves. I have never myself seen a deer engaged in eating a fallen antler, nor, though I have more than once found cast horns on the hills, did the latter present any appearance of having been gnawed.

All the hill men will tell you, however, that it is a well-known fact that red-deer eat the horns that are shed every year, and the late Sir Thomas Moncreiffe once told me that he watched a hind—a cervine Delilah—gnawing the tips of the tines of the horns of a stag that was lying beside her, and which he afterwards shot. In Blair Castle there is a magnificent stuffed stag—"Tilt"—which was reared by the late Duke of Athole, who fed it upon, amongst other things, ground deer-horns. As tame stags often do, "Tilt" became dangerous, and had to be killed when he was eight or nine years old. In size he far surpassed any of the wild red-deer, and had most magnificent antlers. As each year's antlers fell off they were preserved, and form an interesting and instructive series.

Considering how fond cows are of gnawing bones, and also how they will eat any woollen garment they can get at, there does not seem to be anything very remarkable in the fact of red deer consuming shed horns. F. BUCHANAN WHITE

Perth, January 2

VISUALISED NUMERALS

I HAVE lately been occupied in eliciting the degree and manner in which different persons possess the power of seeing images in their mind's eye, and am collecting a large and growing store of materials, partly of verbal answers made by friends to my inquiries, but principally by means of written replies to a printed list of questions that I am distributing. The subject bears in many ways upon psychological and ethnological studies, and I should be glad if the present memoir upon one particular branch of it should induce correspondents to furnish me with authentic information of the kind I seek.

The various ways in which numerals are visualised is but a small subject, nevertheless it is one that is curious and complete in itself. My data in respect to it are already sufficiently numerous to be worth recording, and they will serve to show that parallel results admit of being arrived at in other directions.

I may begin by mentioning one or two general experiences. I have been astonished to find how superior women usually are to men in the vividness of their mental imagery and in their powers of introspection. Though I have admirable returns from many men, I have frequently found others, even of the highest general ability, quite unable for some time to take in the meaning of such simple questions as these. "Think of some definite object,—say your breakfast table, as you sat down to it this morning, and consider carefully the picture that rises before your mind's eye. Is the image dim, or fairly clear? Is its brightness comparable to that of the actual scene? Are the objects sharply defined? Are the colours quite distinct and natural, &c.?" On the other hand, I find the attention of women, especially women of ability, to be instantly aroused by these inquiries. They eagerly and carefully address themselves to consider their modes of thought, they put pertinent questions, they suggest tests, they express themselves in well-weighed language and with happy turns of expression, and they are evidently masters of the art of introspection. I do not find any peculiar tendency to exaggeration in this matter either among women or men; the only difference I have observed between them is that the former usually show an unexpected amount of intelligence, while many of the latter are as unexpectedly obtuse. The mental difference between the two sexes seems wider in the vividness of their mental imagery and the power of introspecting it, than in respect to any other combination of mental faculties of which I can think.

Another general experience is that the power of seeing vivid images in the mind's eye has little connection with high or low ability or any other obvious characteristic, so that at present I am often puzzled to guess from my general knowledge of a friend, whether he will prove on inquiry to have the faculty or not. I have instances in which the highest ability is accompanied by a large measure of this gift, and others in which the faculty appears to be almost wholly absent. It is not possessed by all artists, nor by all mathematicians, nor by all mechanics, nor by all men of science. It is certainly not possessed by all metaphysicians, who are too apt to put forward generalisations based solely on the experiences of their own special ways of thinking, in total disregard of the fact that the mental operations of other men may be conducted in very different ways to their own.

I have much to say on this and cognate topics which I pass by on the present occasion, that I may at once proceed to the subject of this paper. The first section of it is of minor interest and may be quickly dismissed. It is the power of mentally seeing numerals, of holding them fast in the field of view, of perusing them when there, and of working sums by mental imagery in the same form as that in which they are usually carried on with pen and paper.

Here is a well marked case of the power of visualising numerals. The writer is an office-bearer of one of our scientific societies:—

1. If words such as fifty-six be spoken, I most clearly, easily and instantly visualise the figures. I do so almost automatically. I perceive that when I speak the word "thousand" or hear it spoken, the figures at once group themselves together. I find it quite impossible to think of the date of a year without remembering and visualising the figures, though I express myself in words. The figures are always printed; in type and size they resemble those commonly used for the headings of newspapers. I cannot, however, appreciate a back-ground, the figures appear simply in space. I think that by practice and concentration I could hold fast many figures.

The next is by a friend who has a most tenacious memory for numerical administrative details:—

2. I can see and mentally retain many figures, and can multiply four figures by four figures without practice, the operation proceeding visibly in my mind like a sum upon paper.

The following is by a school-boy who is a near relation of a man of the highest mark in science:—

3. I can visualise a fairly long line of figures, and I do mental sums by putting down the working of them in my mind's eye, up to square roots with two figures in the root, and in algebra, to simple quadratics.

A schoolmistress writes:—

4. I can retain several figures in my mental view and work examples, seeing every figure in the process.

A late Fellow of Trinity College, Cambridge, states:—

5. All arithmetical processes performed mentally, are exactly the processes I should perform on paper.

It must not, however, be imagined for a moment, that the processes of mental arithmetic are necessarily wholly dependent on the faculty of visualising numerals. Here is a good instance to the contrary. The writer is the author of a valuable work on a branch of Mental Philosophy:—

6. The numerals are merely ideal sounds [to me], not ideal sights in any way. I have, or used to have, very considerable powers of mental arithmetic and mental algebra, but always used in thought the sounds of the signs. In the process I always forgot every step as soon as I had reached the result of that step.

This last sentence is exceedingly suggestive, and reminds one that many so-called "unconscious" acts are not really unconscious, but are acts characterised by an exceedingly brief and evanescent period of consciousness.

The processes of mental arithmetic are commonly dependent on the representation of more than one sense, as in the following instance:—

7. I can multiply with effort four figures by four; but partly only by images, chiefly by memory.

I am as yet unable to determine the percentage of persons who possess in the various degrees, the power of visualising numerals, because my returns are chiefly derived from persons who are exceptionally gifted. An excellent way of obtaining average returns to psychological questions would be by the help of schoolmasters, who have an admirable field of psychological research immediately before them, which they wholly neglect. If a hundred boys in a large school could be set simultaneously to answer such questions as those I am putting, after their masters had clearly explained their purport to them, and had taken common precautions to insure independent replies, and to sift away lax and untrustworthy statements, the thing would be effected by a single stroke, and both boys and masters would enjoy the satisfactory feeling of having accomplished a substantial piece of scientific research.

I have many curious cases of colour association with the various numerals, but shall only give a very few instances of them, and those incidentally, in the present paper. I shall also abstain at present from speaking of the many different ways in which dates, days of the week, and months of the year are apt to be visualised.

The topic to which I especially wish to direct attention, is the innate and hereditary tendency of certain persons to see numbers in definite and constant arrangements or schemes, whose various characters will be easily understood from the extracts I am about to give and by the accompanying illustrations, which are reductions to a small scale of the pictures I have received, with a necessary sacrifice of detail in a few cases.

The simplest instances do not seem to be the commonest; thus, I have very few indeed that could be classed with the following:—

8. When a child, I counted by means of imaginary cards from ace to ten. My little boy in the same way, used an imaginary domino.

Or this:—

9. I picture numbers in groups, thus 5 is sometimes ⁚·⁚, sometimes ⁖·, 8 is ⁞⁞, 7 is ⁞⁝, 100 is ten rows of ten.

I may as well give the remainder of this communication here; it is written by a lecturer upon mental philosophy. He says:—

10. The numerals 1, 2, 3, 4, &c., from the part they play in the multiplication table, have been personified by me from childhood. 9 is a wonderful being of whom I felt almost afraid, 8 I took for his wife, and there used always to seem a fitness in 9×9 being so much more than 8×8. 7 again is masculine; 6, of no particular sex but gentle and straightforward; 3, a feeble edition of 9, and generally mean; 2, young and sprightly; 1, a common-place drudge. In this style the whole multiplication table consisted of the actions of living persons, whom I liked or disliked, and who had, though only vaguely, human forms.

The schemes in which numerals appear are usually fantastical and sometimes very elaborate. I will (by permission) give the name of the writer of the first instance about to be adduced, on account of the hereditary interest that is attached to it. It is by Mr. George Bidder, Q.C., a son of the late eminent engineer, who was known in early life as the calculating boy. Mr. George Bidder inherits much of his father's marvellous power of mental arithmetic, being able, though not with equal precision and rapidity, to mentally multiply fifteen figures by another fifteen figures. This faculty has been again transmitted, though in an again reduced degree, to the third generation. (*See* letter in the *Spectator*, December 28, 1878, also the early numbers of that paper in 1879.)

He writes to me as follows:—

11. One of the most curious peculiarities in my own case, is the arrangement of the arithmetical numerals. I have sketched this to the best of my ability. Every number (at least within

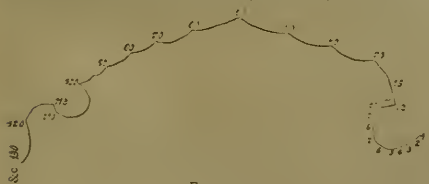

Fig. 1.

the first thousand, and afterwards thousands take the place of units) is always thought of by me in its own definite place in the series, where it has if I may say so, a home and an individuality. I should, however, qualify this by saying that when I am multiplying together two large numbers, my mind is engrossed in the operation and the idea of locality in the series for the moment sinks out of prominence. You will observe that the first part of the diagram roughly follows the arrangement of figures on a clock-face, and I am inclined to think that may have been in part the unconscious source of it, but I have always been utterly at a loss to account for the abrupt change at 10 and again at 12.

It occurs to me that the change is probably due to the wrench given to the mental picture of the clock dial in order to make its duodecimal arrangement conform to the decimal system, and that the same action is repeated at 110.

The next diagram exhibits the most compact of all the mental schedules which I have as yet received:—

12. The representation I carry in my mind of the numerical series is quite distinct to me, so much so that I cannot think of any number but I at once see it (as it were) in its peculiar place in the diagram. My remembrance of dates is also nearly entirely dependent on a clear mental vision of their *loci* in the diagram. This, as nearly as I can draw it, is the following:—

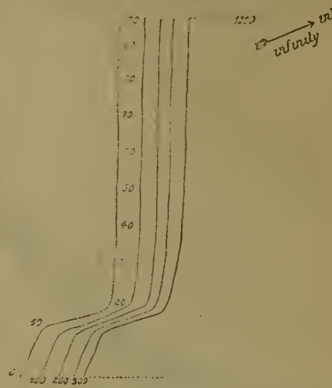

Fig. 2.

It is only approximately correct (if the term "correct" be at all applicable). The numbers seem to approach more closely as I ascend from 10 to 20, 30, 40, &c. The lines embracing a hundred numbers also seem to approach as I go on to 400, 500, to 1,000. Beyond 1,000 I have only the sense of an infinite line in the direction of the arrow, losing itself in darkness towards the millions. Any special number of thousands returns in my mind to its position in the parallel lines from 1 to 1,000. The diagram was present in my mind from early childhood; I remember that I learnt the multiplication table by reference to it, at the age of seven or eight. I need hardly say that the impression is not that of perfectly straight lines, I have therefore used no ruler in drawing it.

Some writers have somewhat rashly asserted that our idea of numbers is always based on our ten fingers and ten toes. There are, however, other forms in use by various nations than those of decimal arithmetic, and the last paragraph of the foregoing seems sufficient to show that the finger and toe hypothesis is not universally true. This opinion was strongly maintained by the lady writer of the following remarks, whose imagery dates beyond her earliest recollections:—

13. The annexed column [a portion only of it is represented here] represents how I see the numbers from 1 to 140. There is no break up to 30, and none from 90 to 130, but I think this is because the three figures at 100 make a sort of break of themselves. After 140 they go on regularly, but farther off. The figures are not one *above* the other, as they appear in the diagram, but are one *beyond* the other, stretching away into space. They are about half an inch long, of a light grey colour on a darker and brownish grey ground.

&c.

Fig. 3.

The next example is very curious; the diagram which accompanies it is carefully and minutely drawn on a large sheet of paper and looks like a detailed route survey made by a careful traveller. I have been obliged to treat it much as a map maker would treat such a survey.

14. I find it very difficult to represent my visualisation of numerals diagrammatically. I scarcely ever see the lower numbers written; I simply know exactly where 6, 7, 4, &c., are to be found. I cannot properly represent the crowding of numbers in some places, nor the edgewise positions they occupy, nor can I at all adequately express the compactness and yet extent of the line. On either side of it there seems to be indefinite space. But there is a boundary at 1, *beyond* which I have to look for *minus* quantities. After 108 the notion of place becomes hazy and indistinct, though I can visualise the higher numbers in respect to their position, if I make the effort. I think of a million as *very* far off and high up. When multiplying for example 5 × 6, I know instantly the spot where the product will be, and look to see what number it is. But if asked to multiply 14 × 17 I first go up to the place whereabouts I expect it will be, and am baffled. I do not know where to look. In the coloured parts, it is the place rather than the number that is coloured, and the number is connected with colour because it happens to be in that place. The brightness and darkness may possibly in the lower numbers have some connection with the events of my life, the numbers which correspond to years of my age which were eventful, being as a rule much more distinct. As a child I had great liking for the number six, arising I fancy from a keen desire to be six years old. I had also an excessive love for blue, so perhaps this accounts for the connection between them. N.B.—I learnt arithmetic in a thorough old-fashioned unintelligent style, the first step being to learn to count without the least conception as to what the numbers meant.

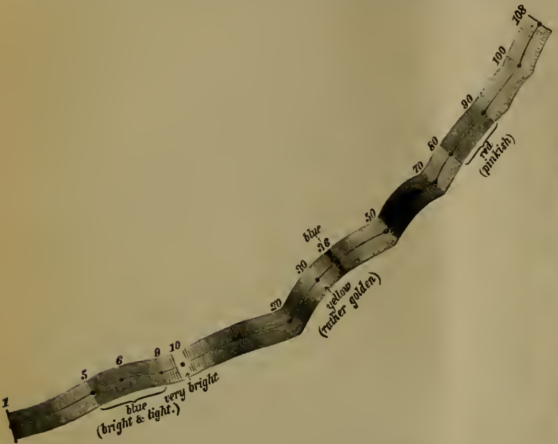

Fig. 4.

Fig. 5.

The writer of the foregoing has two sisters and a brother. One of the sisters sees numerals in a differently arranged diagram, and the figures themselves are coloured, (1) black, (2) white, (3) yellow, (4) red, (5) greenish yellow, (6) blue, (7) black, (8) red, (9) grey, (0) gold. The othe sister has a fainter, but still a decided tendency to ee figures in a mental diagram. It is without colour but has variations of shade. The brother has a definite diagram of numbers arranged in a line sloping upwards to the right as far as 120, and absolutely devoid both of colour and variations of shade. No trace of these colour-peculiarities has yet been made out on either the father or the mother's side, but there is a tendency in both father and mother to visualise in diagrams.

The effects of heredity are also strongly marked in the next set of instances, consisting of two families of cousins. A sister in the first family writes:—

15. From the very first I have seen numerals up to nearly 200, range themselves always in a particular manner, and in thinking of a number it always takes its place in the figure. The more attention I give to the properties of numbers and their interpretations, the less I am troubled with this clumsy framework for them, but it is indelible in my mind's eye even when for a long time less consciously so. The higher numbers are to me quite abstract and unconnected with a shape. This rough and untidy production is the best I can do towards representing what I see. There was a little difficulty in the performance, because it is only by catching oneself at unawares, so to speak, that one is quite sure that what one sees is not affected by temporary imagination. But it does not seem much like, chiefly because the mental picture never seems *on* the flat but *in* a thick, dark grey atmosphere deepening in certain parts, especially where 1 emerges, and about 20. How I get from 100 to 120 I hardly know, though if I could require these figures a few times without thinking of them on purpose, I should soon notice. About 200 I lose all framework. I do not see the actual figures very distinctly, but what there is of them is distinguished from the dark by a thin whitish tracing. It is the place they take and the shape they make collectively which is invariable. Nothing more definitely takes its place than a person's age. The person is usually there so long as his age is in mind.

Another sister says:—

16. I always see figures ascending in a directly perpendicular line in front of my eye [according to the sketch and memorandum sent in illustration, which it is hardly necessary to reproduce, the 1 stands opposite to the eye, and the scale reaches vertically up to 1,000]. Then all becomes vague, but I know that the thousands and tens of thousands are not in the same perpendicular line, and I believe they turn to the left hand.

A maternal aunt of these ladies "sees figures in a diagram," which has not yet reached me, and the other family that I am now about to mention are the children of a maternal uncle. There are three sisters and a brother who have the same faculty in varying degrees.

The brother writes from Cambridge:—

17. Numerals are always pictured by me in a straight line from left to right. They are black, on a ground varying in illumination, which is bright up to 10, then getting very shady from 10 to 20; 20 to 40, bright; 40 to 60, moderate; 60 to 80, shady. Shadiest are from 10 to 20, 60 to 80 or 90, 1,000 to

2,000. The millions are in a vague, bright distance to the right.

One of the sisters writes:—

18. Figures present themselves to me in lines [as in the annexed diagram]. They are about a quarter of an inch in length,

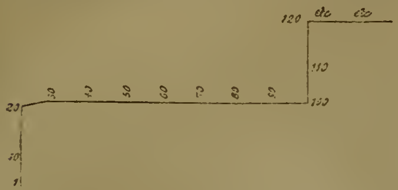

FIG. 6

and of ordinary type. They are black on a white ground. 200 generally takes the place of 100 and obliterates it. There is no light or shade, and the picture is invariable.

Another sister gives a picture in which the numbers form a vertical line from 1, opposite to the eye, up to 100, at which point the scale appears to recede from her.

The third sister writes:—

19. Figures always stand out distinctly in Arabic numerals; they are black on a white ground, of this size [the specimen was

FIG. 7.

clear and round, and in rather large ordinary handwriting], but the numeral 19 is smaller than the rest.

It is curious that the lines of most of the diagrams I have thus far given should be so feeble and, to appearance, wandering, although as a matter of fact they are firmly fixed. Artists speak of the "leading lines" in a picture, and commend pictures in which the leading lines are graceful. I have little doubt that one of the reasons why minds vary in artistic power is that the leading channels in the blank schedules of their minds vary in character. I should expect that natural artists might be found whose habit was to visualise numerals not in shaky lines, but in bold and beautiful curves. In the instances I am about to give, especially in the first of them, there is more tendency to geometric precision, and I should be most curious to learn (by actual and careful test) whether or no such cases are generally correlated with a true eye to straightness, squareness, and symmetry.

In the following example the numbers are not associated with visual figures, but with points on an ascending and descending scale, which is a pure line having neither breadth nor colour. It is described as perfectly flexible and extensible, much, I suppose, as if it were printed on a strip of india-rubber sheeting, and it is applicable to the measurement of large distances or small ones, to fractions, and to straight lines or curves. A very curious description is given in detail, which I will not here reproduce, of the way in which the scale is used in mental arithmetic. The writer adds:—

20. The accompanying figure lies in a vertical plane, and is the picture seen in counting. The zero point never moves, it is *in* my mind; it is that point of space known as "here," while all other points are outside or "there." When I was a child the zero point began the curve; now it is a fixed point in an infinite circle . . . I have had the curious bending from 0 to

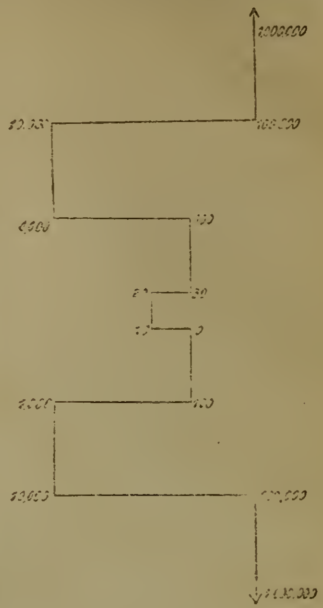

FIG. 8.

30 as long as I can remember, and imagine each bend must mark a stage in early calculation. It is absent from the negative side of the scale, which has been added since childhood.

Another correspondent sees figures in a circle, having 0 at the right hand of its horizontal diameter and 100 at the left hand. Positive numbers are reckoned from 0 to 100 from the right, over the top to the left, and negative numbers the other way. The same takes place with figures between 100 and 200, 200 and 300, &c.

Another correspondent sees them for the most part in a regular row like park palings. The description and sketch are as follows:—

21. As far as 12 the numerals appear to be concealed in black shadow; from 12 to 20 is illuminated space, in which I can distinguish no divisions. This I cannot illustrate, because it is simply dark and light *space*, but with a tolerably sharp line of division at 12. From 20 to 100 the numerals present themselves as follows, but less distinctly:—

FIG. 9.

An account is appended of the way in which simple mental arithmetic is effected by this arrangement, which at present I pass over.

I will conclude my list with a statement written by a mathematical astronomer of rapidly rising reputation, whose "practice of working arithmetic" mentioned in the concluding paragraph must be understood to signify "performing masses of laborious calculations":—

22. The numbers 1, 2, 3, 4, &c., are in a straight row, and I

am standing a little on one side. They go away in the distance so that 100 is the farthest number I can see distinctly. It is dusky grey, and paler near to me; up to 20 it occupies a disproportionate size. There are sorts of woolly lumps at the tens. These pictures are not of such frequent occurrence in my mind as formerly. The practice of working arithmetic has rather expelled them.

Since the foregoing remarks were first sent to the printer, many additional cases have reached me, which I regret to have no space left to include. One very interesting group consists of three cousins and the daughter of one of them. Another case was brought to my notice by a correspondent; it was published in the *Atlantic Monthly*, February, 1873, p. 199, with an accompanying diagram, and is signed by Miss H. R. Hudson. I have little doubt that many allusions to the faculty of visualising numerals in diagrammatic and coloured shapes might be found to exist scattered here and there in various books.

Of the many results to be drawn from the foregoing extracts, I do not at present care to dwell upon more than these. In the first place I am sure that all will agree with me in saying that the descriptions bear evident marks of careful and trustworthy observation. In the second place, although they refer to characteristics which the majority of my readers may not possess, their language is sufficiently clear to convey a good idea of what is meant to be conveyed. In the third place, these independent statements powerfully corroborate and explain one another. Therefore, although philosophers may have written to show the impossibility of our discovering what goes on in the minds of others, I maintain an opposite opinion. I do not see why the report of a person upon his own mind should not be as intelligible and trustworthy as that of a traveller upon a new country, whose landscapes and inhabitants are of a different type to any which we ourselves have seen. It appears to me that inquiries into the mental constitution of other people is a most fertile field for exploration, especially as there is so much in the facts adduced here, as well as elsewhere, to show that original differences in mental constitution are permanent, being little modified by the accidents of education, and that they are strongly hereditary.

I trust, therefore, that the publication of this memoir may prove to be the means of inducing some persons to furnish me with information of the kind I am now seeking. I want to hear of well-marked and properly-authenticated instances of persons who are able to recall, or represent to their imagination, with great vividness, either sights, sounds, smells, or tastes, and to obtain information that may throw light on the peculiarities of the representative faculty in different families and races.

FRANCIS GALTON

42, Rutland Gate, London

ON A MODE OF EXPLAINING THE TRANSVERSE VIBRATIONS OF LIGHT

THERE has been considerable difficulty in arriving at a satisfactory conception of the means by which the transverse vibrations of light are produced in the ether. In the attempt to surmount this difficulty some have gone so far as to conjecture that this structure of the ether must resemble that of a *solid*; for it was imagined that nothing but such a structure could propagate transverse vibrations. Yet the supposition of the ether being anything like a solid appears to be in direct antagonism to the evidence of our senses; for we move about so freely in this "solid" as to be unconscious even of its existence.

My object here is to direct attention more especially to a suggestion thrown out by the late Prof. Clerk Maxwell in regard to this point. This suggestion is contained in the article, "Ether," in the new edition of the "Encyclopædia Britannica," in connection with a notice of a theory of the constitution of the ether (considered in special relation to the problem of gravitation) by the present writer, and published in the *Philosophical Magazine* for September and November, 1877, and February, 1878. After referring to the fact that the present writer "has supposed that the ether is like a gas whose molecules very rarely interfere with each other, so that their mean path is far greater than any planetary distances," Prof. Maxwell continues as follows:—

"He has not investigated the properties of such a medium with any degree of completeness, but it is easy to see that we might form a theory in which the molecules[1] [atoms of ether] *never* interfere with each other's motion of translation, but travel in all directions with the velocity of light; and if we further suppose that vibrating bodies have the power of impressing on these atoms of ether some vector property (such as rotation about an axis) which does not interfere with their motion of translation, and which is then carried along by the atoms of ether, and if the alternation of the average value of this vector for all the atoms of ether within an element of volume be the process which we call light, then the equations which express this average will be of the same form as that which expresses the displacement in the ordinary theory."

There is one point in the above suggestion I would briefly remark upon, viz., the supposition made by Prof. Maxwell that the atoms of ether "*never* interfere with each other's motion of translation" [*i.e.*, never encounter each other]. This supposition seems to have been called for by the fact previously mentioned in the same article ("Encyc. Brit.," p. 572), viz., that "the ether transmits transverse vibrations to very great distances without sensible loss of energy by dissipation," whereas it is contended that if the ether atoms encountered each other (frequently at least), "the energy of the regular vibrations would be frittered away into that of the irregular agitation which we call heat." But I would venture to suggest that, as we have no proof that no dissipation *whatever* of the energy of light takes place in long distances (but perhaps even some indication to the contrary), it would appear evident that no necessity really exists for supposing that the atoms of ether *never* interfere with each other's motion of translation. I think it will be admitted as a reasonable conclusion that so long as the dissipation of the energy (of the light) attendant on the mutual encounters of the ether atoms is no greater than observation allows us to suppose it to be, all conditions are satisfied. Moreover, it would seem that to suppose the ether atoms *never* to interfere with each other's motion of translation would be equivalent to assuming that their mean path is *indefinitely* great, which appears to involve the assumption that the atoms have no finite size or dimensions, which would put a difficulty in the way of a satisfactory or consistent conception of matter. On this ground I would therefore suggest that the atoms of ether may be considered to have a reasonably long free path [which may be conceived as great as we please, by simply conceiving the atoms small], and thus the dissipation of the energy of the light may be reduced within the limits required by observation. This does not alter in the least in its essential details the above suggestion by Prof. Maxwell as to the mode of production of the transverse vibrations of light, which I would accordingly enlarge upon and elaborate somewhat here (in connection with the special structure of gross matter required by the physical theory of gravity). First it is important to observe that many observed facts lead us to infer that gross matter (probably the molecules[2] themselves) possesses a more or less *open* structure (or possesses a high degree of porosity). The transparency of some bodies, the free passage of the magnetic disturbance through all bodies,

[1] I merely substitute "atoms of ether" in the above passage for "molecules," to avoid any possible ambiguity, as the word "molecules" is often applied to the parts of gross matter.

[2] This is also in harmony with the modern theory of vortex-atoms.

and many other well known independent facts render this inference necessary. The fact that gravity is proportional to mass, on the basis of the dynamical theory (first started by Le Sage) also renders it essential to conclude that gross matter possesses an open structure [so that the atoms producing gravity can penetrate and act upon the interior of bodies]. If we admit this, and figure to ourselves the streams of ether atoms passing in all directions freely through the open structure of gross matter, and further, if we conceive the molecules of gross matter to be in a state of vibration (of regular periods, as proved by the spectroscope), then it is evident that these streams of ether atoms during their passage can, from the very nature of the case, be solely effected by the *transverse* component of the motion of the molecules of the luminous body. It is much as if the meshes of a sieve were in vibration, and a continuous stream of fine particles of sand (impelled by a current of air) were urged through it, when in however many different directions the filament forming the meshes of the sieve might be conceived to be vibrating, the sand particles that passed through in the onward stream could be only affected by the *transverse* component of the motion of the meshes. So the atoms of ether in their passage through the vibrating molecules of gross matter are solely affected by the *transverse* component of the motion of the molecules. The ether atoms passing through the open structure of gross matter would be thus periodically deflected (or the ether atom itself thrown into vibration or rotation), and as the transverse impulses (whatever their exact nature) thus received by the stream of ether atoms would be perfectly ryhthmical or periodic, in harmony with the known periodic vibrations of the molecules through which the ether atoms pass, the *transverse* pulsatory or periodic nature of light would thus be produced. This view would also seem to be capable of surmounting in a very simple manner the difficulty that there has been in conceiving how the ether can transmit transverse vibrations to great distances without sensible loss of energy by dissipation. For it is evident that an ether atom after having passed through a luminous body and received energy from it, would have nothing [1] to give that energy (say vibration or rotation) to during its transit, since, by assuming the ether atom small, we may conceive its mean path as long as we please; so, therefore, the energy carried by the ether atom from the luminous body could not possibly be dissipated during the transit of the atom, but this energy would be carried intact by the ether atom (through its normal motion of translation) until the distant object is reached, where the energy is given up in the form of heat and light. The normal motion of translation possessed by the ether atom performs the part of simple carrier of the energy received by the atom from the luminous body.

It might possibly be thought at first sight that this theory had some resemblance in principle to the emission theory of light, but this is evidently not the case, as no atoms are emitted by the luminous body, but simply the atoms of ether in their normal state of translatory motion pass through objects in streams equally in all directions —the ether being regarded simply as a gas (according to the modern kinetic theory) with atoms of very long free path. It is a known mathematical fact that no consequence how close the atoms of ether may be together (*i.e.*, no consequence how many in unit of volume) their mean path may become as great as we please, by simply conceiving the atoms adequately small. It further follows from the known principles investigated in connection with the kinetic theory of gases, that these atoms will of themselves automatically adjust their motions so as to move with perfect uniformity or *equally in all directions;* this adjustment being of such a rigid character that if the atoms were imagined to be disturbed or made to move in the most chaotic manner, they would, when left to themselves, instantly correct the irregularity, and return to the above regular form of motion, *i.e.*, so that the atoms move *equally in all directions.* It follows from this, therefore, that if we take any given point (such as where a luminous body is situated), the atoms of ether will "radiate" from and to this point along all the imaginary radii of a sphere described from this point as a centre; so that those ether atoms which have passed through the luminous point (and have carried energy off with them) will diminish in number (per unit of spherical area) as the *square* of the radial distance from the luminous point, the energy, therefore, diminishing in the same ratio, which is the "law" of light. The "law" of gravity (which is found also to diminish as the *square* of the distance) may be accounted for on the same principle.

It has been shown by the present writer (in the papers published in the *Phil. Mag.* previously alluded to) that in accepting Le Sage's ingenious sheltering principle as the fundamental basis of the explanation of gravity, there is no necessity for admitting any of his postulates regarding the particular motions of the atoms (corpuscles) required to produce the result. For it may be shown that the whole of the conditions requisite for gravity will automatically fulfil themselves by simply admitting the existence of a body in space, constituted according to the kinetic theory of gases (and whose atoms have an adequately long free path). There is no necessity to suppose, with Le Sage, the existence of "ultramundane corpuscles," or that the atoms producing gravity come from outside the bounds of the visible universe, so that a continuous supply of matter from without is necessary to maintain gravity within the confines of the visible universe. On the contrary, the conditions are satisfied by merely supposing the universe to be immersed in a gas, which, *as a whole* (like any other gas) is at rest. The motion (in streams) requisite for gravity takes place solely *within the range of free path* of the atoms of the gas; just (as is known) in every ordinary gas the atoms within the range of free path are moving in streams equally in all directions. The only difference is that in the case of the ether, on account of the smallness of the atoms (which is in harmony with their high velocity), the range of free path is great—equal to the range of gravity. We have no proof that the range of gravity extends across stellar distances, and there is clearly no necessity for assuming it to prevail over greater distances than observation warrants. By the explanation of gravity by the physical theory, the remarkable and anomalous distinction between *two kinds* of matter ("ponderable" and "imponderable") vanishes. Matter is shown of its essence to be all alike, "ponderability," or the tendency to approach, not being an occult or magic quality, but simply an effect dependent on differing dynamical conditions,[1] and the variation of the intensity of which as the *square* of the distance it is as necessary to account for dynamically as in the analogous case of light.

It appears, therefore, from the above considerations, that the same medium shows itself to be capable of accounting for, in their essential groundwork, the phenomena of both gravity and the propagation of light. The theory of gravity is based upon the well-known sheltering principle of Le Sage, which has already found favour with some eminent physicists. The normal translatory motion of the atoms of the medium produces gravity, and this motion serves as a vehicle for the propagation of light, while the light itself consists in the

[1] This holds equally true, whether we conceive space as empty, or space to be filled with a perfect (frictionless) liquid that *plays the exact part of empty space*, in so far as it is known to be impossible to operate upon or communicate energy to such a liquid.

[1] The fact of the property of "ponderability" having been attributed to gross matter as an occult quality (not an effect depending on dynamical conditions), has naturally brought the ether—which does not possess this property—into direct contrast with gross matter, as if it were an anomalous substance, of its essence distinct from gross matter. This circumstance has no doubt naturally contributed to produce a distaste for the study of the ether and to cause some to treat this magnificent physical agent as if it were desired rather to ignore than to take a rational interest in its existence.

abnormal *transverse* disturbance produced in the streams of atoms in their passage through the vibrating molecules of luminous bodies.

Finally, it may be shown that, quite independently of any consideration of the effects of gravity and light, the inference is a necessary one that the constitution of the ether must in principle be that of a gas, because this solution to the problem of the constitution of the ether exhausts the limits of the conceivable: *i.e.*, if any *rational* solution to the problem or *explanation* capable of appreciation by the reason exists, then it would follow that this must be the true solution to the problem. This will become more and more evident on reflecting on the subject. For it is clear that a motion *in straight lines* is the only motion possible to particles of matter moving freely in space; for particles of matter cannot of themselves change the directions of their motions. They can only do this at their encounters. Hence the inference is necessary that the particles of ether move *in straight lines* (and therefore that the ether is constituted as a gas). Hence in principle it seems apparent that the above is essentially the only conceivable solution of which the problem of the constitution of the ether admits. It seems remarkable that this fact (important as it is) is not more generally recognised and appreciated. Can this be referable in any way to the influence the theory of "action at a distance" has had, and that the endless empty and profitless speculations arising therefrom have diverted attention from the subject?

It might be said that we have expressly assumed the existence of "particles" (or atoms) of matter in the above result as to the constitution of the ether, whereas some might contend that the ether is not *atomic* at all My answer to this is, that unless we assume the ether to be atomic,[1] we cannot give any explanation of its properties, and these properties can exist solely in virtue of the explanation that underlies them. In connection with this the following remark of Prof. Clerk Maxwell ("On the Dynamical Theory of Gases," *Phil. Trans.*, 1867, p. 49) may be quoted, as to the point:—

"In certain applications of mathematics to physical questions, it is convenient to suppose bodies homogeneous, . . . but I am not aware that any theory of this kind has been proposed to account for the different properties of bodies. Indeed, the properties of a body supposed to be a uniform *plenum* may be affirmed dogmatically, but cannot be explained mathematically."

Hence to assume the ether to be anything else than *atomic*, would be to affirm its properties "dogmatically." If we avoid this, therefore, we must consider it *atomic* (and therefore a gas): for (as we pointed out), atoms in free motion can only move *in straight lines*. It is of course evident that, unless the atoms of ether be *in motion*, we cannot account for any of its properties, unless, indeed, we resort to the now practically defunct theory of "action at a distance," and assume the atoms to be endowed with mysterious and occult powers, which renders any *explanation* impossible, and only increases instead of diminishing the difficulty.

To illustrate somewhat further the insuperable nature of the difficulty involved, unless we assume the atoms of ether to be in motion in their normal state, I quote the following passage from a lecture by Prof. Tait on "The Position and Prospects of Physical Science," delivered November 7, 1860 (p. 15 in pamphlet):—

"If we suppose it [the ether] to consist . . . of detached particles . . . we are met by the further difficulty, *how* do these particles act on each other, and without some such action there could be no transmission of motion—they are not in contact, there must therefore be something between them to convey the effect. This appears certain, for how can action be conceived as exerted across empty space?"

I will merely here remark parenthetically that the fact appears to have escaped notice here that this difficulty is got over by assuming the particles (of ether) to be *in motion*; for then the particles can act on each other by direct impact without the necessity for anything "between them to convey the effect." The passage goes on to say:—

"We must, therefore, have a second medium to fill the interstices between the particles of ether. If this again consist of detached particles, there will be a third required that these may act on each other—and so on. If, then, we would not have an infinite number of different kinds of matter in each element of space, we must suppose one of these—say the ether itself—to be *continuous*, that is, not consisting of ultimate parts. *How* vibratory motions could be transmitted through such a substance, it is difficult to imagine—the whole subject is beset with overwhelming difficulties."

In the above passage the difficulties that attend the assumption of the ether being a *continuous* substance, or uniform *plenum*, are well illustrated. It will be seen that the main dilemma vanishes by assuming the particles of ether to be *in motion* in their normal state. Indeed, this is evidently the only conceivable way of solving the difficulty.

I would, therefore, venture to suggest that the result above arrived at as a solution to the problem of the constitution of the ether might be worthy of the attention of physicists, especially in its bearing on the explanation of gravity (on the basis of Le Sage's fundamental principle now recognised by several eminent authorities, including Sir W. Thomson)—also in relation to a mode of explaining the *transverse* vibrations of light, the main idea involved in which was suggested by Prof. Clerk Maxwell.

Addendum.—I may mention that I have lately received a book ("Das Räthsel von der Schwerkraft"—Wieweg und Sohn, Braunschweig) through the kindness of the author, Dr. Isenkrahe, of Crefeld, where a theory is applied to the constitution of the ether and to gravity, which resembles in some points that adopted by the present writer. This book bears date 1879, but the MS. was prepared earlier (1877). I may note that a book, "Physics of the Ether" (E. and F. N. Spon), was published by me in 1875, where in principle the same theory of the ether as here given is developed, though it was not applied by me to gravity until 1877. The work of Dr. Isenkrahe contains, in addition, a valuable description and criticism of the various attempts to solve the problem of gravitation. Perhaps I may append, for the benefit of those who are interested in the question, the references to some of the chief of these here, viz.:—

Huyghens' "Discours sur la Cause de la Pesanteur." Leyden, 1690.

Le Sage's theory 1764, given in "Deux Traités de Physique mécanique," by Pierre Prevost.

Sir W. Thomson's development of Le Sage's theory, Royal Society of Edinburgh, 1872, and *Philosophical Magazine*, May, 1873.

Schramm, "Die allgemeine Bewegung der Materie als Grundursache der Naturerscheinungen," Vienna, 1872.

Secchi, "Die Einheit der Naturkräfte" (German edition). Leipzig, 1876.

These facts may show an awakening to the importance of the problem of gravitation, and I may conclude with

[1] It is almost needless to add that the vortex-atom theory is essentially an *atomic* theory. Although it assumes a perfect liquid to fill all space, yet this liquid (outside the portions of it that form the atoms) plays the part of pure space, since it is impossible to communicate energy to the liquid outside the atoms, or to act upon it at all. It is therefore (as far as practical effects are concerned) as if the liquid exterior to the atoms did not exist. The vortex-atom theory does not, therefore, essentially alter (as some might be disposed to imagine) the conceptions of the ancients of indestructible atoms surrounded by space in which they can freely move. The main purpose of the vortex-atom theory is to prove dynamically how atoms can be "*elastic*," and be capable of executing regular vibrations as the spectroscope proves (and actually measures the number of vibrations executed per second, in the case of the molecules of gross matter).

the words of Dr. Isenkrahe [translation]: "One is beginning to recognise that physics has been quietly sleeping for two centuries upon [in the words of Newton] 'a great absurdity,' for which no one less than Newton can be made responsible" [page 125].

S. TOLVER PRESTON

THE NATURAL HISTORY OF THE TRANSIT OF VENUS EXPEDITION[1]

IN 1870 one of our correspondents called attention[2] to the favourable opportunity that would then shortly present itself for the exploration of some very little known parts of the earth's surface. Some of the positions selected by our astronomers for the observation of the Transit of Venus of 1874 were in little known islands of the Pacific and Indian Oceans, and it was pointed out that the addition to the astronomers' staff of a small corps of naturalists would not materially increase the expenditure, and would possibly lead to very interesting scientific results.

The same subject was brought before the notice of the British Association at their Meeting in 1871 by Mr. Sclater,[3] who likewise suggested that so good a chance of adding to our knowledge of the natural history of some of the least known parts of the world should not be thrown away, and urged that Naturalists should be appointed to at least three of the stations to be occupied by the astronomers, namely Kerguelen Island, Rodriguez and the Sandwich Islands.

Subsequently the same idea was taken up by the Council of the Royal Society, who resolved to request the Treasury to attach naturalists to the expeditions destined for the two first above-named localities—"two of the least explored and most inaccessible islands in the southern hemisphere"—and appointed a committee consisting of Sir Joseph Hooker, Prof. Huxley, and Mr. Sclater, to prepare the necessary application to the Government for this purpose. We need not now repeat the arguments which these gentlemen brought before Her Majesty's chief advisers—it is enough to say that they were of a sufficiently cogent character to obtain the sanction of the Treasury to the appointment of four naturalists for the purposes required; three for Rodriguez and one for Kerguelen's Land.

The gentlemen selected for the work by the Council of the Royal Society were for Rodriguez, Mr. George Gulliver, Dr. I. B. Balfour, and Mr. H. H. Slater, and for Kerguelen's Land the Rev. A. E. Eaton. Mr. Gulliver was directed to investigate the fauna of Rodriguez generally, Dr. Balfour was charged with the duties of botanist and geologist, and Mr. Slater was set to dig out the caves of the same island, and to collect the fossil remains of extinct birds known to be imbedded in them. Mr. Eaton was thought to be specially qualified to investigate the fauna and flora of Kerguelen's Land, as having been previously naturalist to one of the Arctic expeditions.

The collections and observations made by these naturalists fulfilled, as we are informed, the expectations of the Council. The results of them are given in the present work, which is issued as an extra volume (No. 168) of the *Philosophical Transactions*.

The plan upon which the collections were worked out, and which is in fact the only plan upon which a mass of heterogeneous materials can be properly worked out now-a-days, is an admirable one. The different objects were assigned for examination to experts in different branches of science, each of whom has prepared his own report on what was submitted to him. These reports, prefaced by a few introductory remarks, and illustrated by notes of the collectors, constitute the volume now before us. It is divided into two sections, the first relating to Kerguelen, and the second to Rodriguez.

After a chapter by Mr. Eaton on the physical features of Kerguelen, and on the previous visits to it by naturalists, we find a series of essays on the botany by Sir J. Hooker, Mr. Mitten, the Rev. J. M. Crombie, Dr. Dickie, and other well-known authorities. Then follows a similar series of memoirs upon the zoology of the same island.

The zoological and botanical collections made in Rodriguez are next treated of in the same way, and we have here also a valuable memoir on the petrology of Rodriguez by Mr. N. S. Maskelyne. From the last-named essay it turns out that the notion that this island consists of "granite overlaid with limestone, and other recent rocks," which was entertained by the Committee of the Royal Society, misled by previous inaccurate observations, is altogether erroneous. Mr. Maskelyne tells us that "the numerous specimens illustrating the rock formations of the Isle of Rodriguez, collected by Mr. I. Bayley Balfour from different localities, need only a cursory inspection to attest the volcanic character of the whole mass of the island.

"Rodriguez, in fact, consists of doleritic lavas that appear to have been poured out at a considerable number of volcanic orifices at successive periods. It would be difficult, without more minute description of the physical geography of the island than is accessible, to assign any precise date of duration to these volcanic eruptions, or to trace with any certainty the degree to which, and the mode in which, subsequent denudation has helped in giving the island its present remarkable aspect.

"But the fact of that denudation and the degree to which alteration has proceeded in affecting the minerals composing rocks that by their position must have been among the later of the out-poured lavas, would point to a remote date, possibly to one contemporary with the tertiary period, as that of the volcanic activity of Rodriguez."

We have not space here to go separately into the numerous essays that compose this work. For many of them, the name of the author is quite sufficient to assure us of their excellence, some of the most accomplished naturalists of the present epoch having contributed to the volume. But it is quite evident that a thoroughly good and satisfactory piece of scientific work has been thus accomplished at a very small cost, and that the council of the Royal Society, who planned the whole scheme and carried it out, and especially those two members of it (Sir J. Hooker and Dr. Günther), who have so efficiently edited this account of the results attained, are entitled to the warmest thanks of all naturalists. Several other nations sent out expeditions to observe the Transit of 1874, and likewise had naturalists attached to their staffs, who have published some valuable observations. But nothing like the handsome and solid volume now before us, with its fifty-five admirably executed lithographic plates, has been produced on this occasion in France, Germany, or America. There are certainly some advantages in having a Royal Society at the head of Science instead of a Royal Academy!

Having said this much, we will venture on two small criticisms:—First, it is a great pity that there are no *maps* given in the volume now before us. Without reference to maps it is not possible to appreciate the significance of many of the observations made by the naturalists, and as no generally available atlas contains charts of such obscure islets as Rodriguez and Kerguelen, maps ought to have been attached to the work itself. In fact, every zoo-geographical memoir now-a-days ought to be illustrated by a map.

[1] "An Account of the Petrological, Botanical, and Zoological Collections made in Kerguelen's Land and Rodriguez during the Transit of Venus Expeditions, carried out by Order of Her Majesty's Government in the Years 1874-75." *Philosophical Transactions* of the Royal Society of London, vol. clxviii. Extra volume, 1879.

[2] See article on the Transits of Venus in 1874 and 1882. NATURE, vol. i., p. 526.

[3] See "Remarks on a Favourable Occasion for the Establishment of Zoological Observatories." By P. L. Sclater, M.A., Ph.D., F.R.S. Rep. Brit. Ass., 1871, pt. ii., p. 134.

Secondly, it is unfortunate that naturalists were not likewise sent to Oahu, in the Sandwich Islands, where there was likewise an astronomical station in 1874. The Sandwich Islands, as was pointed out by our correspondent in 1870, are the seat of a most peculiar indigenous flora and fauna, which is now fast perishing beneath the assaults of European weeds and animals introduced from other countries. Dr. Finsch, who was lately at Honolulu on his way to the Northern Pacific, tells us (*Ibis*, 1880, p. 79) that during a week's stay in that city and its vicinity, he saw *no birds* except introduced species, and had to go far into the interior to obtain examples of the indigenous Avi-fauna, and that the "native forests are going in the same way." It is a great misfortune, then, that this should happen before we have any good account of this peculiar flora and fauna which rivals in eccentricity even that of the Galepagos. And as another Transit occurs in 1882, we trust that should our astronomers again visit any one of the Sandwich Islands group, a staff of efficient naturalists will be sent in their company.

ARTIFICIAL DIAMONDS

UNDER the heading of "The Crystallisation of Carbon" Mr. Crookes writes as follows in the last number of the *Chemical News*:—

Since sending the telegram[1] announcing that carbon crystals, apparently diamond, could without difficulty be produced from any carbon compound, Mr. Mactear has sent me several specimens of his supposed artificial diamond. He has also called upon me with other specimens, and has explained the whole process by which he obtains such remarkable results. As, however, he has sent to the Royal Society a paper which will probably be read in the course of a week or two, I am not yet at liberty to give details of the process.

The general character of the specimens now in my possession may be described as irregularly shaped masses from 1 mm. downwards in diameter, with rounded angles, and showing no definite crystalline appearance. They are whitish looking, translucent, and as a rule lustreless; many pieces are almost spherical and appear like fragments of corundum which have been water worn. Amongst these are perfectly clear fragments larger in size, some being 3 or 4 mm. across, having a conchoidal fracture exactly like glass.

In a paper "On Molecular Physics in High Vacua," read before the Royal Society in March last, and now being published in the *Philosophical Transactions*, I referred to the remarkable power possessed by the molecular rays in a high vacuum of causing phosphorescence in bodies on which they fall, and I remarked that the only body which surpassed Becquerel's luminous sulphides both in brilliancy and variety of colour is the diamond. Most of these gems, whether cut or in the rough, when coming from the South African fields, phosphoresce of a brilliant light blue colour. Diamonds from Brazil shine with different colours, such as bright blue, pale blue, apricot, red, yellowish green, orange, and light green. A beautiful collection of diamond crystals, kindly lent me by Prof. Maskelyne, phosphoresced with nearly all the colours of the rainbow, the different faces glowing with different shades of colour. On receiving the specimens from Mr. Mactear, I immediately submitted them to the molecular discharge. The following are the results I have at present obtained:—

In a high vacuum the specimens phosphoresce brightly of different colours—pale blue, orange, apricot, and yellowish green. The clear glassy fragments are also phosphorescent. The appearance of the phosphorescence is very similar to that shown by small, rough diamonds from Brazil, called in the trade "Boart;" indeed, had I not known the history of the fragments in my tube, I should, from their appearance, have said that they were small fragments of Brazilian Boart.

The opaque rounded appearance of the fragments is unlike that of the natural diamond, but by heating a rough diamond before the blowpipe until it has partly burnt away, it assumes a very similar appearance to that of Mr. Mactear's crystals, and it is therefore not unlikely, from their mode of preparation, that these crystals have undergone partial combustion after their formation—a fact which would explain this difference in appearance. Other specimens having been placed by Mr. Mactear in competent hands, with a view of determining their hardness and chemical properties, I have refrained from making experiments in this direction. W. C.

[1] *Chemical News*, vol. xl. p. 306 (December 26, 1879).

We append a letter on the subject from Prof. Maskelyne in the *Times* of the 8th inst.:—

As I know that a portion of the public is very much interested in the diamond question, and in the result of the interview Mr. Mactear announced that he and I were to have in connection with it, I think, perhaps, it will be well to say that I have had the pleasure of working with that gentleman many hours yesterday and to-day, and that our results so far convince me that, while my own conclusions, as announced in the *Times*, are borne out as regards at least the portion of the substances on which I worked, there are other portions of those substances that differ from these in properties and still require investigation; that, in fact, the material is a mixture of different bodies. When I say that I have as yet no evidence of the existence of crystalline carbon, whether as diamonds or in some other condition, among these bodies, I feel that Mr. Mactear makes a reasonable request of me in asking that I should invite a suspension of opinion regarding a discovery he believes that he has made. A portion of the material he has produced is very hard, and, I believe, bears out his claim to have scratched topaz and sapphire. Mr. Mactear wishes me to add that the diamond has been also abraded by his product and to inclose to you a certificate to that effect. Mr. Mactear wishes me also to state that he claims simply to have produced a crystalline form of carbon irrespective of the question of whether this is the diamond.

I am, Sir, your obedient servant,
NEVIL STORY-MASKELYNE

British Museum, January 7

We may state that in the *Times* of the same date is a certificate from Mr. L. Boston, of Glasgow, that he has been able "to scratch a diamond and to engrave two rubies, two sapphires, an amethyst, and a cairngorm" with Mr. Mactear's "crystallised carbon sand."

THE "TIMES" ON BRITISH BIRDS

NATURALISTS live a life of surprises, but the surprise with which ornithologists must have one day last week received certain positive assurances of the leading journal would surely overstep the bounds of ordinary astonishment. We have, no doubt, been passing through a "silly season" of unwonted severity, as the morris-dance of late performed by many of the pseudo-ornithological correspondents of the *Times* proves; but a recent leading article in that journal eclipses all else that it has published on the subject.

After declaring that "our birds are the glory of the land," and piously ascribing that glory to the upper regions, the writer goes on to compare England with France in the matter of its birds, saying, of course, nothing that was not quite well known before, except the extraordinary statement that "France has produced ornithologists, but they have had to leave her shores." The meaning of this is entirely beyond us, for every one knows who cares to know that France now possesses a large number of ornithologists—and one indeed, M.

Alphonse Milne-Edwards, who on some points is the greatest ornithological authority that has ever lived. We are then told of an Oxford undergraduate who "took a walk with his gun in Bagley Wood and brought home fifty different specimens which he carefully stuffed." "He had a museum," it is added, "of several hundreds." We are not told whether this Oxford undergraduate's conduct is worthy of praise or blame, nor would it much signify, for the writer is evidently confused in his notion of "specimens" and "species." To kill specimens of fifty different *species* in one day and in one wood, though not easy, could no doubt be done in many places, but it would be hard to kill fifty birds that were not different *specimens!* Would the writer also be surprised to learn that "a museum," or a collection, as people nowadays more humbly style it, "of several hundreds," was some fifty years ago by no means uncommon, and that of late years private collections include not only thousands of specimens, but thousands of species?

But now comes the most astonishing assertion of all. We are told that "Mr. Morris describes more than twelve hundred birds," and that there may be no mistake in the writer's meaning, he subsequently repeats the statement in this wise: "Of the twelve hundred British birds, a good many are represented by a single stray specimen," and so on! The ornithologists of this country have hitherto been deemed by their continental brethren somewhat too hasty in enrolling as "British" every chance waif from foreign lands and seas that has had the ill luck to show itself (and of course be shot) within the limits of the United Kingdom, and we have never understood that on the most liberal interpretation of the expression, "British birds," the number has exceeded four hundred. How blind and inefficient have they been when they have omitted more than two-thirds of the species that occur here! It is really to be hoped that the writer of the leading article on English birds in last Thursday's *Times* will bring them to a due sense of their neglected duties by furnishing a list of the 800 species whose rights of citizenship have been so shamefully ignored, and if he will at the same time say in which edition of Mr. Morris's work "more than twelve hundred" British birds are described, he will possibly contribute to a more comfortable understanding of the matter, for Mr. Morris has hitherto been supposed to follow very closely the late Mr. Yarrell in the information he gives, so that when the latter in his last edition included 354 species, the former a few years later made the number 358!

There are many other assertions in the same article which excite a degree of amazement inferior only to the last particularised, and we have heard persons suggest that the writer must have been all the while perpetrating a solemn joke.

EDISON'S ELECTRIC LIGHT

THE *Times* New York correspondent gives some interesting details in Monday's paper of Mr. Edison's new form of electric lighting and the steps by which he was led to its discovery. So far the light has withstood every test that has been tried, and so confident do the public seem that success has been attained at last, that the shares of the Edison Company have risen from 20 dollars to 3,500 dollars.

The Philadelphia correspondent of the same journal gives some further information in yesterday's issue. Probably 200 people make up the population of Menlo Park, we are told, nearly all Edison's workmen and their families. He gets an income of 40,000 dollars to 50,000 dollars a year from his various inventions, and he spends it all, the most of it for machinery and wages, and the balance in charity. The correspondent then gives some interesting details concerning Mr. Edison, his habits, his enthusiasm, and his relations with his numerous employés. There is no discipline enforced or any apparent time-table for work, yet with all hands it seems a labour of love, and if you pick out from the crowd the grimiest and most woe-begone of the whole party of overworked alchemists it will be Edison himself. It appears to have been the system at Menlo Park, as with the alchemists of old, to do most of the work at night, and it seems the regular habit of Edison and his chief subordinates to work straight through the twenty-four hours without stopping, until tired nature compels them to drop down in any handy place and go to sleep. "We went there," the correspondent writes, "hoping that Edison had succeeded, but nevertheless sceptics, and we came away thorough believers. His lamps were burning when we arrived, and they burnt continuously until our departure, excepting from half-past four to half-past five P.M., when about an hour's time was taken in putting in a new generator to do the work, which he had just finished and desired to try. During the daylight we could see the lamps burning, supplied by the first generator, and perceived that the little carbon loop or horseshoe giving the light remained intact. After dark, when the second generator went to work, we saw for three hours the lamps successfully burning as a complete substitute for gas for every purpose for which illumination was necessary at Menlo Park. The gas jets were idle, being put out of use by the steadier and more genial glow of the electric light. We ate our supper by it in the little restaurant that has been established at the Park, and I sat down in Edison's office under two of his lamps attached to a gas bracket and wrote the rough draft of the telegram sent to the *Times*. In this room a telegraph operator worked in a corner with an Edison lamp in a movable table stand illuminating his work. Down stairs his bookkeeper was paying off the hands by the aid of two more electric lights on a gas bracket. Out in the roadway in front of the building two street lamps were set up with the Edison light in full operation. In his workshop the engineer was running his engine and a couple of men watching the operation of the new generator by the light of more Edison's lamps, while in the laboratory some fifteen of them were giving light for various operations, and downstairs a young man sat at the regulator, and, watching another light, by the aid of the galvanometer, kept the flame steady, just as the regulator is worked constantly in the gas-house to adjust the gas pressure, so that it will compensate for turning lights on or off throughout the town. It was between seven and eight o'clock on a dark winter evening, and the electric light had put into disuse both the gas jets and the petroleum lamps that were in profusion around. I visited four dwellings in the village and saw the Edison lamps doing the work of illumination for all household purposes in each of them. In Edison's own house, where he had at least a dozen of them, we remained over half an hour, and I shall never forget the glee with which Edison listened to the reading of a newspaper slip, wherein an ambitious 'expert' offered to forfeit 100 dollars for every lamp that Edison could keep burning over twenty minutes."

NOTES

ON Friday, the 9th inst., the St. Andrew's University Court agreed to report to the Queen in Council in favour of an application by Prof. Swan to be permitted to retire, on the usual retiring allowance, from his Chair of Natural and Experimental Philosophy in the University, on the ground of failing health.

MR. E. W. COOKE, R.A., F.R.S., whose death at the age of sixty-nine years, took place at Groombridge on the 4th inst., deserves some notice in these pages for his connection in various ways with science. From his boyhood he had the keenest interest in natural history, and was probably one of the first amateur horticulturists. He was connected with most of our scientific societies, and was an early member and constant attendant at the meetings of the British Association. His first artistic work was botanical, the drawing of many hundred of the illustrations to London's "Encyclopædia of Plants," all drawn from living specimens. The professional work of Mr. Cooke as an artist was throughout an advancement of science through a channel which we have often had occasion to point out, is generally too independent of the claims of science, and suffers accordingly. Mr. Cooke's representations of natural objects, of plants and animals and rocks, were always scientifically accurate, and his coast scenes are in themselves a geological study. He was always ready to help other artists whose ignorance of natural science was apt to lead them into ludicrous blunders. He was, we believe, one of the first who ever attempted to grow ferns and tropical plants under conditions similar to those under which they are found in nature. Both at Kensington and at Tunbridge Wells his fernery and tropical garden were masterpieces in their way. For his eminence as a horticulturist and for his contributions to geological science by his series of pictures and drawings illustrating the principal geological features of the British Islands, Mr. Cooke was, in 1863, elected a Fellow of the Royal Society. His series of drawings of "Grotesque Animals," published a few years ago, afford a remarkable example of his intimate knowledge of comparative anatomy, as well as of his sense of humour. Mr. Cooke counted among his friends nearly all the leading men both in science and art.

Mr. William Alexander Forbes, B.A., F.Z.S., Scholar of St. John's College, Cambridge, has been appointed by the Council Prosector to the Zoological Society of London in succession to the late Prof. Garrod. Mr. Forbes, who is already well known for his contributions to scientific literature, obtained a first-class in the Natural Sciences Tripos at the late examination at Cambridge, and was designated as specially distinguished in the sciences of comparative anatomy and zoology.

We understand that, at the suggestion of several practical teachers of botany, a new piece of ground at the Royal Gardens, Kew, will, during the ensuing season, be set apart for the study of botany, and that students will, under certain regulations, be able to carry home specimens for examination. Papers recently read at the Chemical Society by Mr. Church on the respiration and transpiration of albino foliage, and at the Linnean Society by Mr. Marshall Ward on the embryology of phanerogams, were in both cases founded on observations made in the laboratory.

The *Journal of Botany* announces the death, at the early age of twenty-eight, of one of the most promising of the younger generation of physiological botanists, Dr. H. Bauke, of Berlin. His researches on cryptogams, and especially on the phenomenon of bilateralness in the prothallia of ferns, gave promise of a brilliant future.

The Fourth Annual Report of the Johns Hopkins University contains much that is of great interest. It gives a sketch of the foundation and plan of instruction of the University, showing how the latter has been based on the best ideas as to what ought to be the functions of a university. The system of fellowships at the Johns Hopkins institution is one calculated to encourage and call forth the best energies of the Fellows, and in the short career of the University the success of these fellowships has been fully shown. The University has the use of the magnificent library of the Peabody Institute of Baltimore, and in its own various laboratories much good work is being done. The University has contrived happily to combine teaching and research in such a way as to give students real help and yet leave the teachers ample time to carry on original work. The *American Journal of Mathematics* and the *American Journal of Chemistry* both emanate from this Institution, while special publications contain the results of biological work, and a long list of papers in various departments by members of the University is appended to the Report. We have also a long list of apparatus for scientific researches involving accurate measurements in the physical laboratory, and of some of the most important apparatus in the biological laboratory. Altogether from this Report it will be seen that the Johns Hopkins University is doing its best to carry out the noble purpose of its founder.

From the Twelfth Annual Report of the Peabody Institute of Baltimore, we see that the magnificent new buildings are now complete and occupied. It now forms one of the best equipped centres of culture in the United States.

In the *Bulletin* of the Paris Anthropological Society (tome ii. fasc. 3) M. J. Geoffroy gives a *résumé* of his great work on the knowledge and denominations of colour, in which he attempts to controvert the views of Magnus and Geiger, and those of Mr. Gladstone, which ascribe colour-blindness to Homer. On the grounds taken by these writers he insists that we should be equally justified in asserting that Corneille, La Fontaine, and others who happen not to mention in their works any one special colour, must have been blind to it; he considers that the delight taken by savages in bright colours is a sufficient proof that the sense of colour is not due to culture.

In the same number M. de Jouvencel draws attention to the curious circumstances that the Latin races by preference take the right side, where the Teutonic races, including our own, and that of Scandinavians, take the left. With regard to the former, he finds a sufficient explanation in the superstition of the Romans, who deemed all omens favourable which manifested themselves on their right side, and *vice versâ*; while the barbarian enemies of Rome may be assumed to have regarded as favourable to themselves whatever the Romans accepted as of evil portent. The Saxon races as masters of the sea and pioneers in the laying of railways, have imposed their own rules of the left side on the French and other Latin nations, who, however, still in driving, riding, &c., keep to the practice of their progenitors.

M. Zaborowski recently communicated to the Paris Anthropological Society his discovery, on the banks of the Lower Vistula, of certain sepulchral vessels of a kind never before described. At the depth of 50-80 centimetres below the surface he found cinerary urns filled with bones, in the midst of which were various objects in bronze, iron, and bone, and over each urn there was a cover, like an inverted bell, resting in some cases on a kind of stand, or plateau. He proposes to give to these singular urns the name of *tombeaux sous cloches*; of which outline drawings with full description of their form and size are given at pp. 337-8 of the *Bulletin* (t. ii. fasc. 3).

The *North American Entomologist* for August, 1879, contains a paper by Mr. A. R. Grote "On the Neuration in certain Genera of *Pyralidæ*," illustrated by a plate with outline figures of the neural characters of fourteen genera, which should prove of great service to students of *Lepidoptera*.

Mr. T. R. Archer Briggs, of Plymouth, announces the early publication of a Flora of Plymouth, including the Flowering Plants and Ferns growing within a distance of about twelve miles from the town. The almost unrivalled critical knowledge of our native plants possessed by Mr. Briggs will render this a valuable contribution to geographical botany.

Messrs. D. M'Alpine and A. N. M'Alpine announce the publication of a Biological Atlas, being a guide to the practical study of plants and animals, illustrating the characters of typical forms by drawings of the object, dissections, microscopic preparations, and diagrams, with explanatory text, specially designed for the London University, Science and Art, Medical, and other examinations, and for use in schools and colleges. The Atlas will consist of 24 plates, containing 423 coloured figures and diagrams, and is to be published by Messrs. W. and A. K. Johnston.

THE Göttingen Royal Society of Sciences offers a prize of 50 ducats for the best treatment, by new researches, of the question as to the processes of development of the adult echinoderm. In addition to what is known of the embryonal development of echinoderms, it must specially be shown how the animal grows from the larva form to the completed system of organs. It is open to competitors either to examine a characteristic kind of development-process in all its features, or by exhibiting the development of different forms, to establish a common behaviour for the whole; in the latter case, the chief agreements and divergences in the formation of the organic system in different forms of echinoderms must be indicated from their earliest occurrence. The Society re-propose their question as to the nature of the *unpolarised light-ray*, researches being desired which will bring conceptions as to natural light of any source, near, in definiteness, to those which theory associates with polarised light. Papers on these subjects have to be sent in before the end of September in 1881 and 1882 respectively.

THE Reale Istituto Lombardo offers prizes of various value in connection with the following among other subjects:—The climatology of Italy; Critical history of the telephone; Œnology, especially in ancient Italy; The nature of miasma and contagion; Motor centres of the cerebral cortex; Etiology of cretinism and idiocy; Demonstration by experiments, whether the generative matter of hydrophobia is a virulent principle or an organic germ; Elucidation of some facts of the macro- or microscopical anatomy of the human brain. Particulars with reference to these will be found in the *Rendiconti* of the Institute (vol. xii. fasc. xvii.-xviii.).

A GERMAN translation of Schiaparelli's work on the planet Mars has just been published by Herr Georgi, of Leipzig.

MR. SHRUBSOLE asks us to say that he will exhibit specimens of the diatoms he states he has found in the London Clay at the annual meeting of the Geologists' Association on February 6.

A SEVERE earthquake was felt at Coire, in the Grisons, early on the morning of the 7th inst.

DURING these last twenty years numerous complaints have been published or sent to the public authorities with regard to the organisation of the observatory of Algiers. This unhappy state of things has now come to an end. This establishment has been placed under the authority of the rector of the Academy, and a lectureship in astronomy has been created. The same decree has organised the several preparatory schools recently created by law. An Oriental Section has been organised, and the lectureship for Arabic existing in Algiers, Oran, and Constantine have been connected with it. Chairs for Mussulman Law, African Geography, African Antiquities or History, have been created by the same decree. M. Pomel, one of the Senators for the Algerian provinces, has been appointed director of the School of Sciences and Professor of Mineralogy in the same schools. He will be obliged to resign his senatorship.

MR. C. LLOYD MORGAN, Associate of the Royal School of Mines, F.G.S., Lecturer on Science and English Literature at the Diocesan College, Rondebosch, Cape Town, has been appointed Examiner in Natural Science at the Cape Town University.
