255. *QUERCUS UNDULATA* var., GAMBELLII, Engelm.—This is the common deciduous-leaved White Oak found in the mountain cañons from western Texas to southern New Mexico and Arizona, northern Mexico, Colorado and Utah. It is very closely related to the eastern *Quercus alba*; and Mr. Edward L. Greene, whose opportunities for studying this tree in the field have been great, insists (West American Oaks, 23,) that it cannot be considered a form of the shrubby evergreen *Q. undulata*, with which it was united by Engelmann. Forms occur, or appear to occur, in the herbarium which seem to lead to a union more or less close of all the Oaks of the interior of the continent; but with Oaks, and indeed, with nearly all trees, a judgment of specific differences and limitations based primarily on studies in the field is the best, and in this case I am glad to have impressions gathered from an examination of dried specimens only, confirmed by Mr. Greene's field observations, and I shall follow him in restoring the *Quercus Gambellii* of Nuttall.

263. *QUERCUS OBLONGIFOLIA*, Torr.—Mr. Greene proposes (*l. c.*) to separate from this New Mexico and Arizona tree the evergreen White Oak of southern California, under the name of *Quercus Engelmanni*. The California tree is larger, with larger leaves, often retuse or emarginate, larger striate acorns and much thicker cup-scales; and in the herba-

rium it is not difficult to distinguish the two plants, which it will be best, probably, to keep separate. It is less evident, however, that Mr. Greene's proposition (*l. c.* 29) that *Q. grisea*, Liebm., is a variety of *Q. undulata*, Torr., to which he would refer also Torrey's *Q. oblongifolia*, can be sustained. The connate cotyledons of *Q. grisea* would seem to separate this from the other Rocky Mountain and north Mexican White Oaks; although *Q. oblongifolia* may well be an arborescent form of the polymorphous and generally shrubby *Q. undulata*. But these are matters which cannot be settled at this time and which only protracted field observations can determine satisfactorily.

267. *QUERCUS VIRENS*, Ait.—Aiton's name (Hort. Kew, iii., 356), published in 1789, must give way to Miller's older one (Gardeners' Dictionary, ed. 8.), published in 1768—*Quercus Virginiana*.

QUERCUS TOMENTILLA.—This evergreen White Oak is closely related to *Q. chrysolepis*, from which it is readily distinguished by the stellate pubescence of the young shoots and foliage and by the prominent primary veins of the leaves. It was discovered by Dr. Edward Palmer in 1875, on the Island of Guadalupe off the coast of Lower California, and has recently been found by Mr. Greene on the Island of Santa Cruz, and last year by Mr. Brandegee on Santa Rosa: and it must now be included in the North American Silva. Its position is immediately after *Q. chrysolepis*.

QUERCUS MOREHUS, Kellogg.—Mr. Greene proposes (*l. c.* 3) to take up this species first described by Dr. Kellogg (Proc. Cal. Acad., ii., 36). It is a small tree, thirty feet high, widely distributed in the California coast-ranges and in the Sierra foot-hills, but nowhere common. It is nearly intermediate in character between the deciduous leaved *Q. Kelloggii*, the common Black Oak of the Pacific coast forests, and the evergreen *Q. Wislizeni*, and it has been suggested that it may have been produced by a cross between these two species—a view which Mr. Greene does not share, and which he believes to have been impossible. I have no knowledge of the plant beyond what has been gained from the examination of a single herbarium specimen in fruit, and from Mr. Greene's description.

277. *QUERCUS FALCATA*, Michx.—There are, perhaps, three older names for the Spanish Oak than that of Michaux published in 1801. It has been sometimes thought that the *Q. rubra digitata* and *Q. rubra montana* of Marshall had reference to this species, but there is a vagueness in the descriptions which leaves some doubt as to just what tree he had in mind. It will therefore be safe to pass by these names entirely and take up the *Q. cuneata* of Wangenheim (Amer. 78, t. 5, f. 14, a), published in 1789, or fourteen years before Michaux's name. Wangenheim's figure represents a leaf of the trilobed form of the species—the *Q. triloba* of Michaux.

288. *QUERCUS CINERIA*, Michx.—The reference of this species to the *Q. humilis* of Walter, which is several years older than Michaux's name, is too uncertain, without an examination of Walter's herbarium, which is preserved in the British Museum, to make any change of name for this species possible.

QUERCUS LEANA, Nutt.—This tree has generally been considered a natural hybrid, between *Q. imbricaria* and *Q. coccinea* or *Q. tinctoria*. It is now known in several widely scattered localities, from the neighborhood of Washington, D. C., to Missouri; and there seems no reason, whatever its origin may have been or however recently it may have appeared, why, if *Q. heterophylla*, which many excellent observers have always considered a hybrid, is included as a species in the American Silva, *Q. Leana* should not be included also. It should follow immediately after *Q. imbricaria* with which its relationship is obvious.

QUERCUS MACDONALDI, Greene.—This is described as a small deciduous tree by Mr. Greene (West American Oaks, 25) who discovered it on Santa Cruz Island, California, with

a variety *elegantula* from the southern part of the state. I have not seen specimens of these trees, and have no knowledge of them beyond that derived from Mr. Greene's descriptions.
C. S. Sargent.

Abies Fraseri.

AN interesting feature of the forest-flora of North America is the multiplication of species of Fir (*Abies*). The American forest, if we include Mexico with its single Fir-tree and consider *Abies concolor* as truly distinct from the Fir of the north-west coast (*Abies grandis*), contains ten species of these trees; while in the rest of the world there are known only eleven species, even allowing that some doubtful ones like *A. Cephalonica* and *A. Appolinis* of the Orient are really specifically distinct from the widely-distributed *A. pectinata* of Europe—a view which has not been held by the most competent observers of these trees. Europe, in addition to *A. pectinata*, possesses a second species (*A. Pinsapo*), confined to the Spanish Sierras, and to some of the high mountain-ranges of north-western Africa. In the Asia Minor and Caucasian region there is a group of four closely allied species or varieties, including the two we have already mentioned and *A. Nordmanniana* and *A. Cilicica*. The forests of the Himalayas contain one species with two rather distinct forms, while another Asiatic species (*A. Sibirica*) is widely distributed through the more northern parts of the Continent. In Japan three species are known. The true home of the genus, therefore, if the multiplication of forms indicates that a genus is more suited to flourish in a particular region than in another, is western North America, where Firs are found upon all the mountain ranges from the Arctic Circle to the high peaks of central Mexico.

Two species occur also in eastern America, *Abies balsamea*, very widely distributed over all the boreal parts of the continent and extending far north from the Atlantic to the Pacific, the only Fir in the Northern States, and *A. Fraseri*, found only upon a few of the highest slopes of the Alleghany Mountains of Carolina and Tennessee, so that, next to the Californian *A. bracteata*, it is by far the most restricted in its distribution of the American species, which usually range over wide areas.

Our illustration upon page 475 shows a characteristic forest of this tree as it appears on the Carolina mountains at an elevation above the sea-level of about 5,000 feet. This particular forest covers the high slopes of the Black Mountain range, a lateral spur from the Blue Ridge near Asheville in North Carolina. The highest point of the range and the highest land in North America east of the Rocky Mountains, Mount Mitchell, appears in the distance.

Abies Fraseri is a small, short-lived tree, rarely growing to a height of more than seventy feet, with a trunk in full-grown individuals sometimes two and a half feet in diameter, with bright cinnamon-red bark, becoming gray as the trees begin to reach maturity.

It is not easy to distinguish at a glance, and without the cones, this species from the northern Balsam. The two trees resemble each other in foliage and in habit, and the appearance of the bark in old specimens is very much the same. The structure of the leaves, however, as Dr. Engelmann has pointed out, offers characters which serve to separate the two species, those of *A. balsamea* being almost destitute of the hypoderm cells which appear on the upper side of the leaf of *A. Fraseri* in an almost continuous layer. The two species, however, are at once distinguished by the cones. Those of *A. Fraseri* are shorter and more oval in outline, with largely exserted and reflexed bracts, while the bracts of the mature cones of *A. balsamea* are included in the scales, or rarely with their points only protruding. The white bands, composed of stomata on each side and parallel with the mid-rib, found in the lower surface of the leaves of all Firs, are much broader (with eight to twelve rows) in the case of *A. Fraseri* than in that of *A. balsamea* (usually with six rows)—a character which

may be relied upon generally to distinguish sterile plants of the two species.

Abies Fraseri was first made known by the Scotch botanist and traveler whose name it bears, John Fraser, who made several journeys to North America between 1780 and 1810 for the purpose of collecting seeds and plants for London nurserymen. Although Michaux, with whom he traveled in Georgia for a short time in 1782, refers to him several times with great contempt as "un certain Mr. Fraser," no one man has contributed more valuable plants to English gardens; and in the list of his introductions, which is published in the *Companion to the Botanical Magazine*, ii., 300, appear the names of some of the best garden plants found in North America, among them *Rhododendron Catawbiense*, parent of all the race of the hardy Rhododendrons of modern days. Michaux must have confounded the Fir of the southern mountains with the northern species, and it does not seem to have been introduced into European gardens until 1811. It is very well figured in the "*Pinetum Woburnense*," published in 1839, from a specimen then sixteen years old in the Duke of Bedford's collection; but it is very doubtful if there are now any old plants anywhere in cultivation. This tree is short-lived, and the plants of Fraser's introducing must have passed away long ago, while of late years seeds of *A. balsamea*, collected in Pennsylvania or in Canada, where specimens are occasionally met with, in which the tips of the cone-bracts are slightly exserted, have been very generally sold as *A. Fraseri*; and it is only within the last dozen years that the Arnold Arboretum has been able to distribute a supply of seedlings of the Carolina tree among the lovers of conifers in the United States and in Europe.

Abies Fraseri has little to recommend it as an ornamental plant; and, economically, few American trees possess so little value. It is perfectly hardy, however, in Massachusetts, and some of the plants in the Arboretum, although scarcely six feet high, have already produced cones.

C. S. S.

New or Little Known Plants.

Aster Herveyi.

THIS very rare plant, of which a figure is now first published upon page 413 was discovered a few years ago by Mr. E. W. Hervey on the borders of an Oak wood near New Bedford, Massachusetts. It was found subsequently by Professor Sargent in Tiverton, Rhode Island, growing on the gravel fill of a new road; and again within a few years by Mr. C. E. Faxon, in Muddy Pond woods, and near Blue Hill, in Norfolk County, Massachusetts.

*Aster Herveyi** is a slender, low plant, growing to a height of one or two feet, with numerous loosely corymbose heads, with lilac or violet rays half an inch long. Like nearly all the North American Asters, it takes kindly to cultivation, and makes an excellent autumn-blooming border plant. The *Biotia commixta* (D. C., "Prodromus," v. 265), an old inhabitant of gardens of unknown origin, is, according to Professor Gray, a robust cultivated form of this plant.

Foreign Correspondence.

London Letter.

I WROTE last week of the splendor of our open-air gardens since the outburst of warm sun after the long period of rain. Not less remarkable, just now, is the indoor garden also, which, after its usual dull season at the height of summer, has begun to assume its wonted gay aspect in autumn, and during the past week I have had the opportunity to see some fine examples of glass-house gardening. At the present moment the plant of plants undoubtedly is that lovely Chilean climber, the *Lapageria*, which is to be found now in almost every green-house throughout the land. In one place I saw a plant covering the entire roof of the green-house, and the

**Aster Herveyi*, Gray, Manual Bot., Northern U.S., 5th ed., 229; syn. Flora, i., 2, 175.

Fig. 131.—*Aster Herveyi*.—See page 472.

shoots were thickly wreathed for several feet with the crimson bell-like flowers of the one sort, and the waxy, pure white blossoms of the Alba variety. There are now several named varieties of the typical *L. rosca*, which vary more or less from the original and from each other. The finest, as regards color, is unquestionably that known as the Nash Court variety, which is now being distributed. The flowers are very large and of

perfect shape, while the color is a rich rosy-crimson. Another sort, called *Superba*, is also very fine, and last week Messrs. Fisher, of the Sheffield Nurseries, who make a specialty of the plant, showed two varieties, named *Floribunda* and *Maculata*, the first, a large-flowered and rich-colored sort, said to be exceptionally floriferous, the other, with flowers of pale rose-crimson, conspicuously veined and spotted with white. These are

among the best varieties, but there are many decidedly bad sorts obtained from seed, being poor in color and small in bloom. Some clever people have hybridized the pure white Alba with the red, the progeny being a mongrel race, neither white nor red. The white still maintains a high price in nurseries, chiefly because its propagation and growth are not rapid, and the finest form of it is always in great demand. The climate of an English green-house seems to suit the *Lapageria* to perfection, due probably to the almost perpetual moisture, for the plant abhors strong heat, dryness and strong sunlight. It is not too much to say that the *Lapageria* is the most popular and most valuable green-house plant introduced during the present century, and it is doubtful if the Veitchian travelers will ever send home a rival to it.

Orchid-houses, so long almost flowerless, are now bright with several early autumn flowers, and none is more beautiful than the Blue Indian Vanda (*V. carulea*). I saw some magnificent plants of it this week in full flower in an ordinary green-house, where the plants have plenty of ventilation and not too much heat, and this is the secret of growing this Orchid well. Many stifle it, with other Vandas from the hot tropics, the result being that the Blue Vanda always looks sickly and rarely flowers well. There are many forms of this Vanda, and there is a wide difference between the finest and the poor forms, the latter having small flowers, almost white, while the best variety has flowers four inches across, of a deep Tyrian purple, tessellated with white veins, and this form, which is a gem among Orchids, I know, exists in one of your famous American collections—that of Mr. Corning, near Albany. Other Orchids in flower and worth notice, would, of course, include the handsome old *Odontoglossum grande*, still the noblest of the genus, and a plant which can be grown to perfection without the aid of a specially constructed Orchid-house; indeed, the best specimens I have seen lately were growing in a green-house with other kinds of plants. The new *Vanda Sanderiana* is not heard so much about now, and there is no disguising the fact that, as a rule, it is a difficult plant to manage successfully. At Kew, where there is a good specimen in flower just now, it is growing admirably in company with other eastern tropical Orchids. There is something very fascinating about the large flat flowers, with their strange combination of color, rose-pink and olive-brown, though they do not captivate visitors so much as the splendid *Cattleya Dowiana aurea*, which for the past week or more has been in perfection. It is not often that this Orchid is seen with four flowers on a spike, and the fact is worthy of note, as it shows how finely the plant is grown at Kew. Another very remarkable Orchid in flower at Kew is an exceptionally fine variety of *Miltonia Moreliana*, which is far finer than the rare *Arorubens*. The flowers are three inches across, the sepals a deep claret-purple, the broad labellum rosy-crimson, reticulated with darker and paler veins. It is known as the Kew variety, and is the envy of all Orchid-fanciers who have seen it during the past month and in former years. Orchid sales are for the moment quiet, but I notice that the wonderfully fine collection of Mr. Partington, at Cheshunt, is to come under the hammer next month. It is well known that some of the finest Phalænopsis in the country are in this collection; and it will be a good opportunity for Americans to secure grand plants. Mr. Watson gave you a description of them recently, and they astonish almost all who see them for their large size and extraordinary vigor.

The cool conservatories at Kew contain numerous out-of-the-way plants in flower that deserve to be more popular, and one of these is a Cape bulb, *Cyrtanthus hybridus*, which, I believe, was raised some years ago in Sir Trevor Lawrence's garden. To describe it, it must be compared with the beautiful old *Vallota purpurea*, or Scarborough Lily, but its flowers are smaller, more funnel-shaped, and more blossoms are borne on the dwarfed spikes. The color is somewhat different, being of a softer scarlet. As it flowers at various seasons of the year it is more valuable as a garden-plant than the *Vallota*, which only flowers in autumn. Another beautiful Cape bulb is a new variety of the well-known *Tritonia aurea*, which has been introduced by Mr. J. O'Brien. It differs from the original in having the petals marked with a large crimson blotch, which, on the bright orange ground, is very effective. There is, also, at Kew, a very robust variety of *Tritonia*, having spikes from three to four feet high, carrying flowers three inches or more across of a richer color than the ordinary sort. It is an invaluable plant for the green-house in summer, and, as it has already found its way into various gardens, it will probably supplant the old form in course of time.

The Neilgherry Lily (*Lilium Neilgherrense*) is one of the leading features at Kew, for, in one of the green-houses, there

are many plants in flower—more than I have seen together before. It is a noble and beautiful Lily, a good deal like *L. longiflorum* in growth and flower, the latter being about eight inches long and of a soft, creamy-white color, which, to artistic souls, is more enjoyable than what they call the cold white of the *Lilium longiflorum*. The Neilgherry Lily has always been considered difficult to grow and flower well, but at Kew they seem to have hit upon its peculiar requirements, as, indeed, they have with every other kind of Lily during the past year or two, as every kind is grown here now better than I have seen them anywhere, although, a few years ago, it was said by Lily experts that it would be hopeless to expect Lilies to thrive on the dry, gravelly soil at Kew. The success achieved proves what may be done by ignoring empirical practice and striking out a new line, as the directors have done here in Lily culture. The other green-house Lilies in flower now are chiefly forms of *L. speciosum* or *L. lancifolium*, though they are quite hardy, and grand masses of them are in flower in the open air. Besides the large, dark-flowered varieties, like Hovey's Melpomene, there are some beautiful effects obtained with the white Krætzneri, and a group of it, intermingled with the blue African Lily, *Agapanthus umbellatus*, produces one of the most beautiful and striking combinations in the green-house—a mixture well worth imitating. Krætzner's white is so much superior to the ordinary white that it is superseding it. The old form is almost always suffused with pink, but the other is pure, and may be readily recognized by the greenish-white ribs on the petals.

Picking out the good things in flower in the stoves at Kew, this week, I should note *Passiflora kermesina* as one of the very best small stove climbers in cultivation. It has for some time past been crowded with its lovely cherry-crimson flowers, while its growth is always elegant, and it is of the simplest culture. *Pleroma macranthum*, also known as *Lasiandra macrantha*, is also a very beautiful and reliable green-house plant for covering a wall, pillar or roof. It now carries a profusion of large flowers of the richest purple imaginable. A new composite from Mexico is likely to prove a good green-house plant. It is herbaceous, with a tuft of deeply-cut leaves, from which arises the tall, slender flower-stalks, with flowers three or four inches across, of the brightest orange-scarlet. The flowers have a single row of florets, very long and narrow, and these reflex prettily, as in the beautiful *Mutisia decurrens*, from South America, which grows and flowers against an open-air wall here. The new plant is named *Gerbera Jamesoni*, and I notice that the chief nurseries are working up stocks of it. It is a cool-house plant, of easy culture, and its flowering season extends over a long period. I know no other composite of exactly the same bright color.

Cultural Department.

Autumn in the Garden.

ALL things considered, the past season has been extremely favorable for hardy flowers, having spared us that most arduous of tasks—persistent watering to supply a deficiency of moisture during the heated term. Every one who has a garden, whether he work in it himself or not, knows the disastrous effect of an extended drought, when, one by one, the flowers begin to flag, unless constantly revived by the garden-hose and frequent stirring of the soil. To neglect this at such a time, whatever the cost of labor, is simply to mar the appearance of the garden for the remainder of the season. The plants may partially revive with the coming rain, but they will have lost that freshness which care might have preserved.

The effect of a generous rainfall the past summer has been apparent in an earlier and more profuse blossoming, together with a stronger growth of stalk and foliage in the case of the majority of flowers. In no plant is this more visible than in the Japanese Anemones, now a carnival of rose and white florescence. For one season, at least, the Japanese Anemone has drunk its fill of moisture; and, wherever placed, this graceful plant is a cynosure and a delight. Charming when dotted amid the shrubbery and borders, it should be far more generally utilized in beds and masses, especially the white variety. The white Phlox, when well grown, approaches but does not equal it, though it is earlier to appear. One of the numerous charms of the Japanese Anemone is its late-flowering habit; the chill autumn equinox comes and goes, but the Anemone still blossoms on. The rose-purple variety, or rather the type, is not so pleasing on first unfolding, but its color improves as its flowering advances and becomes, later on, a distinct and exquisitely beautiful shade which is supplied

by scarcely any other flower except the autumn Colchicum. It is a color we could not spare from the October garden, and in its later stage the flower vies in delicate beauty with its statlier white sister. The Anemone is not over fastidious as to soil, and should be placed both in sun and shade, or partial shade, to lengthen its flowering season.

Fitting companions to the Anemones are several species of the perennial Sunflower, notably the double *Helianthus multiflorus* and *H. orgyalis*. The larger forms, like *H. tuberosus*, are too coarse for the flower-borders proper, or the shrubbery of the foreground. On no account, however, should they be

the grounds. Where a thick, tropical-looking screen is desired during summer and fall, the Eulalia has few equals. *Erianthus Ravennæ*, a tall growing, reed-like perennial from southern Europe, resembles it, but does not equal it for ornamental purposes. Both flower during October, the large plumes of the latter resembling those of the tender Pampas Grass. During July and August *Eulalia Japonica variegata* is always handsome. Less robust than the type, and more sensitive to wind and heavy rains, it is apt to become beaten down in autumn. The smaller variety, *E. J. Zebrina*, its foliage marked crosswise with bands of white and green,

Fig. 132.—The Home of *Abies Fraseri*.—See page 472.

banished, but be placed in the rear garden, or set against a distant shrubbery, where their golden lights may shine. Among the extensive Sunflower tribe there are few species more showy during late summer than the large *Silphium perfoliatum*—a steadfast bloomer throughout August, and handsome enough during its blossoming period to merit a post of honor anywhere. The Sunflowers, it may be said, were born without cultural directions. Nevertheless, in the case of the double Multiflorus, occasional division is of great benefit to the vigor of the plants and the numbers and size of the flowers.

Attractive objects during autumn are the Eulalias, or tall Japanese Grasses, the type being the most robust. This may be used with fine effect on either side of a gate or entrance to

holds itself more erect, and is one of the most distinct and ornamental of rushes or grasses.

A fine combination for a bed might be made with a few specimens of the type for the centre, surrounded by the smaller silver-leaved Zebrina. A bed of purple-leaved Cannas, with their scarlet, Strelitzia-like flowers, fringed with the white Japanese Anemone, would also be worth looking over to see in one's neighbor's garden. And, for a change from the tiresome Geranium-bed, why not a bed of fragrant yellow and white Iceland Poppies, which are so easily raised from seed sown the summer before they are required, to be succeeded by the Salvia's flame. Or, if Geraniums must be used, a bed of the salmon or light-colored kinds, even if they be not quite

so free flowering, to vary the monotony of General Grant, which so often figures as the centre-piece—sometimes even of a clam or oyster bake—upon the lawn.

The first of October finds the large Phloxes mostly past. The trade catalogues abound with so many long lists of varieties that it may be well to specify a few that have been tried and not found wanting. Brilliant and handsome as are the big Decussata Phloxes, they are not without objectionable colors, particularly the rose and rose-purples, while of two varieties, almost similar in the color of their flowers, one may be a much less vigorous grower or have much smaller trusses than the other. Of the whites, *Viège Marie* and *Queen of the Whites* are among the best, the former the tallest and more robust grower and the latest to flower. Of the light reds, *Réve d'Or*, *Gambetta*, *l'Avenir* and *Lothair* are distinct and beautiful, the latter one of the most brilliant of its class, and among the most brilliant of hardy flowers. *Isabey*, a variety recently sent, much resembles it, and appears to be equally vigorous. *Parrai*, a new variety, is the finest of the rose-colored kinds, both in truss and color. Intermediate between white and rose, two old varieties, *Richard Wallace* and *Premier Ministre*, are unexcelled, while *Oberon* still remains the most gorgeous deep red.

Just now the perennial and annual Asters appear, to contribute a needed color—purple and its various shades—a compliment to the hardy Sunflower's gold. Even the common Aster of the fields and road-sides is well worth growing amid the shrubbery and the wild garden, while the China Aster, in its more varied hues, lends an almost spring-time gayety to the garden during late September and October. It is, moreover, very desirable for cut-flowers. Usually, the mistake is made of too early sowing. Sown the latter part of June in shade, in the open ground, the annual Starwort will come into bloom at a time when it is really required. A touch of white frost only accentuates its colors, and, weeded of its objectionable shades, it is among the most desirable of garden annuals. Neither should the old-fashioned *Dahlia* be overlooked by any who have an appreciation for color; it helps to woo the slanting sunbeam and lengthen the shortening October day.

The Angelica-tree, or Japanese *Aralia*, is at present a tropical-looking shrub on the lawn, with its large tripinnate leaves, spiny stems and grand crown of white blossoms. Unfortunately, this is rather tender, requiring protection during winter. The gay flowers of the *Roses of Sharon*, too, an occasional second flowering *Bee-larkspur*, and purple *Clematis*, and the colored fruits of many of the ornamental shrubs are now conspicuous and contribute their quota of color.

But the beauty and pleasure of the garden at this season will depend largely upon the care it receives, and no little work is called for in cutting out the withered branches and removing the withered leaves, as well as keeping walks and borders free from weeds, and the sward properly shaven. We weed and hoe, and stake and "edge" in summer—we neglect the garden in autumn, when, with proper care and judicious planting, it may present an aspect of almost equal beauty. Can all the golden days of summer create a flower more chastely fair than these lovely, nodding Wind-flowers of October, with their spotless petals surrounding the pale-green stigma and feathery-golden stamens; and shall I let this sweetest tribute of the latter year rear its beauty amid neglected surroundings!

While referring to autumnal flowers the question of spring, versus fall planting may be briefly considered. As a general rule, fall planting is to be commended, provided it be done early, the plants thus being enabled to take hold of the soil before winter sets in and obtain a start for the following year. Of course, there are not a few plants which are set out to disadvantage in autumn, though this will depend somewhat on whether the winter prove severe, or whether the plants receive winter protection. So, also, will successful spring planting be determined largely by the weather, as all successful planting will depend upon the condition of the plants when set out. Plants poorly packed and sent from long distances are expensive to experiment with at any season and at any price. Late-flowering plants, like the Wind-flowers and Monks-hoods must be set out in spring; the hardy *Coreopsis* and most of the *Helianthæ*, also, do best when transplanted at that season. *Heilebores* should be moved early in the autumn, and *Pyrethrums*, *Ranunculus*, *Iris*, *Bee-Larkspurs*, *Pæonias*, the large Oriental Poppies, the *Decussata Phloxes*, and most of the *Campanulas* are best transplanted in early fall. Besides being a suitable time for the moving of most perennials, early autumn transplanting has the advantage of seeing the plants established, of more intelligent placing in the borders, and, finally, of a fact accomplished when the first garden Snow-drop proclaims the spring returned. *George H. Ellwanger*.

Rochester, N. Y.

Stove Plants in Flower at Kew.

Ixora macrothyrsa.—This is a most superb plant for the stove. It is unlike all other garden *Ixoras* in the size of its flower-heads, strong plants producing heads fully nine inches across and as full as a Hawthorn blossom. The color is bright, glowing crimson. A plant at Kew has been in flower three weeks, and its blooms are still as perfect as when they first opened. For large stoves no *Ixora* equals this one. The treatment of most of the plants of this genus includes severe pruning every spring and the stopping of the most vigorous shoots, with a view to obtaining compact plants with numerous short branches, each of which will bear a cluster of flowers. But *I. macrothyrsa* must not be treated in this fashion. The branches must be allowed to grow unchecked, and, with liberal treatment, they should become three or four feet long. The longer and stouter the branches, the larger the heads of flowers will be. After flowering, the strongest branches should be cut back hard, and when they have broken again they must be repotted and treated liberally. As a rule, the shoots do not become strong enough to flower until they are about two years old. The garden name for this plant is *I. Duffii*.

Gustavia gracillima.—Although introduced and flowered by Mr. Bull for the first time in 1875, yet this plant appears to have flowered only very rarely. It flowered at Kew in 1883, and is again in bloom in one of the stoves there. It is about four feet high, erect, unbranched, with linear, bright green leaves, and even when not in flower is ornamental. The flowers are developed in clusters on the ripened part of the stem, and they have scarcely any stalk; they are about four inches across, and composed of eight broad, overlapping petals, surrounding a broad disc-like cluster of yellow, purple-tipped anthers. Several other species of *Gustavia* are cultivated at Kew, and have flowered on rare occasions. A considerable number of the section of *Myrtaceæ*, to which *Gustavia* belongs, have flowers of large size and exceptional beauty, but they do not flower under cultivation here. Such are the Cannon-ball tree (*Couroupita*), *Barringtonia*, *Lecythis*, etc., plants which are easy to grow but fail to flower, probably through lack of intense sunlight. *G. gracillima* is a native of the United States of Colombia.

Ataccia cristata.—The very remarkable and ornamental plant grown in gardens under this name belongs to a small, natural order nearly related to the *Amaryllids*. When well managed it flowers freely and presents a picture of more than ordinary attractiveness. It has dark, purplish-green, ovate, thin leaves a foot or so long, with a petiole about four inches long. The flower-scape is erect, about one and a half feet high, stout, angled, purplish, and bearing on the apex four large bracts, two of which are parallel, erect, five inches long, and suggestive of the large dorsal sepal of *Cypripedium Lawrenceanum*; the other two, which are placed beneath the flowers, are boat-shaped. The flowers are purple, one inch across, and composed of six reflexed calyx-lobes, no petals, a ring round the mouth of the shallow tube, and a short, thick, six-furrowed stigma. In addition to the perfect flowers there are also numerous whitish filaments, six inches long, springing from the base of the bracts, and these filaments are really abortive flowers. It is difficult to describe the plant so as to convey an idea of its ornamental character. It should be grown in a moist stove, and potted in fibrous peat and sphagnum with a sprinkling of sand and charcoal. It likes abundance of water all summer, and less in winter. Plants three feet through and bearing thirty flower-scapes have been grown by means of this treatment.

Kew.

W. Watson.

Notes From a Northern Garden.

GRAPES have matured much earlier and more fully this year than usual. We are apt to forget about the seasons, but for Grapes I think this is the earliest here since 1870. Our standard for a warm season is the perfect maturity of the Concord, which is quite rare.

MOORE'S EARLY, or, as I find it sold in Boston streets, the "Early Concord," ripens fairly here, though it is less early than Champion. The season of Moore's Early, Salem, Delaware, Israella and Eumelan are so close together that it is impossible to give either the precedence. In a season that is steadily warm from May to October, the Brighton is very early—even earlier than any above named; but in a summer with "cold spells," like this and last year, it does not even color.

THE CHAMPION GRAPE I have always regarded as the earliest and the poorest of all cultivated sorts—unfit for any but culi-

nary use. But this year it is suprisingly sweet—so much so that I at first thought I must be mistaken in the sort. It is very hardy and productive, and, if it were generally as good as I find it this fall, would be a profitable Grape for the far north. I think a vineyard of it would yield more bushels than a potato patch of the same size.

THE THRIPS increase annually on my vines, but although the foliage appears to be considerably injured, especially on the Delawares, the crop is not noticeably lessened. But I think the vitality of the vines must, in the end, be impaired. The thick, dark foliage of Moore's Early seems to be invincible to this insect.

THE SHIAWASSEE BEAUTY APPLE rises higher in my esteem year by year, as I become better acquainted with it. This season, when there are but few apples, and of these few most are ruined by insects, Shiaswassee is large, fair and perfect. A seedling of the Fameuse, it is yet quite distinct, being larger, more flattened, more brightly red, and distinctly more acid, though with the true Fameuse flavor. The tree is very hardy, having endured several of our severest winters; and above all, in point of comparative merit with its parent, it is free from the fungus spotting so ruinous to the Fameuse.

A NEW APPLE PEST, known in Vermont as "the Railroad Worm," because in its first inroads it followed the tracks, is doing immense damage. At first it attacked only early and sweet varieties, but now does not discriminate, except, perhaps, by preference for the softer-fleshed sorts. This minute insect enters through the skin when the fruit reaches maturity, and bores a net-like track through and through the apple, converting the flesh into a brownish spongy mass, with unaffected pulp in the intermediate spaces. Its presence is indicated in the mature fruit by dark depressed lines upon the surface; but this disfigurement bears but a slight proportion to the actual injury, which results in utter worthlessness, even in apples showing but slight external marks. I call the insect "minute," because, though cutting the apples in search of it at various stages, I have never found it, and should have supposed it some sort of fungus had I not been assured that it is a worm.

Newport, Vt.

T. H. Hoskins.

[The insect referred to is evidently the *Trypeta pomonella*, Walsh, known many years in some of the Western states, but which has not been reported as injurious in this section. The fly, for it is a true fly, is not more than one-fourth of an inch in wing expanse, of a rather deep brownish-yellow color, shining, and with prettily banded wings. The eggs are laid on the apples, usually on the thin-skinned varieties, and the maggots bore in every direction, as described above. In length it does not exceed one-fifth of an inch, and it is of a greenish-white or yellow color. When full-fed, in early September, or even earlier, the larva leaves the apple, drops to the ground, and burrows a short distance under the surface, where it changes to a pupa, emerging about midsummer of the following year. No practical remedies, so far as we are informed, have been suggested, as it has not proved so seriously injurious heretofore as to make special study necessary.—Ed.]

Orchid Notes.

Lælia Perrinii.—This elegant and free-blooming Orchid is not grown so extensively as its merits deserve. With ordinary treatment it grows strongly, and, what is more, produces its flowers at a season when there is the least number of varieties blooming. *L. Perrinii* has stout, deeply-channelled, clavate bulbs, and a single deep green leaf of a leathery texture, and about one foot long. The flowers, from three to six, are about five inches across, and rosy-purple, while the front lobe of the lip is of a purplish-crimson, the throat being white. This species was introduced from Brazil in 1831. It will grow best in an intermediate-house, with a good exposure to sunlight and abundance of air when the weather is favorable. Some pale varieties have been introduced recently, but are still very rare. These are Alba, with pure white flowers; Nivea, white, with the lip margined with rose, and Irroratus, rosy sepals and petals and nearly white lip.

Lycaste (Paphinia) grandis is the rarest and largest-flowered of a singular genus of Orchids now included in *Lycaste*. It is of a very compact habit, scarcely exceeding six inches in height, with ovate-clustered bulbs and thin plicate leaves. The scapes are pendulous, and to show the flowers to advantage the plants should be grown in baskets or small, shallow pans. The flowers are about six inches across, the lanceolate

sepals and petals being chocolate-brown, barred and edged with cream color. The claw-like lip is blackish-purple, with the front lobe cream-colored and surmounted with a tuft of hair. This plant, with its congeners, needs a good deal of heat, and it should never be allowed to become dry. Very little potting material is required, and that may be a mixture of fibrous peat and moss. It was introduced from Brazil in 1884, and a few seedlings from one of the first introductions will soon be in bloom with us.

Odontoglossum Bictonense was the first species of the genus to reach England alive. It has an extensive range through Mexico and Guatemala, and was introduced from the latter country in 1835. Though it may not be compared to its superb and larger-flowered congeners of later introduction, still, when in fine condition, the many-flowered, branching racemes are by no means unattractive. It is of very robust habit, with oblong-flattened bulbs, surmounted by two to three undulated deep green leaves. The stout, erect racemes are often branched, and bear many greenish-yellow flowers, prettily spotted with brown. The cordate-acuminate lip is usually pink, but there are a great many varieties, the most distinct being one with a pure white lip. This Orchid prefers the intermediate-house, in well-drained pots of peat and moss, abundance of water during growth, and a decided rest by withholding the water to a certain extent during winter.

Kenwood, N. Y.

F. Goldring.

Oncidium varicosum Rogersii.—The extraordinary flowering qualities of this *Oncidium* has rendered it very popular, and we now find it grown extensively. Its strong, well-branched spikes, which attain a length of three and four feet, make their appearance at this season, and are laden with massive flowers of great brilliancy; the sepals and petals are small, barred and spotted with brown; the lip, however, is a rich golden-yellow, broad, flat and, in some instances, beautifully undulated, and furnished with a claret-colored blotch in the centre. Spikes carrying from eighty to one hundred flowers are of common occurrence, and even comparatively small plants will produce this number when properly managed. It is, however, advisable to cut the spikes from such plants as soon as the flowers are fully expanded, so that their strength may not be exhausted and prevent their blooming the following season. Like most *Oncidiums*, they delight in an abundance of air during growth and a position as near the light as possible. Very little compost is necessary about the roots, but good drainage is very essential. Baskets are better than blocks. They do not dry out so rapidly during our hot summer weather.

Sophronitis grandiflora.—This is one of the gems of our dwarf Orchids and very easy to cultivate. It occupies very little space, and produces its rich scarlet blossoms at this period with the young growths. The individual flower measures from two and a half to three inches across, and is round, well formed and of good substance, remaining on the plant five or six weeks in good condition. Its cultural requirements are simple, and, if placed firmly in baskets or pans where plenty of light and air is available, it will grow and flower very freely. While growth is being made, it should occupy a cool position, for if grown too rapidly it will not bloom. When the flowering period is over, water may be withheld to thoroughly ripen the bulbs. During the winter months it should be grown in a temperature of fifty-five to sixty degrees. One of Mr. Hicks Arnold's cool houses, in New York, was recently ornamented by a well-flowered group of these Orchids.

Summit, N. J.

A. Dimmock.

Aponogeton distachyon, the Cape Pond Weed, is a pretty and very desirable aquatic plant for the decoration of the greenhouse in winter, not only for its quaint form, but also for its delicious fragrance and the pure white color of its flowers, or, correctly speaking, bracts. The foliage also is most beautiful, being borne on long stems to enable it to float and present its bright, shining, green surface as a foil to the flowers. As it is strictly a winter-flowering plant we have found it difficult to change its season, so as to flower it in summer. If this could be done, the *Aponogeton* could be easily naturalized, and it would prove hardy here in the East, but in the more favored states, as to winter climate, the *Aponogeton* may be easily planted out in streams or ponds and will take care of itself and increase very rapidly. We usually take the roots out of the old soil in September, and plant them in pots suitable in size to the strength of the plant, and then immerse the pot to about twelve inches below the surface, when in about seven days flowers appear simultaneously with the foliage, and at once fill the structure with their fragrance. In this way unsightly cisterns, or other receptacles of water, may speedily

be made to have an interest of their own. It should be added that the soil should be well enriched with well decomposed cow-manure. About one-third of this with the rest of ordinary garden soil, with a sprinkling of charcoal added, will be found a suitable compost for the purpose. If it is desired to increase the stock, this is easily and rapidly done by means of seeds, for after the flowers have been in full beauty for a month the bracts begin to turn green, and seeds are formed, and when these are ripe the bracts dissolve and the seeds sink at once to the bottom and germinate in about seven days. These will form small bulbs the size of a pea the first season, and will flower the second year of their growth, and these increase in size with the strength of the bulb or tuber. After the plants have flowered for six months they manifest a desire to rest, and when this is the case they may be allowed to gradually die off. We then, for convenience sake, keep them out of the water, but never allow them to become dust-dry, just keeping them moderately moist until fall, when they are started again. We are acquainted with no more suitable plan for planting in aquaria or any similar situation. O.

Passaic, N. J.

The hybrid *Montbretias* seem to increase in attractiveness every year, and one can hardly help feeling grateful to the French growers who first obtained them by intercrossing *M. Pottsii* and the old *Tritonia aurea*, or *Crococma aurea*, as it is otherwise called. It was M. Lemoine, of Nancy, who first effected this cross, calling the progeny *M. crocosmiaeflora*. The hybrid combines the vigorous growth and abundant flowering character of *M. Pottsii*, with the large flowers and richer color of the *Crococma*; while, as is often the case with hybrids, it possesses a more vigorous constitution than either parent. The flowers are about half as large as those of the *Crococma*, but of a much richer color, being almost entirely scarlet, and many flowers are borne on each stem that overtops the narrow foliage. The habit most resembles that of *Montbretia Pottsii*, and so rapid is its growth that a small plant will, in a season or two, spread into a mass several feet across, instances of which may be seen at Cheswick and Kew. The hybrid is, moreover, very persistent in bloom, lasting for several weeks, and it does not suffer from excessive rain. The graceful flower-spikes are invaluable for cutting, though they do not last long in vases. There is a bright yellow variety named *Boule d'or*, and other fine varieties have been raised by M. Lemoine.

The Forest.

The Forest Pavilion at the Paris Exposition.

WE have already given some notes on the forestry exhibit made by our own government at the Paris Exposition, and we are glad to add some account of the display made by the French government in the same direction. The following description of the pavilion and the principal forest-material which it contains is the translation of part of a letter to the *Independence Belge*, which was kindly furnished us by a lady much interested in forestry. Next week we hope to publish the more important part of the article, which explains how the actual work of the *Administration des eaux et forêts* is exhibited in photographs, dioramas, models, etc.:

Among the marvels of the Exposition is the pavilion of the Executive Department of Forestry on the Trocadéro, constructed entirely of the trunks of trees. Leaving the broad walk and following a foot-path through the turf, we come to a little hillock of natural rock covered with Ivy and creeping-plants, and, mounting a few steps, hollowed in the rock, or made of natural pieces of wood, we reach the verandah which surrounds this picturesque pavilion.

The peristyle is formed of high columns, which are magnificent trunks, carefully selected, and straight as arrows. Each species is represented by a perfect specimen and all are disposed so as to bring out soft harmonies and contrasts of color.

There are Oaks of various forms, Hornbeams, Elms, wild and cultivated Cherries, deeply-ribbed Locusts, Poplars, black and gray, Firs, with reddish bark, Maritime Pines, with purplish scales, Spruces, Lindens, Ashes, glittering Birches, Beeches, with bark of the finest texture, and Service trees, with a covering like a coat of mail. Every specimen carries its certificate of birth in a label fastened to the bark. Most of them are centennarians, and many are 150 years old.

The walls are covered with a mosaic formed of natural wood, bark and tresses of ligneous fibre; the ceilings are also

composed of original designs in wood, carved and sawn; the capitals, cornices and balconies are of branches, knotted and twisted, as if they were carved; the roof is made of shingles, with the gray and violet shades of slate, and the effect of the whole is charming.

Under the verandah, where Jasmine, Clematis and Ampelopsis climb, rustic seats are hollowed out of tree-trunks, and those who love the forest, and can understand all its poetry and charm, find an indescribable pleasure in resting here in the shade of this rustic colonnade, where they can inhale the aroma of the trees away from the dazzle and bustle of the exhibition.

The interior of this monument of skill is a rectangular saloon, lighted from above, and surrounded by columns which support a gallery. These columns, too, are superb tree-trunks, arranged in pairs of the same species, so as to form frames for as many panels, on which are collected the different articles made out of the various woods.

Near the Chestnut-trees are gathered staves, tubs, pails and floorings; the Larches have churns and bowls; the Alders, kegs for cement, wooden shoes, guitar-handles and tops; the Beech has sabots, heels and soles of galoshes, porringers, bread-shovels, pack-saddles and saddle-bows; the different Pines have baskets, wood for packing-cases, lamp-lighters, bungs for barrels, together with felt and bagging; the Fir has wash-tubs, date-boxes, oars and carved toys. Between the Linden-trunks we find well and capstan ropes, wood for brushes and hoops; between the Maples, tool-handles, teeth for rakes, spigots, fans; the Wild Cherry has pipes, fine sabots, canes and parasol-sticks; the Pear-tree, carved furniture, chests, veneering; the Walnut, gun-stocks and carriage-panels. Near the Ashes are collected yokes, mast-hoops, shafts, flail-handles, rakes, naves of wheels; near the Oaks are casks, barrels and flooring; around the Cork Oaks are hung soles, rosaries of corks and life-buoys. These collections, arranged as trophies and heraldic devices serve as entertaining object-lessons.

In the centre are the machines which saw, hew, split and work wood and convert it into marketable and useful form. A fountain gushes from among the rocks and Ferns, and here and there are suspended stags'-horns, boars'-heads, skins, furs, while deer, squirrels and other denizens of the forest, carefully stuffed, are grouped around.

On the first floor are arranged the glass-cases containing the herbariums and forest-tree seeds; here, also, are carbonized woods, collections of injurious insects, parasitic fungi, and a complete forestal bibliography.

Recent Publications.

Timber and Some of its Diseases. By H. Marshall Ward. Nature Series. Macmillan & Co., London and New York. 1889. Small 8vo, pp. 295, fig. 45.

This work is based on a series of short articles published in *Nature*, to which the author has added a chapter on the theories advanced to explain the ascent of water in tall trees. This chapter, which fills nearly a third of the whole book, is an admirable summary of what has been written on a very important, but perplexing, subject. The author states in the preface that it will perhaps be regarded as too technical for the general reader, which is probably true, but it is of great interest to the student. Had it been possible to give a more detailed account of the anatomy and microscopic structure of the tree-trunk in the opening chapters, there would have been no reason why the general reader who seeks genuine information, rather than mere entertainment, should not find this important chapter not only intelligible, but interesting. The author does not accept the theory of Sachs that the water ascends in the trunk by imbibition, or absorption by the walls of the vessels, nor does he accept without modification the view of Boehm, R. Hartig, and others, that it passes upward in the cavity of the vessels by capillarity and osmosis. The subject, however, is too complicated to be discussed here, and it need only be said that Professor Ward accepts the views of which Godlewski is the most forcible expounder, that the upward current of water is not due to the action of the vessels, including tracheids, alone, but that the living cells of the medullary rays also play an important part in the process, and that the respiration of the protoplasm in these cells is the force to which the upward flow is essentially to be attributed, while capillarity and osmosis play a secondary part.

As it is, the remainder of the book, which is devoted to a description of some of the diseases of wood, is somewhat overshadowed by the prominence given to the subject just mentioned. The account of the diseases caused by *Agaricus*

melleus and several *Polypori*, the canker of Larch-trees, due to *Peziza Willkommii*; Pine-blisters, caused by *Peridermium*; damping-off of seedling-trees, due to *Phytophthora omnivora*, is a simple and clear summary of the researches of R. Hartig, Wolf and others, enriched by notes of observations made by the writer himself. The work is to be recommended to all who wish to obtain a scientific knowledge of the bearings of fungus growth on tree-culture.

College Botany, including Organography, Vegetable Histology, Vegetable Physiology and Vegetable Taxonomy. By Edson S. Bastin, Chicago, G. P. Engelhard & Co., 1889, pp. 451, figs. 579.

This work is a revised and enlarged edition of the "Elements of Botany," published in 1887. The principal changes consist in the enlargement of the chapters on the use of the microscope and reagents, the revision of the portion on Vegetable Taxonomy, and the addition of a chapter on the "Succession of Vegetable Life." The Thallophytes are in the present edition treated under the head of algæ, fungi and lichens, instead of being classified by their mode of reproduction as was the case in the earlier edition. The appearance of a second edition of this work so soon after its original publication indicates that experience has shown it to be well adapted to the class of students who desire a general treatise on botany in a compact form.

Periodical Literature.

There is an interesting article on "Floods and Their Causes," by Dr. Felix L. Oswald, in *Lippincott's Magazine* for August, in which the conclusions coincide with those which have been so often insisted on in these columns.

Dr. Oswald says that while men have been disputing about metaphysical subjects, the very basis of organic life has been disappearing from under their feet; that for nearly 2,000 years the inhabitable portion of the earth has decreased at the average yearly rate of 3,500 square miles, and that in historical times some 7,000,000 square miles along the shores of the Mediterranean, once highly fertile, have been changed into worthless deserts. He quotes Mr. Marsh's declaration, that "another era of similar devastations would make the earth an unfit home for its noblest inhabitant, and threaten the depravation, barbarism and, perhaps, the extinction of the human species," and adds that the evil is chiefly due to river-floods produced by the agency of man, and that these floods are caused almost exclusively by the disappearance of arboreal vegetation, and especially by the destruction of the land-protecting highland forests. He thus describes the results:

"Summer suns scorch the unprotected soil, hot winds absorb its last vestige of moisture and fill the air with clouds of loose dust; the slopes of the naked mountains are torn up into deep ravines, and their mould, carried seaward by every rainy spring, is deposited in the form of festering, miasma-breeding coast-swamps. Springs fail, rivers shrink to feeble streamlets, which, at last, become too shallow even to supply the irrigation-canals by which the starving peasants hoped to relieve their distress. And all that misery is aggravated and perpetuated by the ever-recurring ravages of the winter floods. The melting snows, now no longer absorbed by the sponge-like carpet of moss and tangled roots, run off the hill-slopes like rain from a tile-covered roof, and by their accumulation tend to deepen the gorges of the rocky ravines, which in a few hours pour down, in a mad waste, the moisture which once supplied the springs of a thousand mountain brooks. Swollen by the turbid floods of countless simultaneous torrents, the lowland rivers roll down vast masses of detritus, and, by the inevitable laws of gravitation, cover the fields of their upper valleys with the heavy particles of that diluvium, sand and coarse gravel, while the fertilizing slime is carried down to add its stimulus to the rank morasses of a malarious delta. Thus shoaled by yearly accumulations of sand-banks the river-beds rise higher and higher above their former channels, and in every spring, when more than usually heavy snows are thawed by sudden rains, the uplands send down a deluge which no dams can resist, and which often in a single hour demolishes barriers which thousands of workmen have reared by the labors of many years.

"This brief summary outlines an experience which has repeated itself a thousand times, from the barren slopes of Mount Lebanon to the naked terrace lands of the western Pyrenees, and which will not fail to enforce its terrible lessons on the inhabitants of the western Continent, if the forests of our highland regions should be surrendered to the land-blighting axe."

Dr. Oswald believes that deserts can be redeemed only by

tree-culture. "Dikes are apt to prolong, rather than avert, the mischief of inundations, as the city of Sacramento, California, had a chance to ascertain at its cost; effluent canals degenerate into morasses, and reservoirs, besides being liable to get shoaled by the accumulation of detritus, constitute a constant menace to the inhabitants of the lower river valley."

It is good to see the truth of the relations of mountain forests to irrigation, and to the fertility of the soil of the country, presented in a popular form. The subject is an important one for the people of the United States, because some influential men who advocate the construction of a vast system of artificial storage reservoirs for irrigating purposes, refuse to recognize the value of the mountain forests as natural storage reservoirs and distributors of the water supply, and hold that it would be just as well to destroy them entirely. If this is ever done the lesson will be a most costly one, and will be learned too late to be of any avail.

Correspondence.

The Palm-house at Allegheny City Park.

To the Editor of GARDEN AND FOREST:

Sir.—The finest specimens of Banana plants I have ever seen are in the Palm-house connected with the park in this city. The house was finished in the fall of 1888; the Bananas were planted during the latter part of November. A group of *Musa Sapientum* has now six stems, two of which are maturing large bunches of fruit. The original stem has just been cut down after ripening a bunch of 100 perfect fruits. The stem, at two feet from the ground, is fourteen inches in diameter. The largest plant in the group is twenty-seven feet high, the smallest is twenty-one feet. The spread from outside to outside is twenty-five feet; the leaf-blades, independent of the petiole, are eight feet long and twenty-six inches wide, and altogether the effect of the group is magnificent. Specimens of *Musa Cavendishi* are ten feet high and as many in width, with leaves a yard wide. A bunch on one plant contains no less than 264 perfect fruits. Let me add that unless one has been fortunate enough to eat a banana that has ripened on the plant he has no idea of what a perfect banana is. There are groups, also, of *Musa rosacea* most beautiful in contour. The general effect of these groups are as tropical as possible. The plants are all set out in deep, rich soil, and are abundantly supplied with water at all seasons. Another plant bearing fruit very freely is the Lyre plant, *Philodendron pertusum* or *Monstera deliciosa*. This is rambling over the rock-work, and is a very characteristic piece of verdure. In the same house is a splendid specimen of *Cycas circinalis*, spreading eighteen feet and twelve feet in height. This plant, two months since, produced a perfect flower scape, and has now thirty-six new fronds nearly developed. *Ficus imperialis*, a plant with heart-shaped leaves, eighteen inches across, is seen in a specimen twelve feet high and of great beauty. *Dracæna fragrans* towers up twenty feet, and is well furnished to the ground. A *Pandanus reflexus*, probably the largest plant in the country, is standing on a pedestal three feet from the ground. The leaves touch the ground, and the extreme points are over ten feet high, and the spread of the plant is eight feet. Good examples of the Dove Orchid are in flower, bearing from three to seven spikes, with from twenty to thirty flowers on each.

The entire group of glass houses here were given to Allegheny City by Mr. H. Phipps, Jr., and are open to the public every day. Mr. W. Hamilton, the superintendent, informs me that as many as 2,000 persons visit the green-houses on Sunday alone.

Allegheny City.

J. Thorpe.

Helonias bullata.

To the Editor of GARDEN AND FOREST:

Sir.—A neighbor took me to see a "new plant" which had been found on his land this spring. It proved to be *Helonias bullata*. It is growing on the banks of a small mountain stream in the midst of a "Laurel thicket." There are, probably not more than a hundred plants in the lot, and what seems strange to me is that, although I have searched the same stream up and down for miles and all other like situations in this region, I can find no others.

The location is at an altitude of about 4,000 feet. It is near Short Off Mountain, in Macon County, North Carolina. Does any one know that this plant has been found in the Alleghany Mountains before?

Highlands, N. C.

Frank Boynton.

Notes.

A cluster of grapes weighing five pounds was lately taken from a Vine of the Golden Chasselas variety in Contra Costa County, California.

One of the green-houses in the park of Allegheny City, 150 feet long by eighteen feet wide, is now being filled with Chrysanthemums for display in the late autumn.

Downing's Ever-bearing Mulberry produces ripe fruit for nearly four months in California. In the middle of September the trees were still filled with berries in all stages—from the blossoms to the ripe fruit.

About thirty papers have been promised for the meeting of the Forestry Congress in Philadelphia, and the prospect is fair not only for an entertaining session but for some practical treatment of the more important problems of forestry.

The white-flowered *Desmodium Japonicum*, which comes into bloom at this season just after the showy lilac blossoms of the *D. penduliflorum* have faded, is very beautiful just now and is a most valuable plant for its late blooming qualities.

The published statements that the Plum curculio has at last made its appearance in California are happily without foundation. It seems that Fuller's Rose beetle, which has been very destructive in Los Angeles County, on Evergreen Oaks, Camellias, Palms, etc., was mistaken for the Plum-weevil.

Gordonia pubescens has flowered this year at the Arnold Arboretum, growing in the open ground. The plant was bent over and covered with soil last winter. Though not hardy at Boston it might do well when trained against a sheltering wall. A few of its beautiful flowers would well repay a little trouble and care.

The large rosy fruit of the *Magnolia Umbrella* still makes that tree conspicuous as it has been for several weeks. This is one of the smaller of our native Magnolias, and its large tropical-looking leaves and creamy-white flowers in spring would make it a desirable tree for planting, even without the autumn beauty of its fruit.

The Eaton Grape was grown from seed of the Concord in 1869. The vine is vigorous, the clusters large, the berries nearly an inch in diameter, with a dense blue bloom. On the trial-grounds of the *Rural New Yorker* it ripens just before the Concord. It is juicy, but not of the highest quality. Mr. Carman considers it well worthy of general trial.

A correspondent of the London *Garden* makes the following judicious remarks on the subject of judging vegetables at exhibitions: "Some judges are apt to give weight to exhibits which are out of season, as, for instance, very late Asparagus, which should not have been cut, or very early Celery, which, useful enough for flavoring, would not be asked for as salad during summer weather. Really good products, presenting substantial crops in season, are much to be preferred."

A correspondent of Mr. Peter Henderson recently sent to him, from France, a cluster of grapes upon which some of the berries were green, some black, some half green and half black—the colors divided sharply by a meridian line—and some were striped green and black. This seems like another example of the influence of strange pollen. But a letter which accompanied the grapes stated that all the clusters were mottled in the same way, and had been every season since it began to bear, some nine years ago. The vine is a seedling of unknown parentage.

It is somewhat surprising that two such popular plants as the Dahlia and the Chrysanthemum should have been introduced to English gardens the same year—1789. The Dahlia Centennial has been celebrated with much gusto, and a grand show at the Crystal Palace, and the Chrysanthemum growers are making great preparations for a still more enthusiastic demonstration. A London correspondent writes that by the middle of September the early Chrysanthemums were seen everywhere. The most popular of these early flowers were George Wermig, Madame Desgranges and Précocité—all good.

The September number of *Harpers' Magazine* contains some striking illustrations of forest-trees and forest-scenery in the California Coast Range. Two pictures of Cypress trees at Monterey are especially good; one of them showing the habit and expression of the individual tree with its bare roots hooked about the rocks on the coast, and the other giving glimpses of the mystery and delicate beauty of an opening in the Cypress woods. The illustrations of the Fog among the Redwoods, the Scrub Oak and Chapparal are successful in

catching the spirit of the scenery with much of its indefinable charm.

The committee appointed by the American Association of Nurserymen for the purpose of obtaining lower rates on express lines, have been successful in securing a new classification, under which a reduction of twenty to twenty-five per cent. will be saved on all express charges, on shipments of trees and shrubs, boxed or baled. Such packages are now classed with produce. This is good news to fruit growers, nurserymen and many others. Mr. S. M. Emery and his associates on the committee are to be congratulated upon their success. These organized efforts of the nurserymen have now brought about reduced freight, reduced postage and reduced express charges on nursery stock.

The *Gardeners' Chronicle*, after speaking of the fine display of color made at this season by *Crocodylus aurea*, adds that the variety Imperialis, introduced by Mr. Max Leichtlin, is much finer than the type. The stems are three feet or more high, and the flowers are fully three inches across, with broad segments, and a deep orange, almost scarlet color. Some of the plants of this variety show a slight tendency to the spotting which is so conspicuous in that recently described by Mr. Baker as Maculata. The flowers are large, and the three inner segments of the corolla have each a broad band of purple a little distance from the base. These plants, with the Montbretias and the numerous progeny of the two so-called genera, are certain to be almost as popular as Daffodils when they become better known.

The *Country Gentleman* says that the meagre show of grapes at the New York State Fair brought into prominence an exhibit of the new white grape, Diamond, an entire two-year-old grafted vine with twenty clusters being shown. The grape originated with Jacob Moore, of Rochester, in 1880, from a cross of Iona on Concord. It ripens the last of August or first of September, before the Delaware or Niagara; is of medium size in bunch and berry; pulp tender to the centre and of pure vinous, with a trace of the Iona, flavor; seeds, small. The foliage is said to be strong and healthy; certainly the specimen vine, taken up August 21st, showed well-ripened wood. The name of Mr. Moore, the originator of the Brighton, is a guarantee of a good grape, and from what we have seen of it, the Diamond is the most promising white grape in the market. It is said to keep well and to make a good raisin, characteristics not unusual in choice early grapes, like the Eumelan for instance.

An interesting account of the manufacture of "Buhach," the trade name of a well-known insect-powder produced from the flowers of *Pyrethrum cinerariaefolium* is printed in a recent issue of the *Pacific Rural Press*. This plant, a native of Dalmatia, is the source of the Dalmatian insect-powder, a well-known article of commerce for the past thirty years. Trieste, from which it is shipped all over the world, is the principal market for this product, but California is likely to become a serious rival for the trade. The plant was first introduced into California twelve years ago by Mr. G. N. Milco, a native of Dalmatia. From a small beginning the business of growing the Pyrethrum has been gradually extended. About 300 acres near Atwater, in Merced County, are now devoted to its cultivation, the product being sold all over the United States as "Buhach." The successful cultivation of the plant requires care and constant supervision. The fields are irrigated, and three years from the sowing of the seed are necessary before a paying crop of flowers is produced. The plants continue to produce crops of flowers during several years, although they are most productive at the age of four or five years. "It grows to a height of about thirty inches, and is planted in rows four feet apart and from fifteen to twenty-four inches apart in the row. The flowers are generally harvested in the latter part of May. The stalks are cut at the roots of the plant, and then by the hand the flowers are broken off by passing the stems through a sort of comb, which detaches the flowers, and they fall into a box and are then carried to the drying-ground, where they are spread upon sheets and exposed to the rays of the sun. During the day they are often turned, and at night they are covered to prevent them from absorbing any moisture. The perfect drying of the flowers is a most important operation, as, in order to retain the volatile oil which gives to the powder its insect-destroying properties, it is very necessary that the flowers should be dried quickly and thoroughly, and be protected during the process from all moisture. A light dew falling upon the flowers during the drying process will color them and reduce their value as an insecticide. In this respect the California-grown flowers are better cured and consequently more valuable than those grown in Dalmatia."

Spare the Wild Flowers.

LADY, some time ago, wrote to an English paper complaining that an estate which she had permitted the public to use was being rapidly denuded of its luxuriant growth of ferns by "pirates," who stole them, roots and all, for sale. *Osmunda regalis* was the favorite with the thieves, and great hampers filled with it were seized at the railway station, addressed to a London florist. The *Athenæum*, in commenting upon this letter, states that thefts of a similar kind are frequent in various parts of England, and that many unenclosed districts have been entirely stripped of ferns and flowers, through greed of gain or mere wantonness.

There is so large an amount of uncultivated and unprotected land even in the most populous parts of this country that this pilfering from private homesteads is probably nowhere common. But it is quite time that earnest words should be spoken in defense of the wild flowers which grow in our woods and meadows. In another column of this issue Professor Beal speaks of the disappearance of two interesting plants from a region where they once abounded. Not long before his death Professor Reichenbach wrote to the editor of this journal deploring the wholesale way in which our native Orchids and other delicate herbaceous plants were exported to Europe, and expressing the apprehension that some of the most characteristic plants of the American flora might be entirely eradicated. In the Orchid Notes of this number some facts are given which show that choice and rare plants are in danger of extermination even when they grow in remote and almost inaccessible parts of the earth. Government protection has been given in some instances, and perhaps it will be needed in many others; one of our states, at least, has passed laws to protect certain rare Ferns. At all events it is time that public sentiment in our own country should be awakened to the real danger that some of our native plants may become extinct through greed or carelessness.

The wholesale way in which our flowers, and especially those of early spring, are gathered is a constant source of distress to those who really love them. One who now finds

a flower not actually common, scrupulously hides its birth-place. But rare plants are not the only sufferers. Even so prolific a plant as the Mayflower is now no longer found in places where it once was common. The rage of the average flower-gatherer for quantities as large as he can carry, and his carelessness in gathering, have brought this about. And now that the practice of selling wild flowers in the streets is becoming general, we may look for a still more rapid rate and wider extent of destruction.

Too often it is just those persons who have some knowledge of plants and think they love them especially well who do the most damage in the woods. If a man does not know that the flower he sees is rare, he may leave it where it grows. But if he recognizes its rarity he is sure to pick it. If picking were all, however, the damage would not be very great. But picking often means tearing up plant by the roots; and too often, instead of merely gathering the flower, an attempt is made to transplant its roots. Nothing more exasperates the true plant-lover than this, except in those rare cases when the transplanter knows what he is about, has a suitable spot prepared for his specimen, and is certain to give it the treatment and attention it requires. Even then one may wish that he had left it in its home to propagate itself for the benefit of future plant-lovers. But how trying it is when some enthusiastic young lady or curious boy digs up the rare beauty, puts it in a garden-bed, and then wonders the next year why it does not "come up." The true lover of flowers loves them best when they are appropriately placed and surrounded; and in the case of wild flowers this must usually mean when they are in their own wild home. The desire to own the specimen is more often a proof of mere covetousness than of admiration.

To all who go into the woods and meadows after flowers and foliage this advice may be given: Gather only as many flowers as you really need to embellish your homes, or as you will give away, before they fade, to the poor or sick, which means, probably, not nearly as many as you have been in the habit of gathering. If you want large masses for any special purpose, as for the decoration of a church, take only those which grow in great abundance, like the Golden-rod in autumn, or the White Weed in spring. If an effective mass is your aim, a thousand Daisies will serve as well as would a thousand white Cypripediums, if you could find them! Whatever you take, take it gently and discreetly. Do not cut off the branch of a tree when a twig would do, nor wrench a branch in getting off a twig. Use scissors or a strong knife; not your hands. If you must cut a branch, cut it close to the trunk, that decay may not fasten upon the wound, and take the one which is the least essential to the beauty of the tree. If you want a spray of a young Pine tree, for its feathery green, or a bit of spring-time Red Maple, for its ruddy little leaves, or a branch of Liquidambar for its brilliant autumn coloring, do not pick off the leading shoot—a lateral one will be less missed. When you pick from a small plant use scissors, instead of starting its roots by a vigorous pull. If it is a shrub, do not take all its blossoms, but be content with a few, and complete your bunch from another individual. If it is an herbaceous plant leave some flowers for seed, and if it is a bulbous one, spare leaves enough to insure the bulb's ripening for another year. Never dig a root unless you are entirely certain you know how to make good use of it at home. And, unless the flowers are as common as Daisies or Golden-rod, do not pick them at all if you mean to throw them away the next minute. Gather flowers to bring beauty into your homes, but do not gather them for the mere sake of gathering, for that is lawlessness and waste.

Our freedom in this country hitherto from some of the difficulties which vex the nations of the Old World has resulted largely from our comparative sparseness of population and our great area of unappropriated land. As our population becomes dense we shall have problems of our

own. Under the conditions of our modern life some opportunity for summer rest, recreation and change of place is of great importance to our people. For the inhabitants of the interior of the country, a few weeks by the sea has a greater vitalizing and restorative effect than any other accessible experience. But the time is not far before us when no one who does not own land along the shore will have any right to camp near the ocean, or even to walk over the ground, on any part of the coast that is fit for comfortable occupancy. Parks and pic-nic-grounds along the shore will be fenced in and rented to those who are able to pay for them, and a fee will be charged for admission to places where the view of the sea is good, as people formerly had to pay for every glimpse of the Falls of Niagara. The best places will be taken first, then those not so good, until only the swamps and marshy shores will be left for outsiders, for the people who cannot become proprietors along the coast.

Men who are not yet old have spent summers in delightful solitude at places on the Atlantic coast where there are now streets of costly houses. These changes are inevitable, and they will go on with increasing rapidity. Some good places along the shore ought to be kept free to all orderly visitors forever, to the end that men may walk and meditate by the waves and have their souls uplifted by musing unforbidden where

"Still shouts the inspiring sea."

Such seaside parks might be owned by the state, or by the towns in which they are situated, or by churches or incorporated societies. The method of holding them is a matter of expediency or convenience, but land for this purpose should be secured at many points within the next few years. The matter is of grave and far-reaching importance. Our children are likely to see an almost continuous town along all the healthful and accessible portions of the Atlantic coast-line, with all the land so improved and occupied as to exclude all but the owners. The people of the whole country, through all the generations of coming time, should have some right in the encompassing ocean and along its shores.

The Art of Gardening—An Historical Sketch.

XI.—Rome.

"THE trees," says Pliny the elder, "formed the first temples" of the gods of the Romans. Useful gardens seem from the first to have been more beloved in Rome than in Greece. The kings, according to Pliny, cultivated them with their own hands; and early attempts at horticulture are implied in the familiar anecdote which represents Tarquinius Superbus symbolically decapitating the Poppies of his garden. Pliny mentions window-gardens as of comparatively early origin, although it is impossible to determine the exact period to which he refers. "In former times," he says, "the inhabitants of Rome, with their mimic gardens in their windows, day after day presented the reflex of the country to the eye, when as yet the multitude of atrocious burglaries, almost innumerable, had not compelled us to shut out all such sights with bars from the passers-by."

But it was only when intercourse with Greece, and through her with the customs of Persian luxury, became close and constant, that pleasure-gardening was pursued on any extensive scale. The first great Roman gardens of which we know were formed during the last century of the Republic, but even then many conscientious citizens thought pleasure-gardening a reprehensible form of luxury. Cato would have allowed only gardens of utility, and the rich Pomponius Atticus publicly protested that he had no more than "a little pleasure-wood" near his dwelling. It was during the first three centuries of the Christian era that Rome itself developed into a veritable city of gardens, and that its wealthier citizens luxuriated in vast country homes amid a wealth of architectural and natural or semi-natural beauty which the modern imagination can hardly picture.

In these sumptuous days important city homes had, of course, their court-yards decorated with trees and flowers, while the crowded state of the city brought roof-gardens (*solaria*) into general use. The roof was carefully prepared with successive layers of Larch-wood, Beech-boards, broken

stones and mortar, and potsherds, and then finished with a pavement of stone, brick or even mosaic.* The plants were cultivated in large square boxes and in vases of stone or lead, or even set out in beds as though upon the solid earth.† Large trees were grown on these roofs, and a constant feature was the Vine-arbor or *pergola*, which is still familiar to the eyes of all travelers in Italy. Seneca makes bitter complaint of the extravagance shown in these *silve in tectis*.

The design of several small suburban gardens is preserved at Pompeii, and, although it was a Grecian city, similar arrangements prevailed in those of Roman origin. They were formal little spots, with walls and colonnades, altars and small temples, basins and sculptured figures. In one can be traced twelve large beds, evidently for the cultivation of flowers; but the inhospitable lava-soil usually prescribed the use of great boxes or long stone troughs. Climbing plants covered the walls, or else these were painted with garden scenes, fictitiously extending the narrow area. In the larger provincial towns an outer garden was often connected with the inner one, sometimes forming a vineyard or orchard, but sometimes a little wood or a diversified bit of natural-looking landscape, with grottoes and rills and multitudes of ornamental birds.‡

It is almost impossible, within brief limits, to give even a faint idea of the condition of Rome itself when its urban and suburban gardens were in their prime. Towards the end of the third century after Christ, says Lanciani,§ "there were in ancient Rome eight *campi*, or commons, green spaces set apart mostly for foot-races and gymnastic exercises, . . . and about thirty parks or gardens which, first laid out by wealthy citizens, . . . had been absorbed into the public domain by right of purchase, by bequest or by confiscation." To this list of open planted spaces, free to the people at all hours of the day or night, must be added the cemeteries, "those marble cities of the dead, shadowed by stately Cypress and Weeping Willows; || the sacred enclosures of temples, with their colonnades and fountains, . . . and lastly the great *thermae*," which, nominally baths, were really "gigantic clubs," furnished with every convenience for the enjoyment of in-door and out-door pleasures.

The largest of the "commons" was the Campus Martius, a vast level space—filled with buildings and play-grounds and water-works, and surrounded literally by miles of sumptuous colonnaded porticoes enclosing beautiful gardens—which lay beside the Tiber and extended from the foot of the Pincian Hill as far as the present Vatican Bridge in one direction, and to the Arch of Titus in another.¶ The parks and gardens proper were simply omnipresent. "The city," writes Lanciani, "was not only surrounded and enclosed by them but intersected in every direction. . . . Rome occupies the *thalweg* of the Tiber, a plain less than a mile wide and about three miles long, flanked east and west by parallel ranges of hills. . . . Both ranges were covered with gardens. Let us begin with the east range overlooking the Campus Martius. The Pincian Hill, the promenade of modern Rome, was occupied by the magnificent gardens of Acilius Glabrio. . . . Where the Villa Medici . . . now stands were the gardens of the Anician family. . . . The southwest slope of the same Pincian Hill . . . was occupied by the gardens of Lucullus. . . . The valley between the Pincian and the Quirinal, . . . a charming and undulating district with glens and overhanging rocks, rivulets of pure water and other natural attractions, was the seat of the gardens of Sallust, the finest and most celebrated of ancient Rome." Farther south lay a long line of private and imperial gardens, larger and smaller, "all forming one stretch of verdure more than two miles long and over half a mile broad." In earlier times these hillside districts had been covered with burial-grounds; but, as Professor Lanciani has recently discovered by excavation, these were gradually but systematically buried beneath enormous masses of pure earth, and turned from "pestilential dens into smiling gardens." Mæcenæ began the work on the Esquiline Hill, prompted by a desire not more for the æsthetic than for the sanitary benefit that would result.*

* Jaeger, *Gartenkunst und Gaerten Sonst und Jetzt*.

† Becker, *Gallus*.

‡ Martial calls these suburban gardens *rus in urbe*, now a familiar phrase.

§ "Ancient Rome in the Light of Modern Discoveries."

¶ The Weeping Willow was first introduced into modern Europe from the Levant about the year 1720. It would be interesting to know whether our learned author has documentary evidence for the statement that it was a familiar tree in ancient Rome. The Chinese have known it, however, for many centuries, and that there was a certain amount of commerce between China and Imperial Rome is proved by the fact that in the great collections of objects of art and curiosity displayed beneath some of the public porticoes, Professor Lanciani cites some of Chinese origin.

¶ Jaeger.

* See Horace, *Sat.* i., 8, 14.

"The hills on the west side of the valley were also occupied by an uninterrupted chain of gardens" from Monte Mario to the southern ridge of the Janiculum. "The banks of the river also had been transformed into a garden by Augustus, Pompey the Great, Domitian, Nero, Caligula and others." And in and around the palace of the Cæsars on the Palatine Hill were gardens more sumptuous and varied than all others. Within the precincts of the Golden House of Nero were comprised "waterfalls supplied by an aqueduct fifty miles long; lakes and rivers shaded by dense masses of foliage, with harbors and docks for the imperial galleys; . . . porticoes three thousand feet long; farms and vineyards, pasture-grounds and woods teeming with the rarest and costliest kinds of game; zoölogical and botanical gardens," and an incredible wealth of works of architectural, plastic and pictorial art, among them banqueting-halls with ivory ceilings, "from which flowers and precious perfumes could fall gently on the reclining guests." After the murder of Nero, Vespasian and Titus gave back to the people the greater portion of the ground which he had usurped for his private satisfaction, and the Colosseum was built on the site of his enormous lake. In short, wherever one looked in imperial Rome "in every direction the architectural masses were broken and enframed in the green of gardens and parks,"* while water was used in canals, fountains, basins and cascades to an extent unknown before or since.

The design of the Roman pleasure-ground was, in general, strictly formal, and trees and shrubs were frequently cut into the most artificial shapes. But there were exceptions. The poets constantly protested against the reigning fashions, and perhaps it was owing to their words at this time (as it certainly was in the eighteenth century in northern Europe) that a partial reaction in favor of more natural kinds of beauty came about. Many portions of the great garden of Nero were naturally disposed, and more than one ancient writer comments upon his love for rural, picturesque landscape effects. In the gardens of Lucullus the designs of Oriental pleasure-grounds were imitated.

New York.

M. G. Van Rensselaer.

The Woods of Mount Desert Island.

MOUNT Desert Island has an area of about one hundred square miles, washed by the ocean on the south, by broad bays on the east and west, and almost joining the mainland in the extreme north. Its outline is very irregular, like that of the Maine coast in general, with harbors and indentations everywhere. By the largest of these, Somes Sound, a long, deep fiord of the sea, running far into the land between mountainous shores, the island is nearly bisected. There are thirteen or more mountains, mostly bare, rocky summits, varying in height from a few hundred to fifteen hundred feet, lying across the centre of the island, from east to west, like a great belt, with deep, blue lakes nestled between them. To the north, the north-west and south-west the surface is more flat, with lower, more undulating hills. On the south-east and east the mountains approach the shore very closely in a coast of precipitous cliffs and bold, rocky headlands that has made the island famous. Nowhere on the Atlantic coast of this country is there such a wonderful combination of natural scenery; nowhere a spot where mountain and shore are so blended. For years it has been renowned as the crowning glory of the beautiful, countless-harbored coast of Maine.

The destruction of the forests of the island has already done much to mar the beauty of this unique resort, and, certainly, the importance of preserving the woods which still remain, should be admitted by every lover of Nature. The character of the soil, the ruggedness of the surface, the stunting influence of the cold sea winds upon its southern shore, all make the question of economic forestry one of secondary importance. That trees must be spared not for the lumber they yield, but for the beauty they may add to the landscape, should be the argument to the mind of the land-owners of Mount Desert. Wild beauty means summer visitors as long as the island endures, and such summer residents have, within the last twenty years, made its fame and fortune.

Mount Desert is in no sense an agricultural region. The soil is thin, very little of the surface is level, and the lowlands are so wet that the cost of draining would be beyond the means of the owners. A few favored spots in the northern part of the island, where the climate is more genial, can be profitably devoted to the plow, but the inhabitants of the island could not live by farming alone, and have no excuse for regarding the woods as their natural enemy.

The forests of Mount Desert were once full of wealth, and would still be a source of wealth if the lumberman and the forest-fire had not done their work so well. The first permanent settlement on the island was founded on the lumber business, which drags out a slow existence there to-day. While at its best, the business was profitable; saw-mills sprang up over the island—even between 1865 and 1870 there were at least eight saw and shingle-mills in the three towns of Mount Desert, Eden and Tremont—the brooks ran full and turned the wheels, vessels were built, and the lumber found a ready market. High up on the mountains, through the mountain gorges, along the ponds, everywhere, the great trees growing on the thin but rich wood-soil were taken out, not one by one, but all together, and the forest-fire followed. One of these conflagrations, fed by the dried refuse left by the lumbermen, laid waste much of the central part of the island. To-day nearly every saw-mill is in ruins; the mountains are bare; acres upon acres are overgrown only with a poor wood-growth that years will bring to little or nothing; the soil has been burned off or washed away; the streams preserve no even flow. There is no longer much to fear from lumbering, but two saw-mills at Somesville are still doing infinite harm to the beautiful Great Pond Woods, and should be stopped without delay. If the town of Mount Desert values its attractions as a summer resort, it could well afford to purchase and destroy both these mills, and even support the owners at the public expense if they were unable to earn a living in any other manner.

This great reason for jealously preserving the remaining woods of Mount Desert Island is their infinite value as a part of the wild scenery of the place, and their wonderful attraction to the city-wearied man or woman in search of a summer home and resting-place. With the destruction of the the forest-beauty and the impairment of the scenery will come depreciation in land values and diminished attentions as a summer resort.

First of all it must be understood that here, as on the Maine coast generally, the soil is exceedingly thin along the shores and upon the rocky hills and mountains. If deprived of the protection of the woods this soil is soon washed into the ravines and valleys; if exposed to fire it is burned like fuel. The peaks of Mount Desert were not always barren and desolate, nor were the rocky islets all along the coast bare as they now are, with hardly a bush to cover them. Some of the mountain summits may have been always bare, but it is plain that, as a whole, the mountain masses were well wooded and protected. To-day the steep side of Beech Mountain still shows some of the oldest, most beautiful woods on the island, while upon the sides, almost upon the summits of other greater mountains, we find evidence of great trees gone to destruction years and years ago. What the island was in those early days of its full beauty must be far beyond the conjecture of the tourist of the present time. Some idea of these mountain woods may still be gained by visiting the western peak of Western Mountain, the most beautiful mountain of the island. On the other hand, the eastern peak of the same mountain shows, in vivid contrast, the desolation wrought by fire—a mere mound of white rocks, with here and there skeleton trees, a scene only softened by the covering of green that Nature kindly gives the wounds inflicted on her earth.

In a few localities organizations have been formed to protect the forests from fires, but these should be extended and made efficient, not only to check wood-fires, even the most insignificant, and at the very outset, but to prosecute to the full extent of the law all offenders, whether inhabitants or summer visitors, although, with two or three exceptions, nearly all the wood-fires on Mount Desert have been caused, not by the visitors, but by the gross carelessness of the inhabitants themselves.

The system of wood-chopping is most wasteful. Whoever wants fire-wood for home use at once goes into his wood lot, hacks right and left, leaving behind him a desolate tract covered with debris to dry beneath the hot sun until it is tinder, waiting for a spark to begin still greater destruction. If he owns land in some convenient spot by the roadside, so much the better for him, so much the worse for the scenery! The result, of course, is ruin to the very beauty he should do his best to guard. This is especially to be lamented because such destruction is entirely unnecessary. The forest could be made to supply the needed fuel without destroying its wildwood beauty, which must be spared if the island is to retain its charm. Vigorous public sentiment, and town interference where it is possible, should at once put a stop to such wanton destruction as that on Western Mountain, on the Bubbles, and on the south-western slopes of Sargent's Mountain.

* Friedländer: "Darstellungen aus der Sittengeschichte Roms."

Not very many years ago there was no more beautiful spot on the island than Hunter's Brook Valley. Great woods sheltering the rare, shy wood-plants, and giving deep seclusion, filled the valley and extended up the mountain sides. To the south, the woods became less worthy of the name, but were still woods until the explorer suddenly emerged on the stony beach where the brook emptied into a cove between two mighty headlands, and the ocean lay before him. Northward the brook flowed down amid the wildness of the deep forest from the ravines of the Triad, Pemetic and Green Mountains, and the watershed of Bubble Pond. The spot was one of the gems of the island to every lover of nature. Its beauty, however, did not save it, but proved its ruin. A "practical" man saw dollars in the timber of the wild valley, hired a gang of French Canadian wood-choppers, built a road of a mile or two in length towards the headwaters of the brook, and established a logging camp. Utter ruin followed, the wild woodland became a desolation, and this priceless beauty was lost forever.

In some parts of the island there is a partial realization of at least the practical value of beauty. At North-east Harbor, especially, is there evidence of this. And yet, it will not answer to leave merely a narrow strip of woods along the roads, while the work of destruction is carried on behind them, to repel the very people who bring prosperity to the island.

The method of road-making, now practised, is most destructive of natural beauty and attractions. It is of great importance to the inhabitants to prevent this in every possible way. Many visitors to the island are unfortunate enough to see little further into it than along its roadsides, and these are too often masses of stones, and piles of withered brush. If these waysides cannot be adorned, their natural beauty might be spared. Shrubbery and trees could be left generally, and where cutting is needful, the brush could be removed instead of being left to shut off access to the woods, and to dry into tinder to catch the first stray spark and become a forest-fire. That such devastation is allowed to go without reproof, and that telegraph companies, when erecting poles and stretching wires, are permitted to mutilate trees as they choose, is proof that the authorities do not realize that the beauty of the island is its real value. Some resolute policy must be adopted for protecting the forest-scenery of Mount Desert, or it will be robbed of its peculiar charm and be converted into an inhospitable waste.

Boston.

E. L. Rand.

Notes Upon Some North American Trees.—XIII:

290. *CASTANEA VULGARIS*, var. *AMERICANA*, A. DC.—There is a much older name for the Old World Chestnut than that of Lamark (1783) taken up by Alphonse DeCandolle, namely *C. sativa* of Miller (Gardeners' Dictionary, 8 ed., 1768), already adopted by Nyman and by K. Koch, so that our American Chestnut, considered only a variety of the Old World tree, must become *Castanea sativa* var. *Americana*.

292. *OSTRYA VIRGINICA*, Willd.—The oldest name for our Hop Hornbeam is that of Miller (Gardeners' Dictionary 8 ed., 1768), *Carpinus Virginiana* so that it may be more properly written *Ostrya Virginiana*, Koch, than *Ostrya Virginica*, Willd.

294. *BETULA ALBA*, var. *POPULIFOLIA*, Spach.—It seems desirable to consider our Gray Birch as distinct from its Old-World congener, and to restore to it Marshall's name, *Betula populifolia*. The two plants are distinct in geographical distribution; in the shape of the leaves; in bark, size, and habit. The bracts of the fruiting catkins of the American tree are nearly triangular and covered on both surfaces with pubescence; those of the European plant are contracted into a long, narrow base and are quite glabrous. There are differences, too, in the size of the fruit and in the size and shape of its wings, which will aid in distinguishing the two species.

302. *ALNUS RHOMBIFOLIA*, Nutt.—Dr. C. C. Parry (*Bull. Cal. Acad. Sci.*, ii., 7, 351), shows that this common Alder of California extends through Arizona and New Mexico to northern Mexico, and that *Alnus oblongifolia* of Torrey, (No. 303 Census Cat.) is the same plant, which he distinguishes by the number of stamens which instead of four in each flower are only two, sometimes increased to three or more rarely reduced to one. A specimen collected by Greene at Silver City, New Mexico, shows that this character in the number of the stamens holds good in the

eastern plant. Dr. Parry points out, too, in this paper that *Alnus rhombifolia* may be distinguished always from the northern *A. rubra*, Bong., by its early flowers which begin to appear in California in January, before the leaves of the previous season have all fallen, fertilization being completed by the 1st of February, "at least as far north as the lower Sacramento Valley, the smaller winter streams over which they lean, as well as the adjoining banks, being copiously strewn with the effete male tassels resembling torpid caterpillars."

304. *ALNUS SERRULATA*, Aiton.—This, the common Alder of the southern States, is rather a shrub than a tree, although I have seen it sometimes growing to the height of twenty feet, but always with a number of stems from a common root. It may well be dropped from the *Silva* of North America.

305. *ALNUS INCANA*, Willd.—The common northern brook-side Alder, although it grows sometimes quite tall, is a shrub and not a tree, and it should be dropped from the *Silva*.

306. *SALIX NIGRA*, Marsh.—Under this species should be added var. *longipes*, Andersson in *Ofr. af. Vet. Akad. Forh.* (1858) 22—a rather common Florida tree (St. Mark's, Rugel; Jacksonville, A. H. Curtiss; Duval County, J. D. Smith; Miami River, Sargent), with paler leaves, shorter aments, and longer pedicelled capsules than are found on the ordinary northern form. It is the *Salix Humboldtiana* of Wright's *Plantæ Cubenses*, No. 2132.

315. *SALIX CORDATA*, var. *VESTITA*, Andersson.—The so-called Diamond Willow of Nebraska and Dakota, may be dropped from the *Silva*. It is not probable that any form of *Salix cordata* ever becomes a tree; and the large specimens on the banks of the Missouri River in Dakota, with the peculiar diamond markings, if they exist at all, belong probably to *S. amygdaloides*.

329. *CHAMÆCYPARIS SPHEROIDEA*, Spach.—The first name for this tree is *Cupressus thyoides*, L.; and this specific name should be retained, the name of the White Cedar becoming *Chamæcyparis thyoides*.

330. *CHAMÆCYPARIS NUTKAENSIS*, Spach.—The orthography of the specific name as written by Lambert (*Gen. Pinus*, ii., 18), with whom it originated, is *Nootkatensis*.

JUNIPERUS FLACCIDA, Schl.—Dr. Havard has discovered this north-Mexican Juniper on the Chisos Mountains in western Texas (*Proc. U. S. Nat. Mus.*, viii., 504), and it must be included therefore in the North American *Silva*. It is a shrub or small tree, with shreddy bark, spreading, slender branches, acute and somewhat spreading denticulate leaves, and large globose or tubercled fruit. This is a widely-distributed tree apparently, although nowhere very common. It should follow *Juniperus pachyphlæa* in the catalogue. C. S. Sargent.

New or Little Known Plants.

Dendrochilum filiforme.

THE remarkably well-grown specimen of this lovely Orchid, illustrated on page 485, received the first prize as the best single Orchid at an exhibition of the Massachusetts Horticultural Society in June last. It came from the fine collection of Mr. John L. Gardner, of Brookline, Massachusetts, where it was grown under the care of Mr. C. M. Atkinson, the able head-gardener of the estate. The plant had altogether forty-eight flower spikes, most of them being over a foot long.

A specimen of this size is rarely met with and presents a spectacle not soon forgotten. The individual flowers are small and of a rich yellow color, but they are so abundant and so closely set that they fully justify the name of "The Golden Chain," which has been given to the plant.

Dendrochilum filiforme was introduced from the Philippine Islands as far back as 1836, but it grows also in quantities on Mount Mulu, in Borneo, where I found it a few years

ago growing on trees together with *Calogyne Sanderiana*, at an altitude of 500 feet above the sea. It flowers in its native home in July and August, and enjoys a moist and warm atmosphere, and, therefore, the temperature of a Phalaenopsis house will suit it best; but it can also be successfully grown in the warmer part of the Cattleya house if a more moderate supply of water is given. As the plant flowers on its young growths it should be grown on after flowering, until the young bulbs are fully formed, and then less water and lower temperature may be given to it.

It appears that the plant gets a short rest in its native home, as it begins to grow and flower there again as soon

varieties. Then, of course, a Dahlia centenary would not be complete without its conference and "papers," so we had a history of the flower since its advent on English soil up to the present from Shirley Hibbard, who must have taken a deal of pains to hunt up old references in order to compile the instructive chronicle. He related the early history of the plant from 1615, the date of its introduction to England by the then Marchioness of Bute, then through all its interesting phases of development in the hands of early florists, where and when it first produced double flowers, and how the various sections originated, such as the "Show," "Fancy," "Pompon" and "Cactus," and with all this historical detail were interwoven pleasant anecdotes and incidents. Besides this literary disquisition we had papers on the practical part of the question, such as the cultivation of Show Dahlias by Turner, of

Fig. 133.—A well-grown specimen of *Dendrochilum filiforme*.—See page 484.

as the dry season of three or four weeks duration is over. *Dendrochilum filiforme* is difficult to import, owing to its thin and fleshy bulbs which easily dry or rot off, and this is undoubtedly the reason why it is to-day still comparatively scarce.

Foreign Correspondence.

London Letter.

THE National Dahlia Society always holds a representative exhibition of its chosen flower at Sydenham, but this year every member seemed to exert himself to make the show out-strip in size and interest all its predecessors, and the result was a really grand exposition of the Dahlia in all its sections and

Slough, and of other sections by Cheal, both qualified lecturers.

But though we enjoyed a grand exhibition of the Dahlia, with a creditable literary accompaniment, little good will be derived from this centennial event. Nothing new was brought out in the essays, and no new varieties of the flower were shown. The exhibition, however, showed the rapid advances made of late years in the Cactus, decorative and single forms of the flower, and it plainly showed how rapidly florists are able to create a supply to meet the public demand for any particular class of plants. It seems but a short time ago when there were no single Dahlias except the old *D. coccinea* and its forms rarely seen outside of a botanic garden. Then appeared the beautiful, though tall and coarse growing, Paragon, which seemed to whet the appetite of flower lovers for more. Single varieties at once came in multitudes, until the same

public grew tired of new ones, so that to-day they are not so popular as five years ago. The Cactus Dahlias have almost a parallel history. The original *D. Juarezii* was and is still very beautiful, but, not content with this, the florists took advantage of the demand for the genuine flower to foist upon the public so-called white, yellow and pink Cactus Dahlias, which no more resemble the Juarez Dahlia in form than did the early double Dahlias resemble the exquisitely moulded varieties, the so-called Show and Fancy classes we now have, and which, by the way, seem to be more appreciated than they were a few years ago. What, to me, seems the greatest improvement in the Dahlia is the dwarf race that have appeared lately, and which, for ordinary decorative gardening, will be an immense gain. These plants are not only dwarf, but extremely floriferous, and, for massing on lawns, are invaluable. I saw, a few days ago, a mass of the Glare of the Garden, broadly margined with the pure white Pearl, which only rises eighteen inches high, and I have seldom seen a more effective touch of color on a lawn. A still later improvement is a dwarf strain of single Dahlias, which has just been brought into notice by Mr. Girdlestone, the Secretary of the Dahlia Society, who exhibited them at the centennial. Some of these, which are collectively known as *Dahlia pumila*, are under eighteen inches in height and are most floriferous, so that they are likely to prove good bedding plants. If we can fix a dwarf strain of single varieties it will do away with one of the chief objections to the older and taller sorts, which require a deal of staking and tying. Beyond these there was, among all the novelties submitted to the judges at this great show, no absolute departure in form or color. Among the Cactus section were the following certificated sorts: Mrs. Douglas, salmon-pink; Marchioness of Bute, pale yellow, suffused with mauve; and Centenary Year, scarlet. The tendency of the new single kinds is towards two or more colors in the flowers, the florets being sometimes tipped with a color different from the ground tint, and sometimes collected in concentric zones around the centre.

Though the Dahlia monopolizes the florist's attention for the moment, it will, on the first appearance of frost, give way to the Chrysanthemum, whose society has already begun its active work for another season, and at its first exhibition this week there was a fine display of early-flowering sorts, which, however, are few in number, though one grower managed to get together over forty distinct sorts in bloom. The leading varieties shown are, doubtless, all well known to American florists. They included Madame Desgranges, the white and golden forms; G. Wernig; Mrs. Burrell (last year's novelty), primrose-yellow; Sam Henshaw; Holy Innocents; Pynaert Van Geert; Précocité; Mrs. Cullingford and Mademoiselle Lassali, white. Among the certificated novelties was one under the name of Comtesse F. de Cariat, described as a semi-incurved Japanese sort, of a buff-yellow color. The other certificated sort was Sam Henshaw, also a Japanese variety, with white flowers, and a genuine acquisition to the early-flowering race.

This week the periodical visit of the floral committee to the trial grounds in the Royal Horticultural Society's garden at Chiswick took place, when the merits of various classes of plants were discussed and adjudged. The subjects were Asters, Dahlias, African Marigolds, French Marigolds, Heliotropes, Scabious and Zonal Pelargoniums. Of these there are representative collections of sorts cultivated, including novelties sent by the leading seed-houses on the continent and at home. The Asters make the most brilliant display, and the season seems to have suited them well. After inspecting all the sections, the committee certificated the strains known as the Imbricated Pompon, Dwarf Pyramidal, Hedgehog, Victoria, Cocardeau or Crown, and the new Liliput, a strain of miniature Asters a few inches high, extremely floriferous, and of varied and bright colors. Among the strains to which awards of merit only were given, and which, therefore, were not so commendable as those certificated, were the Dwarf Chrysanthemum, Dwarf Victoria, Dwarf Bouquet and New Victoria.

The Heliotropes considered worthy of certificates were all raised by Lemoine, and were named Fleur d'Ete, with a very large truss of pale purple and of compact growth; Capus, large truss of very deep purple; Victor Durny, a tall and strong variety, with pale purple flowers in very large clusters. New certificated Pelargoniums, also, were mostly all from Lemoine, their names being Charbon, double orange-scarlet; Souvenir de Mirande, single flowers with white centres and cherry-colored edges, and two unnamed seedlings, different in color from older sorts. The dwarf strain of *Scabiosa atropurpurea* is now becoming very popular, especially for market, and Vilmorins strain, named Half-dwarf Blood Red, is one of the best I have seen, and was worthily certificated. Of the French Marigolds,

the new sorts named Electric Light and Dobbies Selected were the best, and among the African Marigolds, certificates were voted to those named Lemon Queen, Prince of Orange and Dwarf Orange (which, by the way, is not very dwarf), and Dwarf Golden, very compact and pretty. Among the Dahlias approved were Professor Baldwin, a brilliant scarlet Cactus variety; Empress of India, the finest deep crimson Cactus sort, and North Light, a scarlet Pompon. Altogether, there is a most valuable series of trials being carried on at Chiswick this year, the importance of which is recognized by all who wish to make selections from classes of plants abounding in varieties. Being grown under precisely the same conditions, the relative merits of every sort may be seen at a glance. The full reports of the committee's observations are published in the Society's journal, issued periodically, so that the fellows of the Society derive the benefit of independent opinion of novelties.

September Notes on Interesting Shrubs.

THE custom of spending the months of July and August at the seaside, now so common among people both from the country and city, naturally involves the loss of appreciation and value for many garden plants which are most attractive at that time. To those living in the country, or who have a rural place in which to spend a month or two in the spring or autumn, it is of importance to have such hardy ornamental plants as are most effective or interesting at these periods. There is naturally no lack of interesting or beautiful flowering plants in May or June, but, when the summer is over, the brilliant colors of autumn foliage and fruit, the Sunflowers and native Asters and Golden-rods have largely to be depended upon to make up for the loss of the greater variety found earlier in the season. But brilliantly-colored foliage in September is dependent, very much, on various meteorological conditions, as the present wet season in eastern Massachusetts has shown in the continued greenness of the leaves of nearly all trees and shrubs. And much of the beauty of some Golden-rods and Asters is destroyed by long-continued rains.

Native woody plants in full flower at this season are rare, but a few have showy fruits, and some foreign species are notable for both flowers and fruit. The showy *Clematis Jackmani* and other kindred varieties are becoming well and widely known. The period of most profuse flowering is earlier in the season, but sometimes a good number of blossoms continue to appear during the early autumn. These flowers are extravagantly admired and praised by most people, but there are a few other, though less striking, species which are equally desirable. The fragrant *Clematis crispa*, with recurved light purple sepals, and *C. Pitcheri*, with its dark, dull purplish flowers, continue to bloom in the early part of the month and the latter species even until hard frost. The Virgins Bower (*C. Virginiana*) is often past its best flowering condition by the first of September, but the flowers are followed by the conspicuous feather-tailed fruit. This species bears staminate, pistillate or perfect flowers on the same or different plants, so that where the ornamental fruit is desired, as well as the flowers, care should be taken to select or propagate (by cuttings or layers) from fruit-bearing plants. *Clematis paniculata*, a closely-related Japanese species, and the Traveller's Joy (*C. vitalba*) of Europe, both flower at about the same time as the last and cannot be called September bloomers. One of the best species is *Clematis orientalis* (*C. graveolens* is a synonym often used) which bears its yellow flowers most abundantly during September, and which becomes covered with the beautiful silvery-white, long-tailed fruit while still in bloom.

Among all the introduced climbing flowering-shrubs few have proved more satisfactory than *Lonicera Japonica*, var. *Hallii*. It differs from the typical *L. Japonica* chiefly in being practically ever-blooming, and from June until after severe autumn frosts its fragrant white and yellow flowers are continuously produced. It is becoming well-known and commonly planted. The well-known and very fragrant Dutch Monthly Honeysuckle (*Lonicera Periclymenum*) also has a few flowers at this season, but they are very apt to be unpleasantly infested by Aphides. *Lonicera Sullivanii*, which has been generally grown as *L. flava*, is frequently met with in old gardens. When trained upon some support or trellis, and well-grown, it is very handsome in September with large clusters, from two to four inches long, of large, shining, bright red berries. *L. hirsuta* and the true *L. flava*, which is very rare, also bear an abundance of fruit, but on account of having a slight bloom it appears less brilliant in color.

Lycium Chinense, which is very closely related to the common Matrimony Vine, is a trailing shrub which if trained to some strong support will grow fifteen feet or more in height. The very long slender branches hang down laden with ovate or oblong, shining, scarlet fruit, which is from half an inch to an inch in length, and with green fruit and flowers in all stages of development.

Perhaps the most remarkably distinct and showy shrub at this season is *Symplocos paniculatus*, a native of Japan. The

on account of its clean foliage as well as the graceful flowers and almost unique fruitage.

One does not naturally associate the autumn with the flowering catkins of Willows and Alders, but late August and September is the season in which the native Sea-side Alder (*Alnus maritima*) blossoms. The male catkins are very large, and the round, cone-like fruit matures in the autumn of the following year. The plant is usually shrubby, but in favorable situations it becomes a small tree twenty feet in height.

Fig. 134.—*Prunus pendula*.—See page 490.

branches of last year's growth are covered with racemes of fruit of the brightest ultramarine blue color and the size of small peas. The leaves are dark green, thick and rough, and not liable to attack by insects. The numerous small, pure white flowers appear in the latter part of May and in early June. This shrub, which appears to be one of the very hardiest, is wide-spreading, and ordinarily grows to a height of six or seven feet at the Arboretum, although it may attain much larger proportions. It is as yet very rare in cultivation, but it deserves, and is likely to have, a place in all collections

The common Spindle-tree (*Euonymus Europæus*) presents considerable variation in foliage and fruit, and there are numerous named forms and varieties to be found in nurseries. Throughout September the pods are conspicuous by their red color, which varies in intensity on different plants. A Japanese variety, known as *E. Europæus*, var. *Hamiltonianus*, has a much more robust habit of growth than the European type, and the pods, which are of a beautiful pink color, also open earlier, in the latter part of the month, and disclose the seeds in the scarlet-colored arils. The well-known climbing

Bitter-sweet (*Celastrus scandens*) does not usually open its showy orange-colored pods and disclose the scarlet covering of the seeds until October. As in the case of *Clematis Virginiana*, where fruit is desired, care should be taken to select cuttings from good fruiting plants. On many of the plants all the flowers are sterile, and consequently produce no fruit.

The native Black Alder or Winterberry (*Ilex verticillata*) is a much-neglected shrub, in spite of its neat, compact habit of growth in cultivation, its delicate early summer flowers, and the abundant rich red fruit of September, which remains until winter, if not eaten by birds. A clear, light yellow-fruited variety is growing at the Arboretum. The less common *Ilex laevigata* ripens its fruit a little earlier in the month than the last species, and, although rather larger, it is similar in other respects, and is equally ornamental.

To the white and blue fruited species of Dogwood, which ripen in August, the present month adds the Flowering Dogwood (*Cornus florida*), with clusters of large, oval, bright red fruit, which make the plant almost as showy as when in flower. Unfortunately, birds, especially robins, are very fond of this fruit, and, in this region, it rarely remains long on the tree after it is ripe. It is one of the very few large shrubs or small trees which show red foliage so early in the season.

Of several species of Hawthorns which ripen fruit during the month there is none so handsome and conspicuous as *Crataegus pyracantha*, a native of south-eastern Europe, where it is evergreen. It is not very hardy here, and is usually much injured in winter, but in sheltered situations it becomes a dense, spreading shrub, which retains its leaves and fruit through the winter. The fruit, which is bright red, is as large as good-sized peas, and thickly set in small corymbs along the branches.

The crimson cone-like fruit of the Magnolias always attracts attention at this season, and, in this vicinity, grafted plants of *Magnolia glauca* showed the scarlet seeds early in the month, much earlier than any other species or than the same species when grown on its own roots.

Arnold Arboretum.

J. G. Jack.

Observations on the Grape Crop.

IN former years the birds have stripped the vines of Early Dawn and some other varieties early in the season, while the Clinton has fallen a prey to them later; but this season they seemed to prefer the Clinton first of all, and long before it fairly began to ripen. From six Clinton vines which were loaded with fruit, every berry was taken two weeks ago. The same is true of Cornucopia, Early Dawn and several others with berries of that size which seems to be preferred. After these, the birds paid attention to Ives, Wilder, Worden, and large grapes of this class. Many of the grapes were only stabbed and left for the bees and wasps to finish. The whole berry was carried off in some cases; but this was not usual as it was with the smaller kinds. Preference was also manifested for the black grapes; the red ones were taken to a limited extent, but so far as I have seen not a white one was molested. Color seems to have been the first attraction, size next, while flavor was a matter of minor consideration. If not, why should sour, unripe Clintons be preferred to sweet Wordens and Wilders?

Many would be ready at once to charge the English sparrows with this destruction, but I have not seen one in my vineyard this season, and I conclude they are not indictable for this offence. The guilty ones are robins, thrushes, catbirds and "chippies." It has been remarked that robins are unusually numerous this season. They picked my black caps early in the season, and made clean work of it, and they did not refuse a meal of strawberries occasionally, and now it is the grapes. Can it be a scarcity of their usual autumn food, or does the increase in numbers account for their increased destructiveness? I have learned one lesson, at all events, which, is that safety in the future can only be insured by bagging every grape.

Bagging grapes has not afforded protection in other regards this year as it has formerly. While some clusters show the dried, mummified carcasses of berries destroyed by Black Rot, many more are of full size, the white ones hard as bullets, of a yellow, golden or leaden hue, with threads of fungus visible through the skin. The peduncle of such berries is invariably black and dead, and has a feeble hold on the berries. How does the fungus get to the clusters? First, it is possible that the spores may have been lurking on the young cluster when bagged; but the chances of this were much reduced in the case of clusters bagged before they bloomed, and these seem about as badly affected as any. My next theory is that the rains, which have been heavy, frequent and almost constant, have

pounded holes through the bags, and through these holes have probably carried the spores which lodged in the cluster, and, under favorable conditions, germinated and grew. In many cases where the young clusters touched the side of the bags exposed to the rain, the bags were beaten so hard against them that grapes not larger than a half-grown pea were forced through and grew to maturity. In some instances these outside berries were the only diseased ones on the cluster, which speaks well for bag-protection. I regret very much that I had not tried a few of the water-proof bags to see if they would have afforded any better protection.

There are also some problems regarding the fructification of the blossoms not easily solved. We would naturally expect the strongest and most vigorous vines to set and mature a large crop, and yet the weakest and feeblest vines are frequently found to have not only the largest crop, but the largest and best developed clusters. Scores of what I consider my best vines have, this season, made a sorry show of ragged imperfect clusters, a result which I have never before seen. There is a cause for this freak, no doubt, but I have yet failed to discover it. Another peculiarity is the unevenness with which the grapes grow and ripen. While the larger portion of the cluster will be fully ripe, the remainder will be green or partly colored. By the time these late berries get ripe, if they ripen at all, the rest of the cluster will be rotten. This feature of uneven ripening was prevalent last season, but far more so this season. The few days' difference in the blooms of the cluster seem hardly sufficient to account for this phenomenon, and I have never heard any attempt to account for it otherwise.

The last and most serious calamity with which our grapes have had to contend has proved the most fatal one. To have them escape mildew, rot, anthracnose, and the whole tribe of insect enemies, and then burst open just as they are at the threshold of maturity is disappointing, to say the least. But nine consecutive rainy days were too much for many kinds, and the way they split was a sorrow to behold. I had a quantity of fine Wilders, which lacked but a few days of ripeness, but the great majority of them cracked and became food for the bees. Cottage, Worden, and many others, fell a prey to the same cause; while Jefferson and Salem are a total loss. Remarkable as the season has been, my Salems were larger and finer than I ever grew, but they have all decayed.

It has often been said that the great diminution of the grape crop throughout the country would enhance prices, so that a partial crop would net as much money, but the present tone of the market does not justify that prediction. Retail prices seem to rule about as usual. I hear of many vineyards being uprooted because the prospect for grape-growers is so gloomy.

In my case, copper sulphate has not given immunity from mildew. This fungus is abundant, although the foliage of my Vines generally is, I think, quite as perfect as usual at this season of the year. Some varieties, of course, are entirely denuded, showing them to be less susceptible to the influence of the sulphate than others, if the retention of the foliage is to be credited to its presence. Perhaps I made too few applications, or more probably the rains washed the sulphate from the Vines as soon as applied. Forty-one rainy days in three months and a half, with much dull and foggy weather between the showers, exactly suited the habits of the fungus and protected it from our remedies. In a season of less moisture, and earlier and more persistent applications, I doubt not the results would be more satisfactory.

The most perfect foliage in my vineyard is on a few Vines of *Vitis rupestris*. They are as fresh and bright as in mid-summer, and I am inclined to think that Professor Munson, of Texas, is on the right track in attempting to evolve from this species and *V. aestivalis* a new race of grapes with iron-clad foliage. My Vines of Woodruff Red, whose foliage appears as wild as the wildest of our *Labrusca* varieties, present the opposite side of the picture, showing that appearances are often deceptive, and that only by actual trial and experience can we determine the endurance of a Vine's foliage. Next to hardiness of wood, this hardiness of leaf is the most valuable quality in a Vine.

Montclair, N. J.

E. Williams.

Stove Plants in Flower at Kew.

Solandra grandiflora.—The Solandras and Daturas are closely related to each other; they are also remarkable as being the largest flowered of the plants included in the order Solanaceæ. There is, however, a disparity between the two genera of some horticultural importance, namely, the shy flowering nature of the Solandra as compared with the Datura. But it seems not impossible that, by proper treatment,

the *Solandra* may be made to bloom every year, and when it does its beauty is of a high order, the flowers being large, trumpet-shaped, not unlike those of *Brugmansia suaveolens*, their color being pale creamy-yellow. There is a fine example of this species now in flower in the succulent house at Kew, and no doubt the dry atmosphere and bright sunshine all summer has had a great deal to do with the free production of the flowers. In moist stoves, although the plant grows very luxuriantly, it cannot be induced to flower. Planted in a bed of poor, sandy soil and trained along the roof-glass, the example in the succulent house makes good growth annually, and this is the third successive year of its flowering there. In winter it gets no water. It is a native of Jamaica, and has been in cultivation since 1781.

Allamanda violacea.—Yellow is the characteristic color of the flowers of all *Allamandas* except this, in which they are purplish-rose, or what is known amongst milliners as crushed strawberry color. Although an unknown plant in English horticulture now, yet it was in cultivation in England in 1861, when it was flowered and described. It is now in flower at Kew. As an instance of the manner in which plants are distributed and afterwards preserved in some out-of-the-way garden, we may mention the fact that the only garden where, on inquiry, this species was in cultivation was the Botanic Garden of Natal, from whence the Kew plants were obtained. Of course it and all other *Allamandas* are natives of Brazil. *A. violacea* has the habit and general appearance of *A. cathartica*, but the leaves are covered with scabrous hairs and they are arranged in whorls of four. The flowers are in terminal clusters, and each one is shaped like the flowers of *A. cathartica*, except that the divisions of the calyx are larger.

Aristolochia ridicula.—Amongst a large number of cultivated species of *Aristolochia*, which are remarkable for the fantastic shapes of their flowers, this is certainly one of the most singular. Mr. N. E. Brown, who is responsible for the specific name, described the flowers as "positively droll, the two lobes on the sides of the mouth of the flower forcibly reminding one of donkey's ears." The comparison is very unfavorable to the plant, for the flowers are certainly beautiful as well as interesting in form and color; they are about four inches long, curved as in the common Dutchman's pipe (*A. Sipho*), inflated at the base, compressed in the middle, then widening again so as to form a broad, curved neck. The outline of the limb or spreading top is that of a Commodore's hat, the mouth of the tube being ellipsoid and filled with white, converging hairs, the two elongated lobes or ears spread in opposite directions, each being one and a half inches long. There are a few club-shaped hairs near the end of each lobe. The color of the tube is greenish-white with purple veins, that of the limb brown with purple markings. The leaves are kidney-shaped, six inches across, and the stem is thin and quick-growing. The whole plant is pale green and covered with long, somewhat stiff hairs. It grows freely in a stove and produces its flowers from the leaf-axils. It is in flower at Kew. Each flower lasts two days. Other *Aristolochias* now flowering here are *A. Brasiliensis*, a grand plant for covering large pillars or trellises in stoves; *A. elegans*, one of the very best of stove climbers, as it grows freely and flowers abundantly, whilst the flowers are large, handsome in form and attractive in color; *A. tricaudata*, with dark, shining purple flowers, which are remarkable for their three long, drooping tails, and a form quite as striking as that of the Chimæroid *Masdevallias*; *A. trilobata*, with elegant, jug-shaped flowers, not unlike the pitchers of a *Nepenthes*. There are, altogether, a considerable number of *Aristolochias* with large, ornamental flowers, but they have one unfortunate drawback, namely, that of a disagreeable odor. In this respect *A. Brasiliensis* is probably the worst, whilst *A. elegans* is the least offensive.

Kew.

W. Watson.

Orchid Notes.

NEARLY half a century ago Mr. James Bateman, in the introduction to his famous work, "The Orchidaceæ of Mexico and Guatemala," wrote: "It is, indeed, probable that Orchidaceous culture will always continue in a comparatively few hands, and it will, therefore, be pursued with the same ardor in the upper walks of life that already, in a humbler sphere, attend the cultivation of the beautiful varieties of the Tulip, Auricula and Carnation." Shortly afterward a writer in the *Gardeners' Chronicle*, in reply thereto, remarked: "I suspect that the time is not far distant when we shall have many of the more-easily cultivated Orchids—*Dendrobium nobile*, for instance, the *Cypripediums*, etc., etc.—going about in the baskets of the itinerant flower-sellers in London, and as easily

grown as *Cactus speciosissimus*." Perhaps the truth lies about midway between these two opinions. We do not remember to have met with any of the numerous vendors of flowers "all a-growin' and a-blowin'" who have included Orchids among their stock in trade, though the last-named writer was, unquestionably, near the truth when he added, "But we must have them for the million."

Orchids for the million we certainly have at the present time, and still their cultivation seems to be extending over a wider field. Most people who have a glass-house of any kind include a few Orchids among their treasures, and, in many cases, with the happiest results. *Cypripedium insigne* is a kind which luxuriates in the temperature of an ordinary greenhouse, and there are many others whose successful cultivation presents no greater difficulties than does a *Cineraria* or Chinese *Primula*.

A mania, it is sometimes called by those who profess their inability to understand it and who prophesy its speedy collapse, like the Tulip-mania of a by-gone day. Twenty-five years the late Professor Richenbach gives it, when he orders that his Herbarium shall be sealed up for that period, "in order that the inevitable destruction of the costly collection, resulting from the present craze for Orchids, may be avoided." Let us hope that it is sealed up—beetle-proof, as well as proof against the ravages of bipeds of Orchidomaniacal tendencies—or we fear that its value will be sadly diminished in a quarter of a century.

But it seems highly probable that the present love of Orchids is based on a broader footing than mere vagary of fashion. Perhaps there is no other class of plants which yields a greater return for the trouble expended. The great beauty of their flowers, their grotesque shapes, their wonderful variety and the long period during which many of them remain in perfection are, perhaps, unequalled in any other group; their small size enables a large number to be cultivated in a comparatively limited space; and, so diverse are their periods of flowering, that throughout the entire year some object of attraction is to be found in the Orchid-house. Plants with so many good points are not likely soon to go out of fashion.

The amount of capital now occupied in the importation and cultivation of Orchids is enormous, and when one remembers the vast quantities of certain kinds which are annually torn from their homes and brought over for the decoration of our gardens the question arises, how long will the supply hold out? Certainly, some species seem to be in imminent danger of becoming as extinct as the Dodo. Some time ago we came across the remark of one collector of a certain species that he believed he had secured the last plant. The Messrs. Veitch remark that the old autumn-flowering *Cattleya labiata* is believed to have been exterminated many years ago, no plants having been imported for upwards of forty years, although it has been diligently sought for by English and other horticultural firms. Can nothing be done to prevent such wholesale destruction?

The beautiful *Disa grandiflora*, the "Pride of Table Mountain," as it has been termed, is no longer in such imminent danger of extermination as was the case a few years ago. Large quantities of the tubers were annually exported to Europe, but the summit of the mountain being crown-land the government has seen fit to intervene, and has restricted the removal of tubers within reasonable limits. Perhaps the principle may yet have to be applied elsewhere.

London.

Calypto.

Odontoglossum Hunnewellianum.—This is a new and handsome species dedicated to H. H. Hunnewell, Esq., of Wellesley, Massachusetts. It was imported in 1888 from near Bogota, Colombia, by Messrs. F. Sander & Co., St. Albans, England, through Mr. Oscar Bobisch. The plants have not yet recovered from the effects of the voyage, and, consequently, only a few flowers have been produced. These are two inches across, but are somewhat larger in the wild specimens seen. The sepals and petals are ovate-oblong, acute, the former being slightly wavy, bright yellow, with a few very large dark brown blotches; the latter are much more wavy on the margins, also bright yellow, and covered with numerous blotches of dark brown. The lip, which reminds one of *O. luteo-purpureum*, is broadly obovate when spread out. It is creamy-white, with crisped denticulate margins, reflexed at the tip and incurved on each side. The surface is covered with brownish blotches, which take the form of small spots at the margins and give the lip a pretty appearance. The crest consists of diverging-toothed keels, with a smaller one between them, while the white truncate limbs of the column are spotted with brown near the slightly crenulate margin. The pseudo-bulbs of this species are two to three inches long,

about one and a half broad, ovoid-compressed, with two edges, and bearing at the summit two narrowly oblong-acute leaves from six to nine inches long. Such is the description of this species as it appears at present, but it remains to be seen what results cultivation will produce.

Odontoglossum Wendlandianum.—This is also a new *Odontoglossum*, introduced to cultivation for the first time, by the same firm, this year from the mountain ranges of Colombia. It has pyriform compressed pseudo-bulbs two to three inches long, and narrowly oblong-acute deep green leaves about a foot long. As yet only few flowers have been produced, but it is probable that next year the true habit of the plant will be seen to much greater advantage. The individual flowers seen were from two and a half to three inches across, with lanceolate-acute sepals and petals, the former being reflexed at the sides, and the latter very wavy on the margins. The ground color of both sepals and petals is creamy-white, thickly covered with brown and crimson spots and blotches, which give the segments a very handsome appearance. The more or less oblong acuminate lip is somewhat like that of *O. crispum*, but is much more wavy at the sides. It is pure white, with several rich brown blotches below the crest, which consists of two long, elevated and deeply-toothed keels in the centre, with shorter diverging ones on each side. The column is whitish, spotted with purple at the side, and furnished with small incised wings.

St. Albans, England.

John Weathers.

Seasonable Work in the Flower-Garden.—Little experience is needed to teach that many of the so-called hardy plants are tender enough in some sections to need protection in the border or to justify the care of lifting and placing them in a frame or some other structure, where frost may be partly excluded. Any plants that remain green above ground through the winter, such as the *Kniphofias* (*Tritomas*), may be lifted, and the tops cut off to within nine inches of the ground, and heeled-in in a cool cellar. It will be found that *Eulalia Japonica*, and its varieties, are not always hardy, and they may be treated in the same way with perfect success. When the plants are lifted annually, and put out in spring as soon as the soil is warm enough, they make better growth, for the reason, perhaps, that it is possible to thoroughly enrich the soil at planting-time. *Montbretias*, *Crocus* *Gladioli* and *Tigridias* may now be lifted and the tops cut, not pulled, off, and stored away in dry soil, where frost cannot reach them. We used to lift *Hyacinthus candicans*, but find that, if planted where there is no danger of water accumulating, it is much best to let it winter out.

If it is desired to increase the stock of any of the tall *Phloxes*, these should be lifted, potted and placed in a cool house, and cuttings made of the young shoots as soon as they are long enough. Young plants are usually far more vigorous than the old ones, as these are liable to become impoverished, and are better replaced by strong young stock. The *Salvias* that are accredited with being hardy are *S. Greggii*, *S. Pitcheri* and *S. farinacea*. All three are too good to risk out-of-doors, and part of them should, at least, be taken in. We have found them stand well enough during some winters, while in others they die. The same may be said of *Anemone Japonica* and its varieties. These should all be lifted, the tops cut off and the roots laid in, in a cool place, the cooler the better, so long as the frost does not get to them. As these *Anemones* have a great tendency to start into growth during winter, if it is desired to propagate them, the tendency may be taken advantage of by cutting all the smaller roots into pieces four inches long and laying them in sand in the propagating-bench. These will start at once, and may be potted, and all will make flowering-plants the next season. We have some 200 plants, all beautifully in bloom, from small roots treated in this way last fall. Any bulbs, such as *Narcissus*, that are yet to be planted, should be got in the ground at once to enable them to get well established before frost, which, fortunately, has been in no hurry to appear this year.

Passaic, N.J.

O.

Prunus pendula.

OUR illustration upon page 487 represents an old and very large specimen of this tree which has already been described in this journal (vol. 1, p. 196), growing in the garden of Dainichido, a temple garden on the road from Nikko to Chiuzenji, and shows the habit which this interesting tree assumes when it is full grown.

The illustration is from a photograph made by Mr. James M. Codman during his visit to Japan in the summer of last year.

The Forest.

The Forest Pavilion at the Paris Exposition.

LAST week we gave part of a letter originally published in *L'Indépendance Belge*, describing the beautiful forest pavilion on the Trocadero, which the French Forest Department had erected, and giving an account of some of the forest-material which has been arranged with exquisite art. The department desired, however, to explain to visitors its method of work, and the result of this work, beyond the mere keeping up of the state forests, building roads through them to facilitate excursions and hunting, and making preparations to cut and re-plant for coming generations. The duty of the foresters does not cease here, and millions are annually expended to repair the accumulated ruin caused by deforestation of the hills and mountains by former generations. Forests are re-planted to resist the force of floods and preserve the mountains from being scoured by torrents and swept down upon the plains. The writer adds :

Numerous are the victories already won. Vast tracts of desert have been re-covered with vegetation; villages are springing up again where whole populations had fled before the invading waters and the danger of landslides; mountains and hills once denuded are now covered with verdure; cultivated fields and orchards have replaced the arid and desert plains.

The Administration of Forests, proud of these results, exhibits them in the form of models in relief, maps and pictures. It has gathered a great mass of documents in two halls, comfortably arranged, where easy-chairs invite the visitor to seat himself in front of wide tables strewn with photographs, albums and numerous publications. Here are views of the torrents of Arbonne, and of Secheron, in Savoy; here are photographs of the basin of the torrent of Vaudaine and of the torrent of Riouchanal, with sections of work already completed there. There are curious models in relief of other torrents, besides dioramas, which give faithful and striking representations of some of the magnificent works in progress. At the end of the forest pavilion are three dioramic views, in an excellent light, with well-studied perspective. Near each one is suspended a placard containing, in large letters, the printed explanation of the enterprise, the means employed and the results obtained. The first is a view of the Valley of Péguerre, near Cauterets. There the object was to keep in place a mountain which threatened to crumble and destroy a pretty town. The soil was loosened by the melting snows, and immense blocks, bowling down the rocky slopes, cannonaded the settlement at Ralliére or that at Manhourat. To rescue the valley, the rocky sands were sown and planted. Walls of stone, without mortar, were placed at all points where there was no chance of grass growing. The work was begun in 1885, and to-day the problem is solved. In the diorama the workmen are seen clinging to the side of the mountain, digging out the rock, blasting, constructing walls and terraces, sowing and planting on dizzy ledges, to which both men and material are hoisted by ropes and windlasses.

Next comes the picture of the torrent of Bourget, in the Department of the Basses Alpes, which had devastated the valley of the Ubaye for years, but is now under control. A series of weirs has been constructed which have raised the bed of the torrent and checked the undermining of the mountain; the violence of the rise of the waters is weakened by diminishing the incline and by successive falls, and the sliding down of the banks has ceased. The diorama shows us these weirs, and the barrier of living basket-work; the forestal guards are there, strengthening the stone work and busy in planting trees to bind the sod. The subjection of the torrent is complete; it is now a gentle mountain stream, bordered by a thousand acres of forest in thriving condition. This work occupied nearly eighteen years.

The third diorama shows the torrent of Riou-Bourdoux, also in the Basses Alpes, noted for its ravages and the most terrible of all the torrents of the French Alps. It destroyed everything in its sudden overflows. Forests, houses, flocks, all had disappeared, swept away by its floods or swallowed up in its deposits of mud, sand and rocks. Not a tree, not a blade of grass, not a living being remained. Barcelonnette, near which it debouches, was endangered. In 1875 the struggle with the torrent began, and now it is vanquished. Here the barrier against floods is a colossal wall of masonry, with hydraulic

mortar buttresses and openings for discharging the water, twenty-eight feet high and 275 feet long; its purpose is to keep back all the solid materials which the torrent carries down and to allow only clear water to pass through. And what a different picture does this region now present! A young forest which has been planted covers the scarred surface with its protecting growth; the soil on the steep slopes is now mantled with grass growing thick and fine; in the valley, once so dangerous, villagers cultivate their lands and Barcelonnette is saved.

This is what is accomplished by restoring the forest and planting trees on a few hundred acres. How many inundations might be prevented, how many annually-recurring disasters averted, if the money and the skill were ready to prosecute more of these effective works.

Near these dioramas are dark chambers, in which the happy idea of picturesque illusions has been carried out. Here is the cabin which serves as a shelter for a gang of twelve workmen; two camp-beds, made of planks covered with straw, blankets and changes of clothing, then tools, shovels, pick-axes, ropes, cans and all the provisions. Here is the interior of a hut for a forestal agent out on a high mountain: An iron bedstead, pine furniture, two chairs, a table and a chest, some shelves on which are placed books, instruments and cooking utensils. Elsewhere we see the forge, set up in a shed made of boughs and ferns, with anvils, bellows, tongs and hammers. All this proves most entertaining to the visitors, and it is instructive as well.

One can imagine that the gigantic trunks from America and Australia consider our modest trees as poor, degenerate species. Beside the Eucalyptus from Victoria and New Zealand, the Mahoganys from Mexico, the Cedars from the Argentine Republic, the big trees of the United States, the Pines from Brazil, the Perobas from the Amazon, and other prodiges from the New World, our Poplars, our Elms, our largest and tallest Pines look like a child's playthings. But our trees, nurtured with so much care and cost, might well retort: "You will not always be giants if those who exhibit you do not heed the lessons taught by the dioramas of Riou-Bourdoux, of Bourget, and of the valley of Péguerre. Let them see what it costs to strip the trees from the mountains without moderation or method; let them ask our foresters what pains and money it costs to repair the recklessness of former generations. The axe and fire and browsing flocks will too soon make your forests as thin and small, and your torrents as destructive as ours."

No doubt our trees are right, and the commissioners from Australia and America would do well to take advantage of their stay on our continent to study the art of cultivating forests and of systematic felling.

Correspondence.

Some Native Vines.

To the Editor of GARDEN AND FOREST:

Sir.—Your admirable articles on Masking House Foundations seem to have had in view suburban houses mainly; but the lack of vines about our country homes is noteworthy. One may ride miles without seeing a well-chosen and carefully-trained vine near a farm-house. There are not infrequently piazzas standing bare in the sunshine, which might be made beautiful as well as comfortable places for the household if shaded and fringed by some festooning climbers. This neglect is less excusable since we have so many desirable native vines that can be had for the digging. Perhaps the Virginia Creeper, always thrifty, and with the crowning excellence of rich autumn color, deserves the precedence; but there are many others worthy of kind treatment. The Ground-nut (*Apios tuberosa*), which I lately saw in bloom, is certainly one of these. It is a twining perennial, with light green foliage, which is ornamental throughout the season, though its chief interest lies in the peculiar color of the flowers and their appearance after most of our familiar native climbers are in fruit. The racemes of chocolate-colored blossoms, paler-hued outside, contrast finely with the green leaves, while the inside has a rich velvety appearance and a pleasant odor of Violets. The specimen which I observed had climbed sixteen feet among the branches of a Larch-tree, bearing clusters of bloom at the axil of each leaf for a good part of the distance. The Moonseed is also easily cultivated, and its twining stems and abundant foliage make a most desirable Vine. Even more abundant is the foliage of the unarmed Smilax, which is also ornamented with umbels of black fruit. And why is not the common Virgin's-bower (*Clematis Virginiana*) planted wherever any planting is done? It is the most beautiful of the

northern Clematises, and can be found in any wooded region. It is never more beautiful than it is along a country road-side but it thrives under cultivation, and makes a wonderful growth in deep rich soil.

Klinger Lake, Mich.

Dorcas E. Collins.

Rosa setigera and Ipomœa pandurata in Southern Michigan.

To the Editor of GARDEN AND FOREST:

Sir.—Mr. B. W. Steere, an intelligent nurseryman, living near Adrian, Lenawee County, in southern Michigan, gives me the following in reference to the Prairie Rose:

"About 1846-47, Barber Perkins made considerable money by shipping the Roses east, where extravagant prices were paid for them. As the excitement ran high, men and boys scoured the woods in all directions from Adrian. They were also found in Monroe County, in the south-eastern part of the state. They were sold as the 'Michigan Rose,' 'Michigan Climbing Rose,' 'Prairie Rose,' and 'Eglantine Rose.'"

"They grew mostly on the rich borders of swamps. In going from Adrian by way of Blissfield to Maumee City in a carriage, years ago, in July, I saw them in full bloom, covering small trees to a height of ten to fifteen feet; and their great clusters of flowers were so abundant and beautiful that the sight of them well repaid one for many miles of travel. The last one that I was sure of here, grew on our place near the river Raisin, but was taken up or destroyed seven or eight years ago. The name 'Prairie Rose,' doubtless came from our habit of calling our swamp meadows, 'prairies.'"

There is one vine which I think must be about extinct here in the wild state, Man of the Earth, *Ipomœa pandurata*. The only one I know of runs over a large quince bush, planted forty or forty-five years ago. It still shows its large flowers in July and August, white, with purple throat. It can look at the sun without blinking.

Agricultural College, Mich.

W. J. Beal.

The St. John's-worts.

To the Editor of GARDEN AND FOREST:

Sir.—I was much interested in Mr. Jack's article on "Hypericums," and I wish to endorse his statement that *H. calycinum* is "decidedly the most interesting and satisfactory." In this conclusion every one must concur who is familiar with the beauty of foliage and flower of this species, to say nothing of the immense value of the plant from its hardness and adaptability for undergrowth and in shaded locations. There are so few really desirable shrubs which succeed under trees and in shady situations, that it is surprising that this fine variety is so little grown or known.

In a trip through England and on the Continent during the past summer, one of the most pleasing and effective things in hardy trees and plants I saw was a solid border of *Hypericum calycinum*, planted on both sides of a walk directly under some double rows of shade. The foliage above was quite thick. Few, if any, sunrays fell directly on the plants at any time during the day. The soil was an ordinary loam, not specially prepared nor over rich. The shade was sufficiently dense to preclude the growth of any shrub or plant not congenial to such conditions, yet the border on both sides, and for the entire length, was a solid mass, about a foot in height, of the most beautiful green, and covered with large, showy, golden-yellow flowers.

Nearly all the Hypericums are largely used for ornamental planting in Europe, but *H. calycinum* is generally considered there—as it will be here in time—not only the most valuable of the species, but for massing in shady situations as almost without a rival or equal in all the long list of dwarf-growing hardy shrubs.

New York.

Fred. W. Kelsey.

A Pleasing Combination.

To the Editor of GARDEN AND FOREST:

Sir.—A lady, and gardening enthusiast, mentioned to me, the other day, a combination which she had used with pleasing effect on her grounds at Wyncote, Pennsylvania—the Trumpet-creeper and Wistaria placed together to help one another rise in life, and drape a gnarled old Cedar-tree.

Possessed of so fine a sense of the beautiful as to have planted the large Dogwood by the hundred upon an extensive lawn as clumps, sections in boundary planting, and notably as a hedge-backing against a row of stately Red Cedars, that forms a protection to one side of her hardy flower-garden, the combination which she emphasizes must, in the very nature of things be a happy one.

Rochester, N. Y.

G. H. E.

Notes.

The *Engineering and Mining Journal*, in advocating some action by government to protect the forests against fires, asserts that these fires have this year destroyed more than the value of all the timber planted, the timber stolen and the timber legitimately cut between the Missouri and the Coast Range.

The Dwarf Gray Willow (*Salix tristis*) should make an excellent plant for the slopes of embankments and excavations along railroads, where it will flourish. It rarely exceeds two feet in height, and has slender stems not more than half an inch in diameter. The roots, however, are often as thick as a man's wrist, so that it is a hard plant to dislodge, and it would render good service in holding a bank firm.

The forest-trees in the vicinity of New York are late this year in putting on their autumn colors. Even the Maples are still green, but the Liquidambars are singularly brilliant in chocolate, bronze, maroon and glowing crimson. The Pepperidge, too, is brilliant in cases where the leaves have remained on the trees, but in many instances the leaves of this tree, and of many others, have fallen prematurely, leaving the branches as bare as they are in winter.

In his interesting article in this issue, Mr. Jack states that *Clematis paniculata* can hardly be called a September-blooming plant in Boston. In the vicinity of New York, however, this admirable species was in full bloom from the 1st until the 20th of September. It may be added that *C. crispa* is still showing flowers, even after quite sharp frosts, and the same is true of *C. coccinea*, whose light coral-colored flowers are yet seen in considerable numbers.

We have received from Mr. S. C. Moon, of Morrisville, Pennsylvania, some very large and beautiful chestnuts from a tree said to be a seedling of the European Chestnut. The variety has been named Numbo, by Mr. Moon, on whose farm it originated more than thirty years ago. When boiled, these chestnuts are of good flavor, but the quality of the meat in its natural state is inferior to that of our smaller nuts. The tree is said to be very hardy, symmetrical in outline, and unusually productive.

Worden's Seckel is a new pear which has been in bearing four years. It is a seedling of the Seckel, but is a more vigorous tree and produces its fruit in clusters. The *Country Gentleman* describes the fruit as above medium size, pyriform, smooth, with clear yellow skin and a broad, rich-red cheek. The flesh is white, fine-grained and melting and of a mild and sweet, pleasant flavor. Altogether, it is one of the most beautiful of Pears, and its quality would be rated "very good." It was raised by Mr. S. Worden, of Oswego County, New York, the originator of the excellent Worden Grape.

Syringa oblata in this vicinity has this year sustained its reputation for freedom from mildew. A small plant observed on Saturday last had foliage as fresh and green as in early spring. About Boston, however, many large plants are slightly but distinctly mildewed, and a young plant in the Arnold Arboretum is mildewed as badly as many of the common Lilacs. *S. japonica* shows no trace of mildew, nor do *S. pubescens* or *S. villosa*. The Chinese and Persian Lilacs are as liable to the fungus as are the varieties of *S. vulgaris*, and, by the way, different varieties standing side by side are very unequally affected.

Agricultural Science for September contains a study of the contents of seed packages obtained from American seedsmen and from Vilmorin-Andrieux et Cie, of Paris. Very little weed-seed was found, and not enough foreign material or imperfect seed to justify the establishment of seed-control stations. The most harmful adulteration of seeds is that of mixing varieties, or of substituting inferior strains or varieties for good ones. But this adulteration cannot be detected by an examination of seeds, and is, therefore, difficult to control. The redress in this case must be demanded of the seedsman by the grower himself after the crop is grown. It is doubtful if the self-asserted irresponsibility of the seedsman, printed upon all seed packets, constitutes any legal immunity from damage in the case of harmful substitutions; at least an English court has decided that such statement does not relieve the dealer. The fact that such instances so rarely come to our courts is proof that adulterations of this character are rare in this country.

The people of the British Islands, as well as the continent of Europe were surprised by a sudden taste of winter on the 16th and 17th of September. Much damage was done to

tender vegetation, especially in Belgium, where there are so many large establishments devoted to commercial horticulture. A correspondent of the *Gardeners' Chronicle*, writing from Ghent, says: "About 2 A.M. on Monday, the 16th, frost came on so suddenly and was so severe that every one was taken unawares, and by daylight it was apparent that a serious disaster had befallen the Indian Azaleas, the plants in most places presenting the appearance of having been singed, and for some miles around Ghent the plants have, with scarcely an exception, suffered alike. The disappointment to buyers will be great, and the loss to the growers will prove to be one of the most serious misfortunes which has occurred within the recollection of the oldest horticulturist in Ghent. Packing operations for export were to commence on the very day of the disaster."

The manufacture of shingles in Oregon and Washington from Red Cedar (*Thuja gigantea*) is a rapidly growing business. Formerly these shingles were sold in Colorado and Utah only. Several of the largest manufacturers last year united to form the North Pacific Consolidated Shingle Company, which now sells 20,000,000 shingles a month, finding markets in Missouri, Iowa, Illinois, Indiana, Ohio and New York. These Puget Sound and Columbia River shingles are absolutely free from knots, and they neither curl, warp nor split, and dampness has little perceptible effect on them. Fort Nesqually, built by the Hudson Bay Company in 1841, was covered with split cedar shingles, which are still sound. Roofs laid thirty years ago, and for years covered with moss, have never leaked and appear little the worse for wear. This Cedar is a great favorite with the Indians who hollow their canoes out of the wood because it is so light, splits so true and works so easily. For the same reasons most of the sash and doors in Washington and Oregon are made of this wood. The tree grows to a diameter of twelve to thirteen feet very often, and in a late number of the *Northwestern Lumberman* is an illustration of a tree which is eighteen feet in diameter.

A botanical garden has been established in the Alps of Valais at an elevation of more than 5,600 feet above the level of the sea. It is situated on a cone-shaped knoll, which is about 200 feet high, and composed of a number of natural terraces, planted with *Pinus Cembra* and Larch, and faces north, east and west. On the summit is a plateau facing the south, on which will be a little chalet, containing the library and herbarium of the garden. The Association for the Protection of Plants has bought the land, and converted it into an alpine garden, for plants from all the alpine regions of the globe. Representatives of the floras of the Himalayas, of the American mountains, of New Zealand, of the Antarctic regions, of the Caucasus, of Siberia, of the Pyrenees, the Alps, the Carpathians, and the Ural, will be separated, and each cultivated in a special division. Naturally, M. H. Correvon was named Director of this new trial-garden, in which he had already planted several thousand mountain plants. This garden is at so high an elevation that interesting observations can be made concerning the floras of all the alpine regions of the globe, on the relations of plants with insects, their acclimatization, variability, etc. Already consignments of plants have been sent to M. Correvon, and a German botanist who is traveling in the East, and is continuing the work of Boissier—M. Bornmüller—has promised some interesting specimens. Other parcels are expected from Canada, Greenland and New Zealand. The *Gardeners' Chronicle*, from which we take these facts, invites all who are in suitable latitudes to send to M. Correvon seeds or bulbs from the northern regions in which they are traveling, for the garden of Bourg St. Pierre, which will necessarily serve later on for the temporary reception of plants from high altitudes which cannot be acclimatized directly with us, but require to be subjected to an intermediate temperature first. In this way, M. Correvon is going to try to acclimatize the celebrated but fragile *Calypso borealis*, which he hopes to introduce into cultivation by accustoming it to this intermediate position.

The Forestry Meeting at Philadelphia.

ON another page of this issue will be found a vivid picture of the desolating progress of fire through some of the most magnificent timber now standing on this continent. League after league of Pine and Redwood on the flanks of the Coast Range and the Sierra, the growth of centuries, is turned to cinder in a night, and the only record of the loss is a paragraph in some local paper. In spite of the immense value of this timber, and of the incalculable importance of these mountain forests as conservative and vitalizing forces in the economy of nature, the man who flings a blazing torch among them is not counted a criminal, and no one interests himself to check the sweep of the flames. This is what is happening in one state now. All summer long conflagrations, tenfold more destructive, have been raging through the vast stretches of timber in the North-west. Every year, in every state, the flames devour the woods wherever any woods remain. It would hardly be an exaggeration to say that the forest fires kindled by the earliest white settlers who landed on this continent have never gone out from that day to this. And fire is but a single agent of devastation. From the turpentine orchards of the South to the logging camps of the North, and even in the wood-lots of the farmer, nothing but waste and improvidence is expected wherever an American carries his axe. The pitiful story of a priceless forest inheritance recklessly squandered, has been told so often that one is almost ashamed to repeat it.

And yet, if an association like the American Forestry Congress is to do any effective work, it must be in the face of just such discouraging facts as these. In spite of all the convincing statistics and arguments so often urged to demonstrate that the nation's welfare, and we could almost say the nation's life, depend upon the preservation of forests, utter apathy prevails where we should reasonably hope for intelligent interest. Only in rare cases has the popular demand been strong enough to compel action by legislatures, state or national, and when laws for the protection of forests have been enacted, public sentiment has been too lifeless to enforce them. The time for missionary work will not be over so long as a thousand square miles

of timber are consumed in a single year in a state like Pennsylvania. The day will come in this country for the refinements of forest practice, when a congress of skilled foresters will be comparing the results of experiments in natural reforestation and artificial planting, and discussing abstruse problems in mathematics and forest biology. But there is no occasion now for close calculations, so long as the people show by their practice that they do not consider the woods of any value whatever.

The diffusion of knowledge and the propagation of ideas regarding the necessity of economic forestry are best carried on by voluntary organizations, like the Pennsylvania Forestry Association; and the joint meeting of this body with the American Forestry Congress this week should be useful in promoting clearness of thought and increasing practical co-operation and efficiency among all public spirited people. The papers and discussions at such meetings are important means of arousing and directing popular thought. Unless based on a general and intelligent appreciation of the value of our forests, laws will avail nothing. Scientific forestry will find no field of usefulness until the people are educated to feel the need of it. The preparatory work accomplished by these agencies is, therefore, of prime importance, and the men and women who are unselfishly devoting themselves to this cause will be gratefully remembered hereafter as pioneers in one of the most beneficent movements of modern times.

A series of letters from the Adirondacks, which lately appeared in the *New York Times*, presents a most discouraging picture of the reservation. The writer has not been able to discover in any part of the wilderness south of Mount Marcy that the state forests have the slightest protection against the timber-thief or the bark-stripper. The forest laws are neither obeyed nor respected, and the state officers not only fail to enforce the statutes, but even help others to violate them. The fact that the commonwealth owns a tract seems to invite trespass, because such trespass is difficult to prove, and even when a logger is detected in the very act of taking timber from the state lands, his friends, the town and county officials, make a compromise which is satisfactory to the offender. The game laws, too, are violated in the same free-and-easy fashion, and no one feels any restraint about catching fish or killing deer at any season or in such a manner as may suit his pleasure. Unless this lawless slaughter is checked, the deer will soon be as scarce in the Adirondacks as the moose is in Maine. Altogether the prospect is most gloomy, and without decisive action by the state and the strong assistance of public sentiment, the beautiful scenery and abundant game of the North Woods will be little more than a memory ten years hence.

The writer does not deal in generalities, however, but cites instance after instance to show how half-grown deer are murdered, how the lakes are fringed with death by rising water backed up by illegally-constructed dams, how timber from government land is openly bought and sold, and how the constituted guardians of the place are helping to desolate it. It is to be hoped that there is a brighter side to this picture. Our own correspondent reported that depredations on state timber-lands were growing less numerous and that there was a gathering sentiment among the inhabitants of the region against further desolation by the axe and by fire. Nevertheless, his conclusions, that from three-fourths to four-fifths of the original forest has already been cut off and that hundreds of thousands of acres have been utterly stripped and ruined by the burning and washing away of the soil, are sufficiently depressing.

What we want are the facts of the case, and it is to be hoped that other papers will follow the example of the *Times*, and make an honest effort to place before the people the true condition of the North Woods. There ought to be enough public virtue left in the state to make it possible to rescue, for posterity, some remnants of this once priceless possession.

AT a meeting of the committee appointed to select a site for the Exposition to be held in this city, it was voted to take possession of as much of Central Park above Ninety-third street as might be found necessary. Who is to decide how much it will be necessary to confiscate, the committee did not divulge; but inasmuch as no considerable amount of land has been secured elsewhere, the action is a threat to vest some unknown body with full power to destroy the best half of the park, at least. It would be unjust to characterize this proposed defiance of law and violation of pledges as audacious or impudent, as some indignant critics have already done. It is simply the outcome of ignorance. The majority of these worthy gentlemen have not even an elementary knowledge of what Central Park is, or what function it fulfills in the life of the city. They offer to "improve" the park, as if an appointment upon some committee by a mayor was all the preparation needed for a work which demands as much taste and skill as do the design and construction of a cathedral, and they propose to obliterate the park, as a park, for several years certainly, and perhaps forever, without the glimmer of a suspicion that they are robbing the people of rights which are plainly guaranteed to them and their children. It remains to be seen whether the city possesses enough intelligence, firmness and civic virtue to resist this dangerous attack upon its grandest public work. We believe the scheme will be defeated.

Color in Flowers.

MR. G. H. ENGLEHEART, writing in *The Garden*, speaks with excellent taste regarding the colors produced in florists' flowers. "Could we appeal," he says, "to a competent florist who was also as refined and sensitive a colorist as, say, Mr. Ruskin or Mr. Albert Moore, I have little doubt but what he would maintain the principle that each flower or race of flowers has its own legitimate and illegitimate, or vicious, ranges of coloring, the former of which should be encouraged to extend and unfold to the utmost, while the latter should be absolutely suppressed. The florist's art may induce false and bad colors in flowers, just as the chemist's art has discovered and brought into ruinous use the horrible aniline dyes. It is no excuse to urge that all colors which appear in flowers are natural and may be retained. Nature (an ambiguous term this) must often be led or restrained, rather than followed, and there is often an 'Old Adam' which must be cast out of flower-kind as sternly as out of mankind. Thus in Primroses the so-called blues, the purples, magentas and all slaty tones are natural, but evil tendencies, and ought not to be tolerated. What should be encouraged, delighted in, heightened to vividness, or subdued to faint, soft tints, and in every way elaborated in this lovely flower, is the whole gamut of true crimson, ruby, maroon, pink, orange and yellow. Sometimes a flower appears which heralds the possibility of a true vermilion Primrose, and there is a cinnamon-brown and a cinnamon-chamois (to coin a word) which might in skillful hands lead to a new and lovely set of colors."

The many tints of white are, of course, also approved and "a Primrose of a Nemophila blue might be an acquisition (though, for my part, I do not feel certain that it would not be astonishing rather than charming), but the links of leaden and livid hues by which it is being reached after are ugly means, to be used and destroyed—not beautiful ends to be exhibited. Let me instance the herbaceous Phlox as a parallel. Here the legitimate and admirable range of coloring is that of pinks, roses, true lakes and crimsons, and especially certain glorious salmon-reds containing possibilities of scarlet and orange, besides the whites. No faintest suggestion of magenta should be tolerated in the Phlox. But when I turn to the florists' catalogues I observe that it is their endeavor and their pride to torture this fine plant, or rather to help it to debase itself, into sullen and impure purples—purple is a word grievously abused by our florists—and that their joy culminates in the production of a magenta with slate stripes. . . . But there may be found, very near to the Primroses, a rightful province for these colors. Turn to the Auriculas, and the true eye will see that purples, plum colors, sapphires, amethysts, lavenders and grays are not only permissible, but delightful and altogether desirable there. This is no mere open question of taste, but a matter of right and wrong, with, no doubt, demonstrable scientific reasons behind it, concerned perhaps with the greater

refraction or absorption of light in Primroses and Auriculas respectively. Some law might probably be established to the effect that blue, and all colors into which blue largely enters, can be pure and lovely only in such flowers as in texture or in tubular construction possess a certain luminous quality or transparency. The Gentian is the typically beautiful blue flower, and the Auricula has accomplished in its blossoms the seemingly impossible combination of velvet and crystal, and so fitted them for the reception of the bluest of rich purple coloring. But Primroses do not possess this crystalline texture or transparency to nearly so great an extent. An entire book might be written upon color in flowers, and many interesting laws traced, from a different standpoint to that from which the subject has already been considered by some men of science."

The writer might have instanced hardy Rhododendrons and green-house Azaleas as classes of plants where vicious colors, especially impure purples and glaring magentas, are far too commonly esteemed. If our readers will study their collections of these plants when in bloom, with the same regard to color that they would bestow in criticising a picture or choosing a ribbon, they will find many which, in Matthew Arnold's phrase, aptly quoted by Mr. Engleheart, should rouse "a sense of lamentation, mourning and woe."

Holiday Notes in Southern France and Northern Italy.

IN this and the following papers I shall endeavor to present some of the more interesting notes taken on a September holiday-trip. Practically the holiday commenced at Aix-les-Bains, for but few disconnected notes were taken by myself or my companion before Aix was reached. Both of us gardeners, looking upon matters horticultural and arboricultural as of the first importance to us, nearly the whole of the time at our disposal was spent in the open air as we journeyed from Aix-les-Bains to Turin, thence to Venice, back to Milan, and thence to the north Italian lakes. After seeing these we made for Genoa and skirted the Mediterranean as far as Marseilles, where the notes will close.

Aix-les-Bains presented comparatively little of interest from a gardening standpoint. The gardens of the Casino and of the Villa des Fleurs—an establishment of a similar character—were gay with gaudy beds, carpet and otherwise, and displayed the same taste, or lack of taste, which characterizes the devotees of the bedding system everywhere. No remarkable trees were noticed, except a fine *Magnolia grandiflora* and a good *Sequoia gigantea*, close to one of the few relics of the Roman period, the Arch of Campanus, a tomb of the third or fourth century, built in the form of a triumphal arch. In the little market place, what struck us most were the large quantities of flowers of the beautiful, fragrant *Cyclamen Europæum*, offered for sale by the peasant women; the flowers were done up in bunches of about a hundred and surrounded by a few of their own leaves. Were only flowers offered for sale no great harm would be done, but if roots are dug up, and destroyed at the rate observed by us, much longer, this charming plant will soon become as much a thing of the past in the neighborhood of Aix-les-Bains as is the Primrose—thanks to the Primrose League—within considerable distances of London. Some dealers had card-board boxes and address labels all ready, so as to leave no excuse for weak-minded plant-lovers not to buy their wares. According to advertisements and placards in the shop windows, etc., the deliciously scented flowers of the Cyclamen are used to perfume almost every conceivable toilet requisite; this, however—knowing something of what perfumery manufacturers are capable—we take leave to doubt.

The finest avenue tree here, and, indeed, in the whole of the region through which we traveled, is the so-called London Plane (*Platanus acerifolia*), misnamed in nearly every nursery and botanic garden of Europe *P. occidentalis*; from the American tree, however, *P. acerifolia* may be distinguished at the first glance by its having numerous buttons in a string. From Aix to the Lac du Bourget grateful shade is afforded by a fine Plane avenue of considerable length. The lake is picturesque and beautiful enough, and is largely visited by those who repair to Aix. The season was too advanced for most wild plants, the most noteworthy ones we collected in flower being *Campanula persicifolia*, the Nettle-leaved Campanula, *C. Trachelium* and *Lonicera Caprifolium*. A tall, perennial, yellow-flowered Salvia (*S. glutinosa*), well worthy of a place in the herbaceous border, was abundant in places along the margins of the woods. Box (*Buxus sempervirens*) grew as underwood on the steep, chalky slopes, and in the clearings Buckwheat was one of the principal crops.

About Chambéry the Walnut is largely cultivated, and gives

a character of its own to the country-side as seen from the windows of the railway-carriage. Beautifully-wooded slopes, ruined castles on commanding spots and smiling valleys combine to render the district between the last-mentioned city and the Mont Cenis tunnel singularly picturesque and beautiful. On the gravelly, stony banks of the rivers Isère and Arc—the train crosses the latter many times—welcome bits of bright color were afforded by bushes, heavily laden with fruit, of the Dog Rose (*Rosa canina*), Barberry, and the Sea Buckthorn, with its long, narrow, gray leaves and innumerable orange-red fruits. After passing through the Mont Cenis tunnel we pass the now deserted Mont Cenis road (constructed under Napoleon I. in the years 1802–5), which continues to ascend the Arc Valley. Here the latter narrows into a wild, picturesque gorge, and the train passes through numerous tunnels, between which we catch glimpses of frontier fortresses, aqueducts, waterfalls, bare, grassless hill-sides, bleak, desolate-looking mountains, on the highest of which snow-fields of considerable size glistened in the fierce sunlight. Then the valley expands, and Susa, with the Arch of Augustus, comes into sight. On the dry, hot banks above the river, a Globe-Thistle (*Echinops*), with its spherical heads of bright blue, was very attractive, and in the small meadows the pale purple flowers of the Meadow Saffron (*Colchicum autumnale*) were everywhere conspicuous. From this point the railway descends rapidly, passes through beautiful Chestnut-woods, and crosses the Dora, whose waters flow into the Po below Turin.

George Nicholson.

Kew.

Small Burial Grounds.

THROUGHOUT the country many public and private institutions can be found, such as hospitals, asylums, almshouses and the like, which are compelled to provide burial grounds of their own. As a rule, these are located upon the most folorn spot which the institutions can command. They are constructed without regard to appearance, and little care is taken of them. The contrast between these ill-kept grounds and a properly maintained cemetery is so great, that one is disposed to consider the treatment of the dead in some of them as almost barbarous. It must be remembered, however, that these institutions often care for the living without charge, and they are inclined to consider their obligations to the dead discharged when a free burial is furnished; and it is little wonder, therefore, that these grounds at last become a neglected Potter's-field. There are no monuments here, no headstones, no shrubbery, no planting of any kind, and the little mound which marks the place of burial will soon settle down in the tangle of briars and weeds, and leave no sign.

Now, plainly, something can be done to render these burial places less offensive. The problem is how to prepare them with little expense and in such a way that little labor will be required to maintain them. If the ground can be selected at a distance of half a mile or a mile from the institution, so much the better. A fair slope or easy undulation is preferable to level ground, and as no expensive treatment is allowed, the dignity which such a place should command must be secured by its general arrangement and by the simple disposition of trees and shrubs. It is desirable to conceal to some extent the actual burial ground from the entrance gate, and to devote a space for an appropriate planting in which the expression of repose and solitude should prevail. Gate piers, built of rubble stones and covered with ivy, would add to the proper character and effectiveness of the entrance. Through this gateway the approach should connect with a circuit road, which may either enclose the grounds where interments are to be made, or give direct access to them. The road or pathway, of some twelve or fifteen feet in width, may consist of a mere excavation of the top soil to the depth of twelve or eighteen inches, its grade being uniform with that of the surface of the ground. It should be seeded with lawn grass, with the edges sodded. The border of ten feet wide on either side of the circuit road, should be planted with evergreen trees, twenty-five feet apart, and a burial plot surrounded in this way is divided into tiers for occupation. These tiers follow the grading of the pathway in

line until the innermost one leaves a space in the center of the plot of from fifty to a hundred feet wide, and this space is reserved for the grouping of trees and shrubs in such a way as to create a picturesque background from any point on the circuit paths. There will be little need of any wheeling over such grounds, and the reason for lowering the pathway is

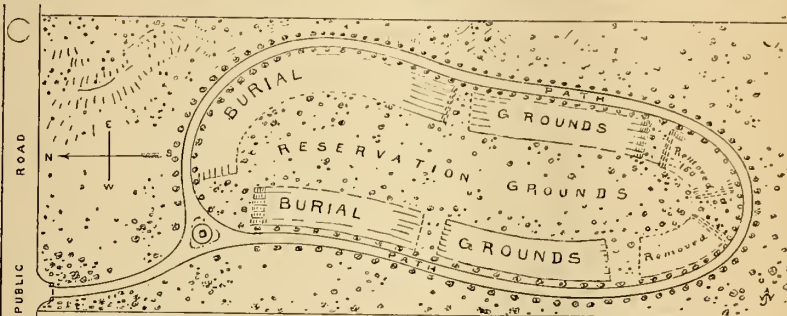

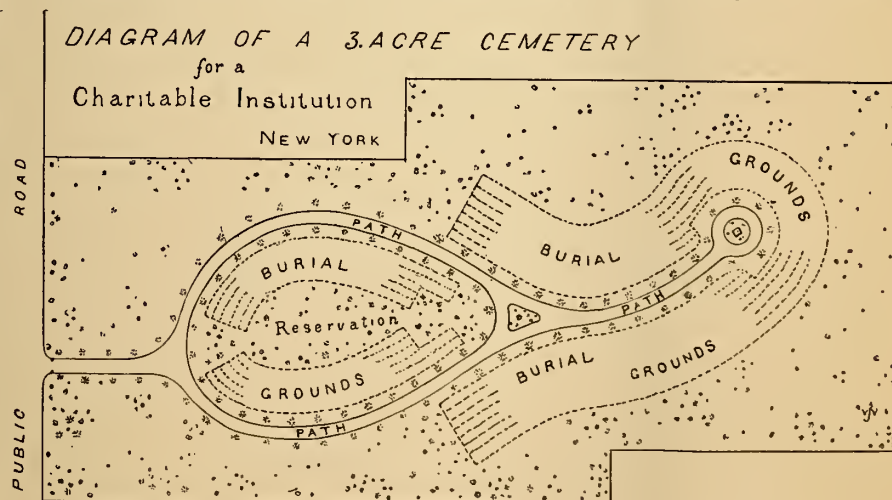

DIAGRAM OF THE CEMETERY FOR THE IOWA HOSPITAL FOR THE INSANE.
AT INDEPENDENCE, IOWA.

simply to establish a permanent mark for the proper line while the ornamental belt of evergreen trees on both sides of the path will mark the border when deep snow covers the ground. An occasional day's work given to cutting grass in the path and on the border is all that will be required to keep such grounds in order. However, if it is possible, a little labor in the care of the burial space and of the trees will add much to the attractiveness of the grounds, or if a little expense can be afforded for some general monument or memorial at some prominent point near the entrance, the aspect of the cemetery would be greatly improved.

To illustrate these principles the above diagram of the cemetery of the Iowa Hospital for the Insane, at Independence, is given to explain the simple arrangement necessary for improving such grounds at the smallest possible cost. The old burial-grounds of this large institution were considered too close to the main building, and a removal was made to this new cemetery, which is a mile and a half from the hospital. The plot is somewhat undulating, the highest point being near the eastern boundary line, with a slope to the west of about four feet in one hundred. The circuit drive was laid out over the most eligible part of the ground, beginning at about fifty feet from the entrance gate, and it follows in its course the natural contour of the land, enclosing an area of some thirty acres. As is customary in such institutions, the sexes are separated, and between the two tiers the so-called permanent reservation ground is now used as an irregularly planted nursery for forest and ornamental trees. Upon a triangular plot at the beginning of the circuit path and in sight of the entrance a plain general monument will be erected. Deciduous and evergreen trees are planted in groups covering

a space between the path and enclosure line, so as to seclude the place more completely from its surroundings.

Many institutions, however, are not able to devote so large an area for cemetery purposes; their grounds are contracted, and therefore an additional diagram is given to illustrate the application of these same principles to a comparatively small tract. The plan given is for an enclosure of only three acres.

New York,

J. Weidenman.

Notes Upon Some North American Trees.—XIV.

352. *PINUS REFLEXA*, Engelm.—Mr. Pringle 'rediscovered' two years ago Engelmann's *Pinus strobiformis* on the mountains of Chihuahua, in the very region where Wislizenus first found it, and his specimens show that *Pinus reflexa* cannot be separated from the Mexican tree, which was known previously from a single cone only. It will be found perhaps that *Pinus strobiformis* is merely a northern form with short leaves, and small cones, of the widely distributed *Pinus Ayacuhuite*, Erh. The two are certainly very closely related and not readily separated.

359. *PINUS TORREYANA*, Parry.—Mr. Brandegee's discovery last year of this Pine on Santa Rosa Island is interesting. It was up to that time, so far as was known, the most local and the most poorly represented in living individuals of all American trees. About one hundred specimens were found growing on the bluffs of the eastern shore (Brandegee in *Proc. Cal. Acad.*, i., 2, 217); and this new and remote station may reasonably be expected to prolong the existence of the species.

373. *PINUS INOPS*, Ait.—This name, published in 1789, must give way to Miller's *Pinus Virginiana* (*Gardeners' Dictionary*, 8th ed.), published in 1768.

377. *PINUS MITIS*, Michx.—This species has sometimes been referred to the *Pinus echinata* of Miller, but Miller's description leaves some doubt as to species he intended to describe, so that it appears advisable to retain Michaux's name, *P. mitis*.

PINUS LATIFOLIA.—Dr. Henry Mayr, the Professor of Sylviculture in the University of Japan, detected in the autumn of 1887 on the southern slopes of the Santa Rita Mountains, in southern Arizona, a part of the range which had not been explored before botanically, the remarkable new species of Pine,* figured upon page 498 of this issue. Its very long leaves, in threes, with persistent sheaths, and with the strengthening cells under the epidermis, and surrounding the ducts, bring it into Engelmann's second section, of *Ponderosæ*, with *P. macrophylla*, *P. ponderosa* and *P. Canariensis*. It is described by Dr. Mayr as a medium-sized tree, about sixty feet high, with thick and deeply-furrowed dark brown bark and stout tortuous branches. The leaf-bracts, reflexed in the bud, are three-quarters of an inch long, acuminate, with scarious, lacinated margins, and contracted into a long, subulate point; leaves serrate, fourteen to fifteen inches long, one-sixteenth of an inch wide, with a prominent rib; sheath persistent, dark chestnut-brown, with a conspicuously-fringed margin; cones sub-terminal, clustered, oblique from the greater development of the outer side, sessile, three to five inches long; the scales, with recurved apophyses, and stout, projecting, mammillary umbos and slender terminal prickles. The seed (imperfect and probably not fully grown) is only one-eighth of an inch long, oval, prominently ridged and light brown; the wing three-fourths of an inch long, widest nearest the base. The cones, which appear to be light brown, leave, in falling, the peduncle, with a few of the lower scales attached, on the branches, resembling in this the cones of *P. ponderosa*. The flowers have not been seen.

This species differs from *P. ponderosa* in its longer and broader leaves, and by the long, round umbo of the cone-scales not unlike that of *P. Coulteri*, although much smaller; it differs from *P. macrophylla*, to which it appears closely related, by the somewhat shorter and broader leaves, always in threes, by the much smaller cones, and by the absence of the stout, broad, much recurved, persistent points of the umbo.

Dr. Mayr's notes give no information of the exact elevation at which this tree was found, but it must have been

considerable, as he found it associated with *Quercus hypoleuca*, and growing just below *Pinus Arizonica* and *P. Chihuahuana*.

382. *PICEA NIGRA*, Link.—Miller's description of this tree (*Gardeners' Dictionary*, 8th ed.) is the first published after the adoption of the binomial nomenclature of Linnæus, and his specific name being adopted the Black Spruce becomes *Picea Mariana*.

383. *PICEA ALBA*, Link.—The White Spruce was described by Miller (*l. c.*) as *Pinus Canadensis*; but that name having been applied by Linnæus to the Hemlock as *Pinus Canadensis*, the next name to be taken up is the *Pinus laxa* of Ehrhart (Beitr., iii., 24), which antedates, by one year, the *Pinus alba* of Aiton, so that the White Spruce should be called *Picea laxa*. Koch (*Dendrologie*, ii., 2, 243) adopts Ehrhart's specific name, while considering *Abies* the correct generic name for the Spruces.

PICEA BREWERIANA.—This distinct Spruce-tree was discovered by Mr. Thomas Howell in June, 1884, on the alpine slopes of the Siskiyou Mountains of northern California. It may be distinguished from all North American Spruces by the long, pendulous branches, flat or slightly rounded leaves and long cones, with thin, spreading, entire scales.*

391. *PSEUDOTSUGA DOUGLASII*, Carr.—Lambert, who first described the tree now very generally known as the Douglas Spruce, named it *Pinus taxifolia* (*Genus Pinus*, i., 51, t. 33); and his specific name must be taken up as it has been already by Dr. Britton (*Trans. N. Y. Acad. Sci.*, viii., 74), who becomes the author of *Pseudotsuga taxifolia*. This change is particularly to be regretted, as it completely disassociates the name of David Douglas from this tree, the most important, perhaps, of his many North American discoveries. Happily, however, the name "Douglas Spruce" is beginning to find a place in the language of the people living in some parts of the country where it abounds, and in British Columbia it is rarely called by any other name; the name of Douglas, therefore, will not soon be forgotten in the land which was the scene of his sufferings and achievements, and which, more than most men in his day, he made known to the world.

394. *ABIES SUBALPINA*, Engelm.—Dr. M. T. Masters would seem to have established the fact (*Gardeners' Chronicle*, 3 ser., v., 172;—*Journal of Botany*, May, 1889) that the *Pinus lasiocarpa* of Hooker (*Flor. Bot. Am.*, ii., 163), based upon a specimen brought by Douglas from our interior northwest region, is what has been called more recently *Abies subalpina*, which would then become *Abies lasiocarpa*, Nutt.; which, however, must not be confounded with the *Abies* (or *Picea*) *lasiocarpa* of gardens, which is the Sierra Nevada form of *Abies concolor*.

397. *ABIES BRACTEATA*, Nutt.—David Douglas, who discovered this species, first described it, calling it *Pinus venusta*. His name was published in 1836 in the "Companion to the Botanical Magazine" (ii., 152), a year earlier than Don's *Pinus bracteata* (*Trans. Linn. Soc.*, xvii., 443), so that the name should now become *Abies venusta*.

401. *LARIX AMERICANA*, Michx.—The oldest name for the eastern Larch is that of Du Roi (*Obs. Bot.*, 49), published in 1771—*Pinus larcina*, so that *Larix larcina*, Koch, "*Dendrologie*," ii., 2, 263, should be adopted.

SABAL species.—The large arborescent Palm of the lower Rio Grande Valley and the east coast of Mexico is a *Sabal* not yet determined, and probably an undescribed species.

PSEUDOPHENIX SARGENTII, Wend.—A small arborescent Palm found on Elliott's Key, Florida, and described in *GARDEN AND FOREST*, vol. i., f. 55, 56. I have received another Florida Palm from the Messrs. Reasoner, of Manatee, who discovered it last year growing in shallow water in the Everglades. The leaves are pinnate, and it is said to grow to a height of forty feet, with slender, often prostrate stems.

**Picea Breweriana*, Watson in *Proc. Am. Acad.*, new ser., xii., 378.—Sargent in *Gardeners' Chronicle*, new ser., xxv., 498, f. 93.

**PINUS LATIFOLIA*, nov. spec.: arbor mediocris, ramulis tortuosis; squamis longe acuminatis, fimbriato-laceris, squarrosis, persistentibus; vaginis elongatis laciniatis, persistentibus; foliis ad apicem ramulorum congestis, ternis, latis, margine serrulatis; strobilibus sub-terminalibus, ovatis, obliquis, 3-5 poll-longis; squamis apophysii ancipiti, umbonem conico uncinatum; seminibus parvis, late alatis.

CONCLUSION.

Thirteen species which appeared in the Census Catalogue as trees are now dropped entirely, later investigation showing that they are shrubs and not trees. These are *Clusia flava*, *Byrsonima lucida*, *Porlira angustifolia*, *Ximenia Americana*, *Pistacia Mexicana*, *Acacia Berlandieri*, *Eugenia longipes*, *Genipa clusiefolia*, *Myrsine Rapanea*, *Forestiera acuminata*, *Alnus serrulata*, *Alnus incana*, *Salix cordata*. Six trees formerly considered species are now reduced to varieties. These are *Magnolia acuminata*, var. *cordata*, *Negundo aceroides*, var. *Californicum*, *Cratægus Douglasii*, var. *rivularis*, *Cratægus Crus-galli*, var. *berberifolia*, *Cratægus coccinea*, var. *mollis*, *Bumelia lanuginosa*, var. *rigida*. Two species, *Ficus brevifolia* and *Alnus oblongifolia*, are reduced to synonyms; making a reduction in all of twenty-one.

Three species, *Tilia pubescens*, *Cratægus punctata*, and *Drypetes glauca*, formerly considered varieties of other species, are now raised to specific rank. Three species, *Eugenia Garberi*, *Quercus Morehus* and *Quercus Engelmanni*, confounded with other species, are now (the last two provisionally) considered species; and twenty-four species are now first added to the list. These are *Xanthoxylum emarginatum*, *Heliella parviflora*, *Kœberlinia spinosa*, *Ilex monticola*, *Rhamnus crocea*, var. *Ceanothus velutinus*, var. *Rhus integrifolia*, *Cercidium floridum*, *Acacia Farnesiana*, *Acacia flexicaulis*, *Pithecolobium brevifolium*, *Lyonothamnus asplenifolius*, *Terminalia Buceas*, *Aralia spinosa*, *Fraxinus cuspidata*, *Quercus Macdonaldii*, *Quercus tomentella*, *Quercus Leana*, *Juniperus flaccida*, *Picea Breweriana*, *Pinus latifolia*, *Sabal* species; *Pseudophoenix Sargentii*, *Palma* species; or, in all, thirty additions to the catalogue, which is thus increased by seven, making the total number of North American trees (exclusive of Mexico), 419, as I now understand them. C. S. Sargent.

The Bur Oak.

THE Bur Oak (*Quercus macrocarpa*) is one of the most widely distributed and valuable Oaks of North America. It may be readily distinguished always by the broad, corky wings found on the young branches, by the large, oblong, lyrate-pinnatifid or deeply sinuated-lobed leaves, twelve to fifteen inches long, with lobes often extending nearly to the mid-rib, and by the large fruit, with a deep, thick cup with pointed scales, those at the top awned and forming a heavy pale fringe, which has given to this tree one of its popular names—the Mossy-cup Oak. The broad ovoid acorn is immersed for half its length or often entirely enclosed in the cup, a character which has given to this tree another popular name—the Over-cup Oak. This Oak, although so generally distributed, is less common on the Atlantic sea-board than it is west of the Alleghanies, and so it escaped the attention of the early botanists and botanical collectors in this country, and was first discovered as late as 1794 by the elder Michaux near the present city of Nashville, almost at the southern limit of its distribution east of the Mississippi River, during his hazardous and memorable journey to the Illinois country. The Bur Oak is now known to extend from Nova Scotia down the coast of Maine as far as the Penobscot, to occur in western New England, in western New York and in Pennsylvania, and then to stretch far to the north-west and to the south-west, and to represent the flora of the eastern part of the continent on the foot-hills of the Rocky Mountains of Montana and in the dry valleys of western Texas. It is the prevailing Oak in the "Oak Opening" of the north-west, and the only Oak that can support the dry climate, and maintain its existence in Manitoba, Dakota and western Nebraska. The most interesting thing about this tree, perhaps, is this power, quite unknown in the other American White Oaks, of adapting itself to very different climatic conditions, which enables it to live in the humid climate of Maine and northern Vermont, to flourish in the somewhat drier climate of the Mississippi Valley, and to exist in the driest and most exposed region inhabited by any of the east American Oaks.

The Bur Oak grows under favorable conditions to a large size. Specimens may still be found in the rich alluvial soils of the lower Ohio Valley 150 to 170 feet high, with straight trunks, six or seven feet in diameter, rising for seventy or eighty feet to the first branches, and covered with thick, deeply furrowed, dark-brown bark. Such a tree is represented in our illustration upon page 500, made from one of Mr. Robert Ridgway's photographs of forest-trees. It grew in southern Indiana, where the Bur Oak attains its largest size and greatest value, and where it is the largest, although not quite the tallest of the Oaks which abound in that part of the country.

The wood of this tree, when it grows under favorable conditions, that is, in deep, rather moist soil, is the most valuable produced by the American Oaks. It is light or dark, rich brown, handsomely marked with the broad medullary rays, heavy, very strong and tough, close-grained, and not liable to warp or open in seasoning. It is classed as white oak commonly, and is not distinguished from the wood of *Quercus alba*.

Quercus macrocarpa is one of the most ornamental and desirable of the American Oaks in cultivation. It is easily raised, and grows rapidly in good soil.

Like all the White Oaks, it is not, when once fairly established, easy to transplant successfully, and it is better, therefore, to set the plants very young where they are to remain, rather than to attempt to move larger specimens. The vigorous constitution of this tree, shown by its power of adapting itself to varied climatic conditions, and the great value of the timber which it produces, indicate that it may prove one of the best Oaks for forest-planting within the area of the region which it inhabits. Foreign Correspondence.

London Letter.

OUR flowers are gradually disappearing from the open-air gardens, and attention is now mainly directed to the garden under glass. An eight-degree frost has already scorched every plant in exposed gardens of such tender constitution as the Dahlia and Tropæolum. The leading Dahlia-growers had planned a great gathering for the last meeting of the Royal Horticultural Society, but only those whose gardens were sufficiently sheltered to escape the frost could exhibit. There was a brilliant show, notwithstanding, and not a few novelties were submitted. The absence of Orchids in numbers is still conspicuous, though their flower season has commenced; but we had a first-rate novelty in a new hybrid from Messrs. Veitch, named Cattleya Miss Harris. It is the result of a cross between *C. Schilleriana* (which, according to the views of some authorities, is either a natural hybrid or a variety of *C. Aclandiae*) and the well known *C. Mossiae*. Comparing this hybrid with *C. Schilleriana*, which parent it most resembles, the flowers are larger, the sepals broader, and the lip larger and of different shape. The sepals are of a rich deep mauve color, and the labellum is crimson-lake, pencilled and netted with deep crimson, which pales to almost white on the throat. It is, therefore, a very showy Orchid, and the fact that the plant exhibited bore four flowers on a spike indicates that it possesses the vigorous constitution and free-flowering tendency of most all Orchid hybrids. It was voted a first-class certificate. The other Orchid, which won a first-class certificate, came from Baron Schrœder's collection, and was quite as remarkable as the Cattleya. It was a variety of *Odontoglossum vexillarium* (now called *Miltonia vexillaria*) named Leopoldi. It is so much like the variety Superba, which created a sensation a few years ago, that at first sight it appeared to be the same, but in Leopoldi the heavy crimson blotch which adorns the labellum is not rayed as is the Superba variety. The body color of the flower is a deep rose-pink, and the flower is altogether smaller than the summer-flowering form of *M. vexillaria*. Both these Superba and Leopoldi varieties appear to be forms of *M. vexillaria rubella*, the name given by Mr. Bull for the autumn-flowering variety, which is always distinguished by the smaller flowers and darker color. I remember seeing the Superba variety sold at Stevens' auction-rooms some years ago, and as nothing before had appeared at all like it, the competition in the bidding was keen. Sir Trevor Lawrence secured it for \$400.

It is still exceedingly rare, though every form that appears so very near it as *Leopoldi* is must lessen its value. The rare little *Masdevallia vespertilio*, which belongs to the *Chimara* section, was shown in flower. Though not a showy Orchid, it is very pretty and interesting, and it was appropriately decorated with a botanical certificate.

A new pure white-flowered *Watsonia* was greatly admired, and won a unanimous vote of the Committee. It is named *W. iridifolia O'Brieni*, having been recently introduced from South Africa by Mr. James O'Brien. In habit of growth and of flower it is a good deal like *W. rosea*, but the snow-white flowers mark it as distinct from any other in the genus. It grows about two feet high, and the flower-stems carry as many as a dozen fragrant blossoms, which open in succession, and therefore will be valuable for cutting, and if it can be induced to flower in winter its value will be enhanced. It is reported to be the only pure white Iridaceous plant in cultivation, but those who make this claim forget the pure white *Freesia*, the white *Crocuses*, *Irises* and others.

The awards of merit were voted to several new Dahlias, the most remarkable of which were the following sorts: Centenary, a genuine Cactus variety, resembling the original *D. Juarezi* in form and size, but of a different, and, if possible, a more brilliant tone of color. It is one of the best of this year's new Dahlias. Guelma is a remarkable single variety, the broad, flat florets being white, edged with cinnamon-red, a strange mixture, and different from any other. Marazion, bronze-yellow, and Conquest, rose magenta, are two good show varieties, while Hester Dorothy is the first of the new Pumila or dwarf strain shown here, and to which I alluded last week. The flowers are large, of fine form and a red-scarlet, and the plant does not exceed thirty inches in height, which is a decided advantage in bedding out or massing. A selection from among the best sorts of Cactus Dahlias shown would include Honoria, yellow; Zulu, black; Miss

Jekyll, orange-red; Annie Harvey, crimson; Sidney Hollings, bright and rich maroon (very fine); Germania Nova, lilac; W. Rayner, red; E. Constance, white, and Henry Cannell, scarlet, the last named being shown by Mr. Cannell, of Swanley, who believes he has in it a good variety. There was nothing remarkable about the other selections, and the majority of the flowers had evidently felt the effects of frost.

Chrysanthemums of the early or September-flowering sorts were strongly represented, but with their out-of-season look, and the absence of bright color in them, beyond yellow, they made a poor display, and though there is much stir made about every new addition to the race, the early *Chrysanthemum* cannot be called a popular flower. One new sort was certificated. It is called Annie Stevens, and is a Japanese variety with long, narrow florets of creamy-white. The fact is we do not want *Chrysanthemums* before November, and then we must have them or have no flowers in our green-houses. Till then we have plenty of brightness in other flowers.

Among the most noteworthy of other exhibits the finest, perhaps, was the new Pitcher plant, *Nepenthes Burkei*, from the introducers, Messrs. Veitch. It is a distinct and extremely handsome species, with pitchers of elegant form, having a broad and peculiarly shaped rim of deep crimson, the rest of the pitcher being pale green, blotched with crimson. It should have been certificated. Scarcely less remarkable was the grand group of the Java *Rhododendrons* which Messrs. Veitch are now putting prominently before the public, and rarely have they put into commerce such valuable garden plants as their new hybrids of this race of *Rhododendrons*. They have now colors among them from the purest whites to delicate

pinks and glowing crimsons, besides every shade of yellow. They are most satisfactory plants to grow, as they flower almost throughout the year.

A splendid show of autumn Roses was made by Messrs. W.

Fig. 135.—*Pinus latifolia*.—See page 496.

Paul & Son, the sorts consisting chiefly of Tea varieties, among them being the new Sappho, the Bride and Corinna, all first-rate for summer and autumn bloom. Among the best of the perpetuals were Mrs. John Laing, Marchioness of Lorne, Pride of Waltham, Ella Gordon and Ulrich Brunner.

The National Chrysanthemum Society last week held a meeting and conference, but the early Chrysanthemums were outnumbered by the Dahlias, which really gave the color to the otherwise dull show. The papers read were mostly of a practical nature, and difficult to epitomize. They contained nothing new.

Rose Notes.

THE summer of 1889 will be long remembered among the Rose-growers of the Atlantic States for its excessive rainfall and the unusual prevalence of dull weather. Naturally the greatest injury has been inflicted upon out-door Roses and especially upon Hybrid Perpetuals that were in preparation for winter forcing. These varieties suffered severely in some localities from the heavy rains, it having been almost impossible to get them dry enough to ripen the wood. This is, of course, a great drawback to the successful forcing of Roses of this class, for, unless the growth is well ripened, failure is almost certain if an early crop is attempted, and, for that matter, matured wood is necessary for the production of a good crop at any time.

In regard to the ripening of Hybrids, an old but good practice is to lay the pots containing the Roses on their sides on the ground, and then to place sashes over them, merely raising them enough at one end to throw off the rain, so that the Roses are kept dry until the wood is sufficiently hardened. A convenient method of growing Hybrids has been adopted by some commercial growers, who plant them out in boxes, about three feet in length by eighteen inches in width, and only four inches deep, and containing about a dozen plants. Boxes of this size are easy to handle and economical in regard to space occupied, and they may be conveniently brought into heat from time to time, so as to secure a succession of bloom. These boxes cost but little to manufacture and can be put together by any man capable of using a hatchet and saw, and, if whitewashed inside and out, or given a good painting with crude petroleum, will last for several seasons. The crude oil is an excellent preservative for wood-work, though the objection has been made to it that the nails draw out of the wood when it has been penetrated by the oil.

This method of growing Roses in boxes may be used not only for Hybrid Perpetuals, but also for other classes, and will be found very convenient where the space can only be occupied by Roses for a portion of the season, as the boxes are readily removed from one house to another. La France Roses can be grown to advantage in this manner, and after a crop of flowers has been cut (say in December), the boxes can be placed in a cold frame and kept rather dry for a time, until the plants are in a good condition to be brought into heat and started afresh for a spring crop. Meanwhile the room inside can be utilized for the growth of other plants, so that green-house space can be kept constantly occupied.

The earliest Hybrids are already in growth, and some of them as early as the last week of September had shoots from one to two inches in length, the most forward sorts being Anna Alexieff and Magna Charta. But such early forcing as this requires much care in regard to temperature, for when kept too warm the growth soon weakens and frequently fails to produce any bloom worth mentioning, and, even under the most favorable circumstances, the quantity of flowers produced will not bear comparison with that of later crops.

Which is the favorite Rose? continues to be a hard question to decide, and can perhaps be best answered by individual growers, each for his own locality. There is considerable diversity in popular favor, though the liking for large Roses seems to be quite general, and therefore American Beauty will undoubtedly receive its full share of attention during the coming winter. And yet, in some of the largest flower-markets, as, for instance, in New York and Philadelphia, Madame Cusin and Madame de Watteville, both pretty, though neither notably large or of specially fine form, are extremely popular and consequently in large demand.

A passing glance at a number of commercial places and also some private establishments shows that Tea Roses in general have not suffered greatly from the dull, damp weather, and the prospect, for the first crop of flowers at least, is a promis-

ing one. Wootton has been planted largely and will undoubtedly be thoroughly tested this season. I lately saw a bench, about two hundred feet in length, filled with this variety, and it presented a fine appearance, though many of the plants showed "black spot" on the foliage, but since there was in the same house a large bench of American Beauty suffering from a bad attack of the "spot," the condition of the Woottons could be easily accounted for.

Holmesburg, Pa.

Richardias.

THE Richardias are a group of five species forming a genus of the great family of *Aroideæ*. They are all natives of the southern half of Africa, and have a thick, lumpy root, and more or less elongated arrow-shaped leaves. The best of them, by far, for garden purposes, is the *R. Ethiopica*, so well known and widely cultivated under the name of "Calla Lily" or "Arum Lily." In a wild state this plant grows frequently in such numbers as to almost exclude all other vegetation from the ground it occupies; a correspondent of the *Gardeners' Chronicle* mentions seeing an island of about twenty acres in Saldanha Bay completely covered with it, and all the plants in bloom.

It is best treated as an evergreen plant, turning the pot containing it on its side in a shady place during the summer, and furnishing water again in the fall. It will retain its leaves during this period of rest, and will grow and blossom with renewed vigor when again watered. It may be treated as a deciduous plant, the root being kept perfectly dry during the winter, like Gladioli, etc., but it suffers much from such usage, and, besides, most persons desire to have it blossom in the winter. If the flower-stalk be carefully cut away, after the spathe has withered, another flower-bud will usually be found at its base, which, with proper treatment, will grow up and blossom. Through ignorance of this fact the whole stalk is generally cut off, young bud and all. There is a variety of this species whose leaves are splashed and mottled with white, but it is a very poor thing, growing very feebly and never flowering. Very vigorous plants sometimes have two spathes, one on each side of the spadix, but such developments detract very much from the stately simplicity of the normal form. *R. Ethiopica* very rarely yields seed.

R. albo-maculata, *R. hastata* and *R. melanoleuca* differ much in nature from the foregoing, for they are all best treated as summer-blooming plants, though the first named will grow very well in pots in the winter. The tubers of these three kinds may be lifted in October, and kept perfectly dry in the winter, and again planted out at the beginning of May. A long row, or a large bed, of strong plants of *R. albo-maculata* is a very beautiful sight, with its profusion of dark green, white-spotted leaves, and its abundance of white spathes, each with a purple spot at its base. Every flower-spathe, after a week or two of beauty, turns greenish, bows its head and bends over toward the earth, and by the middle of September will have ripened a large number of seeds, whitish, round, and as large as small peas. If these be planted in January (under glass, of course), they will show above ground in two weeks, and will make tubers as large as a filbert the first year, and the second year will bloom. Propagation may also be effected by cutting the old tubers in as many pieces as it has buds.

R. hastata and *R. melanoleuca* are less vigorous, and not infrequently rot when planted. I have no doubt that they need more heat than *R. albo-maculata*. Their flowers are yellow, with dark spots at the base; those of *R. hastata* being of a deeper shade than those of *R. melanoleuca*. The leaves of both are faintly spotted with gray.

Orchid Notes.

Vanda Kimballiana.—The Orchid-growing world is indebted to the enterprise of Messrs. Low & Co., of Clapton, for the introduction of this remarkable species to cultivation at the beginning of the present year. It has been dedicated to Mr. W. S. Kimball, of Rochester, New York, by the late Professor Reichenbach, but no information respecting its native country has yet been divulged by its importers.

Plants of this species have lately flowered in various collections in England, and from one which flowered here in the nursery I have been enabled to make the following description: The stem is terete, about as thick as an ordinary lead-pencil, dull green, with numerous dark purplish spots. It is furnished with over a dozen sub-distichous, dull green, more or less drooping leaves, which are from six to twelve inches long, gradually tapering to a subulate point, and deeply

channeled on the upper side, especially towards the sheathing base. About midway on the stem, the erect dull purple peduncle springs from the axil of a leaf; it is about a foot long, the upper portion being flexuose, and bearing eight flowers, which present a very charming appearance. They vary from one and a half to over two inches across, the lower ones being somewhat larger than those above them. The individual flowers are borne on pinkish-white pedicels, about two and a half inches long including the ovary, and have sepals and petals of a delicate white color, faintly suffused with rose in the centre. They are all suddenly twisted at the base—a characteristic of several species of *Vanda*. The oblong-elliptic subacute upper sepals and petals are nearly similar, while the two lower oblong-falcate sepals are much larger. The deep crimson-purple lip presents a very striking contrast to the color of the sepals and petals; it is more or less suborbicular and emarginate, with undulate denticulate edges, while on each side of the opening into the slightly bent, tapering, pinky spur, is an obovate, bluntly-hooked auricle, dull orange outside, and thickly spotted with purple inside.

Although *Vanda Kimballiana* cannot be said to present a robust appearance, owing to its slender cylindrical stems and leaves, nevertheless there is at present every reason to believe that it will be much more easily grown and produce its flowers in greater abundance than some of the species which belong to the same section. Unfortunate as it is for cultural purposes not to know the native country of this species, it may be assumed that its home is somewhere in the eastern tropics, whence come the remainder of its congeners, and that it must, therefore, be grown in a warm, moist atmosphere, in such a position as to obtain as much sunlight as possible. The plants may be grown in clean crocks and charcoal, which should have a layer of fresh sphagnum moss on top, and in spring and summer they may be syringed a couple of times a day, to keep them moist, but not too wet.

Oncidium splendidum.—The earliest knowledge we have of this fine *Oncidium* is from Richards' herbarium, where there is a dried specimen, collected in Guatemala in 1852, presumably by M. Herment. It was not, however, until some ten years later that this collector, who was then living at

Caen, France, succeeded in getting a few plants alive to Europe, and these passed from his possession into that of MM. Thibaut and Keteleer, nurserymen, of Paris, in whose establishment a plant flowered for the first time in January, 1862. All the plants in cultivation at that time were distributed among continental collections, each plant realizing a very high price, and it was nearly eight or nine years after its actual introduction before *Oncidium splendidum* made its appearance in England. Until within the last few years it remained

very scarce, but now that large importations, chiefly from Guatemala, have been received, its price has been considerably reduced, and specimens of it are consequently much more frequently met with than they formerly were.

The chief characteristics of this species are its ovoid compressed pseudo-bulbs, each of which bears a single, very fleshy, dull green leaf at the summit, while a branched scape, from two to four and a half feet long, springs from the base, generally bearing from fifteen to twenty large, handsome flowers, the oblong, recurved sepals and petals of which are more or less of a yellowish-green, transversely barred with large, rich brown blotches, while the broad, flattish lip, often quite two inches across, is of a bright yellow, with one or two reddish-brown blotches at the base, on each side of the three-keeled disc.

As a rule, *Oncidium splendidum* produces its flowers at a season of the year when they are most acceptable, namely, during the gloomy months of December, January and February. I might, however, mention that an imported piece here began to bloom at the beginning of August, and has now been in flower nearly six weeks, and, even while I write, is still

in good condition. Its strong, glaucous green scape is slightly over four and a half feet long, and bears forty-four flowers, the largest and richest-colored I have yet seen.

This species requires to be grown in a warm atmosphere, and should be suspended in baskets from the glass, so as to enable the plants to enjoy as much light as possible. Great attention must be paid to watering, for if too much be given during the growing season, the bulbs are apt to become rotten when their growth is about half finished. As soon as the plants have done growing, the temperature of a cooler house

Fig. 136.—The Bur Oak (*Quercus macrocarpa*).—See page 497.

will help to mature the pseudo-bulbs, which, if well-developed, should produce a good crop of flowers. *John Weathers.*

St. Albans, Eng., September 18, 1889.

Phalenopsis rosea.—A great many plants of this pretty Orchid are now in bloom with us. It grows very freely, producing leathery lanceolate leaves, eight inches to one foot long, dark green in color. The racemes are branching, and bear about thirty flowers, but will continue to grow and flower from the apex for many months. The flowers are about an inch across, with lanceolate sepals and petals, white, tinged with rose. The ovate-acuminate lip is of a beautiful violet-purple, with an orange disc. We find the warmest part of the house suits this Orchid best, and it can scarcely have too much water. Small, shallow baskets should be used, though we have about a dozen doing well on some horizontal rafts of wood, but these require a good deal more water, and, consequently, more care than those in baskets of living moss. *P. rosea*, *P. Lowii* and *P. Esmeralda* are the three species that are in flower in quantity at this season, and will keep the *Phalenopsis* house gay until the standard kinds are in bloom.

Phalenopsis violacea is a showy plant, with round, leathery, deep green leaves. The spike is very short, producing one or two flowers at a time. These are about two inches across, white, deeply suffused with deep violet on the basal half of the segments. The lip is of a rich violet-crimson, with a golden-yellow callus. This Orchid was introduced in 1861. Since then three good varieties have been discovered—*Schröderi*, with flowers of uniform violet-rose; *Murtoniana* and *Bouringiana* both have yellow flowers, but vary in the markings and intensity of color. *F. Goldring.*

Kenwood, N. Y.

Catasetum Bungerothii.—Too much cannot be said in praise of this lovely Orchid, a plant that everybody should grow, and, from all appearances, one that everybody can grow. A basket seems to be the best receptacle for it, and very little potting material should be used, as the roots dislike being buried. Give it the warmest corner and abundance of water, and it will soon give a good account of itself. After growth is matured it should be put in a cooler house and water gradually withheld, but the bulbs must not be shriveled. The large, showy, pure white flowers last quite a long time in perfection in a cool, dry house. Since the introduction of this plant, two years ago, from South America, two excellent varieties have cropped up, the first appropriately named *Aureum*; the other, called *Pottianum*, has the flowers prettily marked with purple, the lip also spotted with same color.

Notes on Hardy Plants.—The present season has been noticeable for the abundance of moisture and the total immunity, thus far, from frost, conditions, taken on the whole, very favorable for the strong growth and flowering of hardy plants. *Anemone Japonica* and its varieties have never made so fine a display as that of the past weeks, the pure white form, *Honorine Joubert*, being most beautiful in its snowy-white petals and conspicuous yellow anthers. The pink form, known as *Hybrida*, is of a lovely shade of bright pink, a most suitable companion plant to the white one. It appears that the proper name of this hybrid *Anemone* is *Elegans*, but in the trade lists this name is very seldom used. We are also growing what is known as the type *A. Japonica*, and, if this is correctly named, it is singular how much more robust and beautiful the varieties are than the parent plant. The flowers of the latter are semi-double and of a dark rosy-carmine, a pretty color enough, but the plant sadly lacks the constitutional vigor so characteristic of the other two varieties. Of *Kniphofias* (since the generic name, *Tritoma*, is doomed to slow death), *K. grandis* has proved itself worthy of the name by its majestic autumnal beauty. These plants have shown to better advantage this year than ever before. *K. grandis* is now bearing numerous grand flower-spikes five feet high; and its bright red and yellow flowers make it the most showy plant in the garden. It is the best of the tall-growing kinds, and is the more valuable on account of its late-flowering habit. This plant has always been known as *Tritoma grandis*, but it appears that we must hereafter call it *Kniphofia aloides maxima*. *K. carnea* is a pretty, remarkable and distinct species; pretty, in that its flower-spikes do not exceed eighteen inches and are most useful for cutting purposes; remarkable in its flowers, which, unlike all other species that have come under our notice, commence to open at the apex of the spike and continue to flower downward; and lastly, distinct in being a native of Abyssinia, while most of this genus hail from South Africa, and also in being strictly

deciduous, the foliage dying down in the fall to a thick, fleshy rootstock, which should then be lifted and potted, and given plenty of heat in spring to induce it to start early. When nicely started it should be planted out in a warm position in good rich soil. Treated in this manner, its liability to be damaged by early frosts is considerably lessened. It is singular that, with all our care and solicitude, we have never been able to obtain a single seed of this plant. All other kinds seed freely with us, and prove only too susceptible to hybridization. We are hoping for good results from the use of pollen of *K. carnea* on species of the evergreen section.

Passaic, N. J.

E. O. Orpet.

Eichornia crassipes.—This fine aquatic has been in bloom in the open air, in several of the basins and lakes of the public squares and parks of New York, the past season, and has made the handsomest display, next to the Water Lilies, of any plant in the collections. It comes from South America, and is a floating plant that sails about the surface of the water as the wind drives it. In general appearance of foliage it is much like the *Calla Lily*, and forms broad, dense masses of stems and leaves, in one basin, covering a space six by eight feet. The base of the leaf-stems is inflated with air, like small bladders, while the white roots hang down in the water. The flowers are in spikes of five or six, as large as a half-dollar, of a purplish-blue, borne twelve to eighteen inches above the water on stout stems, the whole expression of the inflorescence suggesting a spike of huge Hyacinth blossoms. It is very easily grown. All that is needed is to anchor a clump in the water with a stone, or allow it to drift about as the winds will, and the plant will take care of itself. It has bloomed very freely this year, and remains open at night also. A good mass of this plant, covered with its spikes of showy blossoms, is something easily had, and sure to be much enjoyed through July and August. *F. L. Temple.*

Cambridge, Mass.

Two Good Perennials.—Among hardy, herbaceous plants introduced in recent years, *Platycodon Mariesii* and *Polygonum spharostachyum* hold a prominent rank. Both are beautiful, floriferous and very hardy, qualities which make them desirable for our flower-gardens as standard plants. *Platycodon Mariesii* was sent to Europe, from Japan, by Mr. Maries, then in the employ of Messrs. James Veitch & Sons, about eight years ago. It is a dwarfed form of *Platycodon grandiflorum*, small plants only a few months old, and scarcely two inches high, producing one or two large, starry, flat, cup-shaped flowers of a bright blue color. Some botanists merge *Platycodon* into *Wahlenbergia*, others into *Campanula*. *Polygonum spharostachyum* is also a small plant only about a foot in height; it flowers during May and June very profusely, and the rosy-crimson spikelets are very showy among the bright green, graceful foliage. After two months of rest they come forward again and bloom as abundantly as before until the frost in November kills them. The plant is a native of the Himalayas and makes a sort of tuber. It is very hardy.

Baden Baden.

Max Leichtlin.

Resetting in Peach Orchards.—It is a practice of doubtful expediency to set new Peach-trees after an orchard has been planted three years. Peach-trees are short-lived, and an orchard cannot be kept full of trees with profit, unless the trees are all nearly of the same age. If new trees are constantly set in, when the body of the orchard becomes unprofitable, there are still a few straggling and younger trees which the owner dislikes to sacrifice, and which are yet practically of almost no value. Land can be put to better use than to be tilled for the purpose of supporting a few scattering and indifferent trees. But even the more immediate value of trees which are filled in is trifling and seldom worth the trouble they give. They are checked by their well-established neighbors, and yield little. I have had experience for many years in this direction, and have yet to see such an experiment in the Peach-orchard which paid. In Apple-orchards it is frequently profitable, but Apple-trees are set further apart, and the trees are sufficiently long-lived to allow all the trees to even up. I am confident that most growers allow their Peach-orchards to get too old. There should be no sentiment in a matter-of-fact operation like the growing of peaches, and when the trees cease to be profitable on account of age, they should be uprooted. I have seldom known Peach-orchards to be profitable after they were twelve years planted, particularly when they have had good culture and have borne heavily. It is sometimes true that they cease to be profitable at an earlier age. But whenever the time comes, cut them down, root them out, and plant anew, with the same thought for profit that leads you to cut

your Corn or plow under your Strawberries. At any rate, do not be deluded with the notion that continually filling in an orchard is profitable.
L. H. Bailey.
Cornell University.

The Forest.

Recent California Forest-Fires.

FOR nearly six months I have read almost daily accounts of forest-fires in this state. Since the quail-hunters began to shoot over the dry grass and leaves on the hill-sides, the number and extent of these fires has greatly increased. All the great valleys are clouded with smoke, and the fires will probably continue until the rains begin, and that may not be until November.

To illustrate the extent of these fires I will quote the papers for only three successive days, September 16th, 17th and 18th. Forest-fires were reported on the 16th as in the San Mateo woods, only twenty miles from San Francisco, where a strip of heavy Pine and Redwood timber, fifteen miles long and three miles wide, was devastated before the fire was controlled. In this county at this time there were eight or ten smaller fires in the hills, all doing more or less damage. The same day large forest-fires were reported from the Pineries of San Bernardino. In the beautiful Redwoods of northern Sonoma, two fires destroyed 500 acres of Oak and Redwood. A portion of the Madroña and Maple woods, described by me in a recent article in the GARDEN AND FOREST, was burned over, and the famous Guerneville forests narrowly escaped. The same day, in southern Sonoma, 1,000 acres of second-growth timber were destroyed. The woodlands on the hills west of Gilroy were burned over, perhaps 2,000 acres in all. Fires were reported in the Ventura forests, where they had raged for a week. The heavy Oak timber near Oakdale was badly damaged. Fires were east, north and west of Shasta and Redding. There were forest-fires in Alameda, Santa Clara, Humboldt and Fresno. Quail-shooting begins in most of the counties September 15th, so it is fair to suppose that many of these outbreaks of the 16th were due to the quail-hunters.

The next day, the 17th, in addition to the fires already noted, extensive conflagrations were reported from Sierra and Nevada Counties, in the Pine-belt. All the middle foot-hill country was said to be "so full of smoke that one could not see over half a mile in any direction." Large fires were raging in Clarke County, Washington, and along the Columbia at Yaquina City.

On September 18th large fires were reported in southern Oregon, in the Siskiyou region, and in the Pineries of Tehama County and on the borders of Lassen. Almost every day since, items of fires in standing timber have appeared in the local newspapers. Generally the fires start on Government lands and spread to the forests under private ownership. During the present season nearly the whole area of mountain forests of the state has been threatened, and every few miles fires have actually occurred. Some were accidental, some were kindled purposely, some were the results of criminal carelessness. Hardly three arrests have been made in the whole state.

A dispatch from Sonoma County attributes the large fires there to the sheep and cattle men, who annually set fire to the woods and sweep away hundreds of acres of young forest, simply for the sake of a scanty growth of grass that follows for a few years on the surface of the "burn." There is a law against it; but there are so many ways of starting fires without detection, that it would take a large patrol system to protect the Government lands. The quail-hunters cause most of the fires, but if the game laws of the state forbade shooting any game in the forests of California until after the first rains they could do no harm. We have always a month or so of warm, clear weather after the first days of rain—a perfect Indian summer period. This should be the quail-hunter's opportunity, but it is shooting at the earlier season that ruins our forests.

The quantity of game that can be grown in the forests here is remarkable. I am inclined to think that the food-value of the steep hill-sides, cañons and wilder mountains, left in forests, protected against fires, sheep and cattle, and allowed to shelter quail, grouse, pheasants, rabbits, hares, deer, bear and other game of all descriptions, has never been estimated at a sufficiently high figure. Quail at present bring from twenty-five to seventy-five cents a dozen in San Francisco. Put them in refrigerator-cars, and they might be delivered all over the United States. I have no doubt but that the forests are worth more for quail than for sheep.

There is now talk of a law giving the Supervisors of every county, funds to patrol the forests and arrest careless hunters,

campers, sheep-herders and others who set fires. But the average county Supervisor is a slow and inefficient person. If all the forest lands left are withdrawn from sale, and protected by a permanent board of trained foresters, and if the hunting season is changed, the chief danger will come from private tracts. The owners of these tracts must be educated to a knowledge of this subject. Many of the mill-owners of the Pacific Coast are men of intelligence and energy who are well aware of the importance of protecting the forests. But all this work takes time, and many of us fear that the regular autumnal fires will entirely destroy the forests of California long before the public conscience can be aroused.

While I am closing this letter, telegrams in the daily papers state that the mountains for twenty miles east of Santa Anna "are a seething mass of flames." Three thousand sheep have been burned, the timber and brush is swept off, and 50,000 sacks of grain in the valley near the hills will be destroyed, as the fire is descending into the lowlands at many points. Very large fires are again raging in the heavy Redwood forests of Santa Cruz and San Mateo. In some places the owners of small ranches have been forced to abandon everything and hasten to the valley. There is a large fire on Mount Hood, Sonoma County, another at Los Guilicos, a third in the Sierras near Oroville, and a fourth in Waterman cañon, San Bernardino. In this valley, Santa Clara, within twenty miles of San Francisco, the air is heavy with smoke from fires in the mountains, south, east and west. The upper Sacramento valley, for a hundred miles, is under a thick cloud, and at night the red edges of fires can be seen on the hills of both Coast Range and Sierra. When the wind blows from the right quarter the scent of burning Redwood and Pine is easily distinguished many miles away; here in Alameda County we can smell the Redwoods which the flames are destroying at San Mateo, fifteen miles distant, in an air-line, across the bay.

Niles, California.

On Popular Plant Names.

To the Editor of GARDEN AND FOREST:

Sir.—Mr. Manning's letter on this subject in your number of September 14th, which has just reached me, opens a question which, though of great importance to us here in Europe, is, I think, of still greater importance in the United States, where gardening is now taking such wonderful strides, and where few, as yet, have learned to appreciate the importance of uniform and correct nomenclature. The subject has been a good deal discussed with us, and the editor of *The Garden*, who is, perhaps, the leader of the advocates for English names, has endeavored for years past in his paper to introduce and popularize English names for many plants which are more or less known to gardeners. As far as I can see, however, he is not succeeding; and I sincerely hope he will not succeed, because if he does, the confusion of names and the difficulty of knowing what plant people are talking about when they use English names, will be greater than it is now, whilst if we have to use a Latin name after the common one, which is often done in *The Garden*, we only add to the immense number which have to be remembered. Of course, I would never wish any one to give up talking of Roses, Lilies, Primroses or Violets in a general way, or to give up using any local names which are generally used and understood in local parlance. But the vagueness of local names is so great that, in nine cases out of ten, they are useless out of their locality. Perhaps, for instance, I want a particular Lily from Oregon, which I learn is called Swamp Lily in some parts of the state, and writing to a settler for it, I get, instead, a Camassia. I tell the sender that it is not the right plant, but get for an answer, that "he guesses it is what they call a Swamp Lily in his section." Another instance occurred to me last week. A well known and distinguished gardener, who should have known better, wrote and asked me for a plant of "Spatum." I had not an idea what he meant, and wrote back that I could not read the word in his letter. Then he wrote to say that he meant *Lewisia rediviva*. I should have said that if there was a plant whose scientific name was a happy one it was this. For, though it is not always possible to follow the good old rule of giving Latin names which either connect plants with some distinguished explorer, collector or scientist, or indicate some peculiarity of their structure, habit or color, yet it is much more easy to remember such names than a name like Spatum, which means absolutely nothing, and, if used anywhere, is, I suppose, an Indian name, which I never heard of in the native country of

the plant itself. A great deal is said by some of the difficulty of getting unscientific people to use scientific names, but, as the editor of GARDEN AND FOREST very truly points out, every one uses such names as *Spiræa*, *Fuchsia*, *Rhododendron*, and when they have arrived at the stage of distinguishing species, they find it just as easy, and a great deal shorter and more certain, to use the specific name also, than to do as Mr. Manning suggests and coin an English name. For many years English names were coined for new plants in the *Botanical Magazine*, and yet I never hear them used any more than I hear the fanciful English names introduced by Mr. Robinson used by common English gardeners, or ladies, who neither know nor care for the scientific name of a plant. The best name, in the end, must be the name which is most generally used and understood by the greatest number; but directly we allow new names to be coined by persons who are too careless or too ignorant to learn the correct scientific name, endless confusion must result.

With regard to varieties of garden plants which are not known in a wild state, I think that the custom of giving florists' names is perfectly right and proper, because it is highly desirable that the garden origin of such things should be shown by the name, and as the duration of a very large proportion of the varieties of florist-flowers, fruit and vegetables is very short, such long-worded names, as some of our Belgian and French friends give their Roses and Pears, are not likely to trouble us forever. I once heard a distinguished English entomologist exclaim with warmth that such a name as *Korolkowia Swertzowi* was intolerable, but would not a Russian have just as much reason to say that a genus named *Mac-lauchlanii* was unpronounceable? We must always remember that science, of which horticulture is only a branch, is international and cosmopolitan, and though uneducated people will always continue to use vernacular names for the common plants, birds or insects of their own country, yet it should be the common object of all who desire to advance science to use names which can be understood by all who are interested in the same subject. And when I know, as I do, that the editors of the *Gardeners' Chronicle* and GARDEN AND FOREST are quite of one opinion on this subject, I feel very hopeful that they will do all in their power to influence their readers for the common good of England, America and the world.

Cirencester, England.

H. J. Elwes.

The City of Oaks.

To the Editor of GARDEN AND FOREST:

Sir.—Raleigh, the beautiful capital-city of North Carolina, has well been named the "City of Oaks." All through the residence portion of the city these giant relics of the primitive forest-growth are scattered, giving the city the appearance of a great park. Here and there, in the bed of the streets, magnificent Oaks have been allowed to remain and are cherished with religious care, and all over the wide lawns are superb specimens of White, Red, Scarlet and Black Oaks. Two immense Oaks on the lawn attached to Bishop Lyman's residence are particularly noticeable. These two trees alone shade over half an acre of lawn. One gentleman has an Oak which he values so highly that he has effected an insurance of \$1,000 upon it. If it were not for the grand proportions of the Oaks the Elms of Raleigh would be almost as voiceable as those of New Haven. The old specimens of the American Elm are remarkably fine, and the small-leaved or Wahoo Elms have attained here a size which I have never noticed in this tree elsewhere. The Mimosa (*Albizia Julibrissin*) is also seen of unusual size. One on Blount street, I noticed, with a trunk fully two feet in diameter and a great spread of branches. On Hillsboro street I observed a grand specimen of *Cedrus Deodara* full of cones, but the tree is being crowded out of shape by a couple of worthless Silver Maples. Specimens of *Magnolia grandiflora* abound, but all seem rather young, and none are nearly as large as the specimens of this tree in Norfolk, where, in St. Paul's Church-yard, may be seen some of the finest in this country north of the Gulf States.

Raleigh is emphatically a city of homes. Its citizens will have elbow room, and, though only claiming about 15,000 inhabitants, it would furnish space for nearly half a million if built up in the usual manner. But when a Raleigh man builds a house, nothing short of half a block, and, in many instances, a whole block, will satisfy him. He must have a front lawn, with as big Oaks as possible, a paddock for a cow and horse, and a fruit and vegetable garden. He will endure no kitchen in his residence, and he gets rid of its heat and odors by erecting a separate building for this purpose in his back yard.

Just at this season the Tea Roses are the glory of the city. Immense bushes of every shade known in this lovely race are

covered with a wealth of bloom, and the colors have that peculiar depth and richness only found in the cool autumn weather. Marechal Niels clamber on porticoes and over division fences with a perfect abandon, and the cool nights have imparted a rosy hue to their outer petals which adds greatly to the beauty of the great buds. A little later there will be a grand display of Chrysanthemums. They are everywhere, and the myriads of buds now showing give promise of an immense bloom. The carpet-bedding mania has never taken hold here. In all my walks about the city I have seen but one clipped bed of foliage plants, and this was in the yard of a German florist, who, doubtless, would profit by the introduction of the practice, but who, as yet, has been unable to spoil the flower-gardens of Raleigh. The city has been called a slow place, and so, perhaps, it is in business enterprise, but there is a great deal of wealth here, and a cultivated taste for natural beauty which throws an indefinable charm over the whole place, and points it out as a spot where those tired of the hurly-burly can find a dignified repose.

Raleigh, N. C.

Recent Publications.

Days Out-of-Doors, by Charles C. Abbott. New York: D. Appleton & Co.

Dr. Abbott is no mere fair-weather stroller. It is not bright sunshine and balmy air which invite him to wander over meadow and upland, by the brook-side or through the wood-path. The company he seeks does not shut itself up in nest or burrow because the skies are dark and the winds are chill, and, therefore, this calendar leads one not only through the varied seasons of the year, but through the changing phases of each season, and introduces the reader to all the flying and swimming and creeping things which a lynx-eyed naturalist can find. And Dr. Abbott knows when and where to find them, as the readers of his former books discovered long ago. The wary creatures which the unobserving stroller never encounters, all come out to meet him, or, rather, they all find him waiting for them where he knows they are sure to appear, and forthwith they begin to disclose their family secrets in the most unconstrained fashion. What these secrets are Dr. Abbott tells in such an engaging way that many a one will find himself fascinated by the description of some toad or lizard, upon which he would hardly bestow a glance or a thought if it should chance to obtrude itself in person upon his observation; and the reader who is not a student of natural history will be surprised to find how numerous are the forms of lowly animal life about him, and how much there is to interest him in their habits and history.

Dr. Abbott is not primarily a botanist, but an examination of the very complete and satisfactory table of contents at the close of this book shows hundreds of allusions to the trees and shrubs and herbaceous plants among which he held converse with his friends, the birds and beasts, the reptiles and fishes. Perhaps it is because he is less interested in the classification of the wild plants than he is in their appearance and their relation to the animal life about them, that his notes upon the vegetation in the regions where these days out-of-doors were passed have such an open-air freedom and freshness. The lowly growths which creep over the sands of the Pine Barrens, the tall weeds by the wayside, the shrub-thickets in marshy lowlands, and the forest trees everywhere, all find in him an appreciative observer, who catches the spirit of the scene, and portrays, as far as words can portray it, their delicate and elusive charm. A few interesting passages in the book, and notably one descriptive of the wild work of the great March blizzard, will be recognized by readers of GARDEN AND FOREST as having appeared in these pages while the event was still a matter of news, and the passage seems more interesting still, now that it has passed into history.

One cannot read these pages without feeling to how great a degree the pleasure of living is increased by the habit of interested and systematic observation. The man or woman who has learned to be alert for original information about natural objects will find in every brook and hedge-row and wayside, material at once for study and for recreation, and whole days to him are delightful which are dull to his neighbor who cannot distinguish one bird-song from another, nor tell the name or the characteristics of the trees or shrubs which he constantly passes by without seeing them. The influence exerted by a book like this in the one direction of encouraging the practice of taking up some branch of natural science in the natural way is altogether benignant. A man who has acquired a habit of this sort may add but little to the sum total of human knowledge by his investigations, but his life will be more full, happy and wholesome for it.

Notes.

The Agricultural Society of Hérault has opened a subscription for a monument to the late Professor Planchon, who, by his studies of the Vine, and of its greatest enemy, the Phylloxera, rendered signal and highly appreciated services to French agriculture.

A correspondent, referring to Mr. Boynton's note on *Helonias bullata*, writes that he has tried to naturalize the plant on his grounds in Ohio, but found it short-lived, the inland climate being apparently inhospitable. In the damp sand of southern New Jersey the plant seems most at home.

Professor Lintner estimates that if all the species of insects inhabiting the world were known their number would reach a million, and, descending to the consideration of individuals, he adds that he has seen at one glance, within a small extent of roadway, more snow-fleas of a single species than there are human beings on the entire surface of the globe.

The Rothschilds, according to a note in a recent issue of *L'Illustration Horticole*, have established at Jerusalem a School of Agriculture, Vine-culture and Horticulture under the direction of the former head gardener of the Maradja of Cashmere. Ten thousand plants of the Cashmere Vine have been planted, and special attention is to be given to the cultivation of Saffron and plants with sweet-scented flowers for the production of perfumes.

Some carefully conducted experiments at the Ohio Station seem to indicate that winter apples keep longer when picked early. There was practically no difference in the percentage of loss for six months from picking, but after that the apples gathered early were much more sound than the others. The greater part of the loss in weight by drying takes place in the first six months. The apples picked early lose slightly more than those picked late.

In reply to some inquiries in regard to the planting of the slopes of railroad cuts and embankments, Mr. Jackson Dawson, of the Arnold Arboretum, writes that where shrubs or small trees are collected for this purpose from neighboring woods and fields, it is advisable, as a rule, to cut them hard back and grow them for a year in well-prepared ground, before they are set in their permanent position. Mr. Dawson has had extensive experience with native shrubs, but he adds that many trials will be needed before we can know whether a selection of shrubs can be made which will flourish on slopes of clay, for example, without any surface preparation.

A flowering plant of *Vanda Kimballiana*, described in another column of this issue, was exhibited by Mr. John L. Gardner, of Brookline, before the Massachusetts Horticultural Society, on the 7th of this month, and was awarded the silver medal of the Society. It is an interesting fact, significant of the present advanced state of American horticulture, that a plant which was entirely unknown to science up to the present year, and had not flowered in Europe six weeks ago, has also flowered in at least one American collection. The fact that this particular plant commemorates in its name the zeal of an American lover of Orchids, whose collection ranks with the best in existence, is, perhaps, not less significant. A portrait of Mr. Gardner's plant is being prepared for this journal.

The Colonial Board of Viticulture in Melbourne recently proposed the establishment, at public expense, of an experimental vineyard and school of viticulture for the colony. The suggestion has now been accepted by the Minister of Lands, and a site has been selected for the purpose at Rutherglen. The area selected is 200 acres, and it will be permanently reserved for the purpose. Instruction will be imparted at the institution by capable teachers in the most improved methods of vine cultivation, and experiments will be conducted with the view of testing the value of new plants said to be suitable for growth in Victoria. Funds for conducting the school will be provided in the present year's estimates, but pending the formal vote the Minister has authorized the expenditure of a sum sufficient to at once plant twenty acres of the reserve, and so expedite the work.

Mr. George W. Archer, in an interesting paper on "A Trip to Old Baltimore and Other Points in Bush River Neck," which has since been published in the Belair (Maryland) *Ægis*, writes of "Shandy Hall," the home of some of the Hall family for five generations. It was built by Benedict Edward Hall, a stanch and prominent patriot during the Revolution. He says: "In the yard is a group of venerable Box-trees, which are said to have been planted when the older part of the house

was built, in 1701. And it may well be believed; for the group is now so large and compact that, but for the color, it might readily be mistaken at a little distance for a misplaced haystack. But this remarkable growth of Box is thrown into the shade by a White Oak nearly half a mile distant. Not that the Oak literally casts a shade quite so far as that at noon, but that I found it, by actual measurement, thirty-nine feet four inches in girth at the ground, and twenty-one feet seven inches at the smallest part of its venerable waist, where the limbs begin to swell. These limbs are as large as most full-grown oaks. The first one, where it branches off, ten feet from the ground, is exactly twelve feet four inches in girth. The extent of this patriarch, from end to end of its opposite branches, is 123 feet. It stands in an open field, solitary and alone, and I wondered that the lightning left it so long untouched. Not the least remarkable thing about it is, that from tip to root, it gives no hint whatever of decay. If it were a human being I might say it has not a gray hair in its head, nor the sign of a wrinkle on its rugged limbs. A deed of 1672 (217 years ago) designates it as a 'Spreading Oak,' marking a corner of a tract of land."

Professors L. H. Baily, E. S. Goff and W. H. Green were appointed at the last meeting of the Association of Agricultural Colleges and Experiment Stations to report on the nomenclature of kitchen-garden vegetables. In their report just issued by the Department of Agriculture, after stating that a name is bestowed upon a plant solely for the purpose of designating, and not for describing, it, the committee lay down the following rules: 1. The name of a variety should consist of a single word, or at most of two words. A phrase, descriptive or otherwise, is never allowable; as, Pride of Italy, King of Mammoth, Earliest of All. 2. The name should not be superlative or bombastic. In particular, all such epithets as New, Large, Giant, Fine, Selected, Improved and the like should be omitted. If the grower or dealer has a superior stock of a variety, the fact should be stated in the description immediately after the name, rather than as a part of the name itself; as, "Trophy, selected stock." 3. If a grower or dealer has procured a new select strain of a well known variety it shall be legitimate for him to use his own name in connection with the established name of the variety; as, Smith's Winningstadt, Jones' Cardinal. 4. When personal names are given to varieties, titles should be omitted; as, Major, General, Queen. 5. The term "hybrid" should not be used, except in those rare instances in which the variety is known to be of hybrid origin. 6. The originator has the prior right to name the variety; but the oldest name which conforms to these rules should be adopted. 7. This committee reserve the right, in their own publications, to revise objectionable names in conformity with these rules.

The following description of the manner in which floating fields and gardens are formed in China, was condensed for publication in *The Garden* from an article by Dr. Macgowan, which originally appeared in the *China Review*: "In the month of April, a bamboo raft, ten to twelve feet long and about half as broad, is prepared. The poles are lashed together with interstices of an inch between each. Over this a layer of straw an inch thick is spread, and then a coating two inches thick of adhesive mud taken from the bottom of a canal or pond, which receives the seed. The raft is moored to the bank in still water, and requires no further attention. The straw soon gives way and the soil also, the roots drawing support from the water alone. In about twenty days the raft becomes covered with the creeper (*Ipomœa reptans*), and its stems and roots are gathered for cooking. In autumn its small, white petals and yellow stamens, nestling among the round leaves, present a very pretty appearance. In some places marshy land is profitably cultivated in this manner. Besides these floating vegetable gardens there are also floating Rice fields. Upon rafts constructed as above weeds and adherent mud were placed as a flooring, and when the Rice shoots were ready for transplanting they were placed in the floating soil, which being adhesive and held in place by weed roots, the plants were maintained in position throughout the season. The Rice thus planted ripened in from sixty to seventy, in place of 100 days. The rafts are cabled to the shore, floating on lakes, pools or sluggish streams. These floating fields served to avert famines, whether by drought or flood. When other fields were submerged and their crops rotten, these floated and flourished; and when a drought prevailed they subsided with the falling water, and while the soil around was arid advanced to maturity. Agricultural treatises contain plates representing rows of extensive Rice fields moored to sturdy trees on the banks of rivers or lakes which existed formerly in the lacustrine regions of the Lower Yangtze and Yellow Rivers."

Attacks on Civilization.

IT is a matter of importance for the American people to learn as soon as possible that under the conditions of our national life, nothing in our civilization will keep very long. It must be perpetually reproduced, must in some way always be the fresh expression of the life and thought of the time, or it will decay and vanish. Whatever may be true of other countries, with us nothing valuable is ever secure. This is not always understood or remembered, and when any good thing is gained our people are apt to think that continued interest in that particular matter is unnecessary. This baseless notion of security invites attack, and most of our battles have to be fought over again under somewhat different conditions.

It is but a few years since the land about the Falls of Niagara was withdrawn once for all and forever from the realm of money-making uses, and dedicated to entirely different objects. The people of the state, after a most deliberate and thorough discussion of the matter, decreed that here there should be an opportunity for the tranquil, undisturbed exercise and delight of the higher faculties of human nature. The establishment of the State Reservation was a distinct advance in civilization. It cost years of strenuous effort, and a large amount of money. When it was accomplished the friends of human progress rejoiced. But while the quiet festival with which this achievement was celebrated was in progress a new attack on Niagara was planned. Some men could not bear to see so much power going to waste, and they have ever since been busy with imaginative schemes for illuminating the country or propelling its machinery by utilizing the great waterfall.

Niagara is owned by the state of New York, having been solemnly set apart forever from private ownership for the express purpose of preserving its unparalleled scenery. Is it therefore secure? Not at all. An account of the movement for the redemption of Niagara, written in 1885, observes that "great wisdom and decision will always be required adequately to protect the Niagara Reservation from the encroachments of greed and vulgarity. In the nature of things it can never be safe for the

people of intelligence, good taste and public spirit, of the state of New York, or of the country at large, to withdraw all oversight and interest from the management of the Reservation and the care of the scenery about the Falls." Under existing conditions—that is, with our present degree of development—there is no possible arrangement by which Niagara can be made secure. It will be the object of perpetual attack, and will require constant effort for its defense, until the mass and average of the people of our country become sufficiently enlightened to understand the true value of the place and its scenery, and to prize it for the "vital feelings of delight" which it inspires. The men who "saved Niagara" a few years ago will not live to see that time. If the people of this state, and of the country, intend and expect to keep the State Reservation at the Falls free and unspoiled, they must be always on guard. No electric light or power plant of any kind can be established or operated at the Falls without impairing the value of the scenery, and fatally interfering with the objects for which the Reservation exists.

The account already quoted (from the *New Princeton Review*), declared that the movement to save Niagara is of peculiar interest, because it was the first effort made in this country on so large a scale to use the machinery of government for an object of this kind—that is, for a purpose belonging so entirely to the realm of elevated sentiment and noble spiritual emotion. No sordid element modified or degraded the pure ideal which the laborers in this movement set before them from the beginning. No person made any money out of it. There was no stain or shadow of jobbery from the inception to the final accomplishment of the enterprise. Here was a great natural possession of unparalleled beauty, with peculiar power to inspire wholesome and elevated emotions, to calm the fevered unrest of our crowded, hurried modern life; to delight and reinvigorate all who feel that "the world is too much with us, late and soon," and to minister to the sanity and happiness of millions of toiling men and women through all coming time. It was certain to be speedily destroyed and its priceless loveliness extinguished in cureless ruin, unless the state intervened to save it. The great state of New York has never acted more wisely, or more in accord with the highest civilization of the age, than when she devoted a million and a half from the public treasury to make the region about the Falls of Niagara free to her people and to mankind forever. Such objects will always be easier of accomplishment in America because of the precedent thus established.

The truth that the best things in our civilization are subject to constant attack appears also in the difficulty of maintaining parks and open spaces in our large cities. One of the reasons offered in favor of confiscating Central Park for the World's Fair is that a great building, or more than one, erected for the fair, may be left standing permanently, to add to the attractions of the park. To those who understand the true value and uses of a park this would be a reason on the other side. A pastoral park is not a place for buildings, and the minimum of artificial constructions should be the rule in all places of the kind. It was wrong to take a part of City Hall Park in this city for the Post Office, and it is entirely natural that the result of this uncivilized proceeding should be one of the ugliest buildings, for its size and cost, in our whole country. If we had been sufficiently developed to produce a beautiful and noble building we should never have thought of putting it in the park. It would be far better for the city if there were no buildings in this park except the old City Hall, which is the only one possessed of any architectural merit.

Perhaps the necessity of perpetual struggle to maintain what we have, is not so much to be regretted as many people think. The constant wariness and effort thus required are the condition of all farther advance. If it were possible, which it never is, or can be, to make everything safe, we should probably lie down in peace and rot. Luxury and inaction would bring on atrophy of the higher qualities of the national character, and unless they are maintained

in vigorous life, civilization itself would decay. Without these higher moral qualities a nation would not fight even for freedom, though it might try to buy it. The need of serious thought and hard work is not to be altogether regretted, or regarded as a discouraging condition; and even such a manifestation as the raid on Central Park may have its use in making this need still more apparent and urgent. The necessity of struggle is abiding, normal and stimulating.

Chatsworth.

IN the heart of the beautiful Derbyshire country lie, twelve miles from one another, two of the most famous country homes of England—Haddon Hall, one of the residences of the Duke of Rutland, and Chatsworth, the seat of the Duke of Devonshire. At Haddon Hall the house itself is the chief object of interest, being a most picturesque and beautiful structure, no part of which is of later date than the fifteenth century; the once magnificent park was plowed up for cultivation some seventy years ago, the chief residence of the duke being now Belvoir Castle. At Chatsworth, however, the grounds are even more magnificent and famous than the house. The estate is said to have been granted by William the Conqueror to his natural son, William Peveril, and is familiar to readers of Scott's "Peveril of the Peak." In the reign of Elizabeth it was bought by Sir W. Cavendish, who commenced a residence that was finished by his widow, the famous Countess of Shrewsbury. But this house was swept away in the first years of the eighteenth century to make room for an imposing structure to which wide-spreading wings were added by the sixth Duke of Devonshire, who made its grounds to rank among the wonders of the world.*

When the first of American landscape-gardeners, A. J. Downing, visited England in 1850, this duke and his head gardener, Joseph Paxton, gave him hospitable entertainment, and, from a long letter which he wrote home to the *Horticulturist*, we shall take many of the following descriptive passages:†

The house—palace would be a better word—stands in a valley, and therefore makes a less imposing effect as the visitor approaches than do some other English homes of perhaps smaller architectural pretensions. But if the site is thus disadvantageous in one way, it conduces vastly in other ways to the beauty of the domain. The surrounding hills, of picturesque outline and from 300 to 400 feet in height, form from every point of view a beautiful background and setting for the park; and, their sides being filled with prolific springs, it has been possible to utilize water in the pleasure-grounds to a far greater extent than in any other English estate.

The park measures about nine miles in circumference, and its surface is beautifully diversified with hill and dale. The visitor usually enters it by the Edensor Gate, which takes its name from a little village near by, which was wholly rebuilt by the sixth duke, and, with its thirty or forty charming cottages, is, says Downing, "precisely what everybody imagines the possibility of doing and what no one but a king or a subject with a princely fortune and a taste not always born with princes, could do." Each cottage has its garden and stands among beautiful trees, and a wide village green, a village play-ground, school, drying-ground and fountain serve the common comfort as well as delight the eye by their tasteful disposition. From the village to the house "is about two miles through a park, which is a broad valley, say a couple of miles wide by half a dozen long . . . backed by wooded hills and sylvan slopes . . . with a lovely English river, the Derwent, running like a silver cord . . . and grouped with noble drooping Limes, Oaks and Elms that are scattered over its broad surface. . . . After driving about a mile the palace bursts upon your view, the broad valley-park spread out below and before it, the richly-wooded hills rising behind it, the superb Italian gardens lying around it . . . the whole, a palace of Arcadia." The house forms a great quadrangle, in the centre of which is a magnificent fountain. The Italian gardens are a "series of broad terraces on two or three levels, which surround the palace, and which, containing half a dozen acres or more of highly-dressed garden scenery, separate the pleasure-grounds and the house from the more sylvan and rural park. . . . Of course, the Italian gardens are laid out in that symmetrical style which best accords with a grand mass of architecture,

and are decorated with fine vases, statues and fountains. . . . A surface of real dark green velvet of a dozen acres would scarcely soothe the eye more by its look of softness and smoothness than the turf in the Italian gardens at Chatsworth. . . . But the crowning glory of Chatsworth is its fountains. . . ." From the gardens, which extend along the whole house-front of 800 feet, one sees the "carpet of velvet divided by broad alleys enriched by masses of the richest flowers and enlivened by fountains of various forms." And further away is a "mirror-like lake, set in turf and overhung by a noble avenue of drooping Lime-trees, beyond which you catch a vista of the distant hills. . . . Out of this limpid sheet springs up a fountain so high that as you look upward and fairly hold your breath with astonishment, you almost expect it, with its next leap, to reach the sky; and yet, with all this vast power and volume, it is so light and airy and beautiful . . . that you will not be convinced that it is not a production of naturelike Niagara. This is the 'Emperor fountain,' the highest in the world—about the height, I should say, of Trinity Church steeple.† It is only suffered to play on calm days, as the weight of the falling water, if blown aside by a high wind, would seriously injure the pleasure-grounds. . . . As the eye turns to the left the wooded hill which forms the rich forest background to this scene seems to have run mad with cataracts." Towards the base of the hill stands a circular water temple, from which the water rushes out with tremendous force to fall at the back of the gardens down a long flight of very broad marble steps, giving the effect of a waterfall more than a hundred feet high."

Beyond the terraces and flower gardens and more formal lawns "the path becomes wild, and, after a turn, you enter upon a scene the very opposite to all that I have been describing. You take it for a rocky wilderness. The rocks are of vast size, and, indeed, of all sizes, with thickets of Rhododendrons and Azaleas growing among them, Ivy and other vines climbing over them, and foot-paths winding through them." Here, again, are many waterfalls and streams. "Nothing can well look wilder or more natural than this spot; and yet this . . . rock-garden of six acres has all been created. Every one of these rocks has been brought here—some of them from two or three miles away. It is just as wild a scene as one finds on the skirts of some wooded limestone ridge in America . . . yet all traces of art are obliterated. You wish to go onward. No, that you see is impossible; a huge rock weighing fifty or sixty tons exactly stops up the path. Your companion smiles, and with a single touch of his hand the rock turns slowly on its centre and the path is unobstructed. There is no noise and nothing visible to explain the mystery. . . . One of the greatest beauties of Chatsworth lies in the diversity of surface, which . . . offers excellent opportunities for the production of a succession of scenes now highly ornate and artistic . . . now romantic and picturesque."

Closely connected with the name and fame of Sir Joseph Paxton is the magnificent conservatory which stands at about five minutes' walk from the house in the centre of a level forest glade surrounded by fine old trees. It is 300 feet in length and 145 in width, and covers about an acre of ground; and directly through it runs the wide carriage-drive. "All the riches of the tropics," says Downing, "are grown here, planted in the soil as if in their native climate. . . . The surface is not entirely level, but there are rocky hills and steep walks winding over them; and lofty as the roof is (seventy feet), some of the Palms of South America have already nearly reached the glass." A large pond forms a feature of this conservatory, and a gallery is carried all around it, whence the best view of its tropical splendors can be obtained. One notable plant in Downing's time was an *Amherstia nobilis*, the only specimen in Europe, which had been procured in Burmah by a collector specially sent by the Duke. Paxton's success in building this conservatory, which he covered not with flat panes of glass, but according to what is called the "ridge and furrow system," induced him to send in a competitive design when the government was contemplating the erection of a great structure for the first "World's Fair" in 1851, and so great seemed the practical utility of his novel scheme that his services were chosen in preference to those of any architect. The triumph he achieved in his exhibition-building is a matter of history, and no one thought him too highly honored by that "handle to his name," which had never before been bestowed upon a man in his position. The building itself, transferred to Sydenham, is the famous "Crystal Palace" of to-day.

But in the grounds of Chatsworth, as well as in the conservatory, the sixth duke revealed his passion for horticulture and

* Mary Queen of Scots was confined for thirteen years in the old house at Chatsworth, and here the philosopher Hobbes passed many of his days.

† The *Horticulturist*, vol. v., p. 217, November, 1850. See also vol. i., p. 297, where another pen likewise describes the wonders of Chatsworth.

‡ The height of this fountain is 267 feet. The next highest in the world, at Wilhelmshöhe near Cassel, is 190 feet, while the loftiest jet at Versailles rises only to a height of ninety feet.

his willingness to spend vast sums of money in its gratification. The arboretum, as Downing saw it, was about a mile in length, and its trees—forming a complete collection of all that were hardy in that climate—were “neither set in formal lines nor grouped in a single scene, but scattered along a picturesque drive with space enough for each to develop its natural habit of growth.” Many exotic trees, shrubs and flowers, which are now more or less well known, were first introduced to cultivation at Chatsworth, and the story of its plantations would make an important chapter in the history of horticultural progress in Europe.

On the opposite side of the house from the conservatory and arboretum lie the immense kitchen and forcing gardens. Here the most famous item that Downing noted was a Peach-tree “occupying a glass-house by itself and extending over a trellis, say a hundred feet long,” which, Mr. Paxton stated, had borne in the current season 8,727 peaches, of which 926 had been allowed to come to maturity. To show that Paxton knew how to save money as well as to spend it, the duke remarked that the cost of growing his Pineapples had been reduced two-thirds since this great gardener had taken them in charge, twelve years before.

Of course, we have only hinted at a few of the many beauties and marvels of this wonderful place, but enough has been said to explain Downing's enthusiasm when he wrote that, from a tower on a hill-top a mile away from the house, one saw “such a picture of palace and pleasure-ground, park and forest scenery as can be found, perhaps, nowhere else in the circle of the planet.” It is interesting, too, to read his defense of the duke against charges of selfish extravagance. The “refined taste” shown at Chatsworth seemed largely to excuse its magnificence, while “when one sees how many persons are constantly employed in the various works of improvement—and how cheerfully the whole is thrown open to the study and enjoyment of thousands and tens of thousands annually, one cannot but concede a liberal share of admiration and thanks to a nobleman who might follow the example of many others and make his home a closed castle.* . . . One has only to visit Windsor and Buckingham Palace after Chatsworth to see the difference between a noble and pure taste and a royal want of it. The one may serve to educate and reform the world. The utmost that the other can do is to dazzle and astonish those who cannot recognize real beauty or excellence in art.”

To create and maintain a place like Chatsworth needed the conjunction of two exceptional men like the sixth Duke of Devonshire and Joseph Paxton. It was not to be expected that their successors would equal them in enthusiasm, knowledge and taste. Consequently, the Chatsworth of to-day is not quite the place that Downing saw. The great features remain, of course—a noble palace in a noble park, with gardens perhaps too artificial for the taste of the present time, but it is no longer a great centre of horticultural activity and progress.

Asters and Golden-rods.

THE earliest Aster here is *A. cordifolius*, the Heart-leaved Aster in our language. Here are great beds of its large leaves, six inches or more long, covering the ground completely, just here with very few flower-stalks.

Gather it within the dense shade of the copse or forest and compare it with some grown in the open and you may think you have two species. The first has a slender stem, as green as its leaves, and pure white rays; in the sun its stout stalk is red or purple, with a broad corymb of blue or rosy purple flowers, whose disk florets are much more highly colored also; it seems to gain its full stature only in sunny or partly sunny places. You find great masses of its flowers along every wood-side through August and September, but the beds of great leaves are often absent, the plants having only cauline leaves. It is a handsome plant when well grown, and if it has at times a weedy look, it is because it attempts to grow everywhere, whether it can or not.

Almost as early is the Spreading Aster, *A. patens*, with its large, light blue flowers, more perfect in form than the blossoms of *A. cordifolius*. It may be known by its stiff and angular branches, which spread widely, and its narrow leaves, that clasp the stem; though this last habit is not peculiar to this species. It grows beside the first named, but is less abundant, lasting well into September.

The many-flowered Aster, *A. multiflorus*, a large, stout stemmed species, with pure white rays and red or brown disks,

is found here and there, but is hardly common. Its flowers are pretty, but are much concealed by the foliage; they do not make themselves felt from such a distance as those of *A. Nova Anglia* or *A. miser* do.

A larger and more showy species blooms about the last of August, the Red-stalked Aster, *A. puniceus*. It is four feet high, with long, narrow, bright green leaves, red stems, and long and numerous rays of a rich blue or violet, and brown disk florets. It grows in swamps and beside streams. It catches the eye from afar with its strong growth and bright flowers. One may overlook the others, but this one advertises the fact that Asters are in bloom and that autumn is at hand. The first of September brings the best of all, the New England Aster, *A. Nova Anglia*. Its growth started early last spring; it has been patiently building up its strong purple stems, crowded with its neat and abundant foliage, ever since. They are now four or six feet high, as the plants come into bloom. Its almost countless flowers are an inch and a half in diameter, with rays of the richest violet and brown disks which suggest the plush of a bumblebee's jacket. They have a strong fragrance, and are the only scented Asters so far as I know. They smell just like the Witch Hazel's flowers, which you may find before the Asters are gone. Could we see the particles of odor given forth by these two widely differing plants, would they have the same form and size and color? Heat and drought cut short the bloom of the New England Aster—and perhaps that of all other Asters growing in dry soils, for cool rains and gray skies make it glow best and longest. I almost imagine its colors are brighter on hard, poor soil, an effect due, perhaps, to the background of dull brown earth and fading herbage found in such places.

The Acuminate Wood-Aster, *A. acuminatus*, is found in shady woods early in September—a noticeable plant, a foot high, with a loose panicle of large, whitish heads with a spreading cluster of leaves just below it; the lower stem is naked. Soon comes the starved Aster, *A. miser*, one of the most floriferous of plants, in spite of its name; its flowers may be small, but their multitude makes up for that. They are pink, white, purple and blue on the same plant sometimes, due, perhaps, to their varying age, like the blue and paler flowers of *A. patens*. The hard, dry road-sides owe much to the slender growing starved Aster. Frost is nothing to it; it gathers fresh glory from being positively the latest flower. You may find it bending with its weight of flowers in the midst of deep drifts of fallen leaves, while *A. cordifolius* beside it is heavy with its ripened seed. A little spray of its pink and blue flowers, as fresh and bright as though it were the first blossom of spring, is almost more to you than the great purple plumes of the New England Aster were in their time, now so long past.

The Golden-rod contemporary of *Aster cordifolius* is the smooth Golden-rod, *S. serotina*, a fine species, three feet high, with purple stems, smooth leaves, and a bright inflorescence. Tramping through pastures and woods at this time, you see Golden-rods in bloom in the distance which you imagine may belong to other species, but as you come near you see the red stem and smooth leaves of *S. serotina*. *S. altissima* and *S. Canadensis*, upon which the autumn depends for most of its golden effects in these parts, are in bud, and biding their time, which comes in mid-August. They grow a foot high here and eight feet there; erect or drooping, and their variations are endless. Their mission is to light up every field margin, lane and wood-side in the land, and for this none of their forms come amiss.

We now come to a section of the genus that the popular eye hardly holds as Golden-rods at all; no artist puts them into his picture of autumn scenery; they are small, shy, woodland species, doing little to decorate the country. *S. latifolia*, with broad leaves and a golden spike; *S. bicolor*, of slender, erect habit, the only white Solidago, and even this has yellow stamens, whence its name; and the *S. casia*, a lovely plant in woods and shades. Most Golden-rod leaves and stems are rough to the touch and somewhat coarse looking, but no smoother plant grows than the blue stemmed Golden-rod. *S. casia*, a stalk of slenderest growth, having long, narrow leaves and a bunch of flowers at the insertion of each leaf; often gracefully bending like a long, golden garland. Then there is the grass-leaved Golden-rod, *S. lanceolata*, remarkable for its flat topped inflorescence; but no one locality can boast the seventy or more species of these two genera. That purple ridge over there, where they have Huckleberries and rattlesnakes, has a different set, and though the above list contains all my own, and will doubtless hold over large areas of Beech and Maple country in western New York, it will need large revision in the region of Chestnut, Oak and Pine anywhere.

Canaseraga, N. Y.

E. S. Gilbert.

* It is recorded that as many as 80,000 persons had been permitted to inspect not only the grounds but the house also during a single year before Downing's time.

New or Little Known Plants.

Spiræa Millefolium.

THIS remarkable plant, figured on page 509, was discovered in the valley of the Bill Williams Fork of the Colorado River of the West, in the Territory of Arizona, in the autumn of 1853, by Dr. J. M. Bigelow, the naturalist of Lieutenant Whipples' explorations along the thirty-fifth parallel for a railroad to the Pacific. It is now known to occur very sparingly at high elevations from Wyoming to northern California and along some of the mountain ranges of the Great Basin, and on the eastern slopes of the Sierra Nevada to the neighborhood of Owen's Lake, in south-eastern California, as well as in northern Arizona.

*Spiræa Millefolium** is a glandular-pubescent, spreading shrub with a loose habit, growing sometimes to a height of five or six feet. It has stout branches covered with thin reddish bark, separating readily into thin deciduous scales and narrowly lanceolate leaves, which resemble those of *Chamæbatia*, fascicled or sometimes scattered near the extremities of the branches. They are pale gray-green, one to three inches long, twice pinnate, with numerous pinnæ and minute oblong-obtuse leaflets. The flowers are produced in slender terminal panicles six or eight inches long. The calyx is top-shaped, with acute erect divisions rather longer than the tubes, but shorter than the orbicular-obovate white petals, which are about an eighth of an inch long. The stamens are included. The five carpels are nearly pubescent or glabrous at maturity, and two-valved to the base, with seeds the twelfth of an inch long, somewhat attenuated at the two extremities.

I found this plant growing in considerable abundance in the autumn of 1878 on the dry and arid foot-hills of the Monitor Range, above the elevated Fish Spring Valley, south of Eureka, in central Nevada; and was fortunate in securing a quantity of the seeds, which germinated in the Arboretum, where this plant has quite unexpectedly proved entirely hardy, and has produced flowers and fruit for several years. It may now, I believe, be seen also in several European collections. The whole plant, like many others of the Great Basin and other arid western regions, is strongly impregnated with the odor of creosote. *Spiræa Millefolium* will interest probably the botanist more than it will the cultivator of purely ornamental plants, although the foliage is not without beauty.

Maximowicz proposes the genus *Chamæbatiaria*† for this plant, adopting the sectional name in *Spiræa*, first used by Professor J. C. Porter—a view which will not probably be adopted by all American botanists. C. S. S.

Plant Notes.

Vaccinium Vitis-Idæa.

AMONG the many varieties of edible berries that abound throughout Canada, none occupy a higher place in the economy of nature than the northern Cranberry, better known in the south as the Cowberry. Deemed of no value in the warmer parts of Canada, and pronounced by Gray to be "acid, and rather bitter, mealy, barely edible," it seems, when in its own home in the cold, rocky woods of the north, or along the shores of Hudson Bay and the Arctic Ocean, to derive size and flavor from the very conditions that dwarf and kill its less hardy competitors. For there it is not "acid and rather bitter," but simply acid, and far from being "mealy." It is firm and juicy, and, when cooked, is pronounced by those who eat it to be equal, if not superior, in flavor to the fruit of the true Cranberry, *Vaccinium macrocarpon*. Along the Gaspé coast and the north shore of the Gulf of St. Lawrence, the fishermen's families gather this fruit in large quantities for their own use or for sale, calling it the "Low bush Cranberry;" and, throughout the whole of northern Canada, hunters and trappers, as well as the native Indians, have frequently to depend upon it for food when game and fish are scarce.

* *SPIRÆA MILLEFOLIUM*, Torrey, *Pacific R. R. Rep.*, iv., 83, t. 5.—Brewer and Watson, *Bot. California*, i., 179.

† "Adnotationes de Spiræaceis," in *Act. Hort. Petro.*, vi., 225.

But it is not man that this useful berry is of the greatest service. It forms the most important, and, in some places, with the fruit of *Empetrum nigrum*, the sole food of the larger migratory birds, as they return from the south in early spring; and the islands in some of the large lakes of the north and in Hudson Bay are at times covered with geese of several species that have stopped to rest and feed. It is in the spring, immediately after the snow disappears, that this berry seems to be most sought after by birds and animals, partly, perhaps, because it is then soft and sweet, but principally, no doubt, on account of the scarcity of other food, although grouse, partridge and ptarmigan eat it at all seasons, even when only half ripe. In the spring, in suitable localities in the wooded country, it forms the favorite food of the black bear, and on the islands in Hudson Bay and along the Arctic coasts the polar bear spends much of his time in tearing up the low evergreen plants, in order to get at the fruit more easily; for it is on the under side, and almost touching the earth, that the berries are to be found in the greatest numbers. Immense patches of ground covered with the dead plants may often be found, telling where bruin has been at work. All summer long the last season's fruit may be found mixed with the flowers or with the green berries, and is then eaten by many birds in preference to anything else.

J. M. Macoun.

Holiday Notes in Southern France and Northern Italy.—II.

MUCH of interest to the gardener is to be seen in and about Turin, the principal city of Piedmont and once capital of Italy. There are many long, broad, straight streets planted with various species of trees, several gardens and pleasant squares. The most noteworthy features observed by us I shall try to condense into the present paper; many places were, however, visited which lack of space prevents me from mentioning. One of the favorite promenades of the Turin people is the *Giardino Valentino*, on the left bank of the Po; this is easily reached by tram, and is well worth a visit. The royal chateau, "Il Valentino," a turreted building of the seventeenth century (now used as an engineering college), gives its name to the garden. The ground seems to have been well laid out, and is not broken up by paltry beds, as is so often the case in similar places. Groups of Planes, Pines, etc., and a few fine single specimens of *Arbor-vitæ*, Red Cedar, etc., stand out well on the broad stretch of grass, which, however, had a coarse and neglected look in comparison with a well kept English lawn. Rock-work, apparently constructed on false principles, bordered the steps and slopes leading from one level to another, but no plants relieved the bare, even forbidding, aspect of what surely might have been made a pleasing feature.

The Botanic Garden is, like so many continental establishments of a similar character, not open to the public, but visitors desirous of seeing it can obtain admission on application to the doorkeeper. Many very fine trees exist in the by no means extensive grounds, and, among them, the following struck us most: *Zelkova crenata* (grafted on Elm), planted quite small forty-one years ago by the present curator, and now a huge tree four feet through at the base; this is the biggest specimen I have yet seen of this interesting Caucasian tree. *Fagus ferruginea* seems to be quite at home in Turin; in Britain, as far as my experience goes, it makes hardly any headway at all, and is inferior in every respect to the European Beech. The Kentucky Coffee (*Gymnocladus dioica*) was represented by a splendid tree, laden with pods. The most remarkable of the other American trees were a White Oak (*Quercus alba*), about seventy feet high, with a trunk more than three feet through, and a Bur Oak (*Q. macrocarpa*), about the same height, with a trunk two feet in diameter; in Britain and in other countries of northern Europe none of the American White Oaks thrive; on the other hand, the Red Oak (*Q. rubra*) and the Scarlet Oak (*Q. coccinea*) make huge trees, and grow much more rapidly than our European species. A tree of the Bitter Nut (*Carya amara*), with a trunk two feet through, had attained a height of about seventy feet. The first Locust (*Robinia Pseudacacia*) introduced into Piedmont is also to be seen in the Turin Botanic Garden; it is still a fine, vigorous tree. No one familiar with the Sweet Gum of the Levant (*Liquidambar Orientalis*) in British gardens only can form any idea of the beauty of the species under conditions suitable to its development; at Turin it is a graceful tree, from forty to fifty feet high, and it flowers and ripens fruit, though not every year; in England it only makes a dense dwarf bush—specimens at Kew do not seem to have increased in size to any appreciable extent during the last fifteen years or more. *Fortunea Sinensis*, an interesting ally of the Hickories and Walnuts,

Fig. 137.—*Spiraea Millefolium*.—See page 508.

ripens seeds freely under the sunny Italian sky; the Turin plant was a fine, handsome bush some nine feet high. This, as well as the Japanese *Stachyurus præcox*, which flowers and fruits freely in company with the above-mentioned trees, only succeeds under exceptionally favorable conditions in England. Another member of the Walnut family, *Pterocarya Caucasica*, sixty feet high, with a trunk three feet in diameter, was laden

in festoons from the roof. Only a few of the handsome flowers were to be seen at the time of our visit; but when the plant is in full blossom it is, so the Curator informed us, one dazzling mass of deep red. *Tecoma jasminoides*, too, flowers equally freely and attains dimensions as large as those of the plant previously mentioned. *Dioclea glycinoides*, an Australian climber, was very showy with its long racemes of scarlet,

with its long pendulous spikes of small winged nuts. A big Maidenhair tree (*Ginkgo biloba*), seventy feet high, and an *Idesia polycarpa*, thirty feet high, were among the finest of the Japanese trees. The Himalayan Spruce (*Picea Morinda*) was represented by a small group of fine pyramidal specimens from fifty to sixty feet high. *Sterculia platanifolia*, a species which grows so rapidly and produces such a fine effect in northern France, is here a round-headed pollard, the long, thick shoots being killed back more or less every winter.

Amongst other features of special interest noted in the open air were a Jujube (*Zizyphus jujuba*), laden with fruit, and close to it a fine *Aristolochia ornithocephala*, flowering abundantly. The latter, however, will be housed before winter sets in. A nice lot of terrestrial Orchids (European species) were growing in pots, not plunged, but merely standing on gravel in partial shade. A dense covering of the commonly cultivated *Selaginella Kraussiana* made an excellent substitute for the grasses, etc., amongst which they grow in a wild state. This plan is well worthy of a trial, as very few orchid growers, professional or amateur, succeed with many of these peculiarly interesting plants, numbers of which are as beautiful in the color of their flowers as these are quaint and strange in form. In England we do not, as a rule, get sufficient sunshine for the Wild Potato-vine or Man-of-the-Earth (*Ipomœa pandurata*). In Turin, however, it was a splendid object, clothing a stump fifteen feet high, and literally covering it with large, beautiful, white, purple-throated flowers. *I. Quamoclit*, too, generally grown as a warm greenhouse plant with us, was a fine sight in the open, close to the species just named, the finely cut, slender leaves and profusion of bright scarlet flowers affording a combination as charming as it was novel to us.

As far as in-door cultivation is concerned English gardeners have not much to learn from Italian practice. The houses were heated by steam, but the plants, excepting some in a large conservatory, call for no remark. The climbers in the last-named structure were exceedingly fine, and the large, twisted stems of the Bignonias helped one to realize travelers' descriptions of the vines in a tropical forest. *Bignonia Cherere* covers a large space of back wall, and hangs

pea-shaped flowers. A large bush of *Grevillea asplenifolia* (recently figured in the *Botanical Magazine*) was here some fifteen feet high, and bore the name of *G. longifolia*. Close to this was a bush of the Japanese *Osmanthus Aquifolium*, which, on enquiring the reason for its cultivation under glass, we learned, had repeatedly failed in the open at Turin, the winters proving too much for it.

Perhaps the prettiest of the squares is the Piazza dello Statuto, with its huge allegorical monument, commemorating the completion of the Mont Cenis tunnel. As the guide-books say, "the genius of science is seen soaring above a chaotic pile of granite rocks, on which lie the stupefied and conquered giants of the mountain." The mass, at one end of a pretty fenced-in garden, is surrounded by water, bordered with a broad Ivy band, through which, here and there, emerge Yuccas. At the back are Bamboos. There is an excellent piece of turf, with groups of fine Lagerstræmias (in full flower at the time of our visit), *Hydrangea quercifolia*, Judas Tree (*Cercis Siliquastrum*), etc. A good bed of Colocasia and green and red-leaved Cannas was pleasing, and did not look at all out of place.

The Plane, the same as that mentioned in my last paper, is in Turin, undoubtedly, far and away the best street-tree. In some of the broadest streets the trunks of the trees were protected by a fenced-in border, about four or five feet wide, and a hedge of the Chinese *Spiræa Cantonensis* occupied the distances between them. In other places Forsythias were grown under similar conditions, and in others again, Noisette and China Roses. The constant waterings these shrubs require is, no doubt, of immense advantage to the Planes in that hot and thirsty soil. Oak avenues obtained in some parts of the city, and Elms elsewhere, but the oak-stems were riddled by the larvæ of the goat moth, or some equally objectionable enemy to trees, and the Elms were badly attacked by various fungi. The Plane, however, everywhere seemed clear from both fungoid and insect attacks.

The fruits of the Azarole (*Cratægus Azarolus*), about the size of a small Medlar, were offered for sale in the markets. This species is hardy enough with us, but it flowers sparingly and rarely ripens its fruit in the comparatively sunless climate of Britain.

To the south of Turin is the village of Moncalieri, picturesquely situated on a ridge of hills, the highest spot being crowned by the royal château in which Victor Emmanuel died in 1823. From this point the snowy summits of the Alps are visible on the left, and a good view of the Turin hills is obtained. Large Spruces, Junipers, Red Cedars, Weymouth and other Pines adorn the grounds of the château. The wood behind is simply Oak and other indigenous trees. A dazzling mass of blue along the top of a wall in the Via Petrarca immediately attracted our attention. It turned out to be *Ceratostigma plumbaginoides* (better known under its old, but incorrect, name of *Plumbago Larpenæ*). This handsome Chinese perennial evidently requires a sunny spot, a rather dry situation and soil—perhaps rather poor than otherwise—for its beauties to develop to their fullest extent. Along the road-sides we noticed from the train which took us back to Turin fields of Indian Corn, Millet (*Panicum miliaceum*) and *Erigeron Canadense*, a yard and a half and more in height, occurring as a weed amongst the lower-growing crops. This New World weed, now spread over the whole of Europe, was accidentally introduced into Germany, about half a century ago, in a stuffed bird.

Cultural Department.

Notes on Begonias.

DURING the past summer, with its storms and excessive rainfall, which ruined so many ordinary bedding plants and shortened the bloom of all but the most sturdy flowers, one could not but admire the hybrid Tuberous Begonias, which reveled in the abundant moisture and from early July till now have ever shown fullness of bloom which rain-storms seemed only to improve. A wet period which ruined Geraniums and other soft plants left the Begonias in renewed vigor and full flower. The improved hybrids which we now have are the product of many species and selections from various crosses, so that it cannot be said that all seedlings and plants are equally adapted to out-door culture; but with some care one can select such as will prove capital out-door plants, which, planted in proper position, cannot fail to prove satisfactory, at least in this latitude. The proper position seems to be one which receives sunlight only a portion, say an hour or two,

of each day. The soil should be light, rich and perfectly drained. The most satisfactory kinds for such a position are the single ones, and care should be taken to select those of a sturdy and erect habit. The double varieties are of a much more slender habit, and, while not as showy in the borders, they have a grace of their own and are well adapted to out-door culture. Good drainage is of first importance, for stagnant moisture will cause a wholesale rotting of corms and loss of plants. Otherwise there seems no difficulty connected with their culture, though an occasional stem will be attacked in close weather by some parasite.

Like all free flowering, fast growing plants, these, to be well grown, require copious supplies of liquid manure. It is, perhaps, needless to say that hybrid Tuberous Begonias range in color from pure white, through most delicate pinks and salmons, to the clearest scarlets and reds of innumerable shades, and yellows from faintest primrose to clear gold, and are very free from shades of magentas and "blue-reds." In form they range from the single four-petaled flowers, which, in perfection, should make an almost perfect circle, to the fullest double. A stock is readily procured, as they grow rapidly and easily from seed; cuttings strike quickly and corms may be divided to single eyes. It is well in forming a collection to secure at least a few named kinds; a postal note to one of the leading French houses will bring a collection of good named ones (though not the very latest productions) at the cost of ordinary "rogues" or culls here. These superior kinds will furnish abundant seed for future cultivation and better than can be otherwise obtained; for, after trying seed from the most trustworthy dealers, one finds it difficult to believe that the best is sent out.

The cultivation from seed is of the simplest. Scatter it as thinly as possible over some light earth, not too moist, and cover the pan or pot with a glass; over the glass lay paper to exclude light, and keep in a moderate temperature. Do not cover the seed with earth. The pan should not be allowed to dry out, and, when necessary, it must be moistened by dipping it in water, deferring this, if possible, to nearly the time of germination, which will be in about a fortnight. Begonia seeds are so extremely small that the point of a penknife will hold several hundred. The seedlings are not at all "miffy," but are rather tedious to handle, as it is usual to pick them out while so small that they must be handled with a moistened camel's-hair brush, and a smooth ivory point as a dibber.

They bloom while small, and seed sown in January will begin to come into bloom in June, and, perhaps, even earlier. A collection of Tuberous Begonias is incomplete without some of the species, among which there is a wide diversity, both in foliage and flower. To mention only a few, *B. Martiana*, *B. racemiflora*, *B. grandiflora*, and *B. diversiflora*, old introductions, are very interesting and distinct, with lovely flowers (the last named, being a rose color and the others an opaque pink), on short axillary peduncles. *B. Natalensis* is an interesting and distinct species, with small pointed leaves of a light metallic green, red stems, and profuse, small, four-petaled flowers, of a peculiar burnt-orange shade. The habit of the plant is somewhat suggestive of *B. Weltoniensis*. *B. geranioides*, a new species, also from Natal, is interesting from the resemblance of foliage to the Geranium, but its culture has not been successful with me.

Of the later blooming Tuberous Begonias, *B. octopetala* is well known as a sturdy late flowerer, and Lemoine has crossed this with some of the more showy species in the endeavor to improve the flowers and furnish bloom after the ordinary hybrids have passed out of bloom. The new cross has foliage more pointed, but showing clearly the Octopetala parentage. The variety Anemone is but just showing color with me, while the others are but giving indications of flowering. I hope to report later as to this interesting cross.

B. Scharffiana, a new introduction from Brazil, is a fibrous rooted kind, and in a young state seems very promising. The leaves are thick, covered with hairs on both sides, deep green above and red beneath. As the flowers, which are white, are said to be of good size, it will no doubt be an addition to the flowering varieties. Plant fanciers, who are fond of collecting, will find in Begonias a wide field, as there are said to be about four hundred species, with innumerable hybrids, and from the little *B. Imperialis*, with its leaves of embossed velvet, to the giant Rubra, there is a wonderful diversity of size, form, foliage and flower.

Mr. Thorpe has lately, in GARDEN AND FOREST, given a list of some good fibrous rooted kinds, while the raisers of Rex varieties bring forward every season wonderful new varieties to please those who fancy variegated foliage. J. N. Gerard.

Elizabeth, N. J.

Pandanus.

AMONG the various members of this interesting genus are found some of the most useful foliage plants for decorative purposes in general cultivation, and for this purpose some of the species are grown by thousands annually by commercial florists. Being of easy cultivation in most instances, and especially so in the case of the two most useful sorts, *P. Veitchii* and *P. utilis* (if a few reasonable conditions are observed), they have become very well known and appreciated. Though most species of *Pandanus* are natives of the South Sea Islands, many of them may be grown in a moderate temperature, say from 55° to 60°, and, in fact, when grown at this temperature, that is, under cool treatment, the plants are found to be in much better condition to bear exposure to changes of atmosphere such as are unavoidable when they are moved about for decorating purposes.

The best known representatives of the Screw-Pines, as the

off is perhaps the most critical time for them, because if kept too damp or in too close an atmosphere many of them will rot off.

After this period the most necessary points in their cultivation are to keep them potted on, so that the lower foliage does not suffer from starving, and to place them in a light house, only slightly shaded in midsummer, giving them space enough to develop their leaves, for when crowded they quickly become weak and drawn.

Pandanus Veitchii, when well grown, is undoubtedly the finest of the genus, and can be managed in the same way as *P. utilis*, though it is possible that *P. Veitchii* will stand more abuse in regard to over-watering than *P. utilis*. Either may easily be injured in this way during the winter. *P. Veitchii* is only propagated by cuttings, which will root at almost any season if given a reasonable amount of care. They are best separated from the parent plant with a small portion of the hard wood attached, so as to form a heel for the

Chatsworth.—See page 508.

Pandanus family is frequently called, from the spiral arrangement of the leaves about the stem, are *P. utilis* and *P. Veitchii*, the first named being a native of Madagascar, and long known in cultivation, and the latter of more recent introduction, having been one of the many fine plants brought into horticultural use by the late John Gould Veitch.

As is well known, *Pandanus utilis* is readily propagated from seeds, which have become almost a staple article among the larger seedsmen of late years, and when the seeds are received in good condition they will come up in from six weeks to two months from the time of planting if strong bottom heat is given. These seeds, of a peculiar angular shape and from one to two inches in length, are compound, producing several plants from each; and there are sometimes seven or eight shoots, which may be easily separated from the seed with a sharp knife. They should be potted off in two and one-half or three-inch pots, as the size of the plants may require, after which they should be shaded for several days, until they become established. The first few weeks after the seedlings are potted

cutting. Plenty of pot room and light should be given to this plant, as, when well colored, it makes one of the most effective specimens for exhibition purposes.

P. candelabrum, perhaps better known as *P. Javanicus*, var., is another handsome variegated variety of rapid growth, but from its branching habit it makes a less shapely plant than the preceding. It is also propagated from cuttings in the same manner as *P. Veitchii*, and is of easy cultivation.

Among the species with plain green foliage, perhaps *P. reflexus* is the most notable, though rather an unpleasant plant to handle, the long, pendulous leaves being reflexed or recurved to such a degree as to almost hide the pot of a large specimen. Besides this, it is the best armed species of the genus, the spines being very numerous and strong, both on the edges of the leaves and on the under surface of the midrib.

A pretty species of dwarf habit is *P. graminifolius*, a native of Tenasserim, and having narrow, grassy leaves of dark green, edged with small, white spines. It is of branching habit of

growth, and is useful for dinner-table decoration or for small ternerics.

P. heterocarpus, or *ornatus*, is a highly ornamental species from the Philippine Islands, where it grows to a large size. It is a vigorous looking plant, with broad, shining green leaves, which attain a length of five to six feet. It makes a fine specimen where space can be spared to develop it. It will be found to do best in a stove temperature.

The soil best suited for the Pandanus is a rather light loam with a fair proportion of sand and some well rotted manure. The pots should be well drained, so that the soil shall not at any time become sodden. With ordinary care in watering during the winter, the successful cultivation of the plants is not difficult.

Holmesburg, Pa.

The Guava in Florida.

GUAVAS are seldom, if ever, seen in our northern markets in their natural state, although guava jelly is a very common northern luxury. In south Florida they are the peaches of the region, and are grown with but little cultivation. The fruits are very healthful, and when the taste for them is once acquired they are relished as much as peaches, and are prepared for the table in the form of jellies, jams, pies, and served raw with cream. Little attention has been given to the manufacture of guava jelly for market in Florida, but it is confidently believed that it could be made immensely profitable in the southern counties.

Aside from their delicious fruit, the Guava bushes are of value for their ornamental qualities, with their evergreen leaves, polished stem and pure white flowers. The plants attain the height of small trees, averaging from fifteen to twenty feet in their native country (Tropical America). They bear short-stalked, egg-shaped or oblong leaves, with strongly marked veins covered with a soft down. The flowers are borne on axillary stalks, and the fruits vary very much in size, shape and color, numerous forms and varieties being cultivated. Cattley's Guava is the best kind for south Florida, as it is more hardy than any other. The fruits are pear-shaped and of a purple or claret color, and somewhat smaller than the common guava, though more prolific. The fruits begin to ripen in June or early in July, when not disturbed by cold, and continue blooming and bearing without interruption for months.

The soil for the Guava should be moist and rich; and the plants should be copiously watered in dry weather. It is better, in Florida, to train the plants to bush form until the roots get established, which will require several years. They should be protected from occasional cold periods. If the soil is kept rich and moist there will be a crop of fruit the latter part of summer, even though the stems are nipped in the winter.

The fruit is of much too perishable a nature to allow shipment to any great distance in its natural state, and for that reason very little attention has been given to the cultivation of the plants in Florida. A great deal of the low soil in the southern counties is well adapted to the cultivation of this fruit, and at present it cannot be utilized for any other purpose. Land which can be put into first-class condition for the Guava by a little drainage may be had for a few dollars per acre. Low hummock land is especially fitted for the Guava plants. In Monroe, Manatee and De Soto Counties there are several groves of these trees, which annually produce enough fruit for the manufacture of a great quantity of jam and jelly.

The Guava takes its name from the Mexican *Guayaba*, and was probably brought to Florida either from Mexico or the West Indies. The white Guava (*Pisidium Guayaba*, var. *pyriferum*) is sometimes found here, but it is very rare. The fruits are pear-shaped, about the size of a hen's egg, covered with a thin, bright yellow or whitish skin filled with soft pulp. *P. Guayaba* is the most common species and it produces most of the Guava fruit. The trees average from fifteen to twenty feet in height, and the fruits vary very much in size.

P. Guayaba, var. *pomiferum*, is sometimes called the red Guava and produces a large globular or apple-shaped fruit. The pulp is of a dark hue and not so well flavored as the former. It is seldom eaten except when manufactured into jelly or jam.

A few plants of *Pisidium Cattleyanum* make an attractive addition to the shrubbery around the house. The flavor of the fruit is an agreeable acid-sweet, almost like that of the strawberry. The trees produce abundant fruit of a large, spherical shape, and of a fine deep claret color. The rind is pitted, and the pulp is soft and fleshy, purplish near the skin, but nearly white in the centre.

New York.

George E. Walsh.

Orchid Notes.

PREPARATION FOR WINTER.—To insure a good display of bloom from the present time until March and April next, some Orchids will need more than usual attention. During this period a number of the deciduous Dendrobiums contribute their lovely flowers. They have now completed their new growths, and should be removed to a temperature much cooler and drier, with an abundance of air to ripen and strengthen them before they commence to bloom. Avoid keeping the atmosphere moist, or new growth will again start, and this means few or no flowers. They should occupy this position until the nodes show signs of swelling, when they may be returned to their former situation until the flowers are well expanded, and these will remain several weeks in good condition if brought again into the coolest end of the house. *Dendrobium Wardianum*, *D. crassinode*, *D. Falconerii*, *D. Leecheanum*, *D. Ainsworthii* and *D. nobile* are plants which succeed under this treatment. There are also among the Cattleyas some handsome winter-blooming species. The most popular among them is undoubtedly the beautiful *Cattleya Trianae*, an Orchid now largely grown, both for private and commercial purposes, on account of the ease with which it can be flowered, its free habit of growth, and the great variation of its blossoms, which are from the purest white to a fine rosy-purple. The plants of this species have just completed their growth, and in a month hence will begin to enrich our houses with their flowers. From the present time less water should be given until the buds make their appearance in the sheaths, when the supply should be increased. Three to five flowers are produced on a stem, and when cut they keep several days in good condition, and can be had continuously until March and April if a sufficient number of plants are grown. This *Cattleya* is followed by *C. Percivaliana*, together with *C. Mossiae* and its varieties, all very showy plants, and requiring similar treatment.

A few very showy *Laelias* lend to the display at this season, and among them are the beautiful *L. autumnalis*, *L. anceps*, *L. albida* and others, which all do well if exposed to the light until the flowers are well developed, which thus attain greater size and a richer color. In many collections we find *Cypripediums* pushing up their spikes, and the old favorite, *C. insigne*, is crowded with buds, as are *C. villosum* and *C. Harrisianum*, though not so abundantly. These varieties are now largely grown for cutting, because the flowers are stout and durable, and remain several weeks in good condition.

Comparatively few *Oncidium*s appear at this season, *O. tigrinum* and *O. splendidum* being, perhaps, the most prominent among them. Both are bright yellow flowering species. *O. varicosum* is also a showy species, with blossoms produced a little earlier than the two varieties above noted. *Calanthes*, when well grown, are among our finest Orchids. Most of them have completed growth, and will now require less water until the spikes present themselves from the base of the bulbs. Where *Phalaenopsis* are grown, they will be found pushing their spikes rapidly. They should be protected from drip as well as direct sunlight; and should be carefully examined for slugs, which do them much harm. *Celogyne cristata* will soon develop its lovely white blossoms. Plants with newly-made bulbs will not need much water until the spikes are seen breaking from their base. This is a charming Orchid both for cutting and decorative purposes.

Summit, N. J.

A. Dimmock.

Oncidium Lanceanum.—This very distinct and handsome species was first discovered on the banks of the Surinam River, in Dutch Guiana, in 1834, by Mr. John Henry Lance, to whom it was dedicated by Dr. Lindley, who, in his *Folia Orchidaceae*, remarks that "this beautiful plant seems confined to Surinam." Such, however, is not the case; for it has been imported of late years from near the Roraima Mountains in British Guiana, and also from northern Brazil, near Manaos, a town situate at the juncture of the Rio Negro with the waters of the mighty Amazon. There are several plants now in flower here, and they form one of the chief attractions of the Orchid-houses. *O. Lanceanum*, like *O. bicallosum*, *O. luridum*, *O. Cavendishianum* and a few others, is remarkable for the absence of pseudo-bulbs. The broadly oblong-acute, leathery leaves, which spring from knotty rhizomes, are a foot or more long, four to six inches broad, and of a dull green, covered with dark spots, and occasionally suffused with a bronzy tint. At one time these spots were supposed to indicate ill-health, but experience has proved their appearance to be quite natural. The stout, slightly-branched erect peduncle is produced a little below the base of the leaf, and attains a length of one or two feet, bearing, in many cases, from twelve to twenty-four

large flowers, which emit a delicious odor akin to that of vanilla or of garden Pinks. The sepals and petals, with wavy margins, are yellow, tinged with green, the upper concave sepal and the two petals being covered with large, roundish, purple-brown blotches, which become confluent at the base, while the two lower elliptic-obtuse sepals are nearly purple-brown throughout, having a streak of yellow appearing here and there. The lip presents a striking contrast to the other segments in its color, which is a beautiful rose-purple on the broad, flattish anterior lobe, passing along a narrow isthmus into deep mauve-purple at the base, where there are three projecting plates or crests, and a triangular auricle on each side, while the short, thick column is rendered conspicuous by its roundish, incurved fleshy wings of a bright, shining purple.

There are several forms of this fine species in cultivation, but the most distinct are *Superbum* and *Louvrexianum*, specimens of which are now also in flower. The former is distinguished by having larger and more brilliantly colored flowers than is usual in the type, but this is probably owing to its geographical distribution, as it is found only in the region of the Rio Negro. The latter variety, however, which is named in compliment to M. D. Massange de Louvrex, of Marche, Belgium, is remarkably distinct, and may be known at once by the pure white apical half of the lip, the deep purple basal portion of which appears to be thus rendered more intense by the contrast.

For many years *Oncidium Lanceanum* was a difficult plant to grow well, but now that cultivators know its requirements, and the conditions under which it grows in a wild state, it is met with in most collections, as it is found to grow just as easily as its congeners. It might be mentioned that in the Rio Negro region, during July and August, which is the dry season, there is scarcely any rain whatever, and the thermometer reaches ninety-five degrees Fahr. in the shade at two o'clock every afternoon, and does not sink below seventy-five degrees Fahr. at night. Taking this into consideration, and also the fact that the plants receive plenty of moisture by evaporation from the rivers along whose banks they grow, and also by the tremendous torrents of rain at certain times of the year, it is evident that they must be cultivated in a warm and moist atmosphere, with a temperature of seventy to eighty degrees Fahr. during the period of growth, and at the same time giving abundance of water. When in flower less water is required, and a slightly cooler atmosphere will tend to keep the flowers in good condition for several weeks. When the flowering season is quite over the plants should be placed in a cooler house, where they may enjoy a good rest for a couple of months, but they must receive a little water at intervals to prevent the growths from shriveling, as the plants have no pseudo-bulbs to retain nourishment. Well drained baskets, with a compost of rough, fibrous peat and moss, with charcoal mixed, is very suitable, as the baskets can be hung from the roof, thus allowing the plants plenty of light.

St. Albans, Eng.

John Weathers.

The Hardy-Plant Border.—It is a common error to suppose that hardy herbaceous plants need little or no care. Hardy plants require as much thought and attention as green-house plants. Many well recommended and ambitious young gardeners have little experience with hardy plants, and thus the work of planting and cultivating them is too often left to unskilled laborers. Proper preparation of ground, careful selection, judicious grouping and association of color for definite purposes, frequent division and weeding out of worthless kinds, and the propagation of the best species and varieties must always be kept in mind, and all this demands personal interest and supervision.

In addition to the propagation of proved varieties, the enterprising gardener will, every year, test a few new kinds in nursery beds to ascertain their hardiness and floral merits before they are planted permanently or rejected. Where, as is frequently the case, the owner is away from home during the warm months of July and August, special attention should be paid to the grouping of certain kinds for spring and fall displays.

The fall of the year is the best time to prepare the ground, and if the soil is not already rich and deep it should be made so. Many kinds are best planted at this season, and the others should be planted as early in spring as possible. The taller growing kinds should be placed so as not to exclude from view, and shut off light and air from the smaller kinds. If any choice varieties do not seem to make much progress, have them housed or stored in a cool frame for the winter, and take up desirable kinds for propagation during the winter or early spring. Cover the borders with leaves, if obtainable, and just lay

enough manure on them to prevent the wind from carrying them away. Or light manure will suffice when leaves are not to be had. It is better to leave the surface of the soil rather rough, or broken up, than smooth and finely raked. It takes rain without shedding, holds the moisture better, and is not so liable to be parched by the sun after a heavy rain.

Wellesley, Mass.

T. D. Hatfield.

Primula cortusoides Sieboldii is one of the brightest colored species, and in this respect stands unrivaled among hardy Primroses. Our first acquaintance with this plant was made when it was grown in pots for decorating the conservatory, and very suitable it is for that purpose, but now that there is no question of its hardiness, and plants are easily procured, one can muster up courage enough to plant them out in the open ground. Care should be taken when selecting a place for the plants, to choose a half shady position where the rays of the sun during the hottest part of the day may not strike them, as in this climate few Primulas can endure complete exposure to the sun. It is well to bear in mind also that this variety is seen to the best advantage when associated with others of the genus, such as *Primroses*, *Polyanthus* and *Auriculas*, and in this way *P. Sieboldii* shines conspicuously bright, and its large flowers of deep rose, over an inch across, borne on many flowered stems just above the foliage, cannot be surpassed for their pleasing effect in early spring. The foliage dies off completely in fall, and this is the proper time to transplant. It should be borne in mind that this species is strictly surface rooting, consequently the roots should be only slightly covered with soil, and should then receive a top dressing of well decomposed manure. This may be removed in spring, just as the plants begin to show signs of starting, as all the nutriment will have been appropriated by the soil; and as a protection the manure is no longer needed. With us Siebold's Primrose bears seed freely, and if this is sown when ripe it soon germinates, and in twelve months makes flowering plants. We have now a fine collection for flowering next spring. Florists have already been at work on this plant, but the progress made toward improved varieties has not been remarkable. The type still holds its own against all the seedling sorts, although some of these are pretty enough and well worth growing. Amongst them are two white varieties, *Intermedia Alba* and *Grandiflora Alba*. These have the merit of being very distinct. Amongst others we have tried are *Ruby*, *Laciniata*, *Lilacina*, *Clarkæflora* and *Purple Queen*, the varietal names of which are sufficiently descriptive. They are the best of some twelve or more varieties usually seen in trade lists.

Passaic, N. J.

E. O. Orpet.

A contrivance for watering lawns is being largely introduced into English gardens where there is a system of water-pipes. It consists of three or four lengths of wrought iron tubing about one and a half inches in diameter, coupled by short lengths of flexible leather or rubber hose. The tubes are pierced at short intervals with wedge-shaped holes large enough to emit a wide-spreading, fine spray. Each length of tube has a pair of small iron wheels attached, which revolve in all directions, so that the apparatus can be turned about with ease. These portable irrigators have this year been introduced into Kew Gardens by Mr. Nicholson, the Curator, and have given great satisfaction, so that the lawns at Kew, which generally brown early in the season on the hungry, gravelly substratum, have been kept beautifully green throughout the dry summer. These irrigators are likely to become generally used in parks and gardens, as a firm of hydraulic engineers in London is manufacturing them on the same principle, calling them the Kew Gardens Irrigator. The apparatus is by no means new, having been in use many years in Paris, but, perhaps, it is not known to the owners of summer-browned lawns in America. There are two or three patterns (one with socket and ball fixings), but the one described above works most satisfactorily. Besides being used for lawn-irrigation at Kew, Mr. Nicholson has turned it to account in watering specimen trees, which have been greatly benefited thereby, especially evergreens and conifers, which, as a rule, do not get nearly so much moisture as they require even in wet seasons. Fortunately, a rational system of tree-cultivation is now practiced at Kew. Formerly, when once a tree was planted, it rarely received further attention, but now they are periodically top dressed with rich soil and thoroughly watered by the irrigators. The beneficial effects of this treatment of the old trees is seen in a short time by the renewed vigor of branch and leaf. It is hoped that this example, set in a public garden, will be followed in private gardens, where trees so generally suffer from neglect.

Kew.

G.

The American Forestry Association.

The Annual Meeting at Philadelphia.

THE American Forestry Congress held its eighth annual meeting in Philadelphia last week, and changed its name. It is now the American Forestry Association. This is an improvement. The Pennsylvania Forestry Association had its fourth annual meeting at the same time and place. The joint sessions were held in Horticultural Hall, and began on Tuesday evening, continuing till Friday afternoon. Hon. James A. Beaver, Governor of Pennsylvania, and the President of the Association, presided in a vital and stimulating manner, which did much to promote the systematic transaction of business. He was sometimes relieved by Hon. H. G. Joly, of Quebec, and Dr. Charles Mohr, of Mobile. Many interesting papers on forestry subjects were presented—more, indeed, than could be read. At least sixteen states were represented by delegates appointed by their Governors, as was also the province of Quebec. The Board of Education of the city of Cincinnati sent a representative, and there were delegates from some of the agricultural organizations of the country. The Pennsylvania Forestry Association and the people of Philadelphia entertained their visitors with a most engaging and satisfactory hospitality. All conditions were favorable, and the meeting was universally regarded as the best one ever held by the national organization.

The work began on Tuesday evening with an address by Hon. Carl Schurz on the general subject of the importance of forests, and of proper forest management, to civilization and national welfare. It was an interesting and impressive presentation of the facts of the condition and treatment of the forests on our public domain, with illustrations from the speaker's experience while he was Secretary of the Interior. He urged the necessity of the permanent maintenance of forest conditions in mountain regions as indispensable to the permanent and useful flow of the streams having their sources in them. After referring to the important economic considerations which should be recognized in national forest management, he spoke eloquently of the obligation of the people of this country to regard themselves as trustees to whom are committed interests of stupendous magnitude affecting the destiny of millions of human beings through all coming time.

The most important action of the meeting was the adoption of the resolutions introduced by Mr. B. E. Fernow, Chief of the Forestry Division of the Department of Agriculture, by which the association voted to petition the Senate and House of Representatives of the United States to pass an act withdrawing from sale the forest lands of the public domain until a Commission, to be appointed by the President, shall have made the necessary examination and reported to Congress what part of these lands should be kept permanently in forest. The resolutions also ask that the army shall be employed to protect the forests on the public lands from spoliation and destruction, if this becomes necessary, until the Commission shall have reported a plan for a permanent system of national forest management.

This is substantially the course that has been advocated by GARDEN AND FOREST, and which has been approved by a large proportion of the leading journals of the country. The readiness with which the American Forestry Association follows Mr. Fernow's lead in this important movement is an encouraging indication of enlightened and practical judgment, and all serious-minded and patriotic Americans should unite in making an effective presentation of the matter to Congress and to the President, in order that effective and speedy action may be secured. Unless this is done, it will soon be too late to prevent the permanent ruin of some of the fairest and most important portions of our national heritage.

A FORCIBLE SPEECH.

The discussion provoked by these resolutions was one

of the most interesting and useful features of the meeting. The proposed plan was opposed by Mr. Lemon Thompson, of Albany, New York, on the ground that it would be more in accordance with the spirit of our institutions and with our national practice hitherto, to sell all such forest lands to individuals who wish to buy them, and also for the reason that, as a matter of fact, the forests would be better protected under individual ownership than if managed by politicians and office-holders, appointed by the Government. Mr. Thompson was often interrupted, but held his ground sturdily until he had said what he wished. Effective replies were made by Mr. Fernow, by Mr. Herbert Welsh, of Philadelphia, Colonel Edgar T. Ensign, Forest Commissioner of Colorado, and others. But the most thorough and convincing speech of this discussion, and, indeed, of the whole meeting, was made by Mr. Richard J. Hinton. Mr. Hinton has recently attended the Senate Committee on Irrigation through the whole course of its investigations, traveling nearly fifteen thousand miles through the mountainous and arid regions of the west for this purpose. During the course of his eventful life Mr. Hinton has more than once happened to be at hand at the right time and place for action, but he probably has not often done a better quarter of an hour's work than in the forcible address in which he advocated the passage of these resolutions. He showed very clearly how impossible it is that individual citizens, or even the separate states, should deal successfully with the problems connected with the management and course of rivers which are thousands of miles in length, and which flow through the territory of a dozen different states. His arraignment of the criminal and stupid indifference which would wantonly exhaust in the life of a single generation the possibilities of our magnificent national inheritance "through a thousand onward years," and his appeal to the American people to act wisely while there is yet time for effective action, was a passage of remarkable beauty and power.

VARIOUS PAPERS.

In his address Mr. Schurz said: "The destruction of the forests of the country will be the murder of its future and its progress. It seems to me that wherever the forests cover the head-waters of great rivers the Government should keep possession. If the possession is gone, then regain it. Look at the valleys of the Hudson and Mohawk—already the flow of these rivers is diminished from twenty to thirty per cent. If the destruction of the forests continues the United States will be as completely stripped as Asia Minor."

Mr. Fernow, Chief of the Forestry Division, read a carefully prepared paper on "Methods of Forestry Reform." It is the one which he read to the American Association for the Advancement of Science a few weeks ago. We quote his observations regarding

STATE FOREST COMMISSIONERS.

"A state which is administering its trust for the people, a government by the people, who believe in education as the best means of advancing their interests, will not object to providing for the education of their agents, which alone fits them to exercise their duties of governing intelligently. What, then, can be of more pressing need in each state than a forest commissioner, whose duty it shall be to collect the facts upon which the forest legislation for his state is to proceed; who will represent the forest interests of the state; who, in gathering information in regard to the distribution, location, condition of forest areas, the rate and method of their decrease or increase, the relations of supply and demand of forest products, and information in regard to the relation of water and soil conditions in his state to forest areas, can also act as an educator of the people with reference to their forestry interests and as the officer in charge of the observance of forestry laws and forest police; and who would manage state (or school) forest lands where such may exist? Whatever legislation we may ask for, the appointment of such an officer is almost an unavoidable condition to insure the enforcement of forestry laws, while the value of his labors as a bureau of information can hardly be exaggerated or their necessity doubted.

"The same agencies may be employed by the government, to produce an economic reform, that are open to private

endeavor, with the one additional agency of compulsion. Education, persuasion and compulsion are all at the command of government. How are they to be employed? To what extent can they be expected each to do its share in producing the desired result?"

Dr. H. Nicholas Jarchow, of this city, read a paper on "Forestry Legislation in New York," in which he said:

"For the state of New York there is an important reason for a systematic business management of the state forests. Systematic forestry can be practiced only to advantage in large wooded areas. The farmer possessing from 100 to 200 acres will, in treating his wood plot, be led only by his personal wants and desires; the teachings of systematic forestry are to him of no avail, except that he may be induced to adopt a culture with a certain rotation. But it is quite different with the large wooded areas, which cannot be used for any other purpose except for raising forest trees."

GEORGIA PINE.

Mr. S. G. McLendon, of Thomasville, Georgia, read a brief, interesting and valuable paper on Georgia Pine, from which we should be glad to quote at greater length, but have space only for this:

"The practical question which invites solution at the hands of practical statesmanship is the proper method of nursing to ripeness the young trees not consumed, which, as I have said, represent from seventy to seventy-five per cent. of the actual number of trees on each acre. These are, many of them, turpentine at entirely too young an age, and almost literally bled to death. The great enemy of the forest, aside from the axe, is fire—fire which comes in the wake of the turpentine and the one which precedes him. A most thoughtless, and I might justly say insane practice, prevails in the pine region, of burning off the woods in early spring, in order that a small lot of worthless cattle may get an early bite of grass. These burnings impoverish the soil by destroying the vegetable matter that would, if left untouched, enrich it, and also destroy the young Pines that spring up from seed. How serious this damage is the future will fully realize. What the best policy to husband this wasting wealth will be I do not undertake to say, but if, without too serious an invasion of the domain of private right, it could be made penal to box trees less than twelve inches in diameter, and penal to burn the woods or set forest fires, I think a decided advance would be made in the direction of preserving our pine.

"The mill man thins out, the turpentine man destroys. The one cuts down only large trees, not over thirty per cent., while the other boxes not less than seventy per cent. Behind the first the forest fire is hurtful, behind the other it is destructive. In the one case it is simple assault and battery, in the other it is murder."

Mr. E. E. Russell Tratman, of Brooklyn, New York, read a valuable paper on "Economy in the Consumption of Railway Timber," of which the two principal suggestions were the use of other materials as substitutes for wood in constructing and operating railways, and the application of means for increasing the durability of the timber used for railroad purposes.

Colonel Edgar T. Ensign, Forest Commissioner of the state of Colorado, had a good paper on "Government Forest Preserves in the West," which was illustrated by large maps on the stage. He said the experience of the Commission, of which he is the head, had made it plain that national control of mountain forest regions, in which large streams used in irrigation have their sources, is a necessity, and that adequate management by the individual states is impracticable. Few men in the country have more knowledge of the practical problems connected with the functions of mountain forests than Colonel Ensign.

Mr. N. H. Egleston, the Recording Secretary of the Association, offered a series of resolutions expressing the sense of the meeting regarding the work of the agricultural colleges of the country, to the effect that they "should regard it as one of their most manifest duties to give the subject of forestry a prominent place in their curriculums, and that every experiment station should engage in investigating and making experiments in those branches of forestry which have special importance in the localities in which they are situated, or which are of general interest in their relations to agriculture and the arts." They were unanimously adopted.

Dr. J. M. Anders, of Philadelphia, read an interesting paper on "The Removal of Forests a Factor in the Causation of Floods."

Hon. Adolph Leué, Secretary of the Ohio State Forestry Bureau, read a carefully prepared and thoughtful paper on "Forestal Schools."

Professor J. T. Rothrock, of the University of Pennsylvania,

delivered an evening lecture on "The Forest Regions of North America," with stereopticon illustrations. These were remarkably beautiful and accurate, and the lecture was one of the most interesting and instructive features of the three days' meeting.

Professor Albert N. Prentiss, of Cornell University, read a paper on "The Hemlock," which we should like to print. He showed that the rate of growth of this tree is remarkably slow, and that it is being rapidly exterminated, as it is everywhere cut off for all the uses for which its timber is so well adapted, while no effort is made to protect the young growth and thus provide for a succession of crops of this invaluable tree.

Miss Grace Anna Lewis read a paper, which attracted much attention, on "The Oaks of Delaware County, Pennsylvania." It was illustrated by the exhibition of many beautiful paintings of the leaves and fruit of the trees. These were by Miss Lewis' own hand.

Mr. B. G. Northrop read an interesting paper on "Arbor Day in Schools."

A curious and interesting incident of the last hours of the meeting was the introduction of a very brief resolution in favor of taking the duty off lumber. This was offered by Mr. J. D. W. French, of Massachusetts, one of the Vice-Presidents of the Association, who supported it in a few moderate and well chosen remarks. There was no other discussion of the subject. There was not much time, indeed, but what there was, was mostly employed in protesting against any discussion of the resolution, and even against its introduction. Last year at Atlanta it was thought that it would not do to introduce it. But the question of a duty on lumber is entirely legitimate in a forestry association.

We have not space to mention all of the papers. More had been prepared than could be read during the meeting, although most of the time was devoted to them, and not much was used in discussion.

THE PENNSYLVANIA FORESTRY ASSOCIATION.

The arrangements for the meeting were chiefly in the hands of the officers of the national organization who live in or near Philadelphia, of the officers of the Pennsylvania Forestry Association and of the local committees. They deserve much credit for the thorough preparation which anticipated every need of the occasion, and of all who were in attendance. The vigor and efficiency of the state organization is highly gratifying and encouraging.

Very appropriately, the opening and the close of the meeting were in the hands of the Philadelphia forestry people. On Tuesday evening the assemblage was called to order by Mr. John Birkinbine, of the state organization, editor of *Forest Leaves*. He introduced Mr. Burnet Landreth, the President of the Pennsylvania Association, who delivered a graceful and interesting address of welcome, in which he alluded to the establishment in Philadelphia of the first agricultural and horticultural societies, and to the work of the great botanists and dendrologists, who early made the city famous. In the absence of the President, Governor Beaver, the response to the address of welcome was made by the First Vice-President, Hon. H. G. Joly, of Quebec, Canada, who said it was not the wish of forestry reformers to protect the woods against the legitimate demands of the lumberman, or the need of forest products for the use of the people, but only against unwise and wasteful methods of appropriating such products. He added, that there is no real antagonism between lumbermen and the Forestry Association, and that they should work together in harmony for the preservation of the forests in order to maintain permanent sources of timber supply. All of Mr. Joly's speaking during the meeting was of a very thoughtful and substantial character.

The afternoon of the last day was devoted to tree planting in Philadelphia's great park. There was a large assemblage on the John Welsh Concourse, near Memorial Hall. Here again, as at the beginning, Mr. John Birkinbine directed the proceedings. Seven handsome and vigorous young Oak trees, grown from acorns from Bartram's Gardens, were planted. The trees were dedicated to John Bartram, Andrew F. Michaux, Dr. Franklin B. Hough, J. Francis Fisher, Alexander von Humboldt, Governor James A. Beaver and Judge Warren Higley; and brief and interesting addresses were delivered by Mr. Charles C. Binney, Mr. B. E. Fernow, Hon. H. G. Joly, Mr. Rodman Paul, Rev. Dr. J. P. Lundy, Professor B. G. Northrop, and Hon. John Peaslee.

A vote of thanks to the Park Commission closed the convention.

The officers for the coming year are: Hon. James A. Beaver, Governor of Pennsylvania, President; Hon. H. G. Joly,

Quebec, First Vice-President; Mr. N. H. Egleston, Washington, D. C., Recording Secretary; Mr. Charles C. Binney, Philadelphia, Corresponding Secretary; Dr. H. M. Fisher, Philadelphia, Treasurer.

Notes.

The Rev. Lyman Phelps writes from Sanford, Florida, of an Allamanda but two years old which covers a lattice twelve feet high and as many wide, and shows more than 500 flowers in bloom.

The twelfth semi-annual Fruit-growers' Convention of California will be held under the auspices of the State Board of Horticulture, in Fresno, commencing Tuesday, November 5th. Special attention will be given to discussions upon raisins and other dried fruits.

Mr. William Hamilton, Superintendent of Parks in Allegheny City—which until very recent years was an exceedingly smoky city—states that the Ginkgo tree thrives as well in that city and Pittsburgh as the Ailanthus. This means that the smoke and dust of the city do it no harm which can be detected.

Many different modes of keeping ripe grapes have been recommended and adopted, but the two great requirements for success, as noted in the *Country Gentleman*, are continued low temperature, a few degrees above freezing, and well ripened fruit. Badly ripened, and poor, watery grapes will not keep long. Packed in dry or baked sawdust, they are excluded from air currents, and are thus easily kept till midwinter in a cold apartment. The *Agriculturist* says that if wilted and then buried in stone jars three or four feet below the surface, they will come out with stems green and fruit plump and bright.

The fashion of celebrating Arbor Day has traveled as far as Australia, at least. At Adelaide the initiation of Arbor Day was signalized by the planting of 800 trees upon the Park Lands by the pupils of the schools. Many private persons also planted trees on that day in various parts of the colony, and no less than 35,000 trees had been applied for at the Forest Office on the day before Arbor Day. The City and Suburban Schools Arbor Committee forwarded a recommendation to the Ministry to provide for the proclamation of an annual holiday, to be called Arbor Day, when every colonist of South Australia should be invited to plant at least one tree, and they suggested that the first Friday in August each year would probably be the most suitable day in that region.

Our experiment stations have made a good many tests with seed-potatoes, using entire tubers, small and large, and a certain number of eyes from different ends of the potato; but the experiments have given no uniform results. The *Gardeners' Chronicle*, in the last number, sums up a discussion of the general subject as follows: "The gist of the matter seems to be that whole sets should be planted, and these should be denuded of all eyes but a few of those at the crown; and the plants allowed ample space, so that the roots may have a large feeding area, and then the potato crop will be far greater than we are accustomed to have, and the number of sets required fewer." We are inclined to think that in this country potatoes would yield more to the acre if planted more thickly than usual.

Isotoma axillaris is an Australian perennial of the Lobelia family, growing to a height of from six to twelve inches, with bright blue spreading flowers nearly an inch across. It was one of the early introductions from Australia, but of late years has been pushed aside, like many other Australian plants, by newer and therefore more fashionable subjects; and it is now rarely seen outside a few old-fashioned gardens. The most attractive feature, nevertheless, this year, of the flower-garden at Dropmore, in England, was a bed entirely filled with this plant. Although a perennial, *Isotoma* flowers freely the first year from seed, and so may be treated best as an annual when it is intended for summer blooming. As it is a sun-loving and drought-loving plant, it might be expected to succeed in the United States even better than it does in England.

Ulmus umbraculifera is one of the most striking and interesting trees of recent introduction. It is a form of the Old World Elm (*U. campestris*), discovered in Persia a few years ago, and sent by a German gardener in the employ of the Shah to Mr. Louis Späth, of the Rixdorf nurseries, in Berlin, who has propagated it largely by grafting on the common Elm. The largest specimen in Mr. Späth's nursery is a tall standard, with a stem ten or twelve feet high, surmounted by a dense, compact and almost globular head twelve or fifteen feet across. The original tree in Persia is said to be large enough to shelter a regiment of soldiers under its wide-spreading branches. *Ulmus umbraculifera*, worked as a tall

standard, has been planted in considerable numbers along some of the new streets in the suburbs of Berlin—a use for which its peculiar habit seems to adapt it.

The most beautiful flowers, this year, in the small pond devoted to the cultivation of aquatic plants in the gardens of the Trocadéro, in Paris, were two yellow-flowered Water Lilies, in the collection of M. Lagrange, nurseryman, at Oulius (Rhône). They were labeled *Nymphaea odorata sulphurea* and *N. Marliacea* (already noticed in GARDEN AND FOREST, vol. ii., p. 408). Both plants are hybrids, evidently between *N. tuberosa* and the Florida *N. flava*, but *N. Marliacea*, as it appeared in this collection, was far the handsomer and freer bloomer of the two. It is certainly one of the most beautiful of all the *Nymphaeas*; and if it proves hardy here it will be a real acquisition to gardens. A striking plant in M. Lagrange's exhibit was a tall double-flowered *Sagittaria*, labeled *S. Japonica plena*. It is a form of the widely distributed *S. sagittifolia* (var. *diversifolia*), from China, and one of the best aquatic plants of its class, with great clusters of pure white flowers, and bold, broad masses of foliage, sometimes more than three feet high. It may be expected to be hardy in the northern States.

At the recent meeting of the British Association at Newcastle, a report of a committee formed for the purpose of collecting information as to the disappearance of native plants from their local habitats was read. The attention of the committee had been in the main directed to the threatened extinction of rare plants, and the report also spoke of the injudicious action of botanists themselves and of botanical exchange clubs, as being potent factors in the changes which had taken place. The committee observed that the dealer and collector figured largely in the disappearance of Ferns, and in conclusion, suggested to natural history societies and field clubs the advisability of keeping careful guard over any rare plants to be found within their respective spheres of action. Canon Tristram referred to the disappearance of plants, and said that all these plants which they found disappearing could be procured by those who wished them from nurserymen, and the collectors who wished to grow them could get more readily from the dealer plants likely to survive and flourish than by collecting them themselves.

M. André, in a recent number of the *Revue Horticole*, calls attention to the value of *Bouvardia Humboldtii* as a summer blooming bedding plant. This charming species, a native of Mexico and introduced in Europe as early as 1874, seems to be practically unknown in the gardens of this country, although in Paris, Tours and other French cities well grown plants in flower are now not infrequently found for sale in the flower-markets during the summer months. A large bed of these plants, furnished by M. Jean Puteaux, of Versailles, has been one of the most interesting and attractive features of the gardens of the Trocadéro during the past summer. The plants were short, stocky, and covered with their terminal racemes of long-tubed, deliciously fragrant, pure white flowers, which contrast pleasantly with the dark green foliage. M. André calls attention to the fact that the plants of this species will continue to produce their flowers during several months if they are copiously supplied with water, and if the flowers are removed as fast as they fade, that the development of seeds may be prevented.

President Horace Davis, of the University of California, recently received an inquiry from Algeria concerning experience on the Pacific coast with grasses for restraining drifting sands. As much of this kind of work has been done at Golden Gate Park, in San Francisco, the experience of Mr. John McLaren, the efficient superintendent of the park, was asked, and his statement has been forwarded to the distant applicant. Part of the information given by Mr. McLaren is quoted as follows in the *Pacific Rural Press*: "The grasses found most successful here are the Sea Bent grass (*Calamagrostis Arenaria*) and the Bermuda grass (*Cynodon dactylon*), both of which have been entirely successful in holding the loose sand. I would plant the Sea Bent in the most exposed places and the Bermuda on the protected slopes. We plant in rows one and one-half to two feet apart and one foot deep. Where practicable, the plow is used, dropping the roots in each alternate furrow. Where the dunes are too steep for plowing, pits are dug with the spade, and, after planting, the sand is trodden firmly with the foot. The plantations have to be examined after heavy wind-storms to replant any roots exposed by the wind. If seeds only can be procured, I would suggest that they be sown in nursery rows and the plants set out the following season." Of course, there are also many shrubs used, and the nursery at the park has propagated a vast number of the *Leptospermum* and other shrubs which have been found serviceable.

The Nation's Forests.

EARLY in the present year we suggested a plan for the protection and care of the forests situated upon the public domain of the United States, and the property, therefore, of the people. Our suggestions were widely discussed at the time by the press of the country, and received hearty support and endorsement. They were briefly these:

First. That the government should at once withdraw, temporarily, from public sale and entry all its lands upon which forests are growing.

Second. That officers and men should be detailed from the army to protect these forests from fire and theft, as far as it is now practicable to do so, until a permanent forest-organization can be established by the government of the United States.

Third. That the President of the United States should be authorized to appoint a Commission of enlightened men to study the general forest-problem in all its relations, and to present to Congress a scheme of national forest-control and administration.

The American Forestry Association, a body of men and women familiar with the requirements of forest-administration, at its recent meeting in Philadelphia, adopted a resolution, introduced by Mr. B. E. Fernow, embodying the essential features of our plan, and appointed a committee to urge upon the government the necessity of considering this matter. This action of the Forestry Association is important. It brings the whole subject directly to the attention of the President and of Congress in a way which cannot be overlooked. The fact that a simple and economical plan, approved with hardly an exception by the press of the country, has the unanimous support of those persons who possess special knowledge of our forests, and look at them unselfishly and from a national point of view, marks a decided step forward. It is settled, at least, that there is to be concerted action. But it is only a step. Resolutions will not save forests; nor the wisest utterances of the press excite Congress to action. A beginning has been made, and a very good one, but it is only a beginning, and the really hard work is yet to be done. There are still serious

difficulties to overcome before even the most primitive measures of forest-conservancy can be adopted in this country.

The great mass of the people of the United States are ignorant of the history, the requirements and the uses of forests; and are slow, therefore, to respond to appeals made to them for sustained efforts to overcome the indifference of Congress. The number of men and women who know that the prosperity of the country is bound up in its forests, and who are willing to devote their time, labor and money to the promulgation of this fact, is comparatively not large. They live, for the most part, remote from the forests they would see the government preserve. Their interest in these forests is not a personal interest. These far western forests might perish and there would be no perceptible change in the prosperity or in the surroundings of nine-tenths of the people who are now most interested in their preservation. This interest may be a sentimental one, but it is none the less real. It is of that character from which political and economical reforms have sprung, and it is a hopeful and encouraging sign of our national progress that there are men and women in this community who are willing to lend themselves unselfishly to a cause which promises no immediate or personal returns. Opposed to them are men of a very different stamp. These live by despoiling what the others would preserve. They are on the ground; they live upon the forests. Any action of Congress which would check or control their operations in the forests of the public domain would affect at once their personal interests and prosperity. Among these men are some who buy legitimately timber lands from the government and turn the timber into money; others live by pillaging the timber, either openly or under cover of inadequate and badly administered laws. Others, like the shepherds and hunters of California, destroy the national forests for the accomplishment of their own selfish purposes. These various interests are well organized; and the men who live on this accumulated wealth of the nation can afford to pay handsomely to preserve government indifference. They will oppose before Congress, in every way in their power, every effort which can be made to change the laws under which the public lands are administered and disposed of. The opponents of a system of forest-conservancy in the United States have already shown what they can accomplish. There was a bill before the last Congress to make certain changes in the laws under which national timberlands could be disposed of. It proposed to sell the stumpage with certain proper conditions, but not to sell the land. The bill never had the slightest chance. It was killed finally by a member of Congress from Alabama, on the ground that it would work injustice and injury to the people of his state. The truth was that the people of Alabama and of the neighboring states of Mississippi and Florida had been plundering, in one form or another, the public domain for years, and that any change of the law would affect seriously the interests of influential citizens.

It is a difficult matter to oppose successfully all the different interests which have come into existence because the government of the United States has allowed its forests to perish rather than to make a serious effort to protect them; but now that a plan of action has been adopted by the Forestry Congress to which no unselfish opposition can be made, there is at last something definite to work for. The next step to be taken is to increase the popular knowledge of the forest and of its importance, that Congress, influenced by popular demand, may be induced to consider seriously a national system of forest-management; and then the matter being once fairly before Congress, a fight must be made between the people on the one side and a well organized and well equipped body of interested men on the other. There is no doubt which side will win in the long run, and there would be no grave apprehension of ultimate success if forests, especially in dry regions like western America, once destroyed could be restored. But in the case of these western forests delay is fatal, and the fact that they may be exterminated before

we are prepared to preserve them is the serious danger the advocates of forest-preservation have to encounter. More real progress, however, has been made during the past year than has been made before, and this fact is at least hopeful. It now remains for the members of the Forestry Association to put forth their best efforts and use all their influence to carry out the work they have begun so successfully.

Holiday Notes in Southern France and Northern Italy.—III.

AFTER Turin, nothing of importance or of much interest was noted until Vercelli was passed, where a long hedge or two of *Hibiscus Syriacus* furnished lines of bright color as the train passed along. In England this beautiful shrub flowers too late in the season; and generally before the blossoms have had time to open fully, they are destroyed by the cold and wet of late autumn. On the left, after crossing the Sesia, the Alps come into view, the magnificent Monte Rosa group being the most conspicuous. In the neighborhood of Magenta, large tracts of low lands—under water for two months in the year—are devoted to the cultivation of Rice, the cutting of which had commenced the first week of September. The drier spots—after the Rice district was passed—were planted with endless rows of pollarded White Mulberries; the importance of the silk industry to this part of Italy being indicated by the vast extent of land covered by these plants. Between the rows Indian Corn, and occasional Vines, were grown. In the region about Brescia, beautifully situated at the foot of the Alps, Vines were trained to climb tall trees, the long canes being festooned from one stem to another, usually at a sufficient height above the ground to allow of plowing underneath them. Various trees were used as Vine-supports; among them we noticed the Walnut, Maple, White Mulberry and Manna Ash (*Fraxinus Ornus*). Contrary to our expectations, we saw but few so-called Lombardy Poplars in the plains of Lombardy. The White Willow (*Salix alba*) and the Black Italian Poplar (*Populus nigra*) were, however, very common. In a few barren looking places—and these were by no means frequent in the fertile, well cultivated plains—a little color was afforded by a pretty pink flowered *Epilobium rosmarinifolium* (a really pretty plant for the herbaceous border), and one of the Evening Primroses (*Oenothera biennis*). Giant plants of Hemp occurred as weeds here and there in the fields of Maize, amongst which, too, pumpkins of huge dimensions were conspicuous by reason of their bright color.

At Desegnano, at the south-west angle of the Lago di Garda, the largest of the north Italian lakes, an admirable survey of that beautiful stretch of water was obtained. A few miles further, near San Martino delle Battaglie, on the right, is the monument commemorating the battle of Solferino. Fine groups of Cypress (*Cupressus sempervirens*), the form with a compact, flame-shaped habit, surrounded the monument and constituted a striking feature in the landscape; the battle field itself is some five miles away. Verona, next to Venice the principal town in Venetia, is situated at the base of the Alps; Cypress of large size, standing out clear against the sky on the hill-sides, are the most striking objects in the landscape. At Padua, close to the station, *Photinia Lindleyana* has attained tree-like dimensions, and must be a fine sight when in flower. To the left the Tyrolean Alps are visible in the distance, and the traveler is fully occupied with far-away views until Venice, coming into sight, claims all his attention, with its dark blue line of towers and churches rising from the sea.

After consulting guide books as to the location of the Botanic Garden and engaging a gondola, we passed through the Grand Canal, by churches and palaces far too numerous to remember, and through narrow, dirty water-ways, and landed close to the church of San Giobbe, adjoining which (Bædeker had informed us) "is the entrance to the former Botanical Garden, famed for its gigantic Cacti, and now a nursery garden." Instead of a nursery, however, we found a machine factory at work, and although through the half opened door we could see some of the old trees still standing, the doorkeeper refused to allow us to enter the premises without permission from the Direction. He informed us, however, that the Botanical Garden had been removed to a spot near the Abbazia della Misericordia, and so we again journeyed on—through the Ghetto, by no means so squalid and unlovely a quarter as the lower parts of many cities we have seen—by lonely, deserted canals until we reached our destination. A ring at a door in a blank wall by one of the officious idlers who seem to swarm everywhere in Venice, and we were admitted into what at first

we refused to believe was the Botanic Garden. A small square piece of land with a few fruit trees, a few annual and perennial flowering plants, a few vines, gourds, etc., evidences of neglect at every corner; this was the spot we had spent so much time and trouble to visit! The only interesting objects were a huge bush of *Jasminum grandiflorum* in flower, planted out in an open-sided conservatory, and a finely flowered example of *Ipomœa pandurata*, here grown under the name of *I. bulbosa*. The Jasmine is largely grown in Belgium as a winter flowering pot-plant for the English and French markets.

We saw singularly little vegetation on the walls skirting the numerous canals through which we passed; the Pellitory (*Parietaria officinalis*), common throughout Europe, and the Samphire (*Crithmum maritimum*), the fleshy leaves of which are made into the well-known pickled condiment, were the most common. Here and there *Campanula pyramidalis* was conspicuous, with its somewhat strict panicles of handsome blue flowers. None of the white flowered form was seen.

The Giardino Reale, prettily situated on the edge of the lagoon beyond the south end of the Grand Canal, can boast of some fine trees. Among the best are large-leaved Privets (*Ligustrum lucidum*), *Paulownia imperialis*, *Lagerstrœmia Indica*—in flower at the time of our visit—*Magnolia grandiflora*, Deodar (*Cedrus Deodara*), *Kœlreuteria paniculata*, with its large, spreading, upright panicles of red, bladderly fruits, and the Judas tree (*Cercis Siliquastrum*). The turf was thin and poor and the grass long and neglected, giving the whole place an untidy aspect.

The Giardini Pubblici are situated at the extreme south-east of Venice, and are most expeditiously reached by small steam launches, which run at frequent intervals from the grand canal. They were laid out under Napoleon I. in 1807, on space obtained by the demolition of several monasteries. Here many trees and plants of interest were noted. From Garibaldi's statue—on the base of which the Maidenhair (*Adiantum Capillus-veneris*) was growing, apparently self-sown—runs an avenue of Locusts of a curious form. The terminal leaflets on these trees were much developed at the expense of the lateral ones, which were most frequently altogether suppressed. This tree, smaller than the type, is common in European nurseries under the name of *Robinia monophylla*. In the shrubberies on each side of this avenue are huge bushes or small trees of *Ligustrum lucidum*—one of the most valuable evergreens in southern Europe—*Photinia serrulata* and *Euonymus Japonicus*—green-leaved, golden and silver variegated forms, all fruiting freely. The Paper Mulberry (*Broussonetia papyrifera*) here attains a large size. In open spots were splendid bushes of Oleander (*Nerium Oleander*) in full flower, masses of the brilliant scarlet *Salvia splendens*, the gorgeously colored *Amaranthus tricolor*, about nine feet in height, *Canna Ehemanni* in fine flower, and a glorious mass of *Ipomœa Quamoclit*. Roses, with a crop of funnel-like pieces of zinc (fastened round the shoots) filled with soil and covered with moss to retain the moisture, had a strange appearance. This clumsy method of propagation we saw practiced in many places during our wanderings. Results must have been equally good and the labor involved in watering not nearly so great had the bushes been layered in the ground (the layering done in plunged pots if desired), after the common English plan. *Sophora Japonica*, a tree perfectly hardy and free flowering in England, was conspicuous by reason of its long, constricted, bead-like pods; in Great Britain our summers are neither hot enough nor long enough to allow of its fruiting. *Buddleia Lindleyana*, a graceful and pretty shrub, is here quite at home; in England it is killed in most places every few years unless grown against a wall in a sheltered spot. A group of Pines, with *Wistaria Sinensis* climbing among the branches high above the ground, looked picturesque, the light green of the climber contrasting markedly with the dark green of the Pine needles. *Pittosporum tobira*, a Chinese plant with very fragrant white flowers, grows as freely here as does the Cherry Laurel in England, and the commonly cultivated green-house plant, *Habrothamnus elegans*, produces its red-purple panicles in great profusion as a shrubby plant in the sunny south. A few very fine *Libocedrus decurrens*, *Melia Azedarach*, *Albizia Julibrissin*, *Eriobotrya Japonica*, groups of *Celtis australis*—the Micoucoulier of the Provençal poets—a massive belt of *Ruscus hypophyllum*, larger than we ever saw it in England, nearly complete the list of trees and shrubs which we saw in this place. The general condition of the park was hardly satisfactory; each shrub or tree was allowed to struggle for light and air unheeded, and strong growing trees, such as Poplars—altogether out of place in restricted areas—were killing really good plants. No thinning or pruning seemed to be

practiced, and, in some cases, a regular jungle of miserable specimens was the result.

In the Venice market, one much cleaner, more spacious and better arranged than those of some larger cities, fungi, of species and genera eaten elsewhere by only a few enthusiastic fungophagists, were offered in quantity, each seller exhibiting a stamped official certificate of the day's date to the effect that his fungi were wholesome and that he was authorized to sell them. Many Cucurbits, never grown in Great Britain as articles of food, were here, such as Hercules' Club (*Lagenaria gigantea*), the Bottle Gourd (*Lagenaria vulgaris*), *Momordica Charantia*, spiny and green outside, bright red within; and perhaps Pumpkins should also be included in this category. Of this last named vegetable quite a bewildering variety in color, form and size were offered for sale. Baked pumpkin formed the whole stock in trade of many peripatetic merchants, and so did boiled sweet potatoes. Figs of excellent quality were abundant at a penny per pound, good apples brought the same price, and peaches, in enormous quantities, were offered at threepence per pound. Pungent green (unripe) capsicums and yellow sweet ones were marked a penny a pound, and shelled haricot beans, in variety, at low prices. Aubergines, pomegranates, with branchlets attached, the fruits of the Service tree (*Pyrus Sorbus*) and watermelons complete the list of fruits. Excellent vegetables were plentiful, endives showing remarkably good cultivation. Celery was, however, quite green. Apparently not the slightest attempt is made to bleach it.

The Art of Gardening—An Historical Sketch.

XII.—Roman Country-Seats.

WHEN we pass from the Imperial City and its suburbs to the country-seats of its wealthy citizens, we find something radically novel and national. All communities had possessed sacred groves and small gardens of utility and ornament. The Phœnicians had dwelt in suburban villas. The Persians had created wide semi-natural parks, and the Greeks had owned urban pleasure-grounds, most splendidly developed, in such late colonies as Alexandria. But in the latter days of Rome, private citizens seem first to have established themselves in numbers in distant country-seats, marked by an almost impossible luxury in the way of architectural and of natural or semi-natural beauty. Here, once more, we read in the history of gardening a reflex of the social conditions of the place and time. Rome's unprecedented power, gained while the Republic still existed, had brought enormous piles of gold into private coffers, and wealth, authority and travel had united to develop intelligence and taste. Then, when political changes put imperial masters over those who had ruled themselves, they were more and more strongly impelled to flee from the court where their minds and tongues were fettered; where their conscience was perpetually outraged, and where their bodies were often in danger, too. It was frequently the part of wisdom to seek retirement in the country; and we can easily see how its attractions must have perpetually appealed to highly cultivated men, not yet weaned from ideas of freedom, and able to surround themselves, in the heart of Tuscany or by the shores of Como, with all the comfort and splendor of Rome itself.

Fortunately, detailed descriptions of some of these great Roman country-seats have come down to us from the pens of their enthusiastic owners. In a letter to Gallus, Pliny, the younger, speaks of his villa at Laurentinum, on the sea-coast, seventeen miles from Rome, portraying its position close to the water; its little garden with Box-hedges, patched with Rosemary where the salt air had killed the Box; its tennis-court; its long *pergola*, with a sanded path, so smooth that one might walk upon it barefoot; its isolated banqueting-room above the shore, and its Fig and Mulberry trees.

But he paints a much more splendid picture when, writing to Apollinaris, he describes his larger estate in Tuscany. It lay at a "great distance from the sea, under one of the Apennine mountains." The climate was so cold in winter that Myrtles and Olives would not flourish; but the summers were "exceedingly temperate." The view is dwelt upon at length, with its distant mountains in forest, and its nearer fertile little hills, its plains covered with vineyards, "terminated by a border, as it were, of shrubs," its "never-failing rills," and the infant Tiber traversing the plain. The house need not be described. Its principal front looked full south, and was adorned with a spacious portico. "In the front of the portico is a sort of terrace, embellished with various figures, and bounded with a Box-hedge, from whence you descend by an easy slope,

adorned with the representation of divers animals in Box, answering alternately to each other, into a lawn overshadowed with the soft, I had almost said, liquid Acanthus. This is surrounded by a walk enclosed with tonsile evergreens, shaped into a variety of forms. Beyond it is the *Gestatio*, laid out in the form of a circus, ornamented in the middle with Box cut in numberless different figures, together with a plantation of shrubs, prevented by the shears from running up too high. The whole is fenced in with a wall covered by Box, rising by step-like ranges to the top. On the outside of the wall lies a meadow, which owes as many beauties to Nature as all I have described within does to art, at the end of which are several other meadows and fields interspersed with thickets." The dining-room was at one extremity of the terrace, commanding a beautiful outlook. Near it stood a small isolated structure shaded by four Plane trees, in the middle of which rose a fountain with a marble basin, the overflowing waters from which kept the Planes and the lawn fresh and green. This building contained a private dining-room and bed-chamber, and was faced by another portico, another little room, lavishly adorned, and another fountain. After describing other portions of the house—private rooms, hot and cold and tepid baths and enclosed porticoes, one "resembling a grotto"—Pliny says: "In front of these agreeable buildings lies a very spacious hippodrome,* entirely open in the middle, by which means the eye, upon your first entrance, takes in its whole extent at one view. It is encompassed on every side with Plane trees covered with Ivy, so that while their heads flourish with their own green, their bodies enjoy a borrowed verdure; and thus the Ivy twining round the trunk and branches, spreads from tree to tree and connects them together. Between each Plane tree are planted Box trees, and behind these Bay trees, which blend their shade with that of the Planes. This plantation, forming a straight boundary on both sides of the hippodrome, bends at the farther end into a semi-circle, which, being set round and sheltered with Cypress trees, varies the prospect and casts a deep and gloomy shade, while the inward circular walks (for there are several), enjoying an open exposure, are perfumed with Roses, and correct, by a very pleasant contrast, the coolness of the shade with the warmth of the sun. Having passed through these several winding alleys you enter a straight walk, which breaks out into a variety of others, divided off by Box-hedges. In one place you have a little meadow; in another, the Box is cut into a thousand different forms—sometimes into letters, expressing the name of the master, sometimes that of the artificer, while here and there little obelisks rise intermixed alternately with fruit trees; when on a sudden, in the midst of this elegant regularity, you are surprised with an imitation of the negligent beauties of rural nature, in the centre of which lies a spot surrounded with a knot of dwarf Plane trees. Beyond these is a walk interspersed with the smooth and twining Acanthus, where the trees are also cut into a variety of names and shapes. At the upper end is an alcove of white marble shaded with vines, supported by four small Caryatan pillars. From this bench the water, gushing through several little pipes as if it were pressed out by the weight of the persons who repose themselves upon it, falls into a stone cistern underneath, from whence it is received into a fine polished marble basin, so artfully contrived, that it is always full without overflowing. When I sup here this basin serves as a table, the larger sort of dishes being placed round the margin while the smaller ones swim about in the form of little vessels and water-fowl. Corresponding to this is a fountain which is incessantly emptying and filling; for the water, which it throws up a great height, falling back again into it, is, by means of two openings, returned as fast as it is received. Fronting the alcove (and which reflects as great an ornament to it as it borrows from it) stands a summer house of exquisite marble, whose doors project and open into a green enclosure, as from its upper and lower windows the eye is presented with a variety of different verdures. Next to this is a little private closet (which, though it seems distinct, may be laid into the same room), furnished with a couch, and, notwithstanding it has windows on every side, yet it enjoys a very agreeable gloominess by means of a spreading vine which climbs to the top and entirely overshades it. Here you may lie and fancy yourself in a wood, with this difference only, that you are not exposed to the weather. In this place, also, a fountain rises and disappears; in different quarters are disposed several marble seats, which serve no less than the summer-house as so many reliefs after one is wearied with walking. Near each seat is a little fountain, and throughout the whole hippodrome several small rills run wheresoever the

* *Circus* and *hippodrome* have not in these descriptions their primitive Greek meaning, but denote ornamental spaces, surrounded by walks or drives.

hand of art thought proper to conduct them, watering here and there different spots of verdure, and in their progress refreshing the whole." Does the reader wonder, although only the grounds, and not the splendid house itself, have been portrayed, that Pliny had a "very great passion for this villa," which, he says, "was chiefly built or finished" by himself? Or does he marvel that when the great Renaissance of art in Italy occurred centuries later, Pliny's description found a score of commentators and illustrators on paper, or that numerous attempts were made to reproduce the beauties it portrayed?

New or Little Known Plants.

The Japanese Flowering Apple.

THERE appeared on page 260 of the present volume, among the notes of our correspondent at the Arnold Arboretum, an account of the different varieties of ornamental Apple-trees cultivated in that establishment.

No description, however, can give even a faint idea of the wonderful beauty of these plants at their flowering-time, and even the most successful picture fails to show the delicate coloring of the masses of bud and bloom which smother the branches in early spring. One of the most beautiful of these small Apple-trees is that Japanese variety of *Pyrus baccata*, brought by Von Siebold to Europe, and known generally in nurseries as *Pyrus Malus floribunda*. Our illustration, made from a photograph of a tree of this variety which grows in a garden near Boston, shows the habit this plant assumes when it is nearly fully grown, with its long, spreading or upright, wand-like branches and its countless clusters of flowers. The trees are even more beautiful before the flowers are all expanded, as they were when our picture was made, and when the bright red flower-buds mingle and contrast with the pure white petals. There is no tree more beautiful in bloom than this Apple, and none better suited for planting on the margin of a large shrubbery or as a single specimen on the lawn or in a small garden. There is no question of its hardiness; it grows, in good soil, with great rapidity, and it flowers year after year with always increasing profusion.

Entomological.

A Destructive Cornel Saw-fly.

(*Harpiophorus varians*, Norton.)

DURING the past two or three years great injury has been done to the foliage of several species of Cornus by white saw-fly larvæ, which, until the past summer, have remained undetermined. These insects have been especially destructive at the Arnold Arboretum and in its immediate vicinity; but, at other places for twenty miles or more from Boston, their work has been apparent. Indeed, the abundance and destructiveness of these larvæ have caused some people to hesitate about planting specimens of Dogwood for ornament, since, by the end of July or early in August, the plants are apt to be either entirely defoliated or to have their foliage so badly eaten as to become very unsightly. Specimens of the larvæ had been sent to various entomologists for determination, but without result; and other specimens kept in confinement had passed the last moult, but died during the winter or spring without pupating. Early this spring, however, upon breaking a piece of partly decayed wood picked up in the vicinity of Cornus bushes, I found a number of these larvæ within it. Many of them had made tunnels from one to several inches in length, the longest borings being in the most decayed portion of the wood. When taken out and exposed to warmth and light the larvæ moved in a sluggish manner.

Several pieces of wood containing these larvæ were collected and placed in a tight box to await further developments. In the latter part of May the larvæ began to pupate, both in the wood and on the bottom of the box, without making any cocoons, and in a short time the saw-flies began to emerge. The insect proved to be *Harpiophorus varians*, described by Edward Norton as early as 1861 (*Proc. Boston Soc. Nat. Hist.*, vol. viii., p. 156), from specimens collected at Farmington, Connecticut.

The saw-flies were seen flying about the Cornels in the

Arboretum during the first week of June. On June 10th the first eggs were discovered and within a few days they were quite abundant. The eggs are pale green, oblong, and about four one-hundredths of an inch in length. They are deposited singly within the tissue of the leaf on the upper side. From one or two dozen to three or four hundred eggs may be deposited within a single leaf without any very definite order, although most of them are usually disposed in lines parallel with the midrib, or with the principal veins. Each egg makes a little swelling, noticeable on both the upper and the under sides of the leaf, and, with a little practice, egg-bearing leaves may be readily detected.

On hatching, the larvæ emerge on the under side of the leaf. They are then about six one-hundredths of an inch long and pale green in color, with yellowish head and black eyes. When at rest they keep close together, coiled up on the under side of the leaves; and they appear to feed only in the cooler parts of the day, in cloudy weather, or perhaps at night. Of the first leaves attacked, they eat only the more tender parts, and the leaves are left somewhat skeletonized; but as the larvæ get older they devour every part of the leaf down to the midrib. After the first moult, when they are about twelve one-hundredths of an inch long, the larvæ secrete a peculiar, very white efflorescence, by which the back and sides become covered. This is constant after each moult until the last.

This efflorescence is removed by the slightest touch, and when brushed off, the color of the body is a pale greenish white. The head, after the first moult, is black, and the legs and under side of the body yellow. At full growth the average length of the larvæ is about an inch. Some are smaller than others, however, and this possibly indicates the difference of sexes.

When the larva has cast its skin for the last time a complete and surprising change has taken place. All trace of white is gone, and the body is greenish yellow on the back and yellow beneath and along the sides below the spiracles. On each segment along the back are two large and two small black spots, and upon the sides, close above the spiracles, is a row of nearly square, black spots, one for each segment, but so placed as to lap over from one segment to the next.

The terminal plate above the ventral segment is black. The legs and prolegs are yellow, the former having a reddish spot on the outer side near the base. The tips of the claws are black. The great change produced by the last moult has led some observers to suppose that there are two distinct species.

Full growth is attained by most of the larvæ early in August, but some may not reach maturity until much later, and this season a few were noticed to pass the last moult about September 20th. The season last year was not so advanced, and, in some places, large numbers of larvæ were found in September. The larvæ eat very little after the last moult, and very soon they leave the plant and wander away in search of suitable places in which to hibernate. Stray pieces of decaying wood, fence posts and rails, dead branches and the corky bark of old trees are selected. In the Arboretum, many were found even boring into the soft pith of dead stems of Elder bushes. Sometimes two or more occupy one burrow. It is quite possible that some larvæ go into the ground to hibernate, but none have been discovered there.

Specimens confined in a large glass jar refused to enter some soil placed at the bottom, but when pieces of soft wood were put within reach the larvæ eagerly bored into them, and a number also disappeared within the cork stopper of the jar. Once in their burrows, the larvæ become much contracted, and remain so until pupation, which usually occurs only a week or two before the perfect insects appear. The males of the latter are considerably smaller than the females, and in the shape of the abdomen they are less pointed, but, otherwise, they closely resemble the females. These may be identified by the following characters: The abdomen is flattish and reddish brown, sometimes quite dark; the thorax and head shining black; the antennæ, about a quarter of an inch in length, have the three basal joints rusty colored, the fourth and fifth joints black, and the four terminal joints white or yellowish white. The first two pairs of legs are white at the base, the femora are black and red, the tibiæ and tarsi light brown, the latter often very light. The last pair of legs are usually white at base of femora, the rest being black or reddish and tipped with black; the tibiæ are red tipped with black, and the tarsi very light brown or yellowish white. The wings are clear, the outer half having a brownish or smoky tinge, and they expand nearly three-quarters of an inch in the males and almost an inch in some of the largest females. In length the bodies of the former are somewhat more than one-third of an

inch, and those of the latter a little less than one-half of an inch.

In a revision of the saw-flies (*Trans. Am. Ent. Soc.*, vol. i., p. 236), published in 1867-68, the habitats given are Connecticut, New York, Virginia and Illinois, showing that its known range at that time was widely extended.

The best, cleanest and most effective remedy we have tried is the powdered white hellebore. An application of this powder upon the foliage of infested plants soon caused the ground beneath to become covered with dead and dying

that the family to which it belonged was not ascertained.

Much good service seemed to be done by several species of bugs belonging to the family of *Pentatomoidæ*, which attacked and destroyed many larvæ, in the imperfect and mature stages, by perforating them with their slender beaks and sucking the juicy contents of their bodies. *Euschistus fissilis*, Uhler, and a closely related undetermined species, were especially noticeable, and *Negara hilaris*, Say, had the same habit, but was less common.

Fig. 138.—A Cornel Saw-fly—(*Harpiphorus varians*.)—See page 520.
Larvæ before and after last moult. Larvæ hibernating in decaying wood. Female Saw-fly, enlarged.

larvæ. Kerosene emulsion would, undoubtedly, also be effective, as well as Paris green and London purple. But careful experiments should be made with the arsenical remedies, to determine the dilution necessary to prevent injury to the foliage. Where there are but a few plants, the egg-bearing leaves, or the leaves upon which the young are clustered, might be picked off and destroyed. Among the natural enemies of the insect is a very minute fly, which was observed apparently in the act of ovipositing upon its eggs. Unfortunately, the specimen was lost, so

Two of the most beautiful of the species of *Cornus*—*Cornus florida* and *C. Mas*—have thus far escaped injury by these larvæ. *C. alternifolia* also has been untouched. But the foliage of *Cornus sericea*, *C. alba*, *C. stolonifera*, *C. paniculata*, *C. sanguinea*, *C. asperifolia* and one or two others has been greedily devoured. In this region groups of these plants often appear as if they had been visited by fire. The accompanying figure of *Harpiphorus varians* is from a drawing made by Mr. C. E. Faxon.

Foreign Correspondence.

London Letter.

THE event of the past week has been the great exhibition of vegetables at the Royal Horticultural Society's gardens, held in conjunction with a conference on vegetables. It was highly successful, there being a large concourse of visitors, chiefly practical gardeners, to witness a collection of vegetables that has probably never been surpassed in variety or quality in London. The remarkable point about this show was the fact that it had been organized and brought together without the aid of prizes or any reward whatever, beyond the thanks of the Society and the gardening public, so that it tends to prove that there is still abundant energy and resource among English gardeners in this direction, even if the Society itself is not flourishing as much as it did a generation ago.

I will not attempt to detail this enormous vegetable exhibition, because I think your readers are not interested enough in the sorts we grow, and, beyond the multitudes of varieties of every class of vegetables, I must confess that there was little that was novel or out of the ordinary run. I was on the lookout for something new, but failed to see the shadow of anything I had not seen before. I did not even see a dish of the new Chinese vegetable, *Stachys tuberifera*, or Spirals, as the tubers have been appropriately called. It was expected that there would have been a good show of Spirals, but somehow the public has not yet taken to them. Messrs. Vilmorin, the great seed-firm of Paris, showed a few things that seemed to attract everybody's attention, none more than the enormous Capsicums, named Large Bell and Golden Queen. Both these sorts had fruits quite four inches in length and as much across, the one being a bright red, the other a golden yellow. They are therefore highly ornamental and quite worth growing for decoration. There was a large collection of Capsicums from the same firm, but these were the most noteworthy. Messrs. Vilmorin also showed some varieties of Sweet Maize, which, to most people here, were novelties, and are quite likely to find favor if they can be cultivated. One called Extra Early Sweet Maize has a sweet, pleasant taste, even uncooked, and would be delicious after leaving the hands of a skillful cook.

Another novelty was the Melon Pear, an absurd name for the fruit of *Solanum Guatemalense*, which has recently been introduced, I believe, from the West Indies. It is a kind of Egg Plant, but I am told that the fruits, which are about the size and shape of turkey's eggs, and ivory white, are delicious in flavor and suitable for a dessert fruit. It requires to be grown, no doubt, in stove heat.

It will give you some idea of the exhibition when I state that the "Committee of Selection" awarded considerably over 200 certificates of merit to as many varieties which were necessarily not all new, but were selected for first rate quality. The certificate is intended to be a stamp of excellence, so that the public may have some authoritative and independent assistance in making selections. The reports of the committees will be published in a convenient form in due time, and they will undoubtedly be valuable, particularly to amateurs who do not employ professional gardeners. Though September is, on the whole, the best time of the year for a vegetable exhibition, the summer vegetables, such as Peas and Beans, could not be well represented, which was to be regretted.

A conference of growers and others interested in vegetables was held on each day during the exhibition, and the papers read and discussed were all of a practical nature, and they will, like the report, furnish sound information on their respective subjects when published. Among the papers were those by Shirley Hibbard, on Asparagus culture; H. J. Veitch, on the production of new varieties, which was supplemented by good information on the subject by H. Vilmorin, of Paris. Others read papers on Salads, food of plants, improvements in Peas (by the well-known raiser, Laxton, of Bedford), improvement in Potatoes, and on the supply of vegetables for a large family all the year round. All these papers, and the discussions thereon, will be awaited with great interest by gardeners.

During a walk round Kew Gardens to-day, in search of novelties, I came across several most interesting plants in bloom, and the one that most attracted me was Pringle's new Tiger Flower (*Tigridia Pringlei*). It was in full bloom in company with its well-known relative, *T. Pavonia*, from which, however, it may be distinguished at a glance although there is similarity between them. Botanically, the two plants may be distinguished from each other by the different form of the petals and other parts of the flower, besides other less ob-

vious characters. From a garden standpoint it is quite an acquisition, because of its very brilliant color, the sepals being as bright a scarlet as it is possible for a flower to be—so bright, indeed, that the old species and its varieties are dull in comparison with it. Its growth is also dwarfer. The figure given of it in GARDEN AND FOREST admirably represents the plant. The bulb nurserymen are already inquiring for it, as they recognize in it "a good thing."

Another first-rate open-air bulb is the still rarer *Crinum Powellii*, a very beautiful hybrid variety, raised some years ago by a Mr. Powell, who hit upon the happy idea of intercrossing the common *C. Capense*, which is quite a hardy semi-aquatic plant with us, and the much more tender and far lovelier *C. Moorei*. The result of this cross is a plant possessing the hardiness of *C. Capense* and the splendid flowers of *C. Moorei*. In fact, some think that Powell's hybrid is even finer in flower and color than its tender parent. I saw it the other day in an open-air border in a cold part of Sussex, where it had wintered two years and was this season very robust. It had a stem a yard high and bore a half dozen very fine flowers, sweetly scented and of a deep rose pink. The leaves are as narrow as those of *C. Capense*, and it flowers continuously for six weeks. It is decidedly a plant to make a note of, and I believe it would be perfectly hardy in America.

W. Goldring.

Cultural Department.

Rot in Iris Germanica.

IN the cultivation of *Iris Germanica*, which has fleshy, running root-stocks, it is not rare to find a more or less extensive rotting of the root-stocks. The rot renders the affected portion soft and mushy; white, not changing the natural color, and highly offensive. Any portion of the root-stock may be affected, but it is more commonly the older portion, the newer, growing tips being freer from attacks. A large number of maggots were found in the rotten portion of some plants. On showing these to an entomological friend, he said they were the larvæ of a fly which lays its eggs in decaying tissue, and they were to be considered as an effect, not a cause, of the decaying condition.

During the past wet summer serious attacks of rot were seen in some instances. In a friend's garden, in June, large, established clumps of *I. Germanica* were literally rotted away at the roots, so that large masses could be pulled up by a slight twitch of the yellowish, sickly looking leaves. This garden is situated in strong loam in rather low-lying flat land. My own collection, consisting of about one hundred and fifty plants, is growing on a slight slope on strong loam with a sandy subsoil. A few of my plants were badly affected with rot, but none died. Most plants on examination showed slight or considerable injury in June, but have since recovered, and in transplanting them recently all were in good condition, slight traces of rot only being observable. Besides *I. Germanica*, many closely allied species having similar fleshy root-stocks have been observed to show indications of rot similar to that above described; but I have seen no such indications in bulbous species, or species like the *I. lavi-gata* (*Kämpferi*), which have dense, tough, abbreviated root-stocks.

The remedy to apply appears to be removal to a drier, well drained soil, where these Irises will thrive. An occasional extra wet season like the present one will cause some injury in almost any spot; but as the decay is due to super-moisture rather than disease, serious losses need hardly be feared if a suitable situation is selected. In winter it is best to protect German Irises with a light covering permitting a free circulation of air to prevent the retention of moisture. Evergreen branches or salt hay are desirable, as they lie loosely and do not easily rot.

In importing Irises with fleshy rhizomes from Europe I have met with some quite heavy losses, and have seen frequent damage from rotting, doubtless on the journey; whereas other roots, such as Narcissus, Tulips, etc., in the same package with the Irises, have been, in the instances observed, in a perfectly sound condition. It would be a great advantage to purchasers if dealers, in sending such Irises for any considerable distance, would make sure that they are perfectly dry before packing, and then pack them in well dried material. Peat would be desirable for a packing material in such cases, as its antiseptic properties would tend to counteract rotting. A preliminary artificial drying of roots and packing might even be desirable.

Boston.

Robert T. Jackson.

Plants for Forcing.

UNDER this heading it is not intended to present a catalogue of plants suitable for forcing for winter flowers, but rather to call attention to a few well known species as a reminder of the preparatory work, necessary at this season, to get the stock in proper condition for future operations.

The forcing of various plants for winter bloom has been much practiced in the past few years, not only among commercial growers but also in private establishments, and, in consequence, the demand for bulbs, hardy shrubs and other plants for this purpose has largely increased, though it may be said that among commercial growers, at least, the forcing of bulbs seems to have been overdone, and the inevitable reaction appears to be setting in.

This, however, does not affect the utility and propriety of forcing these plants for house decoration, for cut flowers, or

common with all bulbous plants for winter use, it should make the roots first, before the top begins to grow. Otherwise the growth will be weak and the flowers few.

With the Lilies this root-growth may be secured by placing them out in a cold frame after potting, and plunging the pots in coal-ashes, sand or soil, as may be most convenient. They should be allowed to remain in this condition until active root-growth takes place (usually in three or four weeks after potting). They may then be brought into a temperature of fifty-five to sixty degrees, until the flower-buds begin to form, when the temperature may be increased from ten to fifteen degrees without injury to the plants. In fact, I have known *L. longiflorum* flower very well after it had been subjected to a much higher temperature than this.

In potting these Lilies any good loam may be used, with the addition of some short, thoroughly rotted manure, and if

Fig. 139.—Japanese Flowering Apple.—See page 520.

to brighten up the conservatory during the dull days of winter; and it is to this end that the following suggestions and remarks are offered.

In a very prominent place among plants for this purpose is found *Lilium longiflorum*, and also the so-called Bermuda Lily, *L. Harrisii*, the latter being best for early forcing, though *L. longiflorum* will fully repay those patient enough to wait until later in the season for its lovely blossoms, as they have more substance, and, consequently, last longer than those of *L. Harrisii*. The flowers of the latter, however, are larger and are produced in greater profusion.

If required for an early crop, say about the holidays, *L. Harrisii* should be potted in August, so that it may become well rooted before it is brought into the hot-house, as, in

the soil is very heavy, enough sand should be added to render the mixture open, the fact being kept in mind that these plants prefer a tolerably rich compost. As the plants should not be repotted after active growth has commenced, they should be put in pots large enough to contain sufficient nourishment to mature the flowers, with a little assistance in the form of liquid manure at intervals after the flower-buds appear.

For a fair sized bulb of *L. longiflorum* (from six to eight inches in circumference), a six-inch pot will be large enough, but if the bulbs are larger it will be necessary to use eight-inch pots for them, to prevent their becoming starved and losing some of their lower leaves before the flowers are ready to open. The drainage of the pots must be kept in good order, for while enjoying an abundance of water when

making their growth, the roots soon suffer if the soil becomes sodden.

If lifted plants of *Deutzia gracilis* are to be used for forcing, it is now time to secure them, so that they may be potted or planted in boxes and stored away in a cold frame until needed.

This *Deutzia* is among the easiest plants to force, but, if used to any great extent, it is better to grow it in pots for this purpose. If the plants are plunged out-doors in summer they need but little attention. By growing them in this manner the roots are well established, and, in consequence, finer flowers are produced. Besides, the flowers last longer than those on plants which have been lifted from the open ground in the fall and potted up. Some shapely little Lilacs in pots will also make charming objects for conservatory decoration, and these may be readily forced in a Rose house, after they have been treated in much the same way as the *Deutzias*.

Imported clumps of *Astilbe Japonica* are still used largely for winter and spring forcing, and are usually stronger and therefore better than home-grown plants. They should be potted up as soon as received (which is usually about the beginning of November), and require but little heat to start them into growth, though naturally they will not start in so short a time in midwinter as toward spring. Their feathery, graceful spikes of bloom are acceptable at any time, and form a welcome addition to almost any arrangement of cut flowers.

The *Astilbe* is of the easiest culture, the chief requirements for growing it being a light, rich soil, full exposure to sunlight and an abundance of water.

Holmesburg, Pa.

W. H. Taplin.

Water Cress Under Glass.

WATER CRESS is not, necessarily, a plant that can grow only in water; it can be grown from the same roots all winter by any one who can grow a plant. No special care or preparation is necessary. It thrives in cool green-houses, and will grow very rapidly in abundant heat. I have raised Water Cress in this manner for several years, and have it now ready for market, fresh, clean, tender, pungent, in sprays more appetizing than when it is taken direct from its home in or near running water. Cuttings or slips of Cress, preferably the terminal shoots, four inches apart, should be planted about September 1st in the green-house bench in rows five inches apart. The first cuttings are made in about one month or six weeks, leaving a long stub of the first growth and the root undisturbed, and from these will again start another growth, which can be gathered as before.

No special treatment is required. Any soil that will raise good Lettuce will raise Cress; any kind of fertilizer used for vegetables stimulates the growth of this plant; six inches of soil, which should be kept free from weeds, is deep enough for it to grow in.

It is tender in the winter months, and is much better when grown in this way. Those who have used Cress gathered in late fall or in early spring, have noticed the tough leaf and dark foliage of plants grown out-of-doors. No more water should be used than is necessary to keep the level ground damp, not wet.

It is a profitable crop to raise. I retail the strawberry baskets, in which I put the freshly-picked sprays, at ten cents each, and there are from three to five cuttings, according to the temperature at which the Cress is grown. It also grows well in frames, when the thermometer does not fall to thirty-two degrees; but if raised with heat, it grows more rapidly. I transfer my roots from the green-house to hot-beds in March or April, and there they continue their growth.

Any one having even the smallest space at command can grow Cresses. They will flourish in a box or large pot or vase, filled with rich earth, if the roots are strong, in a corner of the conservatory or in a sunny window, and yield a treat both to the sight and taste. Let those try it who love a healthful salad-plant.

West Springfield, Mass.

W. H. Bull.

Oxalis.—The genus *Oxalis* is a very large one. We are told by the most recent authorities that it contains upward of 220 species, one of which, the common Wood Sorrel of Britain, is often spoken of as the Shamrock, as it is found growing in great luxuriance in Ireland. We have seen it covering acres of ground in moist shady woods, and it is not a matter of surprise that the honor of being a "national plant" is sometimes accorded to *Oxalis acetosella*. Here in the eastern states we have also an *Oxalis violacea*, a very pretty plant, with a small bulbous root. It is very suitable for naturalizing in shady places or on rock-work, where the pale violet flowers present in spring a pleasing appearance. We have culti-

vated here for several years another charming species. This is *O. lobata*, a native of South America, and said to be hardy in England, but we have never dared to risk it out here during winter; and, moreover, the heavy rains would completely disfigure its delicate beauty, for foliage and flowers are borne on slender stems about four inches high. The flowers are the size of a dime and the brightest yellow imaginable. In the greenhouse this plant lasts for fully two months in bloom, with a constant succession of flowers. Another plant, *O. Bowei*, perhaps the showiest of the genus, deserves mention as an excellent pot plant. Its foliage is very large, often three inches across, and surmounted by a stem bearing flowers of a bright rose color. These, like all others of this family, close up in the evening to reopen the next day to the genial influence of light and warmth. *O. Bowei* is a bulbous plant also, and is increased rapidly by this means, for where one is planted now there will be five a year hence. After the leaves die down the bulbs should be kept perfectly dry until it is desired to start them again, and by judicious planting at intervals in rich soil, using six-inch pots for three bulbs, *O. Bowei* can be made to flower all through the dreary months of winter, and is a very suitable subject for conservatory or room decoration.

Passaic, N. J.

E. O. Orpet.

Orchid Notes.

Lælia grandis.—This very distinct and handsome *Lælia* first appeared in cultivation in 1849, when M. Morel, of Paris, received a few plants from near Bahia, Brazil, through M. Pinel. In May of the following year a plant flowered with him and was exhibited in London at one of the Regent Park shows. After this event, however, it seems to have disappeared altogether until about 1864, when Messrs. Low & Co. succeeded in importing a limited number of plants through their Bahian collector. Although lost so many years from cultivation since its first appearance, its name, however, was kept up, having been applied to a form of *Lælia purpurata*. Within the last few years *Lælia grandis* has been often imported, but never in very large quantities, and it is this fact which accounts for its scarcity even at the present day.

For the last two months and a half, plants of this species have been in flower here, and have been a great attraction. They have clavate, fusiform stems, which become furrowed when old, bearing a single oblong-elliptic, very leathery leaf of a deep green, while the peduncles which emerge from a large greenish sheath on top of the stem usually bear five flowers, each from four to five inches across. The sepals and petals are nankeen-yellow, the former being lanceolate-acute, wavy and recurved at the tips, while the latter are broader and more crisped on the margins. The trilobed, funnel-shaped lip is creamy white, suffused pale rose and conspicuously veined with purple lines which diverge on the anterior lobe. It might be mentioned that great variation in color exists in the flowers of this species as in others. Sometimes the sepals and petals are veined with purple, especially on the outer surface, while the color of the lip varies from very pale to deep rose-purple.

This species should be treated like *Lælia purpurata* in many ways and may be grown with that species. During the flowering season, which lasts from July to September, the plants require not too much water, although growing slowly. At the end of this period more rapid growth begins and consequently more attention to watering is necessary. Being a native of a warm, moist climate, the winter temperature should be about sixty or sixty-five degrees Fahr., and this may be allowed to rise several degrees during the spring and summer when the sun becomes more powerful.

Grammatophyllum Measuresianum (new species).—This remarkable species has been recently introduced from one of the Philippine Islands by Messrs. F. Sander & Co., St. Albans, England, and dedicated to R. H. Measures, Esq., of The Woodlands, Streatham. A great number of plants having been already distributed among various collections, the following remarks may be, therefore, of more than ordinary interest:

G. Measuresianum is characterized by its masses of oblong, elliptic, slightly compressed pseudo-bulbs, clothed with silvery membranous sheaths, and varying in length from eight to sixteen inches, more or less furrowed when young, and deeply wrinkled when old. Each pseudo-bulb bears at its summit from four to six deep green, persistent, broadly lanceolate, acute leaves, eighteen inches or two feet long. In a wild state from sixty to seventy flowers, each about four inches across, are borne in April on stout, erect scapes, which spring from the base of the pseudo-bulb and are from five to seven feet tall. The narrower petals vary in color from cream to greenish yellow,

and are handsomely blotched with dark brown or blackish purple, the incurved tip of each sepal invariably having a large blotch of the same color. The small lip is pale creamy yellow, with a purple stain outside at the base. The bluntly ovate incurved side lobes are each traversed by seven sepia-brown parallel lines, and the disc, which is covered with fine white hair, has two parallel elevated keels or ridges which terminate in a small, hairy protuberance in the centre of the very small middle lobe, which is oblong in shape, creamy white and lined with purple-brown, while the slender, arching column is white, tipped behind and streaked in front with purple. On each side of the yellow pollen masses, which show through the anther case, is a small purple spot, thus giving the column the appearance of some insect peeping out from between the incurved side lobes of the lip.

It is a peculiar fact, and one worthy of notice, that the first five or six flowers at the base of the peduncle are always abnormal, that is, abnormal in differing from the other flowers, but natural in being always present. These lower flowers possess only two sepals and two petals, all larger and more thickly blotched than in the normal flowers. The column is also present and normal, but the lip and third sepal are entirely absent. I have seen a dried flower of *G. speciosum* having only four segments and a column, but in all the other species known, with the exception of *G. Fenzlianum*, which lurks in some obscure German herbarium, I did not see this peculiarity at all. Neither has it been mentioned in the description of any other species, so far as I can find out, a fact which in itself indicates that abnormal flowers have not been noticed, or surely such a fact would have been mentioned. *G. Measuresianum*, then, possesses the distinction of always having abnormal flowers at the base of the peduncle. Now the question arises, what is the object of these abnormal flowers? In nature everything has its use, but what is the use of these flowers? It is not possible that they can be female, while the others are male, for two reasons. First, because the column is precisely the same as that in the ordinary flower, having its pollen masses and other organs intact; and, second, because the pedicels of female flowers, as in *Cynoches* and *Catasetum*, are, as a rule, much thicker, on account of containing the ovary. But in the abnormal flowers of *G. Measuresianum* there is no difference whatever in the thickness and length of their pedicels and those of the ordinary flowers. If, then, these lower flowers are not female, what are they? Perhaps time will show.

At present little can be said about the cultivation of this species, but, judging from the strong and numerous growths thrown up by the imported pieces here in the nursery, one may safely say that it will not be a very difficult subject to manage. Some of the pieces are done up in well drained teak baskets in a compost of rough, fibrous peat and sphagnum, while others are hung up just as they arrived, in a warm, moist house. No water, or only very little, is given yet, the moisture of the atmosphere being apparently sufficient for their wants, as the pseudo-bulbs have become nice and plump and send out their growths. It might be mentioned that in its native country this species is always subject to plenty of sun and abundance of water during the season of growth, and the sight some of the plants present may be imagined from the fact that the collector saw one piece with fifteen spikes over five feet high, each bearing about seventy fully expanded flowers.

St. Albans, England.

John Weathers.

The Forest.

The Mountain Forests of Vancouver's Island.

THE forests of the mountains in the interior of Vancouver's Island differ materially from those of the low grounds near the coast, while as one travels inland the Douglas Fir (*Pseudotsuga taxifolia*) is the chief tree until an elevation of about 800 feet is reached. It then becomes insensibly intermixed with the western White Pine (*Pinus monticola*) and a sprinkling of Red Cedar (*Thuja gigantea*). Within a few miles of Departure Bay, where all steamers bound for Alaska take in coal, rises Mount Benson, attaining the height of 3,360 feet, at about eight miles in a direct line from the coast. The lower slopes of this mountain are covered with Douglas Fir of enormous size, many of the trees being nearly 300 feet high and over eight feet in diameter. The chief undergrowth is the Bracken (*Pteris aquilina*, var. *lanuginosa*), which is generally from four to six feet high, and so interlaced that to force one's way through it, without first tearing it apart with the hands, is impossible. After this is passed the undergrowth is composed of Salal (*Gaultheria Shallon*), which is, if anything, more difficult to get through. Amongst the Salal

the trees stand closer together, and are much less in diameter, but tower straight as arrows to an immense height. Here the Pine becomes quite frequent and the Salal more interesting, for, in great profusion, the rare *Boschniakia Hookeri* is growing as a parasite upon its roots.

Then, as one ascends still higher, the western Hemlock (*Tsuga Mertensiana*) comes in, and our forest is composed of four species. Gradually the trees grow less in size, until, as the summit is neared, they become stunted, but still healthy and vigorous. On the summit two species appear, as if they were new creations. These are *Tsuga Pattoniana* and *Abies amabilis*.

Later explorations on other mountains showed that the same trees kept their relative position, but toward the north were found at a decreasing altitude. It was ascertained that the forest-trees of one mountain were those of another, and that *Tsuga Pattoniana* and *Abies amabilis* were the rule, and not the exception, as they were in company on every mountain and were the last to disappear at an altitude of about 5,500 feet. Above this very few trees are found, but it was quite evident that their absence is not caused so much by cold as by the immense snowfall of the moist winter, which leaves the mountain summits covered to a great depth in the spring. Close to snow of unknown depth, trees, with a diameter of two feet, are growing vigorously on Mount Arrowsmith, while above them all is snow or depauperated and broken trees, flattened down by the snow, growing while they can, and lying dormant the remainder of the year.

Without exception, the forests of Vancouver's Island are the finest now in Canada. It is sad to think that these noble forests are being devastated year after year by fires started by men who are "improving" the land, and what it is impossible to do with the axe is being done with fire. In every part of the island the timber is sound and fit for market, and it might be kept so but for the recklessness of irresponsible men. For every tree destroyed by the axe a thousand are being destroyed by fire, and year by year the number is increasing. During the last half of July and August and early September (1887) the whole country was enveloped in smoke, and fire met the traveler at every point. A few years more and these noble forests will be but the blackened remains of a glorious heritage, as every year increases the power of the fire and gives it more prepared fuel for the next season. It is not alone on Vancouver's Island that this destruction is going on.

The Olympian Mountains, on the other side of Puget Sound, in Washington, are being denuded in precisely the same way; and this autumn (1889), over nearly the whole of British Columbia and northern Washington, the sky was obscured for six weeks by the dense smoke of the forest-fires raging in all parts of the country.

Ottawa.

John Macoun.

Forest Fires in Northern Canada.

NORTHWARD of the deciduous and mixed forests of southern Canada, a vast belt of conifers, about 700 miles in breadth, stretches for 4,000 miles from the eastern coast of Labrador to the Rocky Mountains and continues beyond them into Alaska. The northern zone of this belt consists of Black and White Spruce and Tamarac, but as we go south these become mixed with Banksian Pine, Balsam Fir, and in the east with White Cedar, and finally with Red and White Pine. Excepting near the verge of the forest, there is also a greater or lesser mixture of Aspen, rough-barked Poplar, White Birch and the various northern Willows, but in a general way this belt may be described as a coniferous forest.

Notwithstanding its immense extent, it may be said that fire has run through every part of it at one period or another. Forests of this kind are particularly liable to destruction by fire. The trees are comparatively small, and where they do not stand closely together the branches grow all the way down to the ground. The open spaces, no matter how rocky, are covered with reindeer mosses, which in the summer-time are as dry and inflammable as tinder, while the deep carpeting of the yellow mosses among the trees is equally dry, and helps to give body to the flames.

The Indian hunter or wild Indian of the north, knowing how destructive forest-fires are to the animals on which he depends for food and fur, takes all possible care to prevent them, yet if one ascends a high hill in any part of these regions, so as to obtain an extensive view of the country, he will find the normal condition of the woods to be "patchey," or to consist of areas of second growths of various ages mixed with others of older timber. The latter may have attained its full growth, and yet not represent the original forest, as it has probably sprung up on ground which had been burnt over at

a time more remote than would represent the life of any of the trees standing upon it. The writer has crossed the entire breadth of our northern forests in many parts, and has found these conditions to prevail everywhere.

Knowing the care which the Indians have always exercised, and the fact that the country had not been invaded by white men, the question arises—what caused these fires which have in turn swept over every part of the enormous country—and not only once, but again and again since a very early period? My answer is that forest-fires are a natural phenomenon, and that the conditions which we find in our northern woods could not otherwise have been attained. These fires have had an effect on the formation of the soil, on the rotation of crops of trees—so necessary to their healthy condition—and on the dispersion of their seeds.

We have both direct proof, and also the evidence of the trees themselves, that forest fires have originated without human agency, and that they have been going on ever since the present species of trees existed—if, indeed, they have not played a part in producing some of their characters. Lightning has been the commonest cause of these fires, although in some cases they may have originated from spontaneous combustion, due to the decomposition of pyrites, which is known to have set fire to beds of lignite in the Saskatchewan region.

In the northern states and the inhabited parts of Canada it is not uncommon for lightning to strike barns and houses and set them on fire in the hot months of summer. This is the season when our northern forests are dry and ready to burn, and we should naturally expect similar accidents to occur among them with at least equal frequency in proportion to area. Examples have been observed where the fire which has destroyed a large area has been traced back to a tree which had been struck by lightning. With an experience of over thirty summers spent in these woods, I have only once actually witnessed a case of this kind. The lightning on this occasion was plainly seen to strike the brink of a wooded bluff near Red Rock, on Lake Superior, and to set it on fire. Owing to the very small number of human beings in these regions, the chances of these occurrences being witnessed are very few as compared with civilized regions, yet the Indians tell me that they frequently happen.

Referring to the evidence afforded by the trees themselves, that forest fires are a natural phenomenon, I shall mention the case of the Banksian Pine. The cones of this tree are hard and remain closed as long as the tree lives. The older ones become weathered and covered with lichens, often indicating great age. The tree may fall down and rot, and the cones fall from the decayed branches, yet they will not open. But if the tree should become scored by a forest-fire, they will immediately gape open, and the healthy seeds will become scattered far and near by the wind.—*Robert Bell, Assistant Director Geological Survey of Canada, in "Forest Leaves."*

Correspondence.

The Lynn Public Forest.

To the Editor of GARDEN AND FOREST:

Sir.—A large proportion of the German cities, if not, indeed, the most of them, have their public forests. These date back to the earliest days, when woodland was held in common to supply the people with fuel and timber. Fortunately the cities have retained their titles to large portions of these adjacent forest tracts, which, administered on scientific principles, are now sources of considerable revenue. But their chief value lies in their service as delightful rambling grounds for the people, and to their existence is largely due the healthy love of Nature and of out-door life that characterizes the Germans. One of the pleasantest features of the city of Leipzig, for instance, is the noble pleasure-ground called the Rosenthal. This is a park consisting of a great central meadow surrounded by woods. The park is continued for miles out into the country by the city forest, which is intersected by rambling paths and roads. In the midst of it stands the famous Thousand Year Oak.

The early towns of New England likewise held their woodlands and pasture lands in common. The second settled town in the Massachusetts Bay colony, now the city of Lynn, had for its common woodland a wild and rugged tract that, from the slight fringe of civilization which had established itself on the shore, began at the feet of the outer crags of rocky hills and stretched away indefinitely into the vast wilderness of the continent. This woodland was held in common until 1706, the proprietors of Lynn being free to enter it and cut all the fuel and timber required to meet their needs. At that date the

tract was divided up among the land owners, subject to the restriction, which still remains, that any man might cross the territory of any other whenever convenience demanded. The greater portion of this territory, within the municipal limits of Lynn, remains in very nearly its original state. It occupies the north-westerly portion, which is a region of rock-ribbed hills, with bold ledges and precipitous crags, the intervening glens and valleys coursed by clear and rapid brooks and rills, and having in their depths extensive swamps and ponds. Its wildness is in marked contrast to the densely populated and bustling city close at hand, whose masses of buildings back up into the outer valleys of the territory.

This region is now to return to its original character of a woodland held in common, with the function, in addition, of a free public pleasure-ground. Its dedication to this purpose has proceeded through successive steps by a sort of evolution. Lynn has been exceptionally fortunate in her public-spirited citizens—men enterprising, progressive, of liberal ideas and cultivated minds. Their life-long acquaintance with this region naturally endeared it to them, and made them ardent lovers of Nature. When the growth of the city demanded a more extensive and systematically planned source of water supply, attention was directed to the valleys of this uninhabited territory, and a magnificent scheme was adopted, sufficient to meet the wants of the public for many years to come. The series of storage basins constructed in the valleys created a number of beautiful and natural looking lakes that, expanding and meandering among the abrupt hills, enhanced the beauty of the landscape. With wise forethought, the Water Board took possession of the lands adjoining the ponds, that they might remain forest covered, making the water supply more steady and preserving it from contamination through private occupancy.

In the meantime the project of converting the remaining portion of the region into a free public forest took shape among a number of citizens by the organization of an unincorporated body called the Public Forest Trustees, whose purpose was to hold in perpetuity, for the free use of the public, all portions of this territory that might be acquired either by gift or purchase. A number of detached parcels were thus secured, the most important of which was the strikingly picturesque and romantic tract around, and including, the famous Dungeon Rock, where pirates' treasure was supposed to be buried, and which for many years, until very recently, was the scene of the excavations of the deluded searchers, the Marbles, operating under spirit guidance through mediums. But, without the right of eminent domain, there was but little prospect that under this plan enough contiguous land could be secured to form a continuous forest-territory, before much of the woods had been hopelessly ruined. Fortunately, public sentiment in favor of the project had been educated to such an extent that the City Council lately decided to take advantage of the Public Park Act of Massachusetts, an appropriation of \$30,000 for the purchase of lands was made, which, in addition to private subscriptions, gives a fund of something like \$50,000 for the purpose. A Board of Park Commissioners, comprising just the right men for the place, has been appointed, and these are now proceeding to take the lands by the right of eminent domain legally conferred upon such bodies.

The Park Commission, the Water Board and the Public Forest Trustees will act in harmony in the improvement and administration of the region as a public forest, which it will be, pure and simple, with no attempt to incorporate the ordinary park features into its plan. There are about 800 acres of land to be taken by the Park Commission, which, with the 200 acres or so held by the Public Forest Trustees and the territory already taken by the Water Board, including about 200 acres in the ponds, will make a total of something like 1,400 acres, which perhaps may be considerably increased by lands which it is desirable for the Water Board yet to take.

The character of the forests is chiefly that of a young and thrifty growth of Oaks and other hard woods, with an abundance of Maples in the swamps, and many groves, clumps and groups of beautiful Pines and Hemlocks, some of which are of considerable age and size. There are passages of romantic sylvan beauty; and numerous legends and traditions, as well as historic incidents, add to the interest of the place. The highest points in the region are somewhat less than 300 feet above the sea-level, but the neighborhood of the ocean gives their altitudes full value, and the various prospects commanded are extensive and unusually impressive. From one eminence there is a broad view over the ocean, on which the rocky peninsula of Nahant seems to be floating, and the populous city spreads out close at hand, in contrast to the

woodland quiet amidst which the beholder stands; from another the prospect to the southward ends with the graceful contours of the Blue Hills of Milton, toward which the vision is gently carried from the rugged woodland foreground by the broadening landscape, and the seaward opening valley frames a vista of the shore-line curving southward to far beyond the entrance of Boston Harbor. Again, there are views over the forest amphitheatre that forms the main feature of the region, with nothing to be seen but wood, water and rock; all traces of civilization are shut out, and on every side the tree-covered hills undulate indefinitely into the distance, so that it seems as if the entire continent might still be the wilderness it was when the Puritans first came here. When the atmosphere is clear Mounts Wachusett and Monadnock stand out sharply in the distance.

It is proposed to develop this region for the convenience and pleasure of the public very simply, in accordance with its wild and natural character. Roads and walks will make the most notable portions easily accessible, and there will be nothing to prevent the visitor from wandering across country to his heart's content. A service of public carriages will be established to make the tour of the forest at cheap rates of fare for the round trip, and passengers will be dropped at successive points wherever they may desire, to continue the excursion in succeeding vehicles on the same tickets. The conditions are favorable for the development of a beautiful forest-growth, and it is intended to apply the most approved forestry methods in the administration. It has been suggested that "the Lynn Commonwood" would be a most appropriate name for the forest, having a historical significance in indicating its original function while also expressing its present character as a public pleasure-ground.

This forest will be the largest area dedicated to public park purposes in New England. Lynn has thus led the way in establishing the first public forest, and has set a noble example which ought not to be without effect upon other communities. Although a local enterprise, its benefits are far more than local. Its value to the neighboring New England metropolis can hardly be overestimated. Lynn is already, geographically, a portion of Boston, and will be knit closer together with the central city as years go on. An eminent landscape-gardener, in a recent examination of the place, predicted that it would become to Boston what Fontainebleau is to Paris, and Richmond and Windsor are to London.

Boston.

Sylvester Baxter.

The Disappearance of Wild Flowers.

To the Editor of GARDEN AND FOREST:

Sir.—You speak in reference to the practice of digging large quantities of popular wild plants from the woods and marshes, and thus nearly, or quite, exterminating some species from certain regions. Many a botanist and lover of nature regrets to see his favorites disappear. In this part of Michigan large orders have been filled from time to time for wild plants. Changes are taking place very rapidly in this part of the state. Swamps and marshes are often drained; then, during some very dry season, fire spreads, accidentally or otherwise, burning deep into muck and sphagnum, destroying many native herbs and shrubs.

Proprietors are still making extensions to their clearings; of course, paying no attention to Trillium, Cyripedium, Isopyrum or Hepatica. They are preparing more land to raise more wheat and corn, and grass to support more cattle to get more money to pay debts or buy more land. If we knew certainly where these clearings were soon to be made, there would be little harm in digging wild plants from them. If we could foresee what woodlands, marshes or ponds would remain "unimproved" for a long time to come, we could make attempts to save some of the gems which thrive there. But, here lies the trouble; we can seldom know what changes will take place in this new country. So far as we are concerned, in central Michigan, it seems about as well to collect choice plants, and let those have them who appreciate and will care for them, as to leave them with the chance that they will soon be burned over or plowed under.

Agricultural College, Mich.

W. J. Beal.

Trypeta Pomonella in New Jersey.

To the Editor of GARDEN AND FOREST:

Sir.—In your note on Dr. Hoskins' article on *Trypeta pomonella* you say it has been known many years in the West, but is not reported as injurious in this part of the country. I have a tree of Jersey Sweet, the fruit of which is invariably so badly infested with the maggot as to be absolutely worthless, and this has been the case for several years. A tree of Golden Sweeting

standing next to it is also more or less infested every year, so that I hardly ever dare to eat one unless I inspect it closely. If the apples are gathered and allowed to stand in a barrel for a week to become mellow, they then show the devious tracks of the disgusting pest through the skin, which is discolored, and if the apples are cut, they will be found often entirely riddled and honeycombed. I have seen apples in Connecticut badly infested with them, and, perhaps, Mr. P. M. Augur, the official pomologist of that state, could tell of Fameuse being entirely ruined by them. I consider it the worst pest we have to contend with in connection with the apple, because it is so minute that its presence is often not suspected till the mischief is done. Many persons have doubtless eaten infested apples in blissful ignorance of the presence of these loathsome insects, as they are hardly visible in their early stages, or in the early stage of their work, so near the color of the flesh of the apple are they. This is the reason, doubtless, why Dr. Hoskins has failed to find them. If in cutting the apples he should dislodge them and get them against the discolored flesh, a sharp, steady look would doubtless be rewarded by seeing them squirm, but, as they are of the color of the apple's flesh, it requires a keen eye to see them. They are small, but powerful for destruction. I have very seldom found them here except in the apples named, but I have seen Fameuse apples in Connecticut destroyed by them. I first noticed them about half a dozen years ago, and was induced to study them and find their authorized name.

E. Williams.

Montclair, N. J.

The Dwarf Weeping Willow.

To the Editor of GARDEN AND FOREST:

Sir.—The Willow spoken of by Professor Budd, of Iowa, as the "Napoleon Willow," is likely, if as hardy as reported, to be an extremely popular tree. But why "Napoleon"? Is it of the species or variety said to hang over the famous grave at St. Helena? This I have supposed to be the common and decidedly tender tree, which can hardly be grown north of Massachusetts, and not very successfully there. My young trees, from cuttings sent by Professor Budd, do not resemble this, having smaller, shorter and darker foliage. They are not yet tall enough fairly to test their hardiness against cold; but as Iowa has as hard winters as northern Vermont, I hope to find them a success. I hardly know of any tree that would meet with a wider sale than a true iron-clad Weeping Willow, and a moderate degree of dwarfness would be an added merit.

Newport, Vt.

T. H. Hoskins.

Recent Plant Portraits.

TULIPA MAXIMOWICZI, Rgl. *Gartenflora*, October 1st; a delicate species, with narrow leaves and small flowers, with acuminate scarlet perianth-segments; a native of Bokara, and closely related to *T. linifolia*.

TULIPA BATALLINI, Rgl. *Gartenflora*, October 1st; a yellow flowered Bokaran species.

Botanical Magazine, October.

DRACENA MARMORATA, t. 7078; a fine tropical species from Singapore, whence it was introduced to Kew in 1882, and flowered there for the first time last year. "The most striking characteristic of the present plant, from a horticultural point of view, is its very large, sessile, plicate, bright green leaves, copiously marbled with white."

PRIMULA PUSILA, t. 7079, A; a common and widely distributed alpine species of the Himalaya, found at elevations of 13,000 to 16,000 feet, where "it forms considerable tufts. Its sapphire-blue flowers are very attractive." Sir Joseph Hooker calls attention to the fact that, unlike many Primroses, it shows through its wide range of distribution no inclination to vary from the type form.

PRIMULA PETIOLARIS, t. 7079, B; of this plant Sir Joseph Hooker remarks "that it is one of the commonest and most variable of the Primroses of India, or perhaps the world. It abounds under innumerable forms throughout the Himalaya, at elevations of 8,000 to 14,000 feet from Garwhal to Bhotan, varying from a dwarf Alpine no bigger than a penny piece, with sessile leaves and flowers, to a coarse herb, with long petioles, spatulate-obovate or orbicular-cordate leaves a span long, and umbelled flowers on a stout scape." The variety figured is that known as Nana. It is represented with short-petioled leaves and short-stemmed pale purple flowers, with a yellow eye.

FRITILLARIA BUCHARICA, t. 7080; a handsome and interesting species, with leafy stems, and lax, many flowered racemes of greenish white, campanulate flowers, rather less than an inch long. It is one of the plants discovered by Dr. Albert Regel in central Asia.

Notes.

An ever-blooming Rose of dwarf habit, with bright pink semi-double flowers, called *Rosa semperflorens Fellenberg*, is used largely in Berlin for the decoration of flower-beds in public squares and private gardens. It remains in bloom throughout the entire season, and appears to be admirably suited for the purpose for which it is used.

The increase in the cultivation of the Chrysanthemum in this country, of late years, is something almost fabulous. It is certainly our most popular flower, and Chrysanthemum exhibitions to be held during the coming month are already arranged for at Charleston, Chicago, Boston, Philadelphia, Detroit, Cincinnati, Indianapolis, Orange, Montreal, and at several of the smaller New England cities, like Worcester, Springfield and New Haven.

A correspondent of *The Garden* (London) calls attention to the beauty of a bed of the Hybrid Tea Rose, Grace Darling, which he had seen blooming in the gardens at Kew during the last week of September. Grace Darling is one of the most beautiful Roses of its class, and was to be seen during the past summer in great beauty and profusion in the flower markets at Carlsbad, in Bohemia. It is a plant of robust habit, with good foliage, producing clusters of fragrant flowers. These, when well grown, are compact in habit, with bright peach-colored petals, shaded to creamy white.

Our attention has been called recently to a charming combination of autumn colors, produced by a plant of the Chinese Wistaria, running through and over a tall mass of the Stag-horn Sumach. The dark rich green of the Wistaria serves to bring out and intensify the scarlet tints of the Sumach. The converse of this effect may be produced by a Virginia Creeper rambling over a Red Cedar-tree—a natural combination often found in the woods and by the roadsides in our eastern states. This natural mingling of scarlet and dark green produces one of the most beautiful effects of autumn color which can be seen in America.

Shortia has long been regarded as one of the rarest plants in the North American flora. Now, however, it is known to be so common, in at least one region, that a long established vernacular name for it is in common use among the few families of mountaineers who inhabit the valleys at the headwaters of the Savannah River, where Shortia is found. Galax, the near relative of Shortia, is known almost universally to the people of the southern Alleghany Mountains as Coltsfoot, from a fancied resemblance of the leaf to that of a colt's foot. The smaller leaf of Shortia, which resembles somewhat the leaf of Galax, is called "Little Coltsfoot."

A hybrid Rhododendron, raised several years ago in Mr. John Waterer's nurseries at Bagshot, in England, is a plant of much promise. It is the result of a cross between the Himalayan *R. Dalhousianum*, and the well known variety of Catawbaianse hybrids, *R. album elegans*. The hybrid has large, deep green foliage; it is a free bloomer; the flower trusses are large, and the individual flowers, which are pure white, faintly marked with small pink spots on the upper lobe of the corolla, are large and possess great substance. This hybrid is quite hardy at Bagshot and there is a chance that it may prove so here in the northern states. It can, in any case, be grown here in a cool house, or with winter protection in a pit or cold cellar.

Maréchal Niel rosebuds, grown in the open air in southern Austria, are sold in large numbers during the summer months in some of the health resorts in Germany. They are often fine specimens, and not infrequently are tastefully arranged with the red and green foliage of the changing Virginia Creeper—a favorite arrangement being three buds on a fan-shaped mass of leaves made to be held in the hand. The beauty of the buds is often sadly marred, however, by the custom which prevails in some places of turning back artificially the outer rows of petals for the purpose of increasing the apparent size of the flowers. A combination of Maréchal Niel roses, with sprays of the foliage of the Purple Beech, is a favorite one, and the contrasting of the two colors produces an excellent effect.

The death is announced of Mr. John Ball, the distinguished English botanist. His studies were devoted largely to botanical geography and to philosophical questions relating to the origin and descent of existing floras. Mr. Ball's best known works are "The origin of the Flora of the European Alps," published in 1878, and his "Contributions to the Flora of the Peruvian Andes, with remarks on the history and origin of the Andean Flora," published in 1885, in the journal of the Lin-

næan Society. He accompanied Sir Joseph Hooker, in 1871, in his scientific mission to Morocco, publishing on his return a catalogue of the plants discovered, with critical introductory observations (his first attempt to explore the chain of the Greater Atlas was made as early as 1851). Mr. Ball traveled extensively and was a practiced and accurate observer, and one of the very best books of recent travels is the one in which he described his South American journey, which carried him round that continent. Mr. Ball was in North America in 1884 at the meeting of the British Association at Montreal, and of the American Association at Philadelphia, later, accompanying his old friend and correspondent, Dr. Asa Gray, on the last journey the Cambridge Professor made to Roan Mountain and other points of botanical interest in North Carolina. Mr. Ball belonged to a school of botanists of which only a few members remain; and he was almost the last of his associates and contemporaries.

Death has ended, too, the long and brilliant career of Leo Lesquereux, the Nestor of our botanists and the most distinguished student of palæontology in the United States. He died last week in his home in Columbus, Ohio, in his eighty-third year. Professor Lesquereux was one of the Swiss naturalists attracted to America by Agassiz, whose assistant he became at Cambridge in 1848. Subsequently he removed to Ohio, and devoted himself almost exclusively to the investigation of fossil plants. His best known publications are a "Catalogue of the Fossil Plants which have been named or described from the Coal Measures of North America," and the "Coal Flora," which formed part of the Report of the Second Geological Survey of Pennsylvania. He contributed a large number of papers upon fossil botany to the reports of the different Government surveys of the western part of the continent. Professor Lesquereux's principal contribution to present botany was his "Catalogue of the Plants of Arkansas," joined to his botanical and palæontological report to the geological survey of that state.

The growth in popularity in Europe of the Tuberous Begonia can hardly escape the notice of the most casual observer. The plants are now seen everywhere. They form the most attractive feature in the flower-beds of city squares in central Europe; they decorate the most pretentious of the ugly gardens of the great hotels, and they may be found growing and flourishing in pots on the window-sills of the smallest cottages in remote Swiss villages. They are gradually driving out the old Scarlet Geranium from cottage gardens. This sudden leap into popularity is surprising because it is barely a quarter of a century since the species from which this new race of Begonias sprung were entirely unknown; and in all the history of floriculture there is not another case of a new race of plants taking at once such a hold upon popular affection. There is danger, however, that the florists will spoil these pretty plants as they have spoiled so many others in their pursuit of novelties, and of new and startling forms and varieties. The double flowered Begonias, which are just now all the rage, are far less attractive than the single flowered varieties; and there is danger, too, that even the single flowers may be made too big and ungainly for harmonious combination with the plants which bear them. The charm of a Begonia flower is in looking like a Begonia flower, and not like a small Hollyhock or a deformed miniature Rose; and yet the best claim the advocates of these double flowers make is that they look like something which they are not—a Rose or a Hollyhock. Still, as long as the public continues to consent to pay three or four times as much for the double flowered varieties as for those with single flowers, the florists can hardly be blamed for devoting their energies to their production.

Catalogues Received.

C. E. ALLEN, Brattleboro, Vt.; Seeds, Plants and Small Fruits.—J. A. DE VEER, 183 Water Street, New York; Choice Holland and Miscellaneous Bulbs, Seeds, Plants, etc.—F. W. KELSEY, 208 Broadway, New York; Hardy Trees, Shrubs, Roses, Bulbs, etc.—HARLAN P. KELSEY, Highlands Nursery, Highlands, N. C.; Plants and Flowers of the Southern Alleghany Mountains.—JOHN LAING & SONS, Forest Hill, London, S. E., England; Dutch, French and other Bulbous Roots, Fruit Trees, Roses, Shrubs, Begonias, etc.—J. L. NORMAND, Hill-Side Nursery, Marksville, La.; Oriental Plums, Peaches, Pears, Vines, etc.—REASONER BROTHERS, Royal Palm Nurseries, Manatee, Fla.; Tropical and Semi-Tropical Fruit Plants, Bamboos, Aquatics, Conifers, Palms, Cacti, etc.—E. W. REID, Bridgeport, O.; Small Fruits, Apple, Pear, Plum, Peach, Quince and Deciduous Trees, etc.—GEORGE RICHARDSON, Lordstown, O.; Rare Water Plants.—G. L. TABER, Glen St. Mary Nurseries, Glen St. Mary, Fla.; Fruit Trees.—JOSEPH TWEDDLE, Vine Valley Nurseries, Stoney Creek, Ont.; Grape Vines.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, NOVEMBER 6, 1889.

The Utility of What Makes Life Interesting.

FOOD, clothing and shelter are the primal, universal wants; but when these are supplied, new needs arise, the wish for increasing comfort and security, and then the desire to make life interesting, so that it may be something more than mere existence. The means to this end are as varied as the special qualities and dispositions of individual men, but, however it may reveal itself, this hunger for something beyond the means of physical subsistence is an ideal element in our nature. It is the origin of poetry and romance, and of all art. It is the source of progress and civilization, and is, indeed, the distinguishing endowment and crown of humanity. It is not enough for men to have food, clothing and shelter in amplest supply. The physical life itself is not prosperous or secure when the mind is starved and dwarfed. Pleasant thought is a vital force. Interesting mental employment promotes health and longevity, and is a necessity for all.

The means, conditions and occupations which make life interesting for some persons have no such value or result for others. The sustaining pleasures of one man would be a burden and weariness to another. Growth carries the same individual beyond the earlier ideal satisfactions, and he discerns more truly what is normal, sane and healthful. A cultivated and developed taste rejects what was once highly esteemed. In an advanced state of society every person would be free to employ his means and opportunities for the satisfaction of his own ideal needs—to pursue the objects which would make life most interesting to him, if he did not trespass upon the rights of others. At the same time every individual would be influenced and aided by the general taste, judgment and culture of the community about him.

The growing interest in out-of-door life, and in means of recreation that can be enjoyed in the open air, is one of the most encouraging tendencies of the time. Gardening and the care of flowers and trees are becoming more and more attractive to thoughtful and cultivated people everywhere. These are sane and wholesome occupations, and they are coming to be depended upon for relief from weariness and "nervous prostration," as it is found that pleasant

activity in the open air is often a more potent restorative than medicine. The primary benefit comes, of course, from our breathing purer air, and more of it, when out-of-doors; but every one needs a more inspiring reason for going out than the bare and depressing thought of the need of improvement to health. It is much better to think about our flowers or shrubbery, or to be interested in plans for the care of a garden or door-yard, than to think of ourselves in any more direct way. In all such activities immediate utility is associated with the more ideal aims.

The best garden or farm is partly a work of art. Its order and beauty add to the interest of life for its possessor, especially if he cultivates it with his own hands and brain. A day laborer with a garden, or a few square yards of ground about his door, has an artist's opportunities in the application of his taste to the capabilities of the area which he plants and shapes. He may have the delight of creating something beautiful and interesting which did not exist before. It is a serene happiness to think out plans for doing the best that can be done with even the smallest piece of ground on which anything can be made to grow. He who has room for trees has it in his power to make enduring changes in the landscape, and the care of even a few trees will supply much of interest from the time they are planted till their protector can walk or rest at will under their shade. One becomes attached to them as to children and friends, and they respond in their way. The watch against their many foes often involves unpoetical activities; but struggle is the condition of all animate being, and life without it, if it were possible, would not be interesting.

The defense of trees against their insect enemies introduces us to one of the most interesting provinces of the out-of-door world, the life of birds and their services to man. In the order of animal existence on our planet they are the natural instrument for keeping insect life down to its normal level and proportion. But we have repressed the bird population in this country to such an extent that we have produced an enormous over-development of insect life, so that the dominion is given over to them, and they have become an all-pervading curse, like that of the frogs in Egypt when they covered the land, entered the houses and climbed into the very bread-bowls. Learned men write books and governments make large appropriations to help farmers, orchard-growers and vine-growers to defend their crops against injurious insects, but if we were civilized enough to protect our friends and allies instead of cherishing our enemies, the birds would soon dispose of most of these pests.

It is often observed that birds are more particular about their food than formerly, and that many of the worst insects are not eaten by them. But that is because their supply of food is so abundant that they can afford to be dainty and to eat only what they like best. It is much the same as if a banquet for a thousand men were served every day for half a dozen. They could taste here and there, and would make little impression on the whole supply. It is so with the birds because they are so few, but if they were protected till the bird population began to press upon their means of subsistence, they would not be so fastidious, and would be glad to get any kind of bug or worm, and would snap up every one that showed his head.

Besides their utility as insect destroyers, birds are among the most interesting and companionable of all living creatures. Few people in this country have any intimate acquaintance with birds and their ways, but those who have studied them in close and pleasant relations know that they have a great deal of individual character and a wonderful and most interesting kind of intelligence. Their music, too, often peculiarly sweet and fascinating, with a mysterious and indefinable quality—a kind of divine suggestiveness—appeals strongly to the higher and gentler elements of our nature. But few persons now hear this music, because the birds that remain are so hunted, terrified and tormented that they rarely feel like singing. If the children and young people of the country were instructed in their homes,

schools and churches regarding man's relation to the earth on which he lives, and his responsibility for the care and ordering of it and its products, not only would there be a saving every year of millions of dollars in the crops of our farms, gardens, orchards and vineyards, which are now destroyed by insects, but life would soon be much more interesting to the wiser race of men and women.

An Associated Press dispatch, dated at Silver City, New Mexico, October 27th, serves to emphasize what was said in these columns last week with regard to the difficulties which will attend any effort to secure from Government consideration even of a comprehensive scheme for preserving the forests on the public domain of the United States. It appears from this dispatch that an attempt made by the agents of the Treasury Department to protect the forests in southern New Mexico from promiscuous thieving has met with violent opposition and protest. The effort of the Government to preserve its valuable timber from being stolen bodily is characterized as "a summary step to paralyze the chief industries of the territory." The owners of saw-mills, who have been carrying on their business for years with timber openly stolen from the Government, receive the sympathy of the community because they have been "made miserable by Government agents," who have attempted to perform the duties of their office. Congress is to be asked to modify the laws so that plunder can be made legal, that the mine-owners and timber-men of New Mexico and of the other territories can carry on their operations without fear of molestation.

The forests of southern New Mexico, covering a mass of high and almost inaccessible mountains, are the most valuable in all the region immediately adjacent to the southern boundary of the United States. The timber which they contain is often large and of good quality, considering that it has grown in a comparatively dry region. These forests, could they be managed with a little care and forethought, are capable of supplying, indefinitely, the people and the mines of New Mexico with timber, and of furnishing a large amount for shipment to the treeless regions east, north and west. The time, indeed, is not far distant when the great body of timber occupying the mountain ranges of southern New Mexico and south-eastern Arizona will, if it can be preserved from needless destruction, become a considerable factor in the timber-supply of North America. These forests, too, assure the integrity of a number of small streams absolutely essential to the existence of the inhabitants of the valleys at the base of the mountains. Were these forests under proper control, and systematically worked, the people of New Mexico would be able to purchase regular and abundant supplies of timber and firewood, and there would be no question of "one-third of the population being driven out of the territory, and of all business being paralyzed" by Government action. The truth of the matter is, however, that the people of New Mexico want their timber for nothing, and that a not inconsiderable part of the population are now in the territory because good timber can be had there for the taking. Settlements have been made and industries have sprung up on this basis, and every effort of the Government to protect its property will be met with determined and well organized opposition.

In this active local opposition lies the great obstacle to forest-conservancy in the United States. The task of preserving the forests of western America is in itself sufficiently difficult to tax the energy and the administrative ability of any nation. No forest region, not even that of India, which has been brought under control, presents anything like the physical and climatic difficulties which a forest-administration would be called on to encounter in dealing with the forests in the central and western parts of this continent. When to these natural difficulties are added national indifference and active local opposition, the prospect of serious reform is not encouraging. And yet if this destruction cannot be stayed, that portion of this continent

beyond the 100th meridian must, with the exception of a few favored localities, be uninhabited before another century has passed; and the people of the United States, whatever their numbers may be, will then be crowded into the eastern side of the continent. The forests mean existence to the people living in more than one-half of the present territory of the United States, and in their future lies one of the great social and economic problems of the twentieth century.

Landscape-Gardening in Persia.

PERSIA has long been famed for the artistic genius of her people. It is less generally known, however, that the art of landscape-gardening has been for thousands of years one of the most characteristic of the æsthetic expressions of Iran. This ignorance is doubtless caused by the fact that examples of the other arts of Persia can be exported or reproduced in color, whereas a garden cannot very well be exported, and few travelers have visited Persia or had the artistic training that would lead them to write intelligently about her arts.

I speak of the landscape-gardening of that country as reaching the rank of an art, because, in the first place, it is an original expression of a national taste for the beautiful, and in the second place, because, like all true art, it is an outgrowth from natural conditions and adapts itself to those conditions.

The climate of Persia makes out-of-door life essential. For nine months no rain falls, and even the wet season, which lasts less than three months, is attended with only moderate rain or snow on the elevated plateaus, which constitute the larger part of the country. The remainder of the year the skies are cloudless, the dews are imperceptible, and the dry air quivers with mirage. The heat is steady, but the nights are cool, owing to the elevation of the country. Exception may be made to these observations in regard to the climate of the narrow strip between the Caspian and the Elbarz Range, forming the northern watershed of those mountains. The vapors of the Caspian striking these slopes deposit a vast amount of moisture, which descends in numerous streams. The northern slope is covered with dense, jungle-like forests, the alluvial lands at the base are devoted to rice fields, and the steaming atmosphere reeks with malaria.

But, on passing the ridge, one enters a dry atmosphere and beholds before him plains extending six hundred miles, often mere waterless, verdureless sand, and always destitute of trees, except where irrigation has been employed. This is the region where the landscape-gardening of Persia has been developed and brought to exquisite perfection.

It is evident that an arid soil and a cloudless sky at once suggest the need of water and shade, and that those must be the prominent objects to be brought together in agreeable combinations, while the scarcity of the population and the engineering difficulties to be encountered must regulate to a large degree the characteristic features of a place. Add to these a third element—the last one would imagine as giving a direction to landscape-gardening—polygamy. This institution shapes almost every phase of Persian life. In the present case the seclusion of the women imperatively controls the arrangement of the grounds as well as of the dwelling apartments, and hence is one of the causes for the constant surprises and variety we find in the country-seats of Persian gentlemen.

In spite of these limitations, artists in landscape do not slavishly follow a fashion or some dominant conventional system of decoration, but allow the *genius loci* to stand at their elbow and direct them how to evoke beauty in accordance with the particular spot that, from an arid rocky slope or a barren plain, is to be transformed into a dream of voluptuous delight.

Having purchased his land, the proprietor does not say to the designer: "What is the latest style in landscape-gardening or in the construction of villas?" But, "What can you make out of this piece of land?" The land is not to be twisted into conventional designs, but the design is to be brought into harmony with the land. The variety possible on this principle in Persia is evident when we consider that the first object of a country-seat is, wherever possible, to locate it on some elevated point, in order to lower the temperature, and approach the sources fed by the mountain snows, the latter in order to have abundant water for irrigation, without which it is useless to attempt culture in that country, either of woodland or tilth.

I cannot better illustrate these statements than by a brief description of a characteristic place in the neighborhood of Teheran. These country-seats, by the way, all have specific names, by which they are known, rather than by the name of the proprietor. Jeferabad includes some sixty acres on the

steep slope of one of the spurs of the Shimran Range. The vegetation is divided between fruit trees, shade trees and flowers, arranged to make an agreeable summer residence and a profitable farm, the latter feature being so distributed as not to be too prominent in a pleasure seat.

The grounds are so steep and broken that a proper site for the residence could be obtained only by terracing. This added to the expense but also to the impressive beauty and majesty of the design, which has everywhere been carried out with an admirable combination of breadth and detail, and a general harmony of effect, which produces an impression on the memory more vivid and lasting than that of many far more elaborate and costly places I have seen in Europe. Herein is exhibited the consummate art of the Persian designer.

The shape of the estate is exceedingly irregular, roughly representing a pear pinched at the smaller end, which is, at the same time, the nearest the base of the hill. It is near this end that the gardens and residence are placed. These might have been more easily reached by having the main entrance to the grounds just at a bend in the road before it descends to follow the roaring brook that comes from the mountains and dashes through a romantic ravine. But to have done this would have been to sacrifice one of the finest effects of the place. This feature of Jeferabad is one of the most effective I have seen produced by the art of landscape-gardening.

Descending into a little hollow, the steep winding road inclosed on either hand with high walls, one comes unexpectedly to a lofty gateway on a widening of the street, the latter intended to afford space for the groups of horses attending the cavalcade of a Persian gentleman. Entering the gate, we look up an avenue of lofty, trimmed Sycamores and Poplars, forming on either hand a stately wall of green, through which glimpses of fruit-trees are seen. This avenue turns a sudden angle and continues up a gentle slope for a hundred yards, leading, apparently, to nothing; so dense is the vegetation, one can form no idea of the character of the place.

Still wondering what he is coming to, the visitor reaches another sharp angle in the avenue, and, without warning, faces a flight of broad stone steps, flanked by a carved balustrade at the end of the third stage of this impressive walk. At the head of the steps is a vast terrace, and, framed as it were between the walls of greenery beyond this terrace, appears a most graceful pillared pavilion surmounting a second terrace, the effect being not less beautiful than some of the restored temples of classic times, lifted toward the blue ether by gradual elevations.

It is not until one actually places foot on the pavement of the first terrace that he has any conception of the delightful surprise that awaits him. He beholds a platform one hundred and twenty yards in length and forty in width, from whence he gazes over the capital of Persia in the distance, an oasis of green on the plains, quivering with mirage fading away to the south. This view is seen through a break, permitted for this purpose, in the wall of foliage that surrounds the terrace.

The terrace is entirely paved, but yet we say this with reserve, as through the centre is a channel for a stream, and parterres abounding with flowers fill a large portion. The northern end is raised a foot and contains a circular tank some fifty feet in diameter. The east side of the terrace is protected by the wall of the second terrace rising fifteen feet. This terrace is of less width, and is, in turn, protected on the east side by a dense grove of Poplars swaying over it, like plumes in the regular trade wind.

The buildings are constructed on these two terraces in a manner to combine effect with the peculiar domestic arrangements of the country, and, at the same time, in a way that could not be admitted in a less mild and even climate. Extending entirely across the northern end of the first terrace are the apartments of the ladies, and these have a separate court, invisible until one enters it. This is paved, and beautified with roses grown in the form and almost the size of Lemon-trees. In the centre of this court is a tank, where the water plays at will; and from this court one reaches a stately apartment, serving as a common room where all can meet and sleep, gossip, embroider or touch the guitar as they choose, listening to the plashing of water from every quarter. For the water, led from the hill above, where it has fed the orchards, passes into the tank of the small court; thence it passes under the women's apartments to toss its spray again in a tank on the southern front of those apartments; thence it bursts forth again with a lofty jet in the large basin, then dashes along the terrace to break down a mimic cascade, and then passes under the dining-apartment at the southern extremity of this terrace, dashing forth down to the brook with the chatter of a mill stream.

In the meantime another branch of this stream is diverted to the second terrace, where it feeds two other basins between the three pavilions, for the master's quarters, which, at regular intervals, crown the centre and each end of that terrace. Thus at will five jets can play at once in this part of the grounds, in addition to two mimic cascades, and the roar of a brook which courses through the orchards. In warm weather the charm of this cooling music can be easily appreciated.

The large grounds which rise in the rear of these artificial works are densely covered with fruit and forest trees, judiciously broken by delightful winding walks, and intervals provided with seats. Here and there a terrace of rough masonry is bolstered against the hill-side, and a deep, rude tank, overgrown with moss and turf, offers, at the highest part, a delicious spot for a fête champêtre, for which purpose it is often employed. Altogether, this portion of the estate forms a romantic wild wood, slightly aided by art and taste.

S. G. W. Benjamin.

Viburnum lantanoides.

IT is a singular fact that with the exception of the poor figure in Audubon's "Birds" no portrait has been published before of this shrub, which is by far the handsomest of the North American *Viburnums*, and one of the most beautiful plants of our flora. The fact that it is impatient of cultivation—for the Hobblebush, or Moosewood, as this *Viburnum* is often called at the north, is the most difficult of all our native shrubs to cultivate—probably accounts for this lack of figures, as American plants have been figured generally in European publications from specimens obtained in European gardens. *Viburnum lantanoides* was not included in either edition of the "Hortus Kewensis," and it is doubtful if it has flowered in a garden very often (a small plant flowered in the Arnold Arboretum this year) or that many persons who are not familiar with our woods in early spring have ever seen it in all its beauty.

It is a tall, stout shrub, with naked winter buds, reaching occasionally to a height of twelve or fifteen feet, with short tortuous stems, rather bare of branchlets, and covered with smooth, dark brown bark, that of the square or angled shoots being red and marked during the second year by numerous white dots. The leaves are confined to the ends of the branches; they are round-ovate, abruptly acuminate, sharply and doubly serrate, pinnately straight veined, the prominent veins connected by conspicuous transverse veinlets; six inches long when fully grown, by nearly as much broad. They are densely scurfy-pubescent when they first appear, as are the broad, stout petioles, the inflorescence, buds and shoots of the year. The flowers are produced in radial cymes, the marginal being neutral, with enlarged, flat Hydrangea-like corollas, an inch or more across. The inflorescence begins to unfold late in April or early in May, the neutral flowers opening first. The leaves are then an inch or an inch and a half long, and conspicuous from the broad prominent veins covered with dense brown tomentum. The flowers are fully open a month later, and the fruit ripens in September. It is coral red as it reaches maturity, turning dark crimson or purple when fully ripe, ovoid, rather flattened, and half an inch long. The stone is flattened, three-grooved on one face, deeply and broadly grooved on the other.

Viburnum lantanoides is found in the forests of New Brunswick and Canada, extending southward through the Appalachian Mountains as far as the high peaks of North Carolina and Tennessee, where it attains on the high western slopes of the Big Smoky Mountains its greatest development, and where specimens fully fifteen feet high of almost arborescent habit are not uncommon.

It approaches the coast at a few points in eastern Massachusetts, but its true home is far north, or on the high mountains. The Hobblebush delights in rather moist soil and in the deep shade of deciduous trees, where it often quite covers the ground, and enlivens in early spring the forests of Sugar Maple, Beech and Birch of northern New England, New York and of the shores of the Great Lakes, with its showy white flowers, and again with the deep, rich claret coloring of its unsurpassed autumn foliage.

Mr. Dawson has tried various experiments in his attempts to cultivate this plant. He finds that when it is grafted upon *Viburnum dentatum* it grows much more vigorously than it does upon its own roots, but that it will not unite with *V. Lantana*. Grafted plants two years old are already larger than wild plants taken from the woods five or six years ago.

Holiday Notes in Southern France and Northern Italy.—IV.

MILAN, the principal city of Lombardy, and one of the wealthiest manufacturing towns of Italy, stands near the centre of a plain which owes its unusual fertility to a system of irrigation more thorough than exists in any similar area in Europe. Indeed, but for its artificial supply of water the region would be scarcely capable of cultivation, for the summer there is hot and almost rainless. As it is, an unusually cold summer is the only thing which affects the crops to any extent.

Close to the central railway station passes a broad avenue of Horse-chestnuts, a fashionable drive, which follows the line of the old ramparts. The public gardens lie on the south side of this boulevard, and they are, as a whole, well laid out and contain a number of very fine trees. In the neighborhood of the Municipal Museum, however, the ground is too much cut up, and a number of flower beds, arranged carpet fashion and otherwise, look paltry and mean. The bedding generally seemed poor, the only combinations noted as good being four large beds bordered with Ivy and filled with *Musa Ensete*, *Canna Ehemanni*, flowering freely, *Colocasia antiquorum*, the Papyrus (*Cyperus Papyrus*), *Panicum plicatum* and *Eulalia Japonica zebrina*. Perhaps the most striking feature of which the gardens can boast—certainly the best from a purely ornamental point of view—were the groups of *Erythrina crista-galli* growing in the grass. The plants were evidently very old, eight to ten feet or more in height, with thick, branched stems and fine heads, the long, erect racemes of richly colored flowers contrasting well with the deep glossy green of the leaves.

Noble groups of *Magnolia grandiflora*, some of the trees laden with fruit, and here and there one bearing a second crop of flowers, filling the air with fragrance, challenged attention. This splendid evergreen never attains such size or luxuriance in England, even under the most favorable circumstances. A rather unlikely companion to the Magnolia, but one, moreover, thriving under the same conditions at Milan, is the Norway Spruce (*Picea excelsa*). A few Deodars (*Cedrus Deodara*) were also noted as being better than any hitherto seen by us in our journeyings. An interesting feature was a group of *Albizia Julibrissin*, a handsome low tree with flat head and horizontally spreading branches, their loose habit and light green feathery leaves forming a striking contrast to the formal growth and dark green needles of the Spruces and Pines near them. Here and throughout southern France *Albizia* (or, as it is frequently called, *Acacia*) *Julibrissin*, with its erect, brush-like racemes of pink flushed, long stamened flowers, is one of the most graceful and ornamental of flowering trees. Planted at the tongue of one of several sheets of water, a fine group of the deciduous Cypress (*Taxodium distichum*) forms a striking effect in this part of the park. Some of the stems were actually surrounded by water, and they had all attained a considerable height. At one end of the group Bamboos offered excellent cover for the water fowl. Here and there on the broad expanse of well kept turf were groups or single specimens of trees. A number of Sweet Gums (*Liquidambar styraciflua*), bearing a crop of their curious fruits, had stems from two to three feet in diameter and about seventy feet in height; these beautiful trees afforded a grateful shade by one of the main thoroughfares. The Kentucky Coffee-tree and American Beech also appeared to thrive well; neither my companion nor myself had ever seen examples in England to compare with them in any way. A group of the fern-leaved variety of the European Beech—clothed to the ground with foliage, with the sunlight playing on the leaves—was most picturesque. Fine Maidenhair trees (*Ginkgo biloba*) were observed, and large bushes of Yulan (*Magnolia conspicua*). Here, too, were huge Chimonanthus bushes and trees of *Cercis Siliquastrum*, conspicuous by reason of the innumerable red-brown pods which covered the stem and large branches. Among the best of the ornamental shrubs were *Abelia rupestris*, a very handsome plant with small glossy leaves, and a profusion of trumpet-shaped flowers, white, faintly tinged with purplish red; *Lagerstræmia Indica* of tree-like proportions in

full flower; *Hibiscus Syriacus* (a long sloping bank facing the Via Palestro, planted thickly with this shrub and kept cut in to one level, produced a novel effect); and *Spiræa Thunbergi* of surprising size and vigor. Except near the Municipal Museum, the lawns were not defaced by meaningless flower-beds, though in a sort of angle we noticed a fine mass of a deep red-leaved *Amaranthus* about four feet high. *Desmodium penduliflorum* was remarkably attractive, both planted singly and in groups, on the turf, the long, slender flowering stems being allowed to droop naturally. The correct name of this plant is *Lespedeza bicolor*, but a plant widely different (of erect habit, with much shorter racemes and greatly inferior from a garden standpoint) is grown in nurseries under this name.

A broad flight of steps at one end, and a steep gravel path at the other, ascend from the grounds just described to the older portion of the gardens, in the centre of which is situated the Art Museum. The difference in level is skillfully utilized for rough, natural looking rockery and climbing plants. Here and there the slope is clothed with Savin (*Juniperus Sabina*), with the edges of the mass irregularly broken; a few plants scattered singly away from the general mass give a pleasing, because natural, effect. Other shrubs are used in a similar manner, but the Juniper mentioned made the most pleasing impression.

Behind the Brera, formerly a Jesuit college, now used as a picture gallery, museum, library and observatory, is a small botanic garden of about two acres in extent. It is well kept, and worthy of a visit from those who love trees. Here are to be seen the first Maidenhair tree introduced into Italy, said to be about 200 years old and thirty-eight metres high. A fine White Oak was about seventy feet in height. The Brera Botanic Garden, too, claims to have the first Black Walnut (*Juglans nigra*) planted in Italian soil. It is now a very fine, perfectly healthy tree. A good specimen of *Celtis australis*, and another of a peculiar form of *Magnolia grandiflora*, with narrow, wavy edged leaves, almost complete the list of remarkable trees. The Magnolia was named *M. Hartwicus*, but it is practically identical with forms grown in Continental nurseries under the name of *M. angustifolia* and *M. salicifolia*.

The central portion of the gardens—the trees were principally crowded round ends and sides—was laid out in six-foot beds, divided into squares of a yard in size by bricks set on edge and half buried in the soil. In these beds herbaceous plants were systematically arranged. A small basin for aquatic plants contained the best mass of *Scirpus Tabernaemontani zebrinus* I have yet seen. To most gardeners this plant, which, when thriving properly, is as handsome as it is curious, is perhaps better known as *Juncus zebrinus*, the name under which it was first exhibited and distributed. A fine Pomegranate, laden with beautiful fruit, occupied a good position close to the Brera. After seeing what is done by the Botanic Garden authorities in so restricted an area, one could not but wish that a larger piece of ground, better situated with regard to soil, exposure and other conditions, could be placed at their disposal.

Kew.

George Nicholson.

New or Little Known Plants.

Gymnogramme schizophylla.

OUR illustration upon page 533 of this issue is made from a specimen plant of the robust form (var. *gloriosa*) of this fine ornamental Fern, which was exhibited by Mr. John L. Gardner, of Brookline, at the Rose and Strawberry Show of the Massachusetts Horticultural Society last June and received the first prize in its class.

This variety, which is of garden origin, differs from the type plant in its more vigorous habit of growth, and in its somewhat larger and stouter fronds, which are from one and a half to two feet long, gracefully arching from above the middle. They are finely cut with very minute, ultimate divisions, bright light green on the upper, and pale or nearly white on the lower surface.

Gymnogramme schizophylla is a native of Jamaica, whence it was introduced into European gardens as late as 1880. It should be grown in a warm, moist house in order to develop all its beauty. The plants are found to do well when the pots in which they are grown are suspended from the rafters or raised on the benches out of the way of neighboring plants. The ends of the long, drooping fronds are preserved in this way from contact with the benches;

and the plants are more easily protected from careless overhead watering, which is apt to destroy or diminish the scurvy powder which covers the under surface of the fronds, and is one of the chief attractions of many species of *Gymnogramme*.

This plant, in common with nearly all Ferns, needs a copious supply of water during the summer or growing months, and should not be allowed to become dry during any season of the year. Thorough and sufficient drainage is essential to its well-being, with sufficient shade during the middle of the day to protect the fronds from too direct influence of sunlight.

would be as effective in autumn as the old garden Crocuses are in early spring. *Gerbera Jamesoni*, a new Composite from the Cape, has all the characters of a first-rate garden plant. It is good for pot culture, and it is also a beautiful border plant. Such, at all events, it has proved to be this year at Kew, where it has made its debut, and where it is flowering in the open border now. It has the aspect of a Dandelion, leathery leaves and scapes a foot long bearing flower-heads four inches across, Mutisia-like and colored rich salmon-scarlet, most bright and beautiful. Each head lasts at least a fortnight. Another pretty Cape Composite which is in full beauty outside now is *Agathaea celestis*, the "Blue Marguerite." Several circular beds of it are now thickly studded with its erect blue-purple flowers. This plant is well worth planting outside

Fig. 140.—*Gymnogramme schizophylla*.—See page 532.

Foreign Correspondence.

London Letter.

OCTOBER is not generally favorable to flowers in the open air, but we seem to look much gayer this month than is usual, this year. Bedding plants are healthy and full of bloom, that king of summer plants, the Scarlet Geranium, being still all aglow. No nipping frosts have come to blacken the face of summer, and the Belladonna is in full glory on the sunny border under the shelter of the Orchid-house, where also the beautiful *Schizostylis* flourishes with its spikes of crimson cups, and the *Zephyranthes* with its large, white, Lily-like flowers. Autumn Crocuses are in their best array. They have been in flower since the middle of last month, and they will last until next month ends, unless a severe frost occurs. There is material in these autumn flowering species of *Crocus* out of which might be developed a race of plants which

for autumn effect alone. It is scarcely a foot high, and is of spreading, branching habit, with elegant spatulate leaves.

Chrysanthemums have begun in real earnest. Of course we have had flowers of these plants since July, and there is the prospect of our soon having them all the year round. But October and November are the richest season, and will continue to be so whatever the breeder may accomplish. The last meeting of the Royal Horticultural Society brought Mr. Cannell and others with some new kinds of Chrysanthemums of much promise. A handsome, reflexed Japanese variety named Doric was selected for a certificate. The flowers are rich yellow, full, of good form and medium in size. *Etoile de Lyon*, also Japanese, with flowers of immense size, the broad, flat florets of light rose color; *Avalanche*, a very fine flower, and one of the best of the Japanese varieties, being white, good in form and of large size; the habit of the plant is dwarf and compact. The famous yellow flowered kind, *Mrs. Hawkins*, a sport from that good old Chrysanthemum, *Wormig*,

was shown in splendid condition by Messrs. Hawkins & Bennett.

Orchids were represented by *Lælia autumnalis alba*, the flowers pure white with a yellow blotch in the throat; *L. præstans alba*, a beautiful novelty, the flowers being pure ivory white, save a crimson tip on the labellum; *Cattleya Hardyana*, the king of all Cattleyas and one of the most attractive of all Orchids; a hybrid *Cypripedium* and a curiously colored variety of *Lycaste plana*.

Hybrid Anthuriums are favorites with the President (Sir Trevor Lawrence, Bart.), who has a very fine collection of them, mostly in large specimens. They are chiefly the progeny of *A. Andreanum*, *A. Ræzlii* and *A. Veitchii*. Flowers of several hybrids were shown at the meeting. For large stoves these plants are most useful, as they flower freely and continuously, their flowers being large and brilliant in color. They are also suitable for mixing with large tropical Orchids, such as Vandas.

Exceptional activity is being displayed just now by those who believe that the position of the English farmer will be immensely improved if he can only be persuaded to grow fruit for the supply of the English market. I refer to this subject because it must be of special interest to your fruit growers and exporters, seeing that from the United States alone close upon six million bushels of apples are annually sent to the English market. It is supposed that we can do without this and grow better fruit at home sufficient to supply every demand. Mr. Gladstone thinks so. He has lately made an important speech on the subject, being himself convinced that we are altogether wrong in not devoting considerably more land to fruit culture than has been done hitherto. The present Lord Mayor of London also takes a keen interest in this question. He has had the Fruiterers' Company to a Mansion House feast, and now he makes an appeal to the public generally for pecuniary aid to the cause of this company. I quote from his letter: "The Fruiterers' Company are making a very laudable effort to bring about the restoration of fruit gardens and orchards in connection with our homesteads and cottages throughout the country." He then points to the "very large sum annually paid to foreigners for apples, pears and plums which might be grown equally well in our own land." Five thousand pounds are needed, he says, to rouse the country to the importance of this question. Prizes are to be offered for the best farm and cottage orchards.

Men who have had long experience in the culture of fruit in England do not believe that the foreign competitors can be easily ousted from the English fruit market. The very same circumstances which enable the foreign corn growers to flood the English market assist the foreign growers and exporters of fruit. Last February I purchased, at a shilling a dozen, Tasmanian apples, which I was assured by a fruit farmer were almost equal to English apples which a few years ago were worth about sixpence each at that time of year. English growers cannot compete against such odds. All we can hope to do is to enable small cultivators to grow a good supply of fruit for their own consumption. It is in this direction that the efforts of the Royal Horticultural Society are likely to do much good. By its splendid exhibitions of fruit, such as were made at the Apple and Pear Conferences held a year or two ago, by the valuable information bearing on the whole question of fruit culture which was the outcome of the conference, and by the publication of this and similar information in its journal, this society has already re-established itself in the favor of horticulturists generally. We are proud of what has been done in the short time since the revival of the society. Three years have scarcely elapsed since the present effort began, and yet the record of work accomplished is probably as good as anything done by the best of your societies. As an instance one might take the last number of the journal, which is devoted entirely to Apples and Pears. It contains 376 pages. The first part is full of valuable information from the masters of fruit culture in England. Mr. Bunyard and Mr. William Paul write on Apples for profit, discussing soil, aspect, methods of culture and the best sorts to grow; Mr. Shirley Hibberd follows on Pruning, and then come three thoughtful papers on the subject of canker in fruit trees. Few men have perfect knowledge of this terrible disease, except that it comes mysteriously and appears to be incurable. Other diseases are discussed in a paper by Mr. John Fraser. Mr. Dunn, Mr. Cheal, Mr. Coleman and Mr. Saunders treat respectively on the best kinds of fruit for Scotland, Sussex, the Midlands and Jersey. Compensation for fruit planting—a subject of vast importance here, but of which you probably know nothing—the cost of railway carriage for fruit, are subjects which receive practical attention. The second part of the journal contains statistical and other

information relating to the cultivation of Apples in this country. Amongst other matters of interest, we find here proof that the following are the best and most generally cultivated Apples in England.

Six best dessert kinds: King of the Pippins, Cox's Orange Pippin, Ribston Pippin, Kerry Pippin, Blenheim Orange, Irish Pearmain. Six best culinary Apples: Lord Suffield, Dume-low's Seedling, Keswick Codlin, Warner's King, Blenheim Orange, New Hawthornden.

The discussion of grafting still continues in *The Garden*. It is condemned by some because it has not succeeded in a few cases, and it is defended by others, generally on the ground of its facilitating the work of the nurseryman. The real heart of the question is missed. Theoretically, grafting as a means of propagation ought to be just as successful as slips or cuttings, and practically we know that it is so. Certain simple rules must be observed by the operator, the first of which is what we may term consanguinity of stock and cion. The condition of both at the time of grafting, the manner of its performance, and the treatment of the grafted plants until the union is perfect, are necessarily important to the success of the operation. If clumsy workmen are employed, or if haphazard grafting is practiced, then failure will come sooner or later. But we cannot abandon grafting on this account. There is scarcely one in a thousand of our fruit trees that was not originally grafted; and many *Coniferae* and other ornamental trees are invariably propagated in that way, because it answers better than cuttings. One might point to numbers of exceptional specimens of rare trees and shrubs which have been grafted, and which, at the least, have not suffered on that account. No one condemns cuttings as "a delusion, a snare and a swindle," because some plants are a failure when propagated by their means. Many of the Pine tribe are useless when obtained from cuttings, as every experienced propagator knows; but there are those who, through ignorance or something worse, sell these plants obtained from cuttings. If we want timber trees we do not get them from cuttings, but from seeds. I am trying to show that if the failure of grafted plants here and there is to be urged as a reason for discarding grafting altogether, then the same argument has equal force in the case of cuttings. I am told that physiologically the union between stock and cion can be made perfect, and that the success or failure of a grafted plant depends solely on what we have called consanguinity. If stock and cion work together and the supply of nutrition is kept up, there is no reason whatever why a grafted plant should fail. On the other hand, a great many plants for which grafting is not suited are increased by its means. Rhododendrons, many Roses, Azaleas, and plants which sucker freely, ought not to be grafted. I helped, some years ago, to graft many thousands of Tea Roses on the Briar and Manetti, but I know now that they are better on their own roots and that they are just as easily propagated from cuttings. I touch upon this subject in the hope that some of your readers will think it worth commenting upon. You do things on such a gigantic scale in America that grafting is sure to be well tested with you.

Cultural Department.

Notes in a Northern Garden.

THE BEET, after the potato, is the favorite garden vegetable, and has a very wide sale in all markets. The long rooted kinds have mostly passed out of favor, though the old long blood beet has never been surpassed in quality. Well shaped beets of the turnip rooted class, round, smooth and with small tops, enjoy the greatest favor. All of these are early, but some are earlier than others, and, of late, the Egyptian has taken the lead, though good only when young. An "improved Egyptian" has lately appeared in the Boston market, which is a decided advance. The Eclipse has not seemed to me to be sufficiently fixed; at least it appears to me to vary too much in color and habit of growth. But the various forms of the dark red Blood Turnip Beet constitute the bulk of this crop as sent to market. In quality, the Bassano has never been surpassed among the early Beets.

Lately, Beets have, in many gardens, been affected with a disease which appears to be identical with the "scab" of the Potato, and, as with the Potato, the use of stable manure seems favorable to its appearance. Where badly affected, the crop is ruined for market.

Most amateur growers fail to thin out their Beets sufficiently, and the result is a small crop of small and inferior roots. In order to get a large crop of really good beets, the ground should be well enriched, and the crop carefully thinned to four inches

apart. Beets three to four inches in diameter are better than smaller ones, and many families understand that these large beets, especially if baked, are far superior for the table to smaller ones.

Beet seed is easily grown, and every gardener who is desirous of fine beets should raise his own seed, carefully selecting medium sized roots, having the characteristics most desired. These should be preserved in sand, carefully set out as early in spring as possible, and the seed stems supported as they grow by small stakes and string. A dozen beets will produce a pound or more of ripe seed.

Is the wild original of our garden Beet an annual, like the

A new Rhubarb bed, which I set out last spring, has surprised me by its remarkable growth. The ground was heavily manured on the surface, and plowed about eight inches deep. Roots with from one to three buds were set rather deeply four feet each way, and did not seem to grow remarkably fast at first. But about midsummer they started ahead with tremendous vigor, and by the middle of September plenty of stalks could be found that would weigh a pound each. What seemed remarkable was, that at that time these stalks were in nice tender eating order, while those from old beds were hard and stringy.

Parsnips, as well as Beets, need careful thinning to produce

Fig. 141.—*Viburnum lantanoides*.—See page 531.

Carrot? It will sometimes send up a seed stem the first year; but also it will occasionally not send one up the second season when set for seed, but will increase in size and be as good for the table the second fall as the first. I have heard of beets in California growing on in this way for several seasons and attaining very great weights, exceeding 100 pounds.

Onions, especially onions grown from sets, have shown a disposition to rot this year. The decay begins in the spot from which the roots issue, and is of a dry character. I have noticed the same thing in "multipliers," or "potato-onions," years ago, but never before in the crops grown from black seed. If this disease extends, it will make onion growing for market an even more precarious business than it now is.

good merchantable roots. I find five inches asunder not too much. The land for Parsnips, unless very light, needs deep tillage to get well shaped roots. If one is growing this vegetable for market the care necessary to get long and evenly sized parsnips is well expended. A load of this character will find a speedy sale where crooked, "sprangly" roots would fail of a buyer.

There is a considerable improvement in Carrots lately. The new Chantenay is quite astonishing in its uniformity and smoothness. Planting an experimental plot among my other Carrots, I am so pleased with it that I shall hardly care for any other sort for market sales.

Newport, Vt.

T. H. Hoskins.

The Grape-fruit in Florida.

FLORIDA is notably the land of flowers, but it is quite as truly a land of fruits. Her Citrus fruits are now known the world over, and her large grape-fruit and shaddock, hitherto little appreciated by northern people, are beginning to appear regularly on our market-stands along with her oranges, limes, lemons, bananas, pineapples and dates. Many persons use the words shaddock and grape-fruit interchangeably, and the shaddock is, in fact, a near relative of the grape-fruit, but is much larger, often weighing from three to five pounds. It is also coarser than the grape-fruit, and has not yet proved very useful, but the tree and fruit as they adorn the lawns of many southern homes are strikingly beautiful. The fruits grow singly on the trees, and look like veritable pumpkins suspended from twigs. The tree comes from China and Japan, and was first brought to the West Indies by one Captain Shaddock, from whom the name was taken. There are said to be upward of forty distinct varieties of the fruit in Florida, some of which are very large and of use for canning or preserving in the same way that citron is put up. The shaddock is also known as pomelmouse or pummellow. This fruit has probably never been exhibited in our northern markets for sale. It is not of sufficient value to warrant shipping it north, for even the natives in Florida seldom take the trouble to gather it. It will doubtless be found of use in time, however, and until then it will ripen and die upon the trees in southern groves.

The cultivation of the pomelo, or grape-fruit, is extending rapidly in the south, and it is becoming a first-class marketable fruit, very valuable in the spring and early summer, after oranges are about gone, and by many people esteemed equal to the orange. When it becomes better known it will be a popular fruit during the spring months. It is prepared for the table by removing the bitter, white membranes and sprinkling the pulp with sugar. In warm weather, after it has been iced, the melting pulp and juice from between the membranes are deliciously refreshing. The pomelo can be grown more easily than the orange, and it yields more to the tree than any other member of the Citrus family. The fruit grows in clusters, two, three or four hanging together from one stem, from which peculiarity the name of grape-fruit was given to it. The trees are beautiful objects covered over with rank, glossy, dark green foliage, and loaded with thousands of bright, pendent, yellow globes. I have seen a twig no larger than my little finger with five or six big pomelos hanging from it. A comparatively small tree will often bear as many as two thousand at a time.

California also produces these fruits, but most of them come from Florida. They are sold on fruit stands according to size at from five cents apiece to fifteen cents apiece for very large ones. They vary in quality as much as oranges do, and while the good ones are very good, the bad ones, if green, are very bad. Those with smooth white skins are the best, and a little rust on them will not hurt their flavor or juiciness. The fruit is always cut from the tree, as the orange is, wrapped in tissue paper, and packed carefully in barrels rather than in boxes. They are not sized as oranges are, but are sent north with the number of fruits in each barrel marked on the outside.

It has been said by more than one southern fruit-grower that a fortune was waiting the man who had the courage to plant a grove of grape-fruit trees, and depend on them for a living. Heretofore there has been no systematic cultivation of the trees. Two or three trees are planted around the yards or orchards for ornaments as much as for anything else, and allowed to take care of themselves. If properly treated, however, their yield would be much larger than it is to-day, and a good profit could be made from them. The trees should be set out about fifty feet apart each way in soil that has been prepared for them beforehand. If possible the young trees should be taken from soil like that on which they are to grow in the future; that is, if they have come from Pine-land they should not be grown on hummock-soil, otherwise the trees will become stunted while adapting themselves to the change of soil, and never perhaps attain the vigorous growth that they should. The holes should be made large and shallow, and the dirt worked among the roots with the hand, until it is packed firmly and settled by shaking the tree up and down. If planted too deep the trees will be smothered, and not do half so well as when given shallow planting. If the soil is at all dry, a pail of water can be given to each tree in planting, so that the earth is washed among the roots, and the surface should then be covered with dry soil. Trees planted in this way, and then mulched, will send out new roots and shoots almost immediately. For young trees with tender, sappy buds, a slight protection of coarse, long grass, found growing spontaneously in every old-field,

if stood up and tied about the trees as gardeners protect Roses from the cold, has been found to repay cost. Muck or commercial fertilizers applied around the roots of the trees, or plowed into the soil generally, will greatly help them in their growth. Weeds should be kept down, and a good way to do this successfully is to plant Cow Peas between the rows, and plow them under. They make a good fertilizer for Florida land. Cultivation should cease late in the season, to allow the young growth to ripen and be in condition to resist frost.

New York.

George E. Walsh.

Orchid Notes.

Dendrobium Brymerianum.—This is a very handsome and interesting Orchid, and should be in every collection. The terete bulbs are about fifteen inches long, very much swollen in the middle and tapering at each end, with four or five persistent lanceolate leaves at the apex. The flowers, which are produced in short racemes from near the top of the bulbs, are about three inches in diameter and of a rich golden yellow. The lip is very much fringed, the front lobe terminating in a long branched fimbriation, which renders this species very striking, and distinct from any of its congeners. *D. Brymerianum* was introduced from Burmah in 1874, but it has never been very plentiful. A few years ago plants from another locality were sent out for this species, but they proved to be a worthless variety, since named *D. histrionicum*. This variety may easily be distinguished from the true species by its short and more swollen stems. The flowers in this variety are small. The peculiar beard-like appendage of the lip being rarely developed, the flowers are often self-fertilized in bud, and do not open at all. *D. Brymerianum* grows freely in the warmest house, is strong rooting, and requires abundance of water during growth. It should not be kept very dry in winter, providing the house is warm.

Cælogyne (Pleione) lagenaria.—This is one of a small genus now included in *Cælogyne*, popularly known as Indian Crocus. It is a charming little Orchid, and its flowers are particularly welcome at this season. The bulbs should be planted pretty thickly in small shallow pans, so that when the flowers appear (which they do as soon as the leaves have ripened and fallen off) they will completely cover the surface of the pan, the flower scape being only about an inch long. This Orchid requires rich soil and liberal treatment during growth, but the bulbs need thorough ripening in a cool house to ensure a good crop of bloom.

Cattleya labiata vera.—This grand old species is now in perfection with us. It is of very distinct habit, and may easily be distinguished from its congeners. The clavate bulbs are about one foot long, proceeding from an unusually thick rhizome, and bearing a very thick coriaceous leaf about ten inches long, both bulb and leaf being suffused with reddish purple. The flowers, usually three on a peduncle, are about six inches in diameter, with narrow sepals, and broad, wavy petals of pale rose. The lip is very handsome, the anterior lobe, which is deeply emarginate, is very crisp and of a deep magenta-purple, with deeper colored veins extending into the throat. The side lobes are convolute and pale rose. A characteristic of this species is the purplish double flower-sheath.

The true *C. labiata* is a very rare plant, though among the first known of the genus, having been introduced from Rio Janeiro about eighty years ago; but as no plants have been found (though diligently sought for) for nearly forty years, the species is believed to have become extinct in its native country. In order to develop its massive bulbs this plant requires very liberal treatment in respect to heat and water, also plenty of air and light, and though it may be kept moderately dry during the winter months, the warmest corner of the house should always be given to it.

The finest specimens and freest grown plants I have ever seen were grown in an old-fashioned flue-heated stove pit, with the pots plunged in tan bark, and this same pit has contributed very largely toward preserving this noble species to our collections.

Kenwood, N. Y.

F. Goldring.

Corydalis lutea.—This pretty *Corydalis* flowers more continuously than any hardy plant I know. Its bright yellow flowers appear in May, and the plant is still bright with them (October 30th), in spite of the severe freezing it has been subjected to; and from May until November there is not a day on which it is not in flower. *Corydalis lutea* is a native of southern Europe, where it grows in waste and rocky places. It has become naturalized through long cultivation in many countries where it did not grow originally, like England and some parts of northern France and Germany, but in this country it is not

seen very often. It is described as an annual or as a perennial, forming a tufted stock of many years' duration. Here it is a true perennial, and has been growing for years in the same place in my garden, where it has become a compact cushion, a foot high and more than two feet across. The leaves are pale green, twice divided, with obovate, cuneate segments, an inch or more broad and cut into three divisions at the extremity. The bright yellow, cheerful flowers, which are rather more than an inch long, are borne in short racemes well above the foliage on slender stems. This plant is easily increased by division or it may be raised from seed. It requires no care or cultivation, and it will thrive in rocky soil and exposed situations, as well as in the best garden loam. It is an excellent rock-garden subject, and a good plant to tuck into some out-of-the-way or neglected corner of a garden, where it will go on flowering and giving pleasure indefinitely.

Boston.

C.

Dicentra eximia.—Last spring we took occasion to call attention to this plant as one of the best of recent additions to the list of native plants, suitable and desirable for cultivation. After the second season's trial of it we cannot forbear to mention the fact that from the first week in May to the last week in October *Dicentra eximia* has been constantly in flower. Moreover, the odor so apparent in *D. spectabilis* and other varieties of the *Fumariaceæ*, is totally absent in the plant under note. The figure of *D. eximia*, given in the "Dictionary of Gardening," is not a good representation of the plant, as it is with us. This may be accounted for on the supposition that the difference in climate affects the appearance of the plant, or that our plant is a geographical form of the plant commonly grown elsewhere under the name of *D. eximia*. Our original plant came from Tennessee, where it is by no means common in a wild state. There, however, it seeds freely, whereas here it rarely produces a seed vessel, owing probably to the absence of the necessary insect agency. The flowers are closed at the apex, and the bees here, when forcing an entrance, injure the organs of reproduction to such an extent as to preclude the possibility of successful fertilization. *D. eximia* must therefore be propagated mainly by division, and this is easily accomplished early in spring before the growth is far advanced. It may also be added that when seed is produced it must be sown at once, and then germination will take place the following spring. Seeds of plants included in the order *Fumariaceæ* are notoriously long in germinating.

The Forest.

Some Japanese Trees in New England.

DR. GEORGE R. HALL is the first American who sent Japanese plants to the United States, in any considerable numbers, at least. His first visit to Japan occurred in 1860; and his first shipment of plants was made not very long afterwards. They were sent principally to Mr. Parsons, of Flushing, who propagated and distributed them, as well as a number of other Japanese plants sent home by Mr. Thomas Hogg, who a little later lived several years in Japan and devoted much attention to collecting seeds and plants for the Flushing Nurseries. A number of Dr. Hall's Japanese plants were planted early on his farm near Warren, R. I. (about 1870), and have grown into what, I believe, are the finest specimens of certain species which can be found in the eastern states. Some of them I have not seen equaled in Europe. A few notes, therefore, upon these trees which I have recently had an opportunity of visiting will, perhaps, be interesting.

The plantations are confined, in the main, to the northern and eastern sides of an open field, on the top of the ridge which extends continuously from the town of Warren to Bristol. It is open to the south-west and fully exposed to the south-west winds which sweep up Narragansett Bay. The situation, I should think, was a very trying one, especially for conifers. The soil of the field, however, is a good strong loam, and close planting has been of assistance to the trees, which are principally conifers.

Two or three specimens of deciduous trees may be mentioned. The first of these is *Zelkova Keaki*, with a short trunk fourteen inches in diameter, dividing into a number of stout, upright branches. This tree has a total height of fully thirty-five feet. It is the only specimen of this plant I remember to have seen growing in the United States, and I have never seen one a quarter of the size in Europe, although larger ones exist, perhaps, in the Mediterranean countries. In habit, Dr. Hall's plant resembles a common form of the American Beech of the same size, and the bark is not unlike the bark of

that tree. The following account of the *Zelkova*, which is one of the largest and most valuable of the Japanese trees, is extracted from Rein's "Industries of Japan" (see GARDEN AND FOREST, page 321 of the present volume), in which will be found the most satisfactory account of the economic properties and uses of many Japanese plants which has been published:

"The *Keyaki* (pronounced *Kéaki*) of the Japanese is a stately, and, because of its wood, a useful tree, found in forests and temple groves, as well as along the sidewalks of village streets, particularly in the neighborhood of Tokio. It sometimes reaches prodigious size, from ninety to 120 feet in height and thirty feet in circumference. In appearance it has a strong resemblance to *Celtis australis*, of the Mediterranean regions, as for instance the fine specimens of this kind in the Botanical Garden at Madrid. But it is also similar to our *Beeches*.

"*Keaki* is the favorite joiner's wood, and plays in Japan the part of oak wood with us, and is somewhat like it. Its most notable recommendations are, that it does not split or warp easily, so that cross sections may be used, that is, for trays and bowls, as is done in the Hakone mountains. It is also noted for its great toughness, elasticity and durability, as much in water as in dry air, if not felled when full of sap. The smooth, gray-white bark resembles in color and thickness that of our *Beeches*; the soft, light-colored sap-wood is quickly transformed into grained wood, whose color varies according to the situation and age of the tree, from light to dark brown. To make it more valuable, the color is often deepened by a long submersion in water before working. *Keaki* is lighter than oak, having a specific gravity of only 0.682. When cut crosswise its small pith-rays are easily distinguished, as is the case with all elms, and the girdles of numberless larger pores on the inside of the year-rings is plainly marked. These pores and their walls show very distinctly even when cut lengthwise. This reveals also the parallel and straight-fibred character of the ordinary wood. It serves the Japanese for many purposes: in ship and house building, in furniture making, turnery ware, and for manufacturing many small articles. It takes different names according to its coloring, the highest estimate being placed on *Tama-moku*, or speckled wood, also called *Tama-no-keaki*.

"In all the qualities which have been mentioned, it excels the other *Ulmaceæ*. On the other hand, its branches are so fine and its foliage, like the *Celtis*, is so light that it cannot be used like the Elm as an ornamental or shade-giving tree. Its draft upon the soil is about the same as with its kindred. It is found in its best condition on light clay soil, in which it can spread and develop its roots symmetrically. It belongs to the lower region of the mountain deciduous forests, and in Hondo seldom grows beyond an elevation of 800 to 1,000 m. It is not widely distributed or frequent, and only attains on the plains, in temple groves and along the roads, those large dimensions which distinguish it beyond all other deciduous trees, except the *Camphor Laurel*."

There is in the garden near the house the finest specimen of *Quercus dentata* which I have seen. It is about twenty-two feet high and well furnished with branches nearly to the ground. It is always a striking plant on account of its conspicuous buds and large, deeply lobed and brightly shining leaves, which are often more than two feet long. They turn, later in the season, to deep orange, but at the time of my visit (October 24th) were quite fresh and green, although the leaves on all the native Oaks in the neighborhood, both White and Black, had changed color some time before, and were falling. This Oak is often grown in Japan, according to Rein, as a small ornamental tree for gardens, on account of its handsome foliage. He found it very common on the island of Yezo, and as a shrub on the borders of volcanic forests in northern Hondo. The wood is said to be coarse grained and to possess little value. *Quercus dentata* is often known in gardens as *Q. Dai-myō*, and it was first distributed from Flushing as *Q. Halliana*.

Near the Oak is a plant of *Magnolia hypoleuca* (GARDEN AND FOREST, vol. i., f. 49). It is much smaller than Mr. Hogg's tree in New York; but the fact that this fine species is hardy in New England is interesting. It is the *Ho-ko-ni* of the Japanese, and Rein gives this description of it:

"This fine, highly interesting tree appears in all the mountain foliaceous forests of Japan from Kiushiu to Yezo, not, however, collected together, but scattered about among other deciduous woods. Toward the north its frequency increases; it attains here, also, its largest dimensions, with trunks of more than six feet in circumference and sixty to seventy-five feet in height. It is found, also, in the high foliaceous forests of middle and northern Hondo, on the island of Yezo, and

even in southern Saghalin. It rivals in height and thickness the other deciduous forest trees in its company, and all the other varieties of its own race, even the North American *M. grandiflora*. Few of its kindred endure the rigors of winter so well.

"Ho-no-ki loves a good soil, and grows best in the shade of high trees, especially the Beech forests. Oaks, Maples, Ashes, and especially *Esculus turbinata* and *Acanthopanax ricinifolia*, are frequently its companions.

"The smooth, grayish-white bark of the straight trunk, which in thick, high forests is branchless to a considerable height, reminds one of the Beech. The crown is formed of thick, widely spreading, but not so numerous nor so ramified branches, and its leaves and flowers give the tree a peculiar beauty."

"Every branch develops about ten leaves, which are crowded together in verticillate form near the end. In the midst of this beautiful wreath of leaves there unfolds, about the middle of May or beginning of June, a splendid large white flower, with a pineapple-like perfume. Even later in midsummer the Ho-no-ki tree presents a surprisingly beautiful appearance. When the wind sways the foliage of the Magnolia-lined mountain side, and the lower side of the leaf is turned upward, the tree looks to one at a little distance as if it were for a second time covered with blossoms.

"By October the trees are bare. The long, ellipsoidal, reddish brown fruit capsules, with their pink seeds, soon follow the leaves. The seeds, like all of this species, soon lose their germinating power, which is probably the main reason why the Ho-no-ki is still a stranger to our European gardens. The Ho-no-ki in Japan surprises and delights every lover of plants, and it is easy to agree with Dupont when he calls it more ornamental than *Magnolia grandiflora*.

"The light, grayish-white wood changes gradually to a deeper shade. It is soft, easily bent, and elastic, and has a fine, even grain, which makes it applicable to many uses. The wood engraver uses it in patterns for cloth printing, and the lacquerer finds it adapted to various small articles. The sides of the pretty, light and durable oval bread baskets are generally made out of Ho-no-ki. Two thin strips of the wood are bent around the elliptical pine wood bottom, their sharpened ends bent over each other and glued, and tacked to the bottom board. Sword sheaths (Katana-no-saya) were also formerly made out of Ho-no-ki. In Niigata and Yonezawa it is used as the groundwork of nearly half of all the lacquer ware, and from it is prepared the soft, fine grained charcoal which is used throughout the whole of Japan for rubbing the lacquer and for polishing the enamel of cloisonné ware."

Taxus cuspidata is represented by a broad pyramidal specimen twelve feet high, the branches covering a space on the ground forty feet round, and producing fruit sparingly. This is by far the finest specimen I have ever seen. *Taxus cuspidata*, according to Rein, is "a bush or low tree eighteen feet high, found mostly in Hida and in Yezo, and used often as a decorative plant. Its highly valued wood is marked by a beautiful red color, fine grain and great toughness. On account of this last quality it is used by the Ainos for their bows." The Japanese Yew is now considered by Maximowicz a form of the widely distributed *Taxus baccata*, the so-called English Yew. As seen in cultivation here it differs from the common forms of that species by its longer leaves and by its more strictly pyramidal habit. There seems no question of the hardness of the Japanese plant, even in the most exposed positions; and as it is the only Yew which grows to any size, which is hardy in the extreme northern and eastern states, it is destined, probably, to play a considerable part in the decoration of northern gardens. This plant is still exceedingly rare in cultivation, and little known in this country and in Europe.

Abies firma appears in Dr. Hall's plantations in half a dozen specimens twenty-five to thirty feet high, with stout, clean trunks, bare of branches to a height of five or six feet from the ground. The specimens are beautifully colored with dark green leaves, and are growing with the greatest vigor, especially the main stems, the leading shoots of the year being all two to three feet long and remarkably stout. *Abies firma* is one of those trees which grows at the top at the expense of the lower branches, which are generally weak, become shaded by those above them, and so die early. This habit takes away from its beauty as an ornamental tree, but makes it more valuable for forest-planting, where the production of long, straight timber, free of knots, is desired. This species, the Momi of the Japanese, is, according to Rein, "spread over the whole of Japan; more general, however, in middle and northern Hondo, and on the southern Islands. It is found chiefly, and

in the highest development, in mixed forests, among the beautiful deciduous woods, at an elevation of between 3,000 and 4,500 feet, seldom isolated. It develops the most magnificent trunk of all the Japanese Firs, and grows in parks and temple groves to a height of ninety to 120 feet, with a circumference of twelve to fifteen feet. In its entire bearing, as well as in the character of its wood, this tree resembles our *Abies pectinata*, but has a much slower growth. Its wood is lighter, rougher and less tough than that of the Pine, hence cheaper and less valued. It is seldom used in house building."

The best specimens of *Picea polita* I have seen are in this plantation, the largest being about twenty feet high. They are all well furnished to the ground, and have stout, vigorous leaders. These specimens, of which there are half a dozen, appear, on the whole, promising, although I noticed on one or two of the trees that the leaves on the lower branches had turned yellow and were falling, a not unusual thing with this tree, which I believe, however, will prove to be one of the most valuable of the Japanese *Abietina* for this climate. It makes, Rein tells us, "a fine stately tree, with the bearing of *Picea excelsa*, belongs to the high mountain districts and northern parts of Japan, and is little used. In modern times, on the island of Yezo, however, it has been much employed in building." This species is the latest of all the Firs to begin its growth here, and would, therefore, be valuable in countries where late spring frosts are common.

Chamaecyparis (Retinospora) obtusa has been used successfully by Dr. Hall in forming wind-breaks, which are now fully twenty feet high; and there are a number of fine single specimens twenty to thirty feet high scattered through the plantation. These represent one of the most graceful and desirable forms of this exceedingly variable species, which, as it is seen here, is very ornamental, although generally unsatisfactory in this country. This tree, in Japan, occurs most generally on mountain-sides, where it grows to a height of ninety or 100 feet, with a trunk three or four feet in diameter. It is the Hi-no-ki of the Japanese, and "is particularly sacred to ancestor cultus (Shinto worship), and is cultivated on this account more than any other. The wood is white or pink, smooth, light and very tough, fine grained, poor in resin and free from knots. It is preferred for lacquer ware, and used exclusively for building Shinto temples. The palaces of the Mikado and his family at Kiôto were always built of Hi-no-ki wood, and roofed with the bark of the tree, which, when very old, can be easily cut into long stripes. Criminals condemned to harikari (disemboweling) were formerly presented with a dagger upon a small white unlacquered table of Hi-no-ki wood, and on a similar one is offered the food and drink to the gods at festivals."

There is a perfect specimen of *Thuopsis dolabrata*, twelve to fourteen feet high, a large size for this country, where this tree is, unfortunately, less hardy than many of the Japanese conifers, but by no means an unusual one in Europe, where it thrives admirably. According to Rein "the wood is yellow, is marked by its durability in water, and is therefore much used for stakes, as well as in ship and bridge building. It is also employed for lacquer wares and window sashes."

There are several specimens of *Pinus densiflora*, thirty-five to thirty-eight feet high, with spreading branches resting on the ground and covered with cones. The trunk of the largest specimen girds forty-two inches three feet from the ground. This is a picturesque, but hardly a handsome, tree. It has the advantage, however, of growing rapidly on poor soil and of being perfectly hardy. It is the *P. Massoniana* of many gardens, but not the true *P. Massoniana* of Lambert, which is a south China species, not hardy here. Rein says that "*Pinus densiflora* (Kuro-matsu) makes the least requirements as to soil of any tree in Japan. If the sand dunes, thrown up by the waves of the sea, have attained some firmness through the settlement of deeply rooted strand plants, among which generally the creeping Juniper (*Juniperus littoralis*) is often found, the Japanese turn them to good use by plantations of Kuro-matsu. This Pine is, therefore, of very much the same importance here as *Pinus Pinaster* in the French Département Des Landes, which has been previously mentioned. From the coast to 300 metres above the sea we find the Kuro-matsu on land that would afford no support to other conifers. It comes to its best as a shade tree on the country roads and in temple court-yards. Trunks from 150 to 200 years old, with a circumference of twelve to eighteen feet, and ninety to 100 feet high, are here not infrequently found."

Two plants in Dr. Hall's plantations, which I take to be *Abies Cilicica*, surpass in beauty the Japanese plants; and if my determination of the species is correct, this is certainly one of the most ornamental Silver Firs which will thrive in the

northern states. These specimens are slender, narrow pyramids, fully thirty-five feet high, and perfectly furnished with branches. These have a tendency to turn up at the ends, and so expose the white under surface of the leaves, thus giving to the whole tree a decidedly silvery appearance, which is striking and beautiful. This species is too rarely seen in collections. It suffers in England from spring frosts, and is, therefore, rarely propagated in English nurseries; and I have never seen a good specimen in Europe. This will sufficiently explain why the Cilician Fir has not been planted more often in this country, in spite of the fact that Dr. Hall's plants and several fine specimens in Mr. Hunnewell's Pinetum show that it is able to adapt itself to the climate of New England.

Variegated Wild Plants.

To the Editor of GARDEN AND FOREST:

Sir.—In 1888, at Nonquitt, Massachusetts, I noted the following variegated plants:

Spartina cynosuroides.—Finely striped with gold. It did not blossom either in that or in the succeeding year, although the green variety adjoining bloomed as usual.

Kalmia angustifolia.—Finely gold-blotched. I distributed a number of herbarium specimens. * On visiting the locality, which was along the road-side, in 1889, I found the whole patch had been cleared off and burnt over.

Rumex acetosella.—In 1889 I found a single specimen beautifully variegated with yellow. It had a more compact growth than usual, and with a little increase of size might have been deemed attractive.

Barbarea vulgaris.—While at the New York Agricultural Experiment Station at Geneva, a specimen very prettily variegated with white blotches was removed to the greenhouse and grown for two years, retaining its variegation during the whole time.

Will some of the readers of GARDEN AND FOREST add to this list?

South Framingham, Mass.

Data Concerning the Growth of Native Trees.

To the Editor of GARDEN AND FOREST:

Sir.—In the spring of 1835, a considerable number of White Pines (*Pinus Strobus*) were planted about my residence. Of these fifteen are still standing and are apparently in full vigor. My uncle, who planted these Pines, states that they were of very uniform size, their trunks measuring about two and a half inches in diameter. At present, the smallest of the series measures forty-three inches in circumference, four feet from the ground, and the largest seventy-nine inches. Nine of them vary from sixty-two to sixty-eight inches. The average circumference of the fifteen trees is sixty-two and a half inches.

These trees were not placed at uniform distances from each other, and some show the certain ill effect of overcrowding. This is conspicuously the case with three of the Pines, and these have suffered. Had the planting been done with greater reference to the future, and an equal chance given each tree, the average circumference would have been greater by at least three inches; the girth of the twelve largest being sixty-five inches. As it is, including the three somewhat stunted trees, the growth (circumferential measurement) has been sixty inches in fifty-four years; an annual increase of one and one-ninth inches.*

These Pines stand upon a bluff, composed of compact, ferruginous sand of great depth, and are exposed to the full sweep of the western and northern winds. In the matter of soil and exposure they have had equal chances. It is not readily seen, if at all determinable, why more of these trees should not have reached the maximum size, and become stately trees, which, in a sadly deforested landscape, are commanding objects.

A year later two Wild Cherries (*Prunus serotina*) were planted near the Pines, by the same person. "These trees were very small," he writes me, "as I pulled them up with my hand and carried them to the yard, as one would a walking stick. Probably neither were more than an inch in diameter." These trees are in full vigor to-day, one measuring seventy-

*Since the above was written, one of these Pines has been felled and the rings of annual growth carefully counted. They are sixty in number, which accords with the history given above of the planting, now nearly fifty-five years ago. It may be well to add that, while each ring is distinctly defined, there are several much larger than the others, and a general increase of the width of the rings upon the south-eastern side of the trunk.

three inches and the other sixty-eight in circumference. The former is fully fifty feet in height; and the crop of fruit it bears annually is enormous.

In 1836 my grandfather found among a lot of Peach-trees that he had purchased an Elm (*Ulmus Americana*) which "was a mere switch." It was planted in an out-of-the-way corner, and is now a splendid tree, with a spread of branches measuring seventy feet. The circumferential measurement, at a height of four feet from the ground, is 103 inches.

Of the Oaks, Cedar and Beech, of which I have many fine specimens upon the farm, I have not been able to gather any definite data, but it would appear that the growth is exceedingly slow after a certain term of years. My uncle is very positive that a Black Oak in the lane and a Red Cedar near by have not increased materially in growth in the past half century. He believes the Cedar to have "quite stood still," and this may not be so strange, for it is known to be considerably over 100 years old. It was a conspicuous road-side tree in 1802. It measures but eighteen inches in diameter.

Charles C. Abbott.

Chrysanthemums at the United States Nurseries.

To the Editor of GARDEN AND FOREST:

Sir.—No horticultural event last year aroused more interest than the exhibition in the fall of a few blooms of the Mrs. Alpheus Hardy, a white Chrysanthemum of unique beauty. On the last day of October I visited the establishment of Messrs. Pitcher & Manda, who signalized the opening of their business career by the courageous purchase of this variety for a much greater price than had ever been paid for a Chrysanthemum. The visitors who will throng these nurseries this week, at the invitation of the proprietors, will find the flowers in more advanced condition than when I saw them, but, even then, the Chrysanthemums were already massed and tastefully arranged in one of the larger houses.

The general effect, as one passes from the Orchid houses and stands on the steps by which entrance is had to the larger and lower house, is one of striking beauty, a great mass of the Mrs. Hardy filling the entire centre, and the fine blooms of the general collection lining the entire outer circuit. Standing here to enjoy the general effect, one notes the strong and weak points of this favorite flower. Certainly no other species gives us the wealth and diversity of bloom, such grand flowers here and delicate ones there, with innumerable shades of color—here the soft white of Mrs. Hardy, there whites of all tones; yellows, from palest primrose to deepest orange; reds and bronzes of seemingly every possible combination. The true blue Chrysanthemum has not appeared, but, unfortunately, there is blue mixed with the reds, and this is the most discordant color in the family. Noting the vigor of the plants and the bold and massive effect of the blooms of a well grown collection, one is impressed with the masculine beauty of this flower, and it seems a pity that it has not been dubbed the "King of Autumn" instead of "the Queen." In the centre bed were planted some 2,000 late struck plants of the Mrs. Hardy, which were blooming freely, although not yet in perfect form. Judging from some grand flowers on the larger plants at the end of the house, this variety is fulfilling all its promises.

Messrs. Pitcher & Manda have also been fortunate in securing the newest seedlings of Dr. H. P. Walcott, who is well known as the first raiser of American seedlings and an enthusiastic amateur. Noticeable among these were Shasta, clear white, globular heads, tubular florets; Semiramis and Tecumseh, both in the way of Mrs. Wheeler; Adirondack, a fine Chinese incurved sort, very pure white; Ramona, an incurved Japanese, light amber; Monadnock, a yellow Gloire Rayonnante, and Manitou. Here are also some promising Short Hills seedlings, the best of which is said to be Number 26, a full globular flower, pink and rather early. Among a consignment of Japanese varieties received this year the most promising are provisionally named 4xxx (white), 18 (bronze), 9 (yellow), 4x (deep yellow). All the well known best varieties are grown, as well as the latest productions of the Continental florists. Some of the most promising of the new kinds under trial are "C. Souchet" (Del.), coppery, reflexed; Suzon (Rey); La Tosca (Del.); M. Louise Leroy (Del.), one of the best of the new whites; M. Constant Varin (Del.), yellow, fragrant; La Fortune (L. Lac.), yellow (extra); Belle Pointevine (Brt.), very fine white, incurved. Those who do not succeed with Empress should try this and Walcott's Adirondack. Of Fewkes' set L. B. Bird and Kioto seem to be the choice.

As is well known this nursery has a grand collection of Orchids, and though comparatively few are in blossom at this

season several charming banks are arranged on the benches, with here and there a gem. Such a plant is *Lælia Eyermannii* alba, the only individual known. *Vanda Sanderiana* and *V. cærulea*, in fine form, are, however, plants which would better satisfy the ordinary eye. Cypripediums are to be seen in apparently countless profusion, they being a great specialty here. Nepenthes, too, are abundant, while great masses of Palms and decorative plants fill every spare space, and all seem in robust health and carefully grown.

A new Cuphea, whose varietal name I did not learn, was shown in a great mass—an almost startling combination of scarlet and purple with white stamens. It is said to be an excellent bedder.

Aside from the flowers one could not but notice the remarkable order, neatness and care everywhere evident, and the vigorous health of all growing things.

Short Hills, N. J.

G.

Notes.

A meeting of influential citizens in the upper San Joaquin Valley has been held to take steps toward securing a large reservation in the Pine and Sequoia forests of the Sierra in the Fresno and Tulare region. The subject will be pressed at the approaching convention of fruit growers in Fresno.

An agricultural and forestry exhibition, under the auspices of the Imperial Agricultural Society of Vienna, will be held in that city next summer, from the 15th of May to the 15th of October. Forest products of Austria and Hungary only will be admitted, but foreigners are invited to exhibit machinery and tools used in cutting timber and manufacturing lumber, and to contribute memoirs on scientific subjects relating to the forest.

The autumn exhibition of the Hampden County Horticultural Society will be held at Springfield, Massachusetts, on November 12th–15th, when it is expected that one of the best collections of Chrysanthemums ever seen in New England will be displayed. The Connecticut Valley Florists' Club offers a year's subscription to GARDEN AND FOREST for the best new seedling Chrysanthemum, shown this year for the first time by the grower and having real merit.

Berberis Thunbergii was, last week, the most beautiful shrub in the Arnold Arboretum to many persons. The plants still retained their foliage, which had turned to the most brilliant scarlet, and were loaded with the bright red fruit, which hangs on the branches until the appearance of the new leaves in the spring. There is certainly no shrub more attractive in the fall of the year than this Japanese Barberry, and none which retains its autumn brilliancy for a longer period. It has proved an introduction of first rate merit.

One of the most beautiful of all shrubs in the color of its autumn foliage is the Japanese *Euonymus alata*, which just now is at its very best. The leaves of this plant turn bright rose colored, something unknown in other plants, or certainly very unusual. The broad, corky wings which grow on the branches give interest to this species, but the flowers and fruit are small and inconspicuous. The beauty of its autumn foliage, however, compensates for this; and this *Euonymus* should find a place in every garden in which shrubs are grown.

Zanthorhiza apiifolia, the Yellow-root of the Alleghany Mountains, a low under-shrub with spreading root-stocks and handsome pinnate foliage, is one of the last plants in the garden to take on its autumn colors, which are brilliant orange and scarlet. This alone would make the cultivation of the Yellow-root desirable. The habit of the plant, moreover, is good; the foliage is always attractive, and, as it grows well under trees and spreads rapidly, it is a desirable subject for covering shaded banks and slopes, in spite of the fact that neither the flower nor the fruit is at all conspicuous.

A combination of autumn colored foliage, which has come under our notice this season, is worth recording. A European Beech and a Scarlet Oak are growing next to each other in a large circular group of trees on the lawn of a suburban villa near Boston. Three or four of the large branches of the Oak have grown through those of the Beech and protrude several feet beyond them. The leaves of the Beech are still as bright and green as they were in midsummer, while those of the Oak have turned brilliant scarlet. The effect of color produced by the contrast of these two trees standing side by side is splendid, and it is greatly heightened by the scarlet branches of the Oak growing as it appears directly out of the green Beech.

The New Hampshire Forestry Commission met at Concord, October 4th, and organized by electing Joseph B. Walker, of Concord, President, G. Byron Chandler, of Manchester, Treasurer, and J. B. Harrison, of Franklin Falls, Secretary. The commission will endeavor to stimulate popular interest in the preservation of the characteristic scenery of the state and to make a thorough examination of the present condition and methods of treatment of the mountain-forests. As New Hampshire has no state lands, nothing can be accomplished for the preservation of the forests except by the intelligent co-operation of private land-owners and lumbermen.

Two years ago a Mr. Barber tried the experiment of planting Pampas Grass on five acres of land in San Bernardino County, California. A few weeks ago he cut from the five acres 70,000 plumes, which he sold for three and a half cents each, or \$2,450 for the crop. The expense of caring for the five acres has not been in excess of \$450, and the crop has netted him \$400 an acre. Next season he expects to net \$500 an acre, as the plants will then be three years old and in full bearing. The demand for the plume of the Pampas Grass is constantly increasing and it has been demonstrated that it can be profitably grown on high-priced land.

The number of Orchids of good varieties, and the quality of the specimens which are now seen in the florists' windows in this city, shows, more clearly than anything else, the great advance which has been made in the general cultivation of these plants in this country and the appreciation in which they are held for decorative purposes. High-class plants like *Vanda cærulea* and other Orchids occasionally seen in the windows of New York flower-sellers will not now be found, it is safe to say, in similar establishments in any other country in the world; while in matters of taste, as shown in the arrangement of the plants and flowers offered for sale in these establishments, the American florist has no equal. The most expensive plants, especially Orchids, are found in New York; greater variety of material, however, better Roses and the best taste in arrangement are now seen in the florists' windows in Boston.

The prizes awarded to exhibitors at the Paris Exhibition were distributed on the 29th of September. The ancient and distinguished house of Vilmorin, Andrieux & Co. received two Grand Prizes—one for flowering plants and one for vegetables. The Forest Department of France received a Grand Prize for its exhibition already described in these columns. Grand Prizes were awarded, among others, to Croux & Fils, and to Honoré Defresne, for their collections of hardy trees and shrubs. A gold medal, the highest award in its class, was given to the *Revue Horticole*, which, in the sixty-seven years of its existence, has exerted an immense influence in shaping and developing French horticulture, and has contained, in the long list of its editors and contributors, the names of the most distinguished botanists and horticulturists France has produced during the last half century. The small assistance France received from foreign nations appears in the fact that only forty-eight awards were made to foreigners for horticultural exhibits; of these only four were English. The United States apparently was not represented in the horticultural exhibition; at least, no award comes to this country.

M. Lemoine, the successful and distinguished hybridizer of Nancy, has produced in his new Gladioli the most striking novelty of recent years among garden plants, and one which, if the early promise of his seedlings is sustained, will give to our gardens a decorative plant of the very first order. As the readers of GARDEN AND FOREST already know, the new hybrid is to be known as *Gladiolus Nancianus*. It was obtained by crossing the hybrid *G. Lemoinei*, one of Lemoine's earlier triumphs, with the scarlet flowered *G. Sandersii*. Too much, certainly, has not been said of the vigor of the plants, or of the beauty of the flowers of this new hybrid. Plants in Lemoine's garden during the past summer were fully five and a half feet high, with long, compact spikes of broad flowers with spreading segments. They vary in color from the deepest scarlet to pale, clear rose, and all are marked with the conspicuous spot, which is the prominent characteristic in the coloring of the flowers in *G. Lemoinei*. The new race flowers in July or early in August; that is, rather earlier than most garden Gladioli. A few varieties have been so far tried and propagated as to permit their being put upon the market this autumn; but among the newer seedlings there are several which now appear more promising than any which have already received names. M. Lemoine received a gold medal at the Paris Exhibition for a collection of cut spikes of his new hybrid.

Work Among the Trees.

IT is now rather late to plant trees, at least in this latitude and further northward. This does not mean that all trees planted later than this will certainly die, for it is possible to remove them at any time during the winter. Nevertheless, trees set out in late autumn are exposed to unusual dangers. The ground will not have time to settle firmly about the roots, which will be loosened as the top sways in the wind. The tree will be more easily lifted by frost and its hold upon the soft earth will be more insecure in time of a thaw. Even if these dangers are warded off by careful staking, there is the more serious one which threatens the tree from its lack of feeding roots to supply the moisture which the drying winds of winter absorb from trunk and limbs, leaving them shriveled and lifeless. A tree planted in early autumn, in ground thoroughly settled, will throw out roots enough before winter sets in to supply this drain.

Now is the time, however, to prepare for planting next spring. Where trees are to be set, ample pits should be dug, the more ample, the better for the health and beauty of the future trees. A hole three feet deep and twenty feet across is none too spacious for a long-lived tree. Into these excavations the loam taken out should be returned, together with enough peat or good soil added and thoroughly mixed with it to supply the place of the poor subsoil, hard-pan and stones which should be rejected. This will settle into a firm bed for the roots of the young trees next spring, when they are placed in the shallow hole, which can then be quickly dug in the centre of the large one. If the young trees have not already been secured and heeled in for the winter, they should be bought now and placed in a cold pit or cellar. It is bad practice to wait until spring to select nursery stock, for at that time the nurserymen are overwhelmed with orders, and they cannot give proper attention to the lifting and packing of their stock.

Planting in spring is half done when it is well begun in autumn. This is an important point gained in tree planting, for time at that season is precious here in the cold north, when the great volume of vegetable life, liberated

by a few days of sunshine, rushes all at once into full activity. To take advantage of this sudden change from winter into summer, everything must be in readiness at the first moment when the ground is dry enough to work and the weather will permit it. No matter how thoroughly we prepare for this season, the working days of spring will be found too few and too short for all the operations which must be crowded into them, and the prudent planter will leave nothing undone which will lessen or facilitate his labors then.

But care for growing trees is quite as essential as the planting of new ones; indeed, as has been often repeated, time and labor are worse than wasted in planting unless the after care is intelligent, determined, ceaseless. Now is the best time for pruning trees, before work among them is rendered unpleasant and unsafe by extreme weather, and perhaps a coating of ice upon the limbs. Many deciduous trees, which seem to be going into decline, can be started into new life by a judicious cutting away of dead or dying branches; but the limbs should invariably be cut back even with the surface of the trunk and the wound should be covered with coal-tar.

This is the season, too, for studying plantations and marking for removal trees which are injuring their more valuable neighbors. No tree can attain its full stature or its noblest expression or have a reasonable hope of longevity unless it is fully exposed to the influence of air and sunshine. Most of our parks and gardens are disfigured by trees which have been dwarfed or starved or forced out of shape by aggressive neighbors. Planting for immediate effect means overcrowding usually, and when the saplings begin to struggle with each other for the mastery, delay is fatal, for they will begin at once to spindle up or bend away toward the light, and soon all will be deformed past remedy.

These autumn days can be used to no better purpose by one who has trees, or hopes to have them, than by a thorough study of his grounds before the snow covers them, a thorough preparation for getting through the spring work without hurry, and a resolute use of the axe wherever thinning out or tree-surgery is needed.

We have spoken of autumn as a season of preparation for work among the trees, and we might have added that no time is more suitable for making plans for next year's operations in every part of the garden and grounds. Now that the summer vegetation is cleared away, the entire place can be studied, and any desirable changes in the general design can be mapped out. But just at this point a word of caution should be spoken. Do not attempt too much. Do not undertake to cultivate too much ground. Do not try to grow too great a variety of plants. There is more pleasure and more profit in cultivating a small garden thoroughly well and in getting the most out of it than can be had from a large piece of ground half cultivated. It is a common mistake to undertake more than can be thoroughly well done. Every man who cultivates a garden, whether he is rich or poor, suffers from this national tendency. We want to grow everything, and a great deal of it, and the result is that nothing is well done and men rarely get the satisfaction from their gardens which their expenditure of labor and energy and money entitles them to. No one man, whatever his resources may be, can grow all sorts of plants well, or get from them all they are capable of. The men who derive the greatest pleasure from gardening are those who grow a few plants, and study thoroughly their needs and habits and learn all about them. And it is such men, specialists, perhaps, they should be called, who advance horticulture, and who, in getting the most for themselves out of their gardens, do the most to increase knowledge and so to advance the interests of the community. It is due to the specialists from Dean Herbert to the intelligent men of the present day who are satisfied with growing and studying one class of plants, wringing from them all their

secrets, that modern horticulture has reached its present state of development.

Do not attempt too much in the garden or on the farm. Do not undertake more than can be done thoroughly well. There will be pleasure and profit in following this piece of advice.

The Art of Gardening—An Historical Sketch. XIII.—Roman Country-Seats.

(Continued.)

WHEN we read Pliny the younger's account of his Tuscan country-seat, the strongest impression we receive is of formality—a semi-architectural symmetry. Yet, a little consideration of his words shows that natural beauties—or those which seemed natural—must have played a considerable part in the effect of his domain as a whole. He does not describe them as he does the artificial features, perhaps because he thought it less needful, perhaps because he would have found it more difficult; but his keen appreciation of them is evident, and the same feeling shows in many other passages of his letters. Nor were his formal arrangements inappropriate in the immediate neighborhood of a house so splendid. Nothing, indeed, could be more thoroughly in keeping with the demands of a refined taste than the garden immediately in front of his house, as described in the first passages, which I quoted, were it not for the omnipresence of fantastically clipped trees and shrubs. The presence of such topiary work was, of course, more offensive here, where a beautiful natural landscape appeared beyond it, than in the smaller enclosures of the *villa urbana*, whence little was visible, very often, except the neighboring gardens. But we may feel sure that in any place a Greek would have protested against it, and so, too, did many Latin poets. Nevertheless, it was greatly loved in ancient Italy, and was, doubtless, the offspring of local taste. The records of Egypt tell, indeed, of clipped trees and of shorn hedges along the borders of the roads;* but the severity of Egyptian taste would hardly tolerate anything beyond spherical, columnar or other simple shapes, harmonious with the architectural forms about them, while the Romans had hunting scenes, ships, climbing serpents, and a whole gallery of like fantastic forms.

Villas, still more splendid than Pliny's, were scattered throughout the length and breadth of Italy, thickly bordering the sea-coast north and south of Rome, dotting the slopes of the Apennines, and nestling by the shores of Como and Garda. So numerous did they become, and so vast were the spaces occupied by their ornamental grounds, even in the time of Cicero, that he complained that no fields would be left for the husbandman to till, and Seneca cried: "There is not a hill which is not covered with your gardens, that is not encircled by your parks, nor far and near a lake where the roofs of Roman grandees do not rise." Nor does Pliny's description give us a complete idea of the extravagance displayed in these pleasure-grounds, and severely satirized by many moralists. He does not speak of their great *vivaria* and aviaries, their costly green-houses, and parterres of colored flowers, nor of the magnificence often attained in the water-works which formed all kinds of fountains and cascades, and even turned clocks and ran organs that yielded sweet music. The chief gardener was called the *topiarius*, so great was the love for clipped trees and shrubs; but an *aquarius* had special charge of the water-works, and innumerable lesser officials attended to the utilitarian parts of the domain. The *topiarius* is the only one whom Pliny the Elder dignifies by the name of "artist." The fact that the actual designer of the grounds is not specialized leads us to believe that the architect laid them out when he built the house, and their character well supports the assumption.

Sometimes we can understand an almost wholly formal arrangement of the pleasure-gardens; but the larger they were, the more features of a natural sort, of course, they were likely to contain, and after a while there seems to have been at least a partial reaction against symmetry and stiffness. One is inclined to fancy that it may have been brought about by the protests of the poets, as was the similar reaction in northern Europe in the eighteenth century. Here, as in the urban pleasure-ground, Nero again appears as the exponent of a taste for natural loveliness. A villa which he possessed in the Apennines, and which was excavated not long ago by Professor Lanciani, lay in a wild gorge, cut by the Anio, which fell

in three cascades into the valley below. Dams retained the water in three large lakes, but their artificiality was not apparent, and from the domain as a whole "art had been thoroughly banished," says the explorer, "and everything left to the free play of nature." Hunting-ledges stood on either side of the gorge, connected together by a daring bridge, and the lakes were overshadowed by great rocks and enormous Oaks. Indeed, as time went on, a truly romantic feeling for wild mountain scenery seems to have developed in these Romans, satiated with symmetrical splendors. Trajan built himself a hunting-lodge high above Nero's, at the very source of the Anio, 3,200 feet above the sea-level, where the prospect was of alpine grandeur and variety; and the ruins on the top of Mount Etna are believed to be those of a villa built by Hadrian, 3,631 feet higher than the summit of the Rigi, 3,277 feet higher than the summit of Mount Washington.*

No place was more famous for its multitude of splendid country-seats than Tibur, the modern Tivoli. Here lay Cicero's estate, with winter and summer dwellings, great baths, now with hot water and again with cold, two gymnasiums after the Grecian pattern, numerous basins and grottoes, and water-works so well supplied that he jestingly called the place his "Nile." Pompey and Hortensius, Crassus and Brutus and Lucullus were his neighbors, each with a stately domain; and the mother of Augustus, like Tiberius himself, was attracted by the natural beauty and the fashion of the place. In later years came the Emperor, Hadrian, too, creating, a few miles from the modern hamlet, the villa which history still ranks among the wonders of the world. It is now a mass of almost undecipherable ruins, but its circuit can be traced for about half a dozen miles; and though some modern pleasure-grounds have been even larger than this, none of them can give us a true idea of the splendor of Hadrian's home. No accurate description has come down to us, but we know that everything that had been attempted elsewhere was here achieved in a more magnificent way. A whole army of artists traveled in the Emperor's service, buying Greek and Egyptian works, or copying originals that could not be purchased, or studying how to imitate them at home. Everything was reproduced, including seven great temples typical of seven different foreign countries, and, to take a striking contrast, the abode of the dead, as poets had pictured it. But the most interesting fact to note is that, amid this multitude of buildings, statues, paintings and formal pleasure-grounds, at least one spot was transformed into the likeness of a romantic natural glen. The famous Vale of Tempe, in Greece, was copied as accurately as human skill could compass. When we remember that this was but the chief among many villas which Hadrian owned, that Tiberius had twelve in various places, and that even private citizens seldom contented themselves with one or two, we gain a faint idea of what the aspect of Italy must have been in the golden days of the imperial power.

The Romans, like the Greeks, learned the lavish use of cut-flowers only in the later years of their national life. The extent to which the cultivation of flowers, and especially of Roses, must, however, then have been carried on, is implied in many familiar anecdotes. Nero's dining-room, for instance, had an ivory ceiling, artfully contrived to shower Roses upon his guests; Heliogabalus caused the floors of his apartments, and even his porticoes, to be thickly strewn with Roses, over which a golden net was stretched to keep the mass in place; and in water-festivals, the surface of the lake was sometimes so closely covered with floating flowers that it wholly disappeared from view. Many large areas in Italy were devoted to the growing of Roses for Rome, and, in winter, whole cargoes were imported from Egypt. It would be interesting to know what methods were used to keep them fresh on the long journey.†

The Violet, Narcissus, Gladiolus, Lily, Hyacinth, Iris, Crocus, Amaranth and Poppy were especially common in Roman gardens—the Lily, by Pliny's witness, being esteemed next to the Rose. But their list of flowers was very short, indeed, compared with ours, and the gardener must have been chiefly occupied in arranging his materials well, not, as too often to-day, in increasing their variety.‡

New York.

M. G. Van Rensselaer.

* Lanciani: "Ancient Rome in the Light of Modern Discoveries."

† Pliny speaks of garlands being brought from India, and even from countries further to the eastward, but it must be thought that these were of artificial flowers, and the idea is borne out by his statement, that no Rose-garlands were at all esteemed in his day unless entirely composed of petals sewn together with the needle, while the "most refined" custom of all was to "present garlands composed of nard leaves or of silk of divers colors steeped in unguents."

‡ Wuestemann is the best authority on the horticulture of the ancients. I have been unable to obtain his books, but Becker quotes freely from them in the notes to his "Gallus." See, also, De Candolle's "Origin of Cultivated Plants."

* Ebers: "An Egyptian Princess." This book, like those of Becker, is a romance, but its author is prominent among the Egyptologists of our day.

Autumn Colors of Foliage.

THE brilliant autumn coloring of many of the trees and shrubs in New England and the northern states and Canada is very widely known and appreciated; and most Europeans, who are so fortunate as to travel in this country at that season, are filled with the desire to reproduce the same effects at home. But the trees which are so gorgeous when the first frost appears here are said to lose much of their native bright autumn effect when transplanted to the gardens of Europe. Various reasons have been advanced to account for this peculiarity, the most generally accepted being the fact that the climate of eastern North America is much less humid than that of Europe. This certainly appears to be an important point, because the brightness of the coloring in a cool, wet season like the present, when growth has continued until frost, is not at all comparable with that of those years when the autumn is dry and there is an abundance of sunshine.

The early autumn frosts are usually considered an important factor in the production of these crimson and scarlet effects, but much more depends upon whether the season is cool or warm, wet or dry; and soil, situation, exposure, etc., also play a part.

Autumn changes in the color of the leaves are said to be due to the disintegration of the chlorophyll or green coloring matter, and the presence of xanthophyll (yellow), and erythrophyll (red) and other coloring matter within the cells.

Frequent studies and notices of the subject are to be found in foreign works and journals.

Among those most accessible and published in this country may be mentioned the notice by Professor Goodale (Physiological Botany, p. 297), and a study of "The Autumnal Changes in Maple Leaves," by W. K. Martin and S. B. Thomas, in the *Botanical Gazette* for April, 1887. The following statement from the latter (pp. 80, 81) is interesting and comprehensive:

"Chlorophyll, manufactured constantly under the influence of light, is as constantly undergoing decomposition by the metabolism of the cell. Under ordinary conditions, the manufacture of chlorophyll is sufficient to cover up its decomposition, and the leaf retains its green color. Under certain changed conditions, however, such as intense light or diminished vitality, the decomposition of chlorophyll exceeds its manufacture, and xanthophyll (probably one of the products of decomposition) appears. In other words, xanthophyll is being formed all the time, but only becomes apparent when the manufacture of chlorophyll is checked. The condition of intense sunlight gives us the occasional summer yellowness, while to lowered vitality must be attributed the failure of chlorophyll manufacture in the autumn. This lower vitality is brought about by diminution of light, lowering of temperature, and probably causes in the plant itself. The common notion that frost is the cause of autumnal coloration is true only so far as it is one of the causes which tend to diminish the vitality of the plant, and so the manufacture of chlorophyll. Autumnal coloration may take place before any frost. Xanthophyll then stains the chlorophyll masses yellow, which were before stained green by chlorophyll. The red coloration is brought about in a very different way, as erythrophyll is manufactured in the leaf, and stains the cell-sap, leaving the chlorophyll masses untouched. This red coloring matter cannot be discovered in any of the crude materials brought into the plant, or in any other part of the leaves, except sometimes in the phloem regions of the petioles. When the leaf falls and the cell sap evaporates, and the chlorophyll bodies die, the erythrophyll lays hold of the cell wall and solid contents and stains them. In this way dried leaves retain their red color. As erythrophyll is soluble in water, however, contact with moisture will soon cause the most of it to disappear."

An experiment, showing the effect of checking the growth of a plant or a part of it, may be made by girdling young branches of some of our trees or shrubs, which will cause the foliage of the part above the girdle to change color while the remainder of the plant is still green. It is interesting to note the peculiarities of the autumn coloring of different individuals of the same species, which often occur in Maples, Oaks, etc. These individual characteristics usually remain constant year after year; and, as some of them are much more desirable than others, it would be an interesting point to prove that such could be perpetuated by grafting as suggested in a former number of GARDEN AND FOREST (vol. i., p. 410). It seems very possible that varying results would be produced, according to the kind of stocks used. Stocks of some of the foreign species might produce quite a different effect in regard to autumn coloring than would be the case if the desired form was grafted upon stocks of the same species.

This is a field for some valuable experiments. If American trees do not produce all their native splendor of autumn coloring when transplanted to Europe, it is also true that, as a rule, few European trees develop much brilliancy when planted here. But it is a well known fact that Japan can furnish many trees and shrubs which, when planted in this country, are quite as conspicuous in the autumn as some of our native species.

There is no class of woody plants in this latitude which contributes such rich autumnal effects in shrubberies or by roadsides as those of the genus *Rhus*, better known as Sumachs. The most striking one of them all (*R. venenata*) is also the most poisonous to nearly everybody, and but very few handle it without some visible evil effects.

The so-called Poison Ivy (*R. Toxicodendron*) also assumes pleasing colors, and is valuable as a covering for stone walls, etc. Its poisonous properties will always prevent it, as well as the preceding species, from becoming a welcome plant in much frequented gardens.

But there are three native non-poisonous species, the Stag-horn Sumach (*R. typhina*), the Smooth Sumach (*R. glabra*) and *R. copallina*, which meet all desires for the bright colors, red, crimson, orange and yellow. The shining, polished looking foliage of the last named species usually becomes of a uniform rich purple.

The Smooth Sumach is also frequently purplish at first, but among the novelties at the Arnold Arboretum there is a form of this species with foliage of an unvarying yellow color in autumn.

Japan also furnishes bright autumn foliaged species, the best non-poisonous species yet introduced being *Rhus semialata*, var. *Osbeckii*, which in favorable seasons assumes beautiful orange and crimson tints. Another Japanese plant, *Cercidiphyllum japonicum*, belonging to the Magnolia family, gives promise of rivaling all other trees in the beautiful tinting of its leaves in favorable seasons or when planted on dry ground. It is as yet, however, too rare and too little known to be fairly judged.

As the Sumachs lead the larger shrubs in regard to autumn colors, so the Maples may be said to be at the head of the list of trees. The Scarlet or Swamp Maple (*Acer rubrum*) assumes rich hues earlier in the season than any other tree; and this is followed, often before any frost, by the orange or gold, crimson or scarlet colors of the Rock or Sugar Maple. The small Mountain Maple (*A. spicatum*) often assumes various rich shades of red. The varieties of some Japanese species, notably those of *A. polymorphum*, which hardly become more than shrubs here, are well known for their beautiful summer foliage, which becomes intensified as autumn advances.

There are few plants of the Pea family which become beautiful on account of these rich colors as the life of the leaves is withdrawn, but, among the exceptions, the Yellow-Wood (*Cladrastis lutea*) is very striking on account of the clear, bright yellow color which it sometimes assumes in October. The leaves of our Ash trees fall early, but before they drop to the ground those of the White Ash (*Fraxinus Americana*) turn a rich brown or olive purple, or occasionally yellow. In its best condition *Sassafras officinale* changes to a delicate buff or orange color.

The bright scarlets and crimsons of the Tupelo (*Nyssa sylvatica*) in autumn always call forth admiration, and, considering the graceful habit of the tree and its bright green leaves in summer, it ought to be more frequently planted for ornament.

The Scarlet Oak (*Q. coccinea*) is well known for the rich scarlet which its leaves assume in late autumn; and the browns, reds, yellows and dark purples of individuals of other species of Oak only make the Scarlet the more conspicuous.

Although the Liquidambar is not considered very hardy in the latitude of Boston, it is much valued further south and west, and is cultivated in Europe for the deep crimson effects of its autumn foliage.

Many of the shrubs which assume rich autumn effects become purplish, often a deep, dull purple, before the red and orange colors show conspicuously. This is especially noticeable in wet seasons and among plants of the Cornel and Heath families. *Cornus florida* is an instance in which the early effect is purplish, changing later to scarlet or crimson above and russet beneath the leaves. Some of the other species of *Cornus* undergo the same changes. Many of the *Vacciniums*, *Andromedas* and *Azaleas* first become purplish, then crimson and orange; and the foliage of a small, southern tree (*Oxydendrum arboreum*) is at first intensely dark and at a distance much resembles that of the Flowering Dogwood. The Yellow-root (*Zanthorhiza apiifolia*) is prized for its bright orange colors of late autumn.

That brilliant autumn foliage is not common to all the species of any genus or habitat is well shown among the Spiræas, in which the Asiatic species, *S. Thunbergii* and *S. prunifolia*, become orange and scarlet, and almost no other species, not even our native ones, are of any autumnal value. *S. Thunbergii* is especially attractive and beautiful at this season.

The common Barberry (*B. vulgaris*) does not often develop very rich colors of foliage, in this country at least, while nearly all the introduced Asiatic varieties and species are conspicuous by their bright orange and scarlet, a Japanese species (*B. Sieboldii*) leading them all in this respect.

But no other Japanese plant can compare in autumnal value with *Ampelopsis tricuspidata* (also called *Ampelopsis Veitchii*, *Vitis inconstans*, Japanese Ivy, Boston Ivy, etc.), and altogether it should be considered one of the most valuable introductions from that country of beautiful plants. In its purples, reds and crimsons and pale yellows, where the direct rays of the sun do not strike, it rivals the beauty of the Virginian Creeper (*Ampelopsis quinquefolia*), which, about Boston, loses its bright crimson leaves before its Japanese relative has attained its greatest glory.

To give details of the changes of all the species of hardy woody plants which possess any value for their autumnal foliage would occupy many pages of GARDEN AND FOREST. Nearly all the genera have some species which have a claim to notice, and often nearly every species belonging to a genus has its own time of changing and peculiarities of tints. Many of the conifers, too, undergo distinct changes in color when the frosts appear, and the leaves of some of the Larches and of *Pseudolarix Kämpferi* sometimes assume a pretty yellow or orange hue before they fall.

Arnold Arboretum.

J. G. Jack.

The India Rubber Tree.

THE "India Rubber" or "Rubber plant" is a familiar and cherished object in many houses. There is not, probably, a plant among those which, during the last twenty-five years, have become really popular for the embellishment of living rooms and conservatories, which is better suited for the purpose; and there are few persons now who know anything about plants at all who are not familiar with the straight stem and splendid great, dark green, lustrous, leathery leaves of the "Rubber plant," which seems able to resist, with impunity, darkness, neglect and drought, and even an atmosphere vitiated by the gases from burning coals. Plants more than ten or twelve feet high are not very often found in our northern cities, and few people, perhaps, who see one of the plants flourishing year after year in the narrow quarters of an ordinary sized flower-pot realize that it belongs to a race of veritable giants, or that the *Ficus elastica*, as our common "Rubber" plant is called by botanists, is, in its native countries, a marvel among trees. Some idea, perhaps, of the manner of growth and of the size which this plant attains in the tropics can be obtained from the illustration upon page 547. It represents a tree of ordinary size and only fifty years old in the Botanical Garden of Peradenya, in Ceylon, one of an avenue of some length. It is difficult to realize that the aerial roots, grown into supplementary trunks, common to many species of Fig (for the Rubber plant is a Fig, and produces miniature figs precisely similar in structure to the figs of commerce), and the great roots twisting like huge serpents in all directions over the surface of the ground, belong to the little pot-plant we are familiar with.

Ficus elastica is a native of the foot-hills of the Sikkim Himalaya of Assam, of Burmah, Perak and of the islands of the Malayan Archipelago. It is a large tree, towering high above the forest, with a broad, leafy crown and immense trunk. Griffith describes, in the *Journal of the Asiatic Society* (vii. i., 132), a tree one hundred feet high, covering with its branches an area of 610 feet, the main trunk seventy-four feet in girth, while the trunk with its supplementary stems was 120 feet in circumference. This species of Fig, like many others found in the tropics, is an epiphyte—that is, the seed from which it springs germinates upon the trunk or branch of another tree. The young plant sends down roots to the ground, and as

these grow they gradually smother the host-plant, and form an upright stem which in time becomes the support of the Fig-tree. The fruit of this species, which is probably never seen outside of the tropics, is ovoid, about the size of an olive, and greenish yellow in color.

Ficus elastica is a favorite ornamental tree throughout the tropics, and is largely used in the East Indies for shading avenues, for which purpose its wide-spreading head admirably fits it. It is cultivated in Assam, where large plantations of this tree have been made in recent years, for the caoutchouc, which it yields in large quantities, although it is now generally believed that Para rubber, the product of several species of Hevea, especially of *H. Braziliensis*, a large evergreen tree found on the banks of the Orinoco, retains its firmness longer and possesses greater strength and elasticity.

Ficus elastica was cultivated in England as early as 1815, and whoever first thought of using it for house decoration made a happy hit. It was probably first used in this way, to any great extent at least, in Berlin.

New or Little Known Plants.

Staphylea Bolanderi.

THE number of genera of woody plants with representatives in each of the great botanical regions of the North Temperate Zone, the coniferous and the ament bearing genera excepted, is not large. The discovery a few years ago in northern California of the Staphylea, which is figured upon page 545 of this issue, added this genus to the number. The flora of eastern North America contains, *S. trifolia*; *S. pinnata* inhabits central Europe; *S. Colchica*, which is by far the handsomest of the genus, is found in the Orient; *S. Emodi* in the Himalayas, and *S. Bumalda* in Japan.

*Staphylea Bolanderi** was discovered by the excellent collector whose name it bears on McCloud's Fork of the Sacramento River, in the neighborhood of Mt. Shasta, in April, 1874; and afterwards it was found again in the same region by Mr. J. G. Lemmon in fruit. It is a shrub with stout branches, covered with reddish brown bark, that of the year pale green or straw colored. The leaves are three-foliate, with broadly oval or orbiculate, glabrous, serrulate, abruptly acuminate leaflets. The flowers are greenish white, with exserted stamens and style, the sepals rather shorter than the petals. The fruit, which is rather narrow for the length, is two and a half inches long, with slightly flattened seeds one-fourth of an inch long.

Staphylea Bolanderi is apparently one of the rarest shrubs of the Pacific forests, and has not been introduced into cultivation.

C. S. S.

Plant Notes.

The Cloudberry. (*Rubus Chamæmoris*.)

THE Cloudberry, which is found in few localities south of the Canadian boundary, and even then not in great abundance, is quite common and greatly prized in Newfoundland, Labrador, Nova Scotia and northern Quebec. It is known under various names, and is very abundant through northern Canada, extending from the Atlantic to the Pacific, and north to the Arctic Sea. Growing always in peat bogs at the south, and further north in open boggy places in woods, it is found in the greatest profusion on the barrens beyond the northern limit of tree growth, occasionally ripening its fruit even within the Arctic Circle. In spite of the fact that it is very susceptible to frost, and that frequently the fruit does not mature at all, it seems to improve in quality, like a few other berries, toward the northern limits of its distribution.

Rubus arcticus and *R. Chamæmoris* are frequently found together; the broad, rose colored flowers of the one contrasting beautifully with the large, white Anemone blossoms of the other. The Cloudberry resembles none of its congeners in color or in flavor. The rich amber or golden berries are only slightly tinged with deep red on the side toward the sun;

* *Staphylea Bolanderi*, Gray in *Proc. Am. Acad.*, x. 69.—Brewer & Watson, *Bot. California*, i. 108.

and they never have more than the slightest trace of acidity. Indeed, so tasteless is the berry that it can hardly be eaten at all until almost ripe. The berries when apparently mature are often dry and insipid, tasting not unlike a very young apple; indeed, the name "Bake Apple Berry," by which it is known

White Raspberry of cultivation; and then if eaten in small quantities it is perhaps the most delicious of our northern berries. The *habitants* of Quebec and the Indians prefer it just as it approaches ripeness and before it has lost its acid taste; but to southerners it is at that time hardly palatable.

Fig. 142.—*Staphylea Bolanderi*.—See page 544.

in the maritime provinces, may have been given to it on account of the real or supposed resemblance of its flavor to that of a baked apple.

When quite ripe, however, the Cloudberry has an intensely sweet, honey-like flavor, slightly recalling that of the large

It is known in northern Quebec and about Hudson's Bay as the Yellow Berry, and in that part of the country there is no fruit more sought after for cooking. A small amount of sugar is needed in preparing it for the table, and jam made from this berry has such a rich and delicate flavor, so unlike

that made from any other fruit, that at several of the Hudson Bay Company's posts large quantities are preserved and sent to friends at home. The Chipewyan Indians of the Mackenzie River Valley make a sugar from the juice of the birch in which the Cloudberry are cooked, and, prepared in this manner, they are considered a great delicacy. Few birds eat the Cloudberry, so that when they are not picked by man they decay slowly on the vines and finally drop to the ground.

Foreign Correspondence.

London Letter.

SOME of your readers may be glad to know what plants are the most attractive in our warm houses at this time of year. The following are exceptionally good at Kew just now. They are not new, indeed some are of the oldest of garden plants, still they do not appear to find much favor nowadays:

ÆSCHYNANTHUS SPECIOSUS.—This plant has been gorgeous with flowers since June and there are still several specimens in full bloom. There are few plants more charming than this, whether it be in flower in summer or in November. It has numerous erect stems, eighteen inches high, bearing opposite, ovate-lanceolate, dark green leaves, three inches long. The flowers are in terminal fascicles, strong stems bearing as many as twenty flowers, which all open together. They are erect, and each one is composed of a five-lobed subulate calyx and a tubular corolla three to four inches long, curved at the top where the mouth is divided into four rounded lobes. The color is bright orange, with scarlet lobes and a line of black dividing the orange from the scarlet. The flowers remain fresh more than a fortnight. The plants should be grown in pots in a compost of turfy peat, leaf-mould and plenty of sand. They like abundance of moisture and a stove temperature all the year round. This species was introduced in 1847 by Messrs. Veitch through their collector, Lobbs, who found it growing freely, attached to the trunks of large trees in Java.

COSTUS IGNEUS.—This species was introduced from Bahia by Messrs. Linden in 1882. As a flowering plant it is much the best of the several species of Costus that are in cultivation, being of dwarf, compact habit, easy to cultivate, a free bloomer, with large and bright colored flowers. Here it has been in flower all summer—not a succession of plants, but the same plants from June until now. Its stems are herbaceous, about a foot high, with elliptical-lanceolate dark green leaves, the points slender and acuminate; their length is about six inches. The flowers are in terminal clusters or heads, and each head is composed of a great number of scales and buds. One or two flowers are expanded at a time and remain fresh about a day. Each flower is composed of a large, circular, wavy lip which measures two inches across, the other lobes small, whilst in the middle there is a tongue-like appendage to the sessile anther. The color is bright, glistening orange red. The color and form of the flowers are exceptional among stove-plants. Besides this we have *C. Malorteanus*, which has short stems, large, orbicular, fleshy, hairy, gray-green leaves and heads of crimson flowers. For tropical aquaria this species is of value, as it likes water and becomes attractive with liberal treatment. *C. speciosus* has stems four feet long and crimson flowers. *C. spiralis* is similar, but smaller in leaf and habit. The genus is a large one and it occurs in all the tropics. In some species, as, for instance, *C. spiralis*, the flowers are sometimes terminal on the leafy stems and sometimes on short stems which spring direct from the rhizome, as in the Gingers.

BEGONIA HAAGEANA.—The merits of this new Begonia were mentioned incidentally by me in a letter last year. A year's further trial has proved the plant to be of first-rate merit as a garden Begonia. Among the many species of evergreen Begonias grown at Kew, this one stands out prominently on account of its bold habit, handsome foliage, floriferousness, and the size and beauty of its flowers. These are colored a soft rosy white, with conspicuous crimson hairs on the outside of the sepals; the male flowers are one and one-half inches across, and they are in very large branching racemes, strong stems producing racemes nine inches across. The female flowers are smaller and in looser racemes. The plants at Kew are now in full flower. In the hands of a clever hybridizer, such as Monsieur Lemoine, this species might be made much of. It was introduced from Brazil by Messrs. Haage & Schmidt, of Erfurt, and it flowered for the first time, at Kew, in 1887. A figure of it is given in the *Botanical Magazine*, t. 7028, under the name of *B. Scharffii*. This is, however, a different species, which was introduced at the same time as *B. Haageana* and belongs to the same section.

DISSOTIS INCANA.—This is one of a genus of Melastomads

found in Africa, mostly in the tropics. Until this species was introduced, none of those tried had proved of any value for the garden, but this one is handsome enough to find favor with many. It has numerous, erect, four-angled stems which spring freely from the root-stock and grow to a length of about two and one-half feet. The leaves are three inches long, opposite, ovate-lanceolate, with prominent nerves on the surface covered with scabrid hairs. The flowers are borne in large, terminal, spike-like racemes, the length of which is sometimes eight inches, and thickly crowded with deep purplish crimson flowers. These are one and one-half inches across, and composed of five ovate, overlapping petals, and urn-shaped, green calyx with five small sepals, purple anthers and yellow filaments. They are not unlike the flowers of a *Monochætum*; but the plant is more vigorous and the flowers more abundant than in any of that genus. The Kew plants were introduced from Natal in 1886, under the name of *Osbeckia Umlasiana*. They have been grown in pots plunged in a border out-of-doors all summer and removed into a green-house to flower.

IXORA MACROTHYRSA.—I have already described this to your readers, and only refer to it now because in addition to its display in August it is now again beautiful with flowers. This time the plants are younger, having a single stem, erect, two feet high and crowned with a magnificent head of rich scarlet flowers. Nothing would be finer in the stove than this.

The meeting of the Royal Horticultural Society, on Tuesday, October 22d, was well attended, in spite of one of our famous London fogs. The exhibits were more than usually interesting, some of the groups being extremely fine. There were a few good Orchids, amongst which was a very fine specimen of Tantz's variety of *Odontoglossum grande*, the flowers remarkably large and well marked. *O. Insleayi splendens aurea*, not nearly as good as the type, has a bright yellow lip, with brown markings, the sepals pale coffee colored. The golden variety of *O. grande* was also very fine. *Dendrobium formosum*, var. *giganteum*, from Mr. Gladstone, received a cultural commendation; the specimen, a very fine one, was well flowered. *Cattleya aurea*, var. *Blenheimensis*, from the Duke of Marlborough, appears to differ very little from the old Dowiana, and *D. Statterianum*, from St. Albans, with fine rosy purple sepals and deep purple lip, does not seem to differ much from *D. superbiens*.

Epidendrum sceptrum, a novelty from Sir T. Lawrence, received a botanical certificate. The racemes are large, crowded with bright yellow, purple marked flowers—a very interesting species. *Cælogyne speciosa*, from the same garden, was very fine. The Messrs. Veitch, of Chelsea, as usual, had a very handsome group of mixed plants, amongst which were many rare and a few new plants. Amongst the rarer plants were *Dracæna Doucettii*, a nice habited and remarkably distinct form, the leaves variegated white and green, promising to be a useful adjunct to table decoration and for like purposes. The Crotons were very nicely colored, as were the Palms, *Sarracenia Chelsoni* and the new *S. Wrigleyana*, the latter very fine and distinct. *Gynierium argenteum variegatum* looks like a hardy plant, and if so will certainly be one of the plants of the future. The leaves are very handsome, the variegation yellow and bright green, being very striking. A new *Carex*, called *C. species variegata*, received a first class certificate. The leaves are very narrow, grass-like, green on the edges, with an ivory white centre. The habit resembles that of an *Isolepis*, with broader foliage, and altogether a more attractive appearance. A remarkable and very interesting new hybrid Rhododendron was shown in flower, and received a first-class certificate. It is called *R. Indico-Javanicum*, and is a cross between *R. Javanicum* Lord Wolseley and *Azalea indica*, Stella. The flowers are darker than those of the Rhododendron, the substance much better, and the shape altered to a narrow, and, for their size, longer tube, the limb spreading very little. The leaves of the specimen in flower were nearly or quite those of the Rhododendron, while another specimen, not in flower, from the same seed-pod, had leaves decidedly those of an Azalea. This is the first cross of its kind, and, besides being full of interest botanically, will prove very useful to horticulture. The Messrs. Veitch also sent a very handsome collection of autumn foliage. To you in America this will appear trifling perhaps, but as the product of a climate like that of England, wonderful, to say the least, were Japanese Maples of all shades, from blood red to golden yellow, exquisite in shape and cutting; *Populus fastigiata*, clear lemon yellow; *Rhus* of various species; Liquidambar, and the handsome red leaved Guelder Rose. The collection was very large, the leaves being simply laid on the table in bunches, and were very effective. There were also close by a very fine group of cut blooms of hybrid Rhododendrons and a charming

mixed bunch of *Pernettyas*. A group of dried grasses from South Africa attracted a good deal of attention, the chocolate brown *Cyperus* or *Carex* being highly ornamental. The *Chrysanthemums*, though few, were choice, Stanstead Surprise, a seedling from a Japanese variety, from J. Laing & Son, being of fine form, and a warm rosy crimson color. It received a first class certificate. Stanstead White, an incurved Japanese, pure white, of large, fine form, is very distinct and desirable. M. Benard, a reflexed Japanese, with purple amaranth, very large flowers, attracted much attention. From Kent, the home of flowers, M. Pankoncke, madder brown, received an award of merit. William Neville also received an award of merit. It is reflexed, orange buff and of very fine form. Eynsford White was perhaps the finest in the show. It is far superior to Avalanche, the florets broad, strap-

These autumn *Crocuses* are very ornamental, filling up a large gap at a time when flowers of this nature are rather scarce, and especially in the rock-garden, where the groups of alpines have long since begun to show the sere and yellow leaf. The majority of them are very easily cultivated, and a few of them, notably *C. speciosus*, *C. medius* and *C. nudiflorus*, multiply with surprising rapidity. Their only fault, if such it may be termed, is that most of them flower before the leaves have attained any material size; but even this is easily remedied by planting them, as is now almost universally practiced, among Pinks, and other loose, tufty plants. In this matter, however, they are free from one great objection we have always felt to the autumn *Colchicums*, which are also erroneously called autumn *Crocuses*—that is, the large and very ugly leaves produced by the *Colchicums* in spring, if planted in borders

Fig. 143.—*Ficus elastica* in the Botanic Garden at Peradenya, Ceylon.—See page 514.

shaped, reflexed and pure white. It looks like a huge snow-ball. M. Charles Lebrsq, a single variety, with citron or Indian yellow flowers, small, but abundant, also received an award of merit. Octavie is an extremely pretty *Begonia*, and very useful for autumn cutting, the flowers double, white, and remarkably like those of the *Camellia*. *Gymnogramme schizophylla*, var. *gloriosa*, from Mr. May, received a bronze Banksian medal. It is a most lovely form. The *Adiantums* in this group, as usual, were finely colored. W. Watson.

Cultural Department.

Autumn *Crocuses*.

THE autumn *Crocuses*, of which there are now twenty distinct species, exclusive of well marked or garden varieties, have flowered remarkably well in English gardens this season, notwithstanding the unusually large rainfalls of last year,

or beds which at this time are expected to look their very neatest. It would be a pity to discard them on this account, however, and we have compromised the matter by planting them in the grass in the pleasure garden or park, where they do very well and make a pretty feature. The spring *Crocuses* are abundant enough, including all the different forms and bright colors of *C. aureus*, *C. chrysanthus*, *C. biflorus*, and the handsome various-colored *C. Imperati*; but the autumn ones, amongst which we have also a pure yellow, several purples of different shades and many whites, come, as already stated, at a time when such flowers are scarce, and, therefore, they are doubly welcome. It is rare to see these *Crocuses* destroyed by frosts; the earlier ones, beginning with the middle of August, are over before the frosts are severe enough. Heavy rains do most damage, and this is more apparent in the absence of a ground-work which serves as a support to the long and usually weak flower-tubes. *C. Sharojani* is the first to make an appearance, about the middle of August, and in very hot

seasons as early as the end of July. It is the only species in which the previous year's leaves live until the autumn flowering-time. The flowers are of good size, deep orange and very attractive. It is a native of the north-west Caucasus; its scarcity being somewhat remarkable, seeing that it grows intermixed with the more common *C. vallicola*. It increases very slowly. *C. vallicola* follows closely, and is usually in flower about the beginning of September. Balansa says that in its native home, the Alps of Trebizond and Lazistan, it flowers as early as July. The flowers are usually of a pale cream color, and it is the only species in which the segments have fine, thread-like appendages at their summit.

C. nudiflorus follows next, being rarely later than the beginning of September. It is a very hardy species, naturalized in several counties in England, notably Nottingham, where we believe it is plentiful still. It is the old *C. Pyrena* of Parkinson, with large, unstriped, bluish purple flowers, the tubes unusually long, and, unless supported, very liable to be destroyed with heavy rains. The corms throw out long stolons, and where not confined sometimes become troublesome. The pure white variety is very desirable, common about Biarritz, Astureas and in the Pyrenees.

C. zonatus, which we also find in gardens as *C. Kotschyanus*, is one of the newer species, discovered in 1855 in the mountainous districts of Cilicia, to the north of Taurus. It is one of the early ones, but not so regular as some of the others. It is one of the freest flowering and most useful of the autumn species, increasing with rapidity and very hardy. The flowers are lilac or rosy lilac, veined on the inside with five to seven purple lines, and with a bright orange base and yellow fringed stigmata.

C. iridiflorus (*Byzantinus* of Parkinson) is a very remarkable species, intermediate almost between a Crocus and an Iris, and on this account Schur proposed the generic name of *Crociris iridiflorus*. It is the tallest, and, with the exception of *C. medius*, the largest of the genus. The outer segments, of a clear, rich purple, are almost twice the size of the pale lilac inner ones, forming a very odd and remarkable flower. A native of Transylvania, flowering late in September.

C. speciosus is perhaps the commonest and most serviceable of all the autumn species. Its geographical distribution ranges from northern Persia to the Caucasus and Transylvania, and there is a record of its occurrence in central Asia Minor, where it was gathered by Kotschy in November, 1859. It produces, in great abundance, large, rich, bright lilac flowers, the inner surface feathered with numerous, dark purple, much branched lines from base to summit of segments. It multiplies rapidly by cormlets formed at the base of the old corms, as many as a dozen to each.

C. pulchellus follows the last very closely, and may be readily mistaken for *C. zonatus*, the color of their flowers being very similar. It usually begins to flower about the middle of September, and in mild autumns continues to flower until near Christmas; outer segments self-colored, on outside pale lilac, the inner surface faintly marked with purple lines, the anthers white, stigmata orange. There is also a rare white variety. Native of the Bosphorus, where it is found in heathy thickets.

C. Asturicus and *C. Clusii* are very nearly allied, both having purple flowers and leaves appearing at flowering-time.

C. ochroleucus, a charming little white flowered species, flowering from about the middle of October to December; creamy white with bright yellow throat; from northern Palestine and Syria.

C. medius is one of the most delightful of the autumn Crocus, producing abundantly large, bright purple flowers, with huge spreading masses of bright scarlet stigmata, very hardy and increasing rapidly. It is found on the Riviera, at Mentone, etc.

C. longiflorus is a very neat species; the flowers are lilac veined purple, the stigmata nearly entire and of a bright scarlet. It increases very rapidly. A native of southern Europe.

C. Salzmanni has varied purple flowers, and *C. lævigatus* creamy color striped purple flowers. *C. Cambessedesii*, the flowering season of which varies under cultivation from October to April, has pale buff flowers with purple featherings on the outside. *C. serotinus*, *C. Hadriaticus*, *C. cancellatus* and lastly *C. sativus* and its numerous very fine varieties, Cartwrightianus, white, with scarlet stigmata, are all effective. These are all in cultivation in English gardens, and are much appreciated. Could a home be found for them in America, where the summer is hotter and the chances of ripening more certain than it is with us, they would be worthy though humble companions to your Michaelmas Daisies and other late autumn-flowering plants.

Kew.

D. Dewar.

Notes on Forcing.

THIS is an important part of the winter work of gardeners, and preparation for it now demands attention so that the stock may be ready for an early start and a proper rotation. And although, in the forcing of Dutch bulbs, Lilies-of-the-Valley, etc., to which attention is now invited, the details are familiar to most plant-growers, yet it may be of benefit to some novices to have a few hints in regard to this interesting, though not specially intricate process. The first essential is to buy good stock—sound, solid bulbs, or large, plump pips, as the case may be—and to store them away in pots, pans or boxes as soon as received, so that a good foundation of roots may be grown by the time the bulbs are required to be brought into heat.

In regard to Lily-of-the-Valley there has been some slight difference of opinion as to where the best roots are produced for forcing, but in my experience those grown in the vicinity of Berlin have proved far superior to any Holland-grown pips, both in size and quality of bloom, and they can also be forced earlier than the latter. For late forcing the difference is not material, though even in that case the German pips usually produce the finest flowers. When grown in pots, the undivided roots or clumps may be used, and, as they generally throw up more leaves in proportion than the selected or separated pips, they are more effective, though the latter offer one advantage in allowing a more regular arrangement of the spikes of bloom, and particularly when the plan used by some of the London market-growers is adopted. This plan is to force the pips in a bench of sand or light soil, over a strong bottom heat to start them, keeping them there until the flowers are almost ready to open, when they are taken up and potted. After keeping them for a day or two, to enable them to overcome the shock, they are sent into market.

The ordinary method of forcing Lily-of-the-Valley for flowers is to pot the pips or box them as soon as received, taking care to keep the points of the shoots well above the surface of the soil. After this a good watering should be given to them, when they should be placed in a cold frame, where it will be found best to cover them at first with a thin layer of long litter, or straw from the manure-heap, and over this to spread from one to two inches of soil; the litter is put on first, so that the pots may be more readily cleaned off afterward when the soil becomes frozen, the straw preventing the soil from sticking to the pips.

On bringing them into the house in which they are to be forced, the boxes should be placed on a bench, to which a steady bottom-heat of from eighty-five to ninety degrees can be applied; and by covering the pips with a layer of sphagnum and enclosing the bench in a sort of box or cover made of sashes, shutters or oiled muslin, as may be most convenient, so as to exclude a portion of the light and at the same time to confine the heat, a more regular temperature can be preserved. By this system the flower-spikes may be sufficiently drawn to stand well above the foliage, though more light should be admitted before the flowers begin to open, else they become thin and flimsy in texture and consequently do not last long. In fact, at this stage they may be taken out of the forcing house and put in a cooler one to harden off and open their flowers. The time occupied in forcing Lily-of-the-Valley on this plan is from twenty-one to twenty-four days, according to the time of the year in which the operation takes place, and it is therefore easy to gauge the time of bringing in fresh instalments of the pips to insure a steady succession of flowers.

Tulips, Hyacinths, Narcissi, etc., for forcing, should be potted as early as possible, and for this purpose good, light, rather sandy loam is preferable, if it contains a fair mixture of manure. In potting the points of the bulbs should be kept well above the surface of the soil. They should then be placed in a frame and buried to a depth of three to four inches in coal ashes, sand or light soil, the ashes being preferable because they are somewhat repellent to earthworms.

After the bulbs are well rooted they may be brought into heat as required, and in the case of the Tulips it is well to shade them enough at first to draw the flower-stems up to a fair length, as otherwise some of the varieties are liable to grow too short in the stem to be effective either for cutting or for decorating.

Hyacinths and many of the Narcissi force easily and do not require much heat; in fact, they are frequently forced underneath the benches in green-houses, from whence they are brought into prominence as the flowers appear.

Holmesburg, Pa.

W. H. Taplin.

Spiræa Kamtschatika, recently described in the *Gardeners' Chronicle* as a new plant, has long been known in American gardens under the provisional name of *Spiræa species*, Japan, of which country it is a native. It has also been called *S. gigantea*, a name which is very appropriate, inasmuch as it is the largest herbaceous species with which we are acquainted. It attains a height of from eight to ten feet, the tall, erect stems being clothed with large palmate foliage, somewhat resembling that of a grape vine. The stem is terminated by a large branching panicle of creamy white flowers. It is stated in the *Gardeners' Chronicle* on the authority of Pallas, that the natives of Kamtschatka eat the young shoots in spring uncooked, also the roots during scarcity of food in winter, while the leaves are used in soup. Be this as it may, the plant is a desirable one to associate with other tall growing subjects, as a background to the flower border, where its distinct appearance arrests attention at once. There is one thing to be borne in mind when planting it, and that is that strong sunshine is liable to scorch the young growth, so that a position in which it can have shade and plenty of moisture at the roots is essential to the success of this gigantic *Spiræa*.

Sternbergia lutea.—This plant, often called *Amaryllis lutea*, has afforded for the past month one of the prettiest bits of color in the garden. The bright yellow flowers resemble the *Crocus* somewhat in general appearance, but they are much larger and of longer duration. The most important feature of the plant is its autumnal flowering. When the ground is covered with fallen leaves it is a particularly pleasing sight to see the bright green foliage and yellow flowers peeping up and braving the frosts that have laid low every other flower. The *Sternbergia* is perfectly hardy here with us when provision is made for throwing off the snow and water in winter. This we do with perfect success by placing a sash over the bed. The foliage dies down early in summer to rest the bulb until early autumn, when growth recommences. Indeed, having had occasion this summer to shift our stock of bulbs, we allowed them to remain for some time in an open box without soil or moisture, and yet flowers were produced and fully expanded before they were planted in the soil. The bulbs are usually the size of those of a *Narcissus* and they should be planted about four inches deep. A cold wet soil in winter should be avoided.

Catasetum Bungeorhizii.—I recently had the pleasure of seeing, in the establishment of Messrs. Siebrecht & Wadley, at New Rochelle, a fine specimen, in bloom, of this finest of recent introductions among Orchids. The plant under note was a particularly fine form, with large cup-shaped flowers of the purest white, broken only by a spot of bright orange in the centre of each. Much has been written and said of this beautiful Orchid, but judging from the specimen we saw it seems impossible to over-praise so fine a novelty. We noticed, also, a batch of *Cypripedium Spicerianum*, which, for size and rude health, left nothing to be desired. This variety and *C. insigne* are in great demand for cut-flower work. *Cattleya Warneri* was represented by several forms strikingly rich in color, and *Oncidium Varicosum* by a number of large branched sprays, which, when grouped with other Orchids and Maidenhair fern, had a charming effect. A number of *Chrysanthemums* from Japan were just unfolding their first flowers, and among them were some new varieties which will no doubt be heard of later on. O.

Passaic, N. J.

Storing Root Crops.—Many roots, like turnips and carrots, can be safely wintered in earth pits, and even apples, if properly treated, can be kept, with little loss, in the same way. The real danger is not from cold, for the frost can always be excluded by a sufficiently thick covering. The danger from heat is much more serious. On this account the roots should not be lifted until the weather is cool, and they should not be placed at once in the pit or root-cellar, but laid in small heaps of four or five bushels and covered lightly with straw. If they remain in this way for a week or so, covered with shutters to protect them when it rains, they can, after the so-called sweating process, be removed to the pit. Even then they should be lightly covered with straw at first and the earth should be applied gradually as the weather grows severe, so that they will remain uniformly cool and escape heating. It is well to place a drain-tile at the top of the cone for a ventilating chimney, and if the crop is large, so that it can be placed in a long windrow, the chimneys should be set about six feet apart. These long piles can be five or six feet wide and from three to four feet high. The trench, or bottom of the pit, need not be more than eight inches below the surface. Of course, no wet, soft or decayed roots should be placed in pit or cellar. Pars-

nips and salsify are better flavored if left in the ground; but it is troublesome to lift them in winter, and, therefore, part of the crop can be placed in a cellar and covered with sandy soil. The tap-roots should never be cut, nor should the tops, especially of beets or salsify, be cut close to the crown. If a root cellar is used, it should be dry, well ventilated, rather dark and kept at a uniform temperature not higher than forty degrees.

Long Island.

C. G.

Prolonging the Tomato Season.—All who are fond of the peculiar flavor of the tomato should know how easily the season of this vegetable may be prolonged. By simply covering the plants with old carpets, or any other convenient fabrics, during nights that threaten frost, the plants may often be kept in a growing condition for days, and even weeks, after unprotected plants have perished. When the nights become very cold, a hot bed frame may be placed over two or three vigorous plants, and covered with sash. The sun shining through the glass at midday will give sufficient heat to mature the fruit quite rapidly. As the last resort, the green fruits may be picked and spread out on a shelf in a chamber, or cellar, where they will ripen slowly for two or three weeks after herbage out-of-doors has been killed by frost. If they do not ripen as rapidly as is desired, the maturity may be hastened by transferring them to a shelf in a warm part of the kitchen.

The National Flower.

To the Editor of GARDEN AND FOREST:

Sir.—The interesting communication in GARDEN AND FOREST of the 10th of July, from the pen of Mrs. Van Rensselaer, on "The Choice of a National Flower," effectually disposes of all claims to that honor of the Trailing Arbutus, so sweet and shy; the aggressive Ox-eyed Daisy of the early summer; the too æsthetic Sunflower of the dog days, and the graceful Golden-rod of the fall-time. And the merits of the *Kalmia*, or Mountain Laurel, are so attractively set forth that one is almost convinced that it is in all respects the most suitable floral emblem to share with the great American eagle in decorating our flags and banners, shields and seals, and all other national and official ensigns.

Granting all that has been said in approval of the *Kalmia*, the fact remains that it is generally known, where known at all, by the common name of Laurel, which is also the botanical or scientific name of a large genus of plants not indigenous to our country, among them the *Laurus nobilis*, the Laurel of the ancients. This shrub is a native of the Mediterranean coast, and has been consecrated since time immemorial to priests and sacrifices, heroes and victors in wars and games of skill, and has been celebrated accordingly. To poet, painter and sculptor it still affords inspiration for realistic and conventional emblems and designs. Our Laurel is so called on account of a resemblance of its foliage in shape and evergreen color to this European Laurel, although very dissimilar in flower and quite destitute of odor or beauty in fruit, and very distinct in all its family relations.

Now if our Laurel is selected for the national flower, how are the two celebrated plants of the same name and similar in foliage ever to be distinguished? It would seem that confusion must arise. At this moment an instance is recalled in which a famous American poet mentions the two in the same poem as if they were identical. This is a most serious objection to our Laurel as a national flower. True, it is in some localities known by the undignified name of "Calico-bush," on account of its spotted flowers, and in others as the "Bush Ivy," on account of the similarity between the shining green of its foliage and that of the *Hedera*; again "Spoonwood," for what reason who can tell? But no one would wish to have any of these names substituted for Laurel, even if it could be successfully accomplished, much less the name of "Sheep-poison" or "Lamb-kill," as certain varieties are sometimes called on account of the poisonous qualities that lurk beneath the beauty of their foliage.

All that has been so charmingly said in its favor can, however, be as truly said of the *Magnolia grandiflora*, and added to this are a great majesty and dignity, unexcelled by any tree of the American forest. In the great Bald Eagle as a national emblem we have the king of birds. Why not in flowers choose the acknowledged queen? The blossom of the *Magnolia* is beautiful in color and form, and blessed, to a remarkable degree, with delicious fragrance. The tree is royal in size, almost too symmetrical in outline of foliage, has a handsome,

smooth bark, and dense, large, dark green, thick leaves. It is so distinctive in all its parts as never to lose its identity. Gray describes it as "a noble tree, remarkable for its delightfully fragrant flowers, its thick evergreen leaves, with a shiny, polished, deep green surface above and rusty below."

It is cultivated in all parts of the United States and of Europe where it is hardy, and indeed all over the world where there are parks and gardens, as one of the choicest and most desirable acquisitions. Its stateliness and individuality rival that of the Egyptian Lotus, and it is quite as graceful. It has, as a type or model for artistic variation, all the advantages possessed by the Laurel, in addition to its character and loftiness. No poison lurks beneath its charms, no ignominious common name vulgarizes and offends fastidious taste and feelings. It is seldom spoken of except by its name, *Magnolia*, and even its Indian name, Toola, is melodious. On the contrary, many sentimental associations are connected with it in its native home, and it has been more than once the inspiration of the artist's pencil and the poet's song. Its succession of flowers continues several months in favorable situations, and the flower lasts long after cutting.

Would not its sculptured form, either natural or conventionalized, adorn the triumphal arch or garden gate with equal appropriateness? Would not its pure creamy color against the shining green foliage, its stately grace of carriage, be a royal subject for the painter's canvas and equally embellish the frieze or dado of the columns in the new library, or the border of a one-cent postage stamp?

The inflorescence of the *Kalmia* is in showy umbels, gradually blooming from the centre outward, so that until late in its short season of blossoming a terminal edge of half developed flower-buds adds grace and charm to the cluster; but a solitary blossom is so rarely separated from its companions that it would hardly be recognized except by the close observer.

It is true, perhaps, that an individual flower of the Mountain Laurel, with its sea shell, pearly tints and delicate markings, its perfectly regular and symmetrical five-lobed corolla, with its unvarying flutings and deep dimples that so carefully imprison the ten anthers of the daintily arched filaments, and make it look, as a lady devotee to fancy work expresses it, "as if it had so much work on it," are more exquisitely beautiful and bewildering than the great creamy bowl-shaped blossom of the *Magnolia*, with its smooth, thick, velvety texture, simpler form and less intricate disposition of the numerous stamens and pistils; but it surely has less character, and is less imposing and architectural. Is not the larger flower, which always blooms in solitary grandeur, although less complicated in form, with its conical buds, trinity of sepals, large, broad, smooth petals, with imbricated under edges and narrow clawed bases arranged uniformly around the many quaint stamens and pistils on the long receptacle, each making a fairy cavern filled to overflowing with delicious odors, far better for the designer's use and much more easy to identify than the more intricate and wonderful *Kalmia*?

And if there is any lack of dignity and variety and adaptability for the designer's purposes in the bud and blossom, this is more than made up in the unique egg-shaped fruit, with its overlapping ruby red carpels, each of which, on bursting into perfect maturity, discloses two berry-like seeds attached by spiral threads, making it unusually attractive and offering endless possibilities to the artist.

No one ever saw a noble specimen of this stately tree—which often reaches a height of more than a hundred feet, with its broad spreading lower branches towering in a pyramidal form toward the sky, with tier on tier of its lovely, large, milky blossoms, each well poised against the background of dense dark green, glossy foliage—without pausing to exclaim upon its majesty and grandeur. The only objections that can be seriously brought against it are, perhaps, that the individual flower is too large and rare to be utilized as a badge or personal decoration, and that its distribution over the country is somewhat local. And yet it abounds in a larger section of the country than the Mountain Laurel, and its rarity is one of its charms. Its representation upon flags and banners, frescoes and tiles, shields and escutcheons, monuments and columns, tapestries and draperies of every material, would soon make it as familiar as the great Bald Eagle, of which a living specimen is now a very great novelty.

The bird of freedom was chosen, we are told, for our great seal and coat of arms as an emblem of self-reliance, liberty and strength; and what flower can be named that will so favorably compare with it in representing these same desirable qualities as the *Magnolia*? In making selections from our native flora and fauna, it would seem to strike the interested observer that a comparison would be somewhat like this—the

Trailing *Arbutus* to the pretty bobolink, the graceful Golden-rod to the much loved robin redbreast, the common Ox-eyed Daisy to the blackbird or blue jay, the Sunflower to the æsthetic owl, and the *Kalmia* to the beautiful oriole. But what could be found in the floral world so symbolical of the power and strength, liberty and freedom of the great American Eagle, as the majestic and imposing *Magnolia grandiflora*?

Magnolia grandiflora was among the favorite trees, if not the especial one, of Washington. An imposing specimen over seventy-five feet high, known to have been planted by his own hands, still flourishes at Mount Vernon; and every year since this modern Mecca has been accessible to the public, each fallen petal of its faded blossoms, every glossy leaf of its rich foliage and every seed that drops from its fruit-pods have been carried away as precious souvenirs by the visitors to that hallowed spot.

Would it not be graceful and fitting in these times, when greater fraternity of feeling in all sections of the country is desired, for the north to take conspicuous part in adopting for the national floral emblem this queen of our southern forests?

Washington, D. C.

Mary Fuller.

[*Magnolia grandiflora* is not only the most beautiful tree of our Atlantic forests, but it is one of the most beautiful known anywhere. Its comparatively restricted range—for it grows naturally only in a narrow belt of country on the south Atlantic and Gulf coasts—might be used as an argument against the adoption of this *Magnolia* as the national flower. *Magnolia*, moreover, is not American exclusively, and there are rather more species in eastern Asia than in America, where, with a single exception (*Magnolia glauca*), they are confined to the southern states and to Mexico. The range of *Kalmia*—an exclusively North American genus—is wider than that of all our *Magnolias*, being found from Canada to Texas; and it is certainly much better known to the great mass of the American people than any *Magnolia*. The objection which can be made to it as a national flower is that it is not found in the Rocky Mountains or in any part of the country west of them.—Ed.]

Correspondence.

Chrysanthemums at Orange, New Jersey.

To the Editor of GARDEN AND FOREST:

Sir.—Mr. T. H. Spaulding's Chrysanthemum-houses at Llewellyn Park, New Jersey, at present contain a very large and interesting collection of flowers, and are well worth inspection. Visiting this establishment a few days since, I found the early varieties already cut over and marketed, and the mid-season kinds in full bloom. Of the new American introductions for 1889, it was a pleasure to note an unusual number of valuable additions. Mrs. Hardy was in excellent form, though small, from late obtained stock. Mrs. Carnegie was the same bold, dark colored flower shown last year, but this variety evidently does not enjoy close air or confinement. Mrs. W. K. Harris was a disappointment, as seen here, and not equal to H. Cannell, which it resembles. Excellent (Waterer), a most charming soft pink; Sunnyside (Craig), reflexed flushed pink, a grand flower; T. C. Price (Waterer), cream pink; Mrs. Jessie Henszey (Harris), canary; Mrs. A. C. Burpee (Craig), reflexed yellow, and Mrs. S. Houston (Waterer), white, were the pick of the Philadelphia varieties of 1889.

Of Fewkes' set, Neesima, Lincoln and Kioto, yellow, Empress of Japan (Belle Hickey), fine white incurved, and L. B. Bird, are all acquisitions. Mrs. Fottler has not fulfilled its promise.

S. B. Dana, a "brunette," is a market variety, an early, free bloomer of distinct color. Henderson's Mrs. Humphreys, small white, and Harris' Snowball, are synonymous. Baronald is in the way of Moseman, but more full. Geo. Atkinson, fine white; Llewellyn, Indian red, thin but distinct; Mrs. William Barr, wide petals, deep red with blue-red reverse, comprise the best of Spaulding's set seen.

The English kinds, as usual, comprise some good novelties. Sunflower is one of the best of the new yellows, an immense flower of light appearance. Mrs. Walters, a sport from Edward Audiguer, and one of the darkest of Chrysanthemums, is a first-rate sort of largest size. Mrs. F. Jameson, a brunette, and Stanstead White, of peculiarly neat form, are all promising, though on weak plants they were not in first-rate form. Mrs. Haggas is the latest sport from Mrs. Heale, a charming, soft

yellow Chinese incurved. Violet Tomlin, a sport from Princess of Wales of the same section, has fine form, but is of that distressing color known by florists as violet-rose. C. Orchard, after the fashion of Mrs. Wheeler, is an exhibition flower of largest size. Mrs. J. Wright, a large, deep and graceful white, is a first-rate addition, and one of the best of the season.

The French still produce annually a great number of fancy kinds, many of which, if poorly grown, can scarcely be distinguished from each other, but every year adds a few very good ones. The most promising here are Madame Edouard Lefort (Del.), a very deep maroon, with gold reverse and ends of petals laciniated and laced with gold, in the way of Macaulay; M. Bourignon (Del.), a purple-red reflexed, silver centre; Compte de Mun (Del.), cream and white; F. Marrouch (Aud.), yellow; M. J. N. Pigmy (Aud.), a white Soliel Levant; Madame Lay (Aud.), carmine-rose; M. Bernard (Brt.), violet-amaranth.

Mr. Spaulding has a great number of seedlings, the most promising of which has been named Ada Spaulding, a very solid sphere of white, shading to pink on the lower petals. The effect of a well grown flower is that of a large Pæony, though it is well incurved and belongs to the Japanese section, not being so closely imbricated as the typical Chinese. As grown here, the second season, in all forms, it appears to be a variety of great merit. This flower was awarded the Harrison Cup at Indianapolis, November 5th, as the best American seedling not yet introduced.

E. G. Hill, a fine yellow, flamed with red on its lower petals, will be fine if it retains its character. I fancied, among a great number, Cyclone, a white R. Crawford; 770, a bronze copy of same, 789, a very full Mrs. Wheeler; and Zenobia, a large white with wide petals. It would be interesting to know if, among original species from which our hybrids have been obtained, there is a scented one. Otherwise it is difficult to account for the appearance of an occasional variety with a decided perfume. A little lemon colored Pompon seedling here has a most pronounced odor, in the heat of the sun quite overpowering. Mr. Spaulding has fixed a white sport of Mrs. Gerard, which he has named Marie Ward, a most exquisite flower of distinct form. I noticed here one feature of very great interest to growers—the culture of the main crop in wooden boxes six feet long, a foot wide and a foot deep, such as are used by Rose-growers. Six plants were grown in each box, and were in excellent condition. Of course, such boxes require much less care and are less expensive than pots, more rapidly shifted into the houses, and in every way more convenient when the plants are grown for cut flowers for market in large quantities.

Orange, N. J.

G.

Recent Publications.

The Genus *Masdevallia*.

A Manual of Orchidaceous Plants Cultivated Under Glass in Great Britain, by Messrs. James Veitch & Sons, Chelsea.

A fifth part of this very useful work has just been issued, and is devoted to those charming little plants, the *Masdevallias*, and a few closely allied genera. Few other groups have increased so rapidly during recent years, and the available information is so widely scattered that the work will be welcomed by cultivators and others. And it is not too much to say that the same high standard of excellence which has characterized the early parts of this work is here fully maintained.

Masdevallia was established by Ruiz & Pavon, toward the end of the eighteenth century, for a single Peruvian species, which, strangely enough, is unknown to modern science. In 1832 Lindley enumerated three species in his "Genera and Species of Orchidaceous Plants," and thirty years later the number had only increased to thirty-six. At the present time, through the discoveries of travelers on the upper slopes of the Andes, 125 species is said not to be an exaggerated estimate of the numbers. Some of these are not in cultivation, and others have but little claim to be cultivated for ornament; but we notice that the selection given by Messrs. Veitch numbers some sixty species, exclusive of hybrids.

A large amount of useful and interesting information is given as to the homes of these plants and the conditions under which they grow, and from it the following is condensed: *Masdevallias* are alpine plants, having their homes on the mountains of tropical America. They grow in a variety of situations—on the ground, in the crevices of rocks, on the trunks and branches of trees, and even on the roofs of buildings, but always where there is but little soil, or where there is but a small accumulation of vegetable matter. They first appear on the Peruvian Andes, about the fifteenth parallel of latitude, and extend as far as the mountains of south Mexico, being most numerous in New Granada; while a few outlying species are found in

the mountains of Brazil and Guiana. Some of them occur within the *Odontoglossum* zone, but usually they are found at a higher elevation and above the limits of the forests. In round numbers, they may be said to occur between the elevations of 6,000 and 13,000 feet, a few of them ascending to near the snow line. In these elevated regions the *Masdevallias* live under very different climatic conditions from those under which they are cultivated in Great Britain, owing to the greater rarity of the air, its diminished capacity for absorbing aqueous vapor, and other local causes; nevertheless, their culture is not attended with any special difficulties.

Several features of interest present themselves on glancing through the work. Take *Masdevallia Chimara*, for example, where we note that no less than six Reichenbachian species are reduced as varieties of one polymorphic species. Seven varieties are admitted, but we read that "there are other *Chimæra* forms in cultivation, named and unnamed, so intermediate in character that they may with equal right be referred to either of the two between which they stand."

"The habitat of *Masdevallia Chimara* is restricted to a comparatively small area on the western Cordillera of New Granada, extending from Frontino, near Antioquia, to a few miles southward of that town. Its vertical range is from 4,500 to 6,500 feet; it grows chiefly on trees and shrubs, preferring the forks of the branches, where there is a small accumulation of decaying vegetable matter, and where there is shade and moisture. In those localities in which *M. Chimara* is most abundant the atmosphere is always at or near the saturation point, and fogs and mists are almost of daily occurrence for more than nine months of the year; but at the higher limits of its range, where these hygrometric conditions are less pronounced, the plants are much less vigorous, but flower more freely; the leaves are swollen and more leathery, the flower-scapes shorter and erect, and the flowers are smaller in all their parts."

Masdevallia coccinea, "a charming thing, with flowers as red as a soldier's coat," is a name which has been floating through the books like a ghost, without any one knowing what it really stood for, and consequently we read with interest that the plant has been identified, and is none other than *M. Lindenii*; of which *M. Harryana* is supposed to be only a variety. The confusion seems to have arisen through the true plant being first confounded with *Masdevallia militaris*, and then with *M. ignea*, and those who would read the history of this confusion should refer to the pages of the *Gardeners' Chronicle* for August 31st last, where the matter was sifted by Mr. Rolfe, of Kew. And so it appears we must write *M. coccinea* for this showy species, whose flowers vary from a deep, rich crimson-purple, through magenta-crimson, crimson-scarlet, scarlet, orange and yellow to cream white.

"Its principal locality," we are told, "is on the eastern Cordillera, between Sogamosa and Concepcion, where its vertical range is 7,000 to 10,000 feet; it is particularly abundant on that part of the Cordillera called the Sierra Nevada de Chita, where it spreads in uninterrupted masses for miles, covering acres upon acres of the upland slopes, growing in the partial shade afforded by the low shrubs that abound in the place. When in bloom these masses of *Masdevallia* present one of the most striking floral sights it is possible to behold, even in tropical lands."

These extracts will afford a glimpse of the valuable information to be found in the pages of the work. One of the illustrations calls for a remark—and, by the way, the same or a very similar one has appeared in the pages of the *Gardeners' Chronicle*. It is *M. racemosa*, with fourteen flowers, all expanded at the same time, and as three is the highest number seen in cultivation, we cannot but think some mistake has been made. The raceme certainly goes on lengthening and producing new flowers, but these are borne in succession, not synchronously. We recently saw a dried specimen which had been carefully glued to a sheet of paper, and which exhibited all the flowers of the raceme expanded at once; but the most cursory examination showed that the flowers had all been carefully attached to an old raceme. The moral is self-evident.

Notes.

Mr. C. L. Allen sends to this office a fruit of the Chinese Quince weighing considerably more than a pound. The flesh is dry, bitter and puckery, but the odor of the fruit is delightful.

A new Veitchian hybrid *Cypripedium*, not yet in commerce, to be called T. B. Haywood, is now flowering for the first time in America, in Mr. Ames' garden at North Easton. It hardly seems very distinct, or superior to many of its predecessors.

Lydia W. Shattuck, who recently died at an advanced age, had been teacher of botany in Mount Holyoke Seminary for no less than forty-one years. To the interest attracted by her teaching was largely due the founding of Williston Hall and its scientific collections.

In the article entitled "A Destructive Cornel Saw-fly," on page 521 of this volume, at the fourth line of the second column, the phrase "in the imperfect and mature stages" should be transposed so as to read "which, in the imperfect and mature stages, attacked and destroyed many larvæ."

A new variegated form of the east Asian Hercules' Club (*Aralia Chinensis*), the leaves broadly blotched with yellow, in the exhibit of the Associated Nurserymen of Boskopp, will be prized by people who are interested in plants with abnormally colored foliage—a class with which our gardens seem already sufficiently supplied.

A correspondent in California sends us a specimen of cork two inches thick, taken from a Cork Oak planted at San Gabriel twenty-eight years ago. The specimen is a part of the third crop produced by this tree. The prospect that the cultivation of the Cork Oak will become a large and profitable industry in some parts of California is excellent.

Abies subalpina, a native of the forests of the Rocky Mountains, where it is found growing only at high elevations, still remains one of the rarest of the American conifers in cultivation. It may interest the cultivators of such plants to know that a considerable stock of well grown young specimens of this species can be found in Mr. John Waterer's Nursery, Bagshot, England.

A personal letter from the Director of the gardens of the Villa Thuret calls attention to the value of *Lippia canescens* as a permanent lawn plant for California and similar dry regions. This plant spreads by means of prostrate stems, and is not affected by the hot, dry summers of Provence. M. Naudin will distribute a few seeds to Californians who may desire to experiment with it.

Mr. S. B. Parsons writes that no shrub on his grounds excels our native *Itea Virginica* in the splendor of its autumn colors. Even now, after the leaves have fallen from nearly every other shrub, they are still abundant on the *Itea*, and of a solid crimson color. This shrub also has the merit of blooming in late June and July after the mass of shrubs have passed their season of flowers.

Secretary Rusk, in his report just issued, urges upon the government the duty of assuming a more definite supervision over the forests of the country, or, at least, over such forest-areas as are owned by the government, and occupy positions of importance in the regulation of the water-flow and other climatic conditions. At present, he adds, we are without definite knowledge of the extent, location, condition and value, direct or indirect, of the forest property now in the hands of the general government; much less do we know of the forest condition of the country.

Plants of the European Spindle-tree (*Euonymus Europæa*) are remarkably fine this year in the neighborhood of Boston. This species, of which a number of varieties are in cultivation, attains the size of a small tree. It is perfectly hardy, the habit is good, the fruit is abundant and conspicuous, and the leaves late in autumn assume a brilliant scarlet color, which contrasts agreeably with the red and rose-colored fruit. The European tree far excels its American relatives in the brilliancy of its autumn coloring, which, perhaps, is not surpassed by that of any other European plant.

It is not, perhaps, generally known that *Parrotia Persica*, a tall shrub from the Orient, related to our Witch Hazel, is perfectly hardy in the northern states. This plant has long been valued in European gardens for the brilliant yellow tints the foliage assumes in winter, and in this country, even where bright-colored autumn foliage is the rule rather than the exception, *Parrotia* is well worth cultivating for the display of color it makes during the first week of November. There is a second species, *P. Jacquemontiana*, a native of Cashmere, which has probably not been introduced into the United States.

Lincoln Park, in Chicago, contains St. Gaudens' admirable "Lincoln," and not far away from it stands Mr. Boyle's group of Indian figures called "The Alarm," an interesting if somewhat immature work, far above the average of the figures which people our eastern parks. To these has recently been added a third statue, said to possess unusual artistic merit. It

was given by the Honorable Lambert Tree, formerly our minister to Belgium, and was executed by the Belgian sculptor, Jacques de Lalaine. It represents La Salle. The figure is bronze, of heroic size, and shows the explorer in travel-worn garments, standing with one foot on the prostrate trunk of a tree and gazing earnestly toward the south-west.

Gardeners rarely select herbaceous plants on account of the autumn colors of their foliage, and there are not many plants which belong to this class which are distinguished in this particular. A notable exception is the Japanese *Lysimachia clethroides*, the leaves of which are colored during the first ten days of November bright orange and scarlet. This is a handsome and a perfectly hardy plant, well worth a place, too, in the garden for its long, one-sided, curved spikes of white flowers, which are nearly half an inch across. It grows to a height of two to three feet, and its only drawback is that it grows too vigorously and spreads too rapidly by its underground stems. It is not easy to eradicate it from a garden when it is once fairly established.

All the monstrosities in the way of "floral decorations" with which our pleasure-grounds are deformed, we too commonly credit to the gardener in charge, forgetting that he is employed by others, and may possibly but execute their definite biddings. According to a letter in the *American Architect and Building News*, great injustice is done to one executive at least. Speaking of Jackson Park he says: "Here Garfield, made entirely of Cacti, reposed one year; here the lamented Jumbo, made of exactly the same material as the President, bristles each summer; and not far off, a gentleman on a bicycle, a loving couple in a boat, a sun-dial, a calendar, etc., bloom and flourish. The head gardener has very recently published a protest in an agricultural paper against these abominations; but how can he dispense with them when people enjoy them, children cry for them, and the Park Commissioners insist on having them?" Undoubtedly the same influences control many other parks all over the country, and it is time that the gardener should be relieved of a portion of the obloquy and that the public should be told where the responsibility rests.

Robert Douglas & Sons, of Waukegan, Illinois, have just signed a contract with Mr. George Vanderbilt to make a plantation of trees on his estate near Ashville, in North Carolina. About 1,000 acres are to be planted eventually, although the present contract is for not less than 300 acres, to be planted within twenty-four months. Twelve hundred trees are to be planted to the acre, the planters agreeing to cultivate them during two years, and to deliver at the end of that time not less than 1,100 trees to the acre. White Pines (*Pinus Strobus*) are to be planted principally, with four per cent. of Douglas Fir, as an experiment, and a few deciduous trees will be mixed through the conifers. Plants from twelve to eighteen inches high will be used. Mr. Douglas, who is on the ground giving his personal supervision to preparing the ground, proposes to plant fifty or a hundred acres this autumn for the purpose of testing the possibility of late autumn planting. Mr. Vanderbilt's experiment is an important one, and will be watched with interest. This is, without doubt, the first attempt at tree-planting on so large a scale which has been made in the southern states.

Monsieur André describes in a recent number of the *Revue Horticole* the new hybrid, *Hypericum Moserianum*, which attracted much attention this summer at the Paris Exposition, where it was one of the most interesting of the newer hardy plants shown. It was obtained by Monsieur Moser, of Versailles, by crossing *Hypericum patulum* with *H. calycinum*. The hybrid unites the qualities of the two parents and is considered superior to them both. It is a shrub three to four and a half feet high, with numerous upright branches gracefully arching above the middle. They are round, at first red, but eventually turn green, and are covered with opposite, entire, subsessile, oval, obtuse, opaque leaves, which are dark green above, paler and glaucous on the lower surface, and from one to two inches long by half an inch wide. The inflorescence is terminal, simple, or with three flowers which are an inch across, with a spreading, slightly cup-shaped corolla, of bright, clear yellow, concave petals, and purple stamens. The hybrid might be described as a tall growing, large flowered *Hypericum patulum*, resembling *H. calycinum* in the size of its flowers and in the texture and arrangement of the foliage. *Hypericum Moserianum*, if it proves hardy in this country, as there is every reason to believe that it may, will make an interesting and valuable addition to our list of hardy summer-blooming shrubs.

The Chrysanthemum.

THE celebration in England, and in several countries on the continent, of the hundredth anniversary of the introduction of the Chrysanthemum into European gardens, is one of the most interesting horticultural events of the year. It can hardly be said that these festal ceremonies have done or will do much to kindle the enthusiasm of Chrysanthemum growers, for the simple reason that the ardor of their devotion is already a proverb, and it could hardly be more fervent. Thirty-five years ago an eminent horticultural authority declared that the passion for Chrysanthemums had become a mania in the British Islands; and certainly the zeal of English horticulturists in this direction has known no languor since. But this centennial commemoration has really done much to stimulate historical research. All the records of the century have been ransacked for facts and illustrations that will throw any light upon the origin and development of the flower, and, after the elaborate treatment of the subject by the horticultural press and the publication of the papers read at the Chiswick conference, little will be left untold of the history of the Chrysanthemum since its invasion of Europe a hundred years ago—or should we say two hundred years ago? The *Gardeners' Magazine*, which is the earliest of English horticultural journals to issue a centennial number—and an admirable number it is—repeats the quotation from Jacob Breynius in the “*Prodromus Plantarum Rariorum*,” a work published in 1689, in which six varieties of the Chrysanthemum are described as cultivated in Holland at that time; and who knows for how long a period before? There is little doubt, however, that these flowers were subsequently lost to Dutch gardens. At least when the large flowering Chinese Chrysanthemum was re-introduced a century later, the gardeners of Holland knew nothing of it.

But the Chrysanthemum has a long history as a cultivated flower in the gardens of Asia before it was introduced to European civilization, whatever may be the exact date of its advent there. In northern and central China it has been grown with rare skill from the earliest times of which that ancient race has any authentic record. The well-

known dish in the Franks' collection in the British Museum, decorated with this flower, is more than 450 years old, and in Japan it was wrought on the hilts of imperial swords forged seven centuries ago. But there is an earlier history still, of which no record exists in porcelain or bronze, and many a botanist would rather be able to identify the wild species from which the Chrysanthemum originated than to be familiar with all its garden history.

Glancing for a moment at the history of the Chrysanthemum in Europe, one is struck by the remarkable series of surprises which have occurred at intervals to revive or increase the popular interest in its cultivation. Of the three plants introduced a century ago, a purple one alone survived, and its value as an autumn flower was at once appreciated. Rose colored and buff flowers appeared a few years later, followed by the quilled yellow, the Spanish brown and the large lilac, and soon a white sport from the purple variety revealed the variable character of the plant and aroused the eagerness of collectors, so that during the first twenty years of this century it already ranked among the most popular of garden flowers. About the end of this period, striking novelties in form and color were imported, until fifty well-tested varieties were found in English gardens. None of these could win a first premium in an exhibition now, but many of them had wonderful beauty of form, and, judging from the illustrations then published, they were characterized by a wayward grace in the disposition of the long florets which in recent times would be attributed to a mixture of Japanese blood. Meantime the Chrysanthemum, under the sunny skies of France, had been ripening seed, and ardent admirers of the flower began to raise seedlings. Growers in Jersey soon followed, and even in England, where a sunless climate made the ripening of seeds a difficult matter, some seedlings were raised; and in 1835 appeared, among others, the variety known as Nonpareil, which is still grown and exhibited. The introduction of the Pompon class in 1846 was another distinct advance, and Chusan Daisies, as these flowers were called, at once became reigning favorites in France. The great exhibitions began in the middle of the century, and since then the evolution of the flower has been closely watched by enthusiasts in its culture in all the temperate climates of the globe. Varieties which did not bloom until late in spring were followed by precocious kinds, which flowered in August, until the year was almost girdled with Chrysanthemums. Then came Mr. Fortune's notable introduction of the Japanese varieties. These were contemptuously received by the old school of florists because they failed to conform to the rigorous standard of perfection. But of the seven original importations five are still common in gardens, while Golden Dragon and Grandiflorum retain their position in the foremost rank of exhibition flowers.

But the prime value of these introductions from Japanese gardens was not revealed until they proved their potency as parent plants in the hands of the hybridizer. Colors have been intensified until we can reasonably hope for a clear crimson, and cultural surprises in the matter of form and habit have signalized almost every exhibition season. The latest astonishment came two years ago, when the Mrs. Hardy bloomed in Boston, and this year a flower with the same downy pubescence, but a different color, has been found in a Japanese importation by Mr. Peter Henderson. What will be the next surprise? The blue flower, reputed as hiding somewhere among the temples of the East, is no doubt a myth. But was the painting of a climbing Chrysanthemum seen by Mr. Molyneux a product of the imagination only? Can anything be hoped from an infusion of the blood of any of the wild varieties, especially from that of some ancestral type? Such a return to original sources might restore the vigor of constitution which pampering for many generations has impaired. Time alone can answer these questions; but we may rest assured that whatever changes may come, the Chrysanthemum will retain its hold upon popular affection.

In American gardens the Chrysanthemum has long been

a reigning favorite, and American gardeners can claim a fair share of credit in developing its beauties. Our climate offers exceptional advantages for the production of seedlings, and the names of Dr. H. P. Walcott, W. K. Harris, John Thorpe and T. H. Spaulding will always be honorably associated with the history of the plant. Enthusiastic cultivators of *Chrysanthemums* were confined, a few years ago, to the more eastern states; but they are multiplying all over the country, and perhaps the finest collection of flowers ever seen in America was exhibited at the late show in Indianapolis. That popular appreciation of our flower is not on the wane is evident from the fact that the best *Chrysanthemum* blooms have been selling in the New York market at five and six dollars a dozen, and in one instance which has lately come to our knowledge, twenty-five flowers were sold by the grower for twenty-five dollars.

Among the Pines of Northern Michigan.—I.

THE southern peninsula of Michigan has no mountains nor very high hills nor any rocky surface worth speaking of within its borders. There are hills, plenty of lakes, and a fair proportion of swamps and marshes. The streams are usually slow in the north, and naturally clear, but the largest ones are often made muddy by the logs floating down to the mills.

White Pine once extended to a line running nearly west from the foot of Lake Huron. Probably nine-tenths of the merchantable Pine has now been removed. This has been taken nearly clean from the southern part of its former limits and in the vicinity of large streams. The lumberman has chased the Pines, Hemlocks and Cedars back from the streams and railroads over the hills, and when too remote for convenient transportation, he has constructed new railroads into the heart of the timber. It is a rare thing to see a good forest near a railroad.

Where the soil was of good quality much of the stump land has been cleared and converted into farms, but where the soil was poorest much of it still remains nearly as it was when the lumberman left for new conquests. It is no longer thought necessary to depend on a river to float logs to market. As proof of this, Mr. Potts has constructed a railroad along the Au Sable River to Lake Huron, on which he transports logs to his large mills. He avoids losses, saves time and money, by abandoning the old slow process of employing a boom company to take charge of his logs while passing down the river.

The attention of one riding for the first time along any of the railroads of northern Michigan is sure to be arrested by the dead standing or fallen Pines, mostly small and slender, or knotty and forked at the top; trees left because there was no money in them. If recently abandoned and killed by spreading fires, the bark still covers the trunks, and most of the limbs are there; if abandoned and killed some years before, the bark has fallen, leaving a smooth trunk, which reveals every unevenness in the surface, and the ends of many limbs have broken off and fallen. The period of lumbering is indicated by the signs above mentioned, as well as by the size of the young growth which is covering the ground. The small young trees and the shrubs still standing, though dead, often tell of the destructive sweep of one, two, three or more fires since the largest trees were cut and removed.

Three to six weeks in each summer of the past two years spent in traveling in the northern half of the lower peninsula has made me somewhat familiar with this portion of Michigan. The experiment station of the Agricultural College is testing a few acres of Jack Pine plains in five different counties of the state. In connection with this work, I take great interest in studying the native plants with reference to species, distribution, modes of growth and adaptability to cultivation. In new ground, roughly cultivated, and sown to Grasses or Clovers for two years, the increased vigor of some of the herbaceous perennials has been very noticeable.

A large Hemlock near the margins of a recently cleared forest does not give much indication of the genuine grace and beauty of a young tree well grown in an open space. The trunk is nearly cylindrical till we come to limbs near the top, which tapers rapidly to the apex. The limbs leave the trunk at a very wide angle. Dead Hemlocks present a peculiar picturesque and rugged appearance not easily forgotten. In the swamps, or near them, are many Balsam Firs, some of them with long, dense, conical tops. The Spruces are slender, with branches slanting downward quite rapidly and curving outward at the ends.

The Arbor-vitæ or White Cedar is everywhere in the swamps and varies much in appearance. In autumn we see the dead or dying fan-shaped branches and leaves among those of more recent growth, which are green. Every one has an idea of the shape of the trunk of a well grown White Cedar, as they are almost the only trees used here for telegraph poles. Very large trunks are sometimes seen, where trees have not been much crowded and where the soil and climate are suitable. We measured one at three feet from the ground, with a diameter of four feet and four inches. It tapered very rapidly, and was not much higher than some of the larger telegraph poles in large cities. The tree stands near Kingsley, in the south-eastern part of Grand Traverse County.

The Norway Pine, as it is always called by lumbermen in Michigan, is the Red Pine (*Pinus resinosa*, Ait.). It is abundant on the sandy lands above referred to, sometimes scattered here and there in open places among the Jack Pines, or occasionally found in large groves in which there are but few other trees, and so thick that underbrush is very scanty. A low tree, with a large top, as found in open places, makes a rapid growth, consequently has much sap-wood. They are called Black Norways by lumbermen, and are considered of little value. Tall trees, where they have been crowded, have small tops, and long, naked, straight trunks. These are called Yellow Norways, as most of the wood is heart-wood and yellow. The bark is not in vertical folds or ridges, as is familiar in the White Oak and Tulip tree, but comes off in irregular patches or scales from an inch to three inches in diameter. The bark is dull red in color. The top is more nearly like that of the Austrian Pine than that of any other tree in general cultivation. It has a healthy, sturdy look, and in every respect, so far as observed, is a much finer ornamental tree than the Austrian Pine. The seeds are not abundant, hence young trees are not often raised and put on the market. The trunks are extensively used for flooring, bridges, timbers for frames of houses and piles. In Kalkaska County I measured a sound stump three feet and three inches in diameter, though most of the logs cut at the mills would not exceed a foot and a half in diameter.

Across the Jack Pine plains, in many places, teams may be driven almost anywhere. A road soon becomes worn and cuts into the sand. A new road is easily made by cutting a few trees and bushes, or, perhaps, with no outlay of labor. Roads are cheap and abundant, running everywhere, often confusing the stranger, as he may not know whether this is a highway or a road leading to a camp or a small farm-house. These winding roads, in open places through the valleys and around or over the gentle hills among the Jack Pines and scarlet rocks, are often very pleasant, though in time they become monotonous to the traveler.

Agricultural College, Mich.

W. J. Beal.

Hardy Shrubs with Ornamental Fruit.

A FEW notes on the appearance of certain shrubs in this region may be of interest to eastern readers.

Rhamnus Caroliniana, as it grows in the grounds of the Agricultural College here, is a neat, tree-like shrub of five feet in height. The broadly lanceolate, recurved leaves are three to five inches long, shining dark green. The foliage alone would render it highly ornamental, but with the added attraction of its load of brightly colored fruit it becomes one of the most desirable specimen shrubs for the lawn. The fruit is a three-seeded, globose drupe, the size of a small cherry, borne in simple panicles of three to six in the axils of the leaves. About the 1st of August these take on a color too deep for scarlet and yet not crimson, the effect of which, in contrast with the dark polished leaves, is wholly pleasing. This color is maintained till the last of September, when they ripen to a waxy black.

The next botanical order affords two attractive plants which are abundant in the wooded ravines of eastern Kansas and as far west as the Solomon Valley. These are the Wahoo and the Bitter Sweet.

The Wahoo or Burning Bush, *Euonymus atropurpureus*, is found in thickets along the borders of timber, growing to the height of six or eight feet—a perfect miniature tree. The odd little velvety, dark brown blossoms will be noticed only by the real lover of trees and woods; but the brilliant coloring of the autumn fruit challenges the admiration of every passer. The outer coating of the fruit is pale crimson, showing, as it opens, the seeds encased in a deep scarlet aril. The European Wahoo, growing in our trial rows, has fruit a little smaller, with the seed enclosed in an orange aril.

The closely allied Bitter Sweet, *Celastrus scandens*, twines so closely with the branches of its supporter that the rambler

among the trees is constantly startled with the vision of sober, gray Elms and Oaks bearing drooping panicles of orange and scarlet fruit. These plants may be procured in abundance to adorn the humblest yard, while they would not be out of place on the most elaborate grounds.

The eastern Snowberry, *Symphoricarpos racemosus*, has not proved as thrifty a grower with us as in its native haunts; but some plants which I rooted under glass last winter have made a growth of two feet since they were planted out, and are bent to the ground with their weight of snowy white berries. Its more western cousin, the Coralberry, *S. vulgaris*, is so much of a nuisance along roadsides and in pasture lots that its long, slender stems, covered with the currant-like crimson berries, seldom get credit for the beauty they possess. This little shrub would be valuable for planting on embankments or other places where needed to hold the soil, as well as to hide an unsightly place.

The Wolfberry, *S. occidentalis*, is found abundantly on the head waters of the Solomon River and is equally as hardy as the last. It is more stiff and erect in habit, and the fruit, a trifle larger, is white. Neither of these should be planted where their propensity for sprouting from the roots can do harm.

Two Privets growing in our nursery-rows seem worthy of mention in this list.

Ligustrum buxifolium bears an abundance of berries in erect, close heads, several often branching from one stem, the terminal one being the larger. The other is represented by a single unnamed bush. This bears larger berries in a loose, raceme-like cluster, which becomes so heavy that it weighs down the slender stem, making it almost pendulous. These shiny black bunches are so numerous that the plant is a very pretty sight. Specimens of this I referred to Professor Sargent last year and he regarded it as a large fruited variety of *Ligustrum vulgare*.

The Black Alder of the Prinos division of Ilex, *I. verticillata*, thrives well in our trial rows, and those plants which fruit bear a heavy annual crop of the brilliant scarlet berries which make them so ornamental in autumn and early winter. The leaves are dull and without much beauty in our climate, but they fall early, thus better displaying the wealth of fruit.

A specimen or two of this, placed where their bright color is thrown into relief by some dark background, makes a pretty picture.

Holiday Notes in Southern France and Northern Italy.—V.

LAKE Como, in the opinion of many the most beautiful of the north Italian lakes, is enclosed by an amphitheatre of mountains, some of which rise to a height of 7,000 feet. Olive groves and terraced vineyards occupy a large portion of the lower slopes, and Chestnuts and Walnuts ascend to the very crests of the lower mountains wherever soil enough for them is to be found. Large Fig-trees are a feature near the villas by the edge of the lake; in vases along the walls of several villa gardens we noticed the scarlet flowered *Russelia juncea*, and in the shrubberies a number of ornamental woody plants which have already been mentioned in these papers. Como itself, the capital of the province, is a quaint town; it contains many large silk factories. It is interesting, too, as being the birthplace of both the elder and the younger Pliny, and of the electrician, Volta, whose statue occupies a prominent position near the quay.

From Menaggio a narrow gauge railway runs to Porlezza, at the north-eastern extremity of the Lake of Lugano. The highest point of the line is upward of 600 feet above the Lake of Como, beautiful views of which are obtained from the windows of the carriage. The journey by steamboat from Porlezza to Lugano—the largest and busiest town in the Swiss canton of Ticino—is a delightful one; in our opinion the scenery is more picturesque than on the Lake of Como, that of the eastern arm of the Lugano Lake being wild and deserted. On the lower slopes the vegetation seems nearly the same on both lakes.

In the pleasant garden of the Hotel du Parc, at Lugano, on the site of the suppressed monastery of San Maria degli Angioli, the following notes were made: *Buddleia Lindleyana*, with drooping inflorescences eighteen inches long, here attained a height of ten feet, and formed graceful, floriferous bushes; in most nurseries it is another species, *B. Japonica*, Hemsley, which passes under this name. The latter plant, too, has been a good deal confused in gardens, botanical and private, and numerous figures and descriptions of it have appeared in horticultural publica-

tions under the name of *B. curviflora*, W. & A., an appellation which rightly belongs to quite a different plant. Bushes of *Deutzia gracilis*, six feet high, surpassed in size and vigor any we had previously seen; the season's shoots measured about four feet in length. Even when cultivated with every care in Britain this charming shrub is a pigmy compared with the Swiss specimens just mentioned. Beds of Indian Azaleas well set with buds gave promise of a fine show of flowers; large bushes of Moutan Pæonies made us "covet and desire other men's goods." *Viburnum Awafuki* (according to Laval-lée's list identical with *V. odoratissimum*) excited our admiration. One bush formed a beautiful cone about fifteen feet high, and its large, leathery, glossy leaves of the darkest green made a fine foil for the cymes of coral-red fruits. The deliciously scented but inconspicuous blossoms of *Osmanthus fragrans* appealed strongly to the sense of smell and led to our discovering the plants. The Chinese are said to use the flowers for scenting tea. *Magnolia* (or rather *Michelia*) *fuscata* thrives well at Lugano—a mass of them in flower would be almost overpoweringly sweet. As an edging (and a capital one too) for shady walks and also as a sort of turf covering to the bare ground under the dense shade of trees, *Fluggea Japonica* was successfully employed. This pretty little plant, with its dark green, grassy leaves and blue berries, is frequently called *Convallaria Japonica* in English nursery-lists, and also *Herbe aux turquoises* in French ones; there being not many things which thrive under these conditions, it seems desirable to call special attention to the merits of this plant.

Beau-Séjour, a dependence of the Hotel du Parc, has a still finer garden. There we noticed fine *Arundinarias*, twenty feet high, *Osmanthus fragrans*, eight feet high and as much through, and *Abelia rupestris*, of still larger size, literally covered with flowers. Cherry Laurels, trained into an arch, made a delightfully cool and shady approach along one side of the front garden from the gateway to the hotel. The more spacious grounds behind the hotel rise rapidly and many beautiful plants were noted. On a sunny wall fruiting Citrons were very attractive, also Oranges laden with fruit. In the border at the foot of the same wall was a large bush of a white flowered Abutilon and another of *Eupatorium odoratum*, which by Christmas will be a mass of scented white flower-heads. A huge tree of the Yulan, *Magnolia conspicua*, a fine tree of *M. macrophylla*, about forty feet in height, and a large *M. grandiflora*, were the most remarkable of the flowering trees. *Edgeworthia chrysantha*, eight feet high by about ten feet through, profusely set with flowers, was conspicuous with its fine foliage; even under glass in England we cannot get this handsome Indian plant to thrive so well. *Benthamia fragifera* (the genus *Benthamia* is now merged by Bentham and Hooker into *Cornus*), another Himalayan shrub or small tree, of considerable beauty and interest, was as much at home here as in the warm, equable climate of Cornwall; the white-bracted flower-heads, like those of *Cornus florida* on a smaller scale, are showy, and the fruits, when ripe, are not unlike a strawberry. Camellias, Azaleas and Hydrangeas were represented by fine bushes, and *Chimonanthus fragrans* by the largest specimen we had ever seen. Photinias and the Loquat (*Eriobotrya Japonica*) were also good, as was also a very large plant of *Aesculus macrostachya*. *Elæagnus glabra*, a handsome Japanese evergreen, occurred as a climber; its long sarmentose shoots had wound themselves in among the branches of a cluster of Pines and had attained a height of about forty feet. In this part of the world this species makes one of the best of hedge plants.

American Vines made excellent arbors in the gardens of the cafés, hotels, etc., facing the lake, and the enormous crop of grapes borne by them could not fail to attract a good deal of attention among the cultivators in a district where Vines are everywhere grown. Here and there *Vitis vinifera* was used for shade, but for vigor and free-bearing qualities it compared most unfavorably with the American species; we learned, on inquiry, that these latter are now used extensively as stocks whereon to graft the more delicate Old World varieties, and that Phylloxera, the great curse of many European Vine-growing countries, is, by this means, to a considerable extent checked. In southern France we saw many establishments specially founded for the propagation and sale of American Vines.

At Ponte Tresa, where we leave the lake and take train to Luino, the railway is a narrow gauge adhesion line and commands magnificent views. For some distance the line follows the valley of the Tresa, a picturesque mountain torrent which here forms the boundary between Switzerland and Italy, and numbers of Italian custom-house officers, armed with carbines, patrolled the banks to prevent smuggling.

New or Little Known Plants.

A New Winter-blooming Begonia.

(Begonia Triomphe de Lemoine.)

THIS hybrid Begonia, of which a portrait of the original plant appears on page 557, is a novelty which has received much attention in Europe during the past year. It is very free flowering; it remains in flower for months, and it can be grown and flowered, apparently, with very little trouble. The habit of the plant, as our illustration shows, is excellent. The foliage is good, and the flowers are brilliant, recalling in color those of *Impatiens Sullani*.

We are indebted to Monsieur Lemoine, to whose skill in hybridizing we owe this handsome plant, for the following note regarding it, and for the photograph from which our illustration has been prepared.

"The new Begonia was obtained by impregnating the flowers of *Begonia Socotrana* during the winter of 1887-88 with pollen from another species, probably *B. Razlii*. The flowers of *B. Socotrana* had been fertilized by a number of species, but only a single cross was successful. Whether the pollen-parent was *B. Razlii* or not, the seedling in less than a year formed a mass of foliage sixteen inches high by twenty-eight inches in diameter. The hybrid may be described as follows:

"The stems are herbaceous, spreading, then erect and branching into numerous flowering branches. The leaves are large, coriaceous, orbicular, rather oblique; the margins slightly cinereous; six inches in diameter; those at the base of the stem much the largest. The flowers are produced in dichotomous cymes from the axils of the leaves. The male flowers, with four petals, measure one and a half inches across, and are rose-carmine in color, the buds being rather brighter carmine before the flowers expand. The female flowers are exceedingly rare. More than 600 flowers have been open on the plant at the same time, and it has been so covered with bloom as to resemble an immense bouquet.

"This Begonia budded the 1st of December, 1888, and the first flowers opened toward the middle of January. It was still covered with flowers in the month of May, when it was exhibited at the Paris Exhibition, and excited the admiration of every one who saw it.

"The plants should be plunged out-of-doors during the summer, and grown in a cool house during the autumn and winter."

Nancy.

V. Lemoine.

Viburnum Sieboldii.

THIS handsome plant is a native of Japan, and was first described by Miquel from specimens gathered by Von Siebold in 1861.* Here, in cultivation, it is a stout shrub with spreading and finally with upright branches six or ten feet high and covered with smooth, ashy-gray bark. The leaves which appear early in May are, when fully grown, three and a half to five inches long by an inch and a half wide, and are borne on stout petioles, an inch and a half long; they are oval or obovate, sharply and remotely serrate towards the extremity only, with prominent midrib and primary veins. The lower surface, young shoots and buds are covered thickly with rusty-brown hairs, which are scattered also over the upper surface of the leaves. These at maturity are dark green and lustrous on the upper, and paler on the lower surface. The flowers with truncate calyx-limb and rotate corolla, are creamy white, and produced in flat, rather few-flowered cymes, terminating the branches. The fruit is black, half an inch long, with nearly triangular seeds conspicuously grooved on the back. The leaves when bruised and the wood possess, even more strongly, the peculiar disagreeable odor of our native *V. Lentago*. The flowers open here during the first week of June and the fruit ripens in September, at which time the plant is particularly ornamental, the stout branches of the abundant cymes having turned bright scarlet.

* *Viburnum Sieboldii*, Miquel *Prodr. Flor. Jap.*, 155.—Maximowicz, *Mel. Biol.* x., 660.

Viburnum Sieboldii, according to Maximowicz, is not a rare plant in its native country, being found along streams at the foot of the mountains in dense woods. It was introduced into cultivation through Mr. S. B. Parsons of the Flushing Nurseries, to whom American gardens are indebted for so many fine Japanese plants. He sent it to the Arboretum several years ago, and has propagated it largely. It is perfectly hardy, flowers freely every year, and requires no special soil or care.

C. S. S.

Plant Note.

Myrica rubra.

THIS is a comparatively newly discovered Japanese evergreen. It is a fruit tree, producing a highly flavored edible fruit, an inch in length by three-quarters of an inch in diameter, and in shape resembling a Blackberry. It is firm and contains a single seed of light weight. The fruit is dark red, almost black, but there is also a light rose colored variety the fruit of which is said to be sweeter than that of the one first mentioned, although it is not quite so large. The fruit ripens in Japan in the early part of July and can be used for many purposes. It is now used as a dessert, and is sometimes preserved. The extracted juice can be used as a beverage in its fresh state, and by slight fermentation produces a delicious wine. The foliage resembles that of a small leaved evergreen Magnolia, and is firm and leathery. The tree is ornamental, and its bark can be used to make a dye of a beautiful fawn color. It is not a very hardy tree, but will succeed well in a climate where the Fahrenheit thermometer does not fall below 20°, and where the summer is sufficiently hot.

I think it would thrive in the southern part of California, in all the southern states of the United States, in Central America, Mexico, Italy, Spain, and the southern part of France. It is questionable whether it would succeed in England, Germany, and in the northern states of America; certainly not without very adequate protection during the winter.

The propagation of *Myrica rubra* will be best accomplished through its seed, as the wood is too hard for cuttings.

The growth of the tree is rather slow, but if planted extensively it will pay well in time, as the trees not only will produce a delicious fruit in abundance, but will yield also a fine bark, which can be used for dyeing purposes, and a splendid timber showing a mottled grain better than the best Maple. The wood is light, tough and lasting, and is now used in Japan for fine cabinet work.

The seed should be sown in a light loamy soil, and placed on bottom heat if obtainable. The seed should be shaded with boards if possible, otherwise with a thick mulching of straw or other vegetable matter about a foot deep. Seeds must not be exposed to the sun's rays or to too much light.

Plants are at present very scarce, as the Japanese have not sufficiently appreciated the beauties of this tree to properly propagate it, but seeds can be collected.

Louis Boehmer, in *The Garden*.

Cultural Department.

Bromelias.

ANY one who is acquainted with the variety of form and beauty of colors which are characteristic of a large number of the *Bromeliaceæ* cannot easily comprehend the want of interest shown in these plants by horticulturists generally. Fashion reigns in horticulture as in many other things, and fashion having decided against Bromelias, they are scarcely known in gardens—always, of course, excepting that king of fruits, the Pine-apple. The late Professor Edward Morren, of Liege, who was not only the botanist of the order, but loved and cultivated the living plants as well, had the richest collection of species known. For their accommodation he had specially constructed houses, in which the requirements, real or supposed, of Bromelias were as carefully provided as is done for Orchids by their admirers now. I had the pleasure of seeing this collection when it was at its best, and it struck me then as being not only unique in character, but exceptional also in the interest and charm of the plants themselves. Huddled together, or, as is too often the case, placed in an out-of-the-way corner and neglected, Bromelias have a woeful aspect which is scarcely calculated to make people admire them. But when properly cultivated and arranged with taste and care, a collection of these plants forms a really fine feature.

In their vegetative characters, time of flowering, duration of the flowering season, as well as in the form, size and colors of their flowers, Bromelias are quite as varied as Orchids. There is, of course, a great difference between the two families, yet as plants of decorative value Bromelias are almost equal to Orchids. To persons who have learned to despise the former from having seen a few ill-grown examples, such as are often met with, this may sound like heresy. Unfortunately I cannot say, go to Liege and be converted, as when Professor Morren died the plants were sold, a large number of them having been purchased for Kew. But there are good collections of Bromelias in many continental gardens; Makoy & Co., of Liege, have an exceptionally large and rich nursery collection. In addition, they have also a private collection of these plants, kept solely for their own enjoyment, and not for trade purposes, a fact which speaks for itself. At Kew the collection of Bromelias is the richest by far ever seen in England. There are always a good many kinds in flower, and it is remarkable how many visitors take an interest

considerable, so many of the genera of this order being largely represented in gardens, and, as is usually the case, their history and nomenclature were all in confusion until Mr. Baker's book made all things plain. It is very agreeable news to bulb fanciers to hear that Mr. Baker will soon issue a similar handbook on *Irideæ*. The allied order, *Liliaceæ*, he dealt with some years ago in the *Journal of the Linnean Society*. In the interests of horticulture an appeal might be made to Mr. Baker to give us a handbook of *Liliaceæ*, uniform with that on the *Amaryllis* order. The *Linnean Journal* is not easily accessible to gardeners. At any rate some of the principal horticultural genera of *Liliaceæ* might be dealt with in this way. Gratitude displays itself by asking for more!

The Bromelia book contains descriptions of over 800 species, or more than double the number estimated by Bentham as recently as 1883, and this number will, Mr. Baker thinks, fall far short of what will ultimately be found.

The number of genera admitted is thirty-one. These are divided into three tribes. (1.) *Bromeliæ*; ovary inferior, fruit

Fig. 144.—*Begonia Triomphe de Lemoine*.—See page 556.

in and admire them. Still, fashion rules. No one has taken a fancy to Bromelias and horticulture loses in consequence. Fifty years ago hardly any one grew Orchids. It was not until the Duke of Devonshire, on seeing *Oncidium Papilio* in flower at Chiswick, was so struck with its beauty that he determined to build houses for and collect them, that the cultivation of Orchids received any attention from amateurs. The Duke set the fashion, which, once started, grew rapidly. Orchids deserve all their popularity; Bromelias deserve a great deal more than they enjoy.

Mr. John Gilbert Baker, of the Herbarium Kew, has been for many years identified with this family. Whilst Morren lived Mr. Baker was content to be thought second to him in a knowledge of Bromelias. Now, however, Baker is the only acknowledged authority, and his title to be considered so is unmistakably shown in the "Handbook of Bromeliaceæ" which he has just published.* The book is uniform with those already published by him on the "Fern-Allies" and the "Amaryllideæ." The value of the latter to horticulturists is

indehiscent. (2.) *Pitcairniæ*; fruit a three-valved capsule, seeds not funicled. (3.) *Tillandsiæ*; fruit a three-valved capsule, superior, seeds funicled. A considerable proportion of the genera are unrepresented in gardens, having apparently small claims to beauty. Of the genera cultivated or worth cultivating, the following are the largest in number of species and the most striking in floral characters:

KARATUS.—(Thirty-six species.) These are mostly robust plants with long ensiform, channeled, prickly edged leaves; flowers arranged in a large dense globose head and surrounded by bracts and leaves which are often very brilliant in color. In large tropical houses they are most effective. At Kew when in flower they attract great attention, and even when not in bloom they are ornamental.

CRYPTANTHUS.—(Twelve species.) These are usually remarkable for their prettily variegated leaves. *C. bivittatus*, *C. Makoyanus*, *C. Lubbersianus*, *C. zonatus* and *C. Bueckeri* are delightful little foliage plants, easily cultivated and always attractive. The flowers of this genus are white and not ornamental.

* George Bell & Sons, York Street, Covent Garden. Price, five shillings.

ÆCHMEA.—(One hundred and twenty-eight species.) Over thirty of these are grown at Kew, some being of large size, others small. The flowers are sometimes in a dense head, which nestles down in the middle of the rosette of leaves; in these the leaves are most attractive, the upper ones being almost wholly deep crimson or purple or spotted. Other species have a long panicle inflorescence, with red leaves and bracts scattered along it. They are, as a rule, very ornamental.

BILLBERGIA.—(Thirty-six species.) This genus is best of all in a garden sense. The leaves are usually folded, forming a sort of vase, and in some of the species they are prettily variegated. The inflorescence is in the form of a dense or lax spike, or sometimes a large branching panicle. It is clothed with large boat-shaped, brilliantly colored bracts, especially towards the top. The flowers are tubular, conspicuous, nearly always bright colored. Every one of the species deserves to rank with first-class flowering stove plants.

PITCAIRNEA.—(One hundred and thirty species.) This genus, also, is rich in good flowering plants. The leaves and habit are variable, but as a rule they are grassy, graceful, bright green, and in a large tuft. The flowers are on erect or arching panicles; they are numerous, tubular, large enough to make a display, and nearly always very bright in color, namely, scarlet, crimson, yellow or blue. Several species previously known as Puyas are included here, such as *P. carulea*, a truly beautiful plant, with flowers on a large, stout, erect panicle, each flower almost as large as a *Lapageria* and colored a rich peacock blue. This and several others Mr. Baker has seen fit to call Pitcairneas.

PUYA.—(Fourteen species.) The giants of the order belong to this genus. The leaves are long, rigid, armed with sharp teeth, and the flowers, which are usually two inches, or even more, long, are produced in profusion on very stout, erect spikes. One described has flower stems thirty-three and one-half feet high, the flowers disposed in panicles and reckoned at not less than 8,000! There are some magnificent life-size paintings of several Puyas in the North gallery at Kew.

CARAGUATA.—(Thirty-nine species.) Handsome, stemless plants, *Tillandsia*-like in habit and foliage, the two genera differing only in the former having a gamopetalous corolla. The flowers are on erect spikes, sometimes in a globose head, crowned with a tuft of usually bright colored small leaves. The lower part of the spike is often clothed with bright scarlet bract-leaves. The species in cultivation are very ornamental. *C. lingulata*, *C. sanguinea*, *C. Tahnii* and *C. musaica* are fairly well known among stove plants.

TILLANDSIA.—(Three hundred and twenty-three species.) This genus now includes *Vriesia*. It is very variable in size and beauty, but a large number of handsome garden plants are among those already introduced to cultivation. The leaves are unarmed, in some species prettily varied or variegated, *i. e.*, *T. hieroglyphica*, *T. fenestralis*, *T. tessellata*; in others they are of a uniform brown or pale plum color, *i. e.*, *T. amethystina*, *T. angustifolia*. The flowers are brilliant in color in all the *Vriesia* section, bright yellow and scarlet or crimson predominating. In *T. Lindenii* and its variety *Vira* they are of quite exceptional beauty. *T. regina* is of very large proportions, almost as large as a Century plant.

Enough, I think, has been said to show that the order is all that is claimed for it here, and Mr. Baker's book is exactly what was wanted to give a correct idea of the horticultural merit of many of the Bromeliads at present known.

W. Watson.

Figs in the South.

THE Fig succeeds on any kind of land in the South, clay or sand, high or low, hummock or Pine, and requires little or no cultivation. It comes early into bearing, only two years from the cutting, is easy of propagation, and may be trained to tree shape and growth by allowing only one shoot or stem to the root. The chief obstacle to drying the fruit in the sun in Florida is that the ripening occurs during the periodic wet season. It begins to ripen about the first of July for the general crop, and fruit has been obtained from the cutting the first year.

The varieties that have given the best satisfaction in this state are the White Adriatic and White Smyrna, which are very choice for drying or table use; Celestial, very sweet, small and a prolific bearer; Black Ischia, a bluish black variety of good quality, and the Brown Turkey, another prolific bearer.

These situations best suited for the Fig-orchard are those which have a northern exposure, which will serve as a sort of protection from the cold. If a southern exposure is selected, the young trees will take on such a rapid growth during winter

that a sudden frost will kill them while in the sappy state. A northern exposure keeps back this growth, and makes the young shoots strong enough to resist the ordinary attacks of frost. As we come farther north, in Georgia and the Carolinas, where the frosts are heavier, this precaution is needed all the more. The frost does not easily kill the trees, but it sets them back in their growth, and prevents the maturing of good crops of fruit.

The fig is destined to become an important fruit in the South, and when better methods of drying them for the market are observed the imported fruit will be driven out of the market as completely as Mediterranean oranges, lemons and other tropical fruits have been in the past. Fig culture for profit has not, so far, obtained much success in this country, but many are now going into the business for money. Experiments were made last year in several parts of the south in placing green figs upon the northern markets. The success of the enterprises seems to have justified the growers in their expectations of a profitable business, and larger groves have been planted since.

The figs are sold in any kind of condition, often being put up in old pickle jars or bottles of different sizes. This is very different from the nicely packed, pressed and dried fruit that comes from the Mediterranean, with the trade-mark and label of the growers marked fancifully on the box covers. In order to compete successfully with the imported fruit, it is necessary to have the fruit properly prepared, and neatly put up, according to rule, in a regular preserving factory. Fresh figs could also be sent north as well as the dried fruit, and there is no doubt but the demand for them will be great.

Fig-trees do the best when planted in rows about fifteen feet apart each way. The fields are marked off in squares, and holes dug for the cuttings, or young trees, to be put in. The cuttings consist of twigs of last year's wood, which are buried in the ground about six inches from the surface. The cuttings can be taken off and planted in a trench until early spring, when the Fig trees are beginning to put out their leaves. When the trees get very large every alternate one can be taken out, often with the best results. There is little cultivation needed after the trees once get a start. *George B. Walsh.*

New York.

The Flower-Garden in Autumn.

THE time to protect the flower borders has now arrived, and preparation should at once be made for this work before the advent of severe frost, for although this may be delayed for some weeks, yet everything should be ready for it. We often observe elaborate directions about "cleaning up," but some gardeners carry their worship of the idol of cleanliness too far. We should never forget the necessity of leaving on the plants just that natural form of protection which they duly provide for themselves—that is, dead leaves and flower stalks. An example or two will illustrate my meaning, and the rest can be left to the judgment. Many gardeners, for the sake of appearance, in fall cut off all ripened foliage from such plants as *Iris laevigata*. Now, we have proved to our satisfaction that this is highly injurious, as frost and melted snow make use of the opportunity to get down into the very hearts of the plants, and the inevitable result is that next season one waits in vain for the reappearance in their accustomed vigor of the young shoots, and when they do come they are liable during the earlier stages of their growth to be injured by late spring frosts if deprived of their natural protection. *Eulalia Japonica*, and its varieties, are plants that are generally regarded as of doubtful hardiness, and we confess to having lifted them every fall during the past two seasons. However, we have taken notice of a large circular bed of this Grass at a neighboring railroad-station which thrives amazingly year after year, by no means on account of the attention given to it, but simply because it is left alone until the time for tidying up in spring, and then the tops are cut off. Meanwhile some of our own plants, left out, with their tops cut off and carefully covered with soil, were completely killed, not one surviving. Another instance of mistaken zeal is the removal of the dead flowering stems of Lilies. These, of all other plants, are susceptible to injury from moisture in winter, and when the stems are removed an excellent passage for water is made straight to the centre of the bulbs, and decay is the inevitable result. Nature has tried to enforce this lesson upon us by the tenacity with which the perfectly lifeless stems cling to the living bulbs until the young shoots are prepared to take their place in spring, after which the old stems are easily removed. Many other instances might be cited, but the judgment of the cultivator may be relied upon to furnish them for himself. The

object in view while writing this is to point out that, while "cleanliness is next to godliness," it is by no means the best practice to remove every vestige of dead leaves and flower stems from the flower-garden while protecting the flowers against the ravages of a winter's frost. *E. O. Orpet.*

Passaic, N. J.

Palms for Small Places.

WHEREVER a green-house, if only a small one, is found in connection with an American garden a *Latania* or two at least is likely to be found, and yet there seems, in some quarters, a lack of positive knowledge as to the most suitable species and varieties of Palms to be grown in places having only

with their glaucous under surfaces, making it one of the most ornamental and effective plants in cultivation, either for the green-house or on the dinner-table. This plant is a native of South America, and grows best in a stove temperature. It does not require heavy watering at the root, at least during the winter, but enjoys copious syringing overhead in bright weather.

Next in merit to this, perhaps, on the ground of general utility, though of very different appearance, are the different kinds of *Rhapis*, an elegant and very distinct family of Palms, from Japan and China. Palms of this genus are dwarf growers, of bushy habit, throwing up numerous cane-like stems, well clothed with shining, dark green, flabellate

Fig. 145.—*Viburnum Sieboldii*.—See page 556.

limited accommodations. In the minds of many persons, a Palm is always associated with spacious and lofty conservatories, and although it is true that ample room is needed for the best development of many species, this is by no means a general rule.

Perhaps, therefore, it will be worth while to invite attention to a few of the many species well adapted to more modest quarters—that is, to those of comparatively dwarf habit and of easy cultivation.

At the head of the list of miniature Palms should be placed *Cocos Weddelliana*, the dwarf Cocoanut, one of the most graceful of Palms, its delicate, pinnate leaves of dark green,

leaves, which are very tough in texture and capable of withstanding much hard usage.

R. flabelliformis is adapted to a variety of uses, and is equally effective for house-decoration, for the conservatory or for sub-tropical bedding in the summer, and it will thrive under green-house treatment. A prettily variegated form of this is also in cultivation, but is more rare and also more delicate, and is therefore not to be recommended for general use. *R. humilis* is also an excellent variety, somewhat similar in general appearance to *R. flabelliformis*, but having longer leaflets, which are gracefully arched.

Among the Fan Palms, probably the hardiest and most

easily procured (with the exception of *Livistonia Chinensis*) of the dwarf growers are found among the *Chamærops*, a genus widely distributed. Probably the best known of them are *C. Fortunei* and *C. humilis*, the latter being a native of southern Europe; and although it has been known to reach a height of twenty feet, yet it may be considered a dwarf plant, from the fact that it takes a number of years before it forms any trunk, and its growth is always slow.

Another handsome plant well suited to our purpose is *Livistonia australis*, formerly known as *Corypha australis*, a sturdy grower, and capable of bearing great changes of atmosphere without much injury. This also belongs to the Fan-leaved section, and, though of slow growth, it is highly ornamental, and will flourish in a temperature of fifty degrees; and is useful as an out-door plant in the summer.

Where a stove temperature can be afforded them, some of the *Calamus* will be found a welcome addition to the collection, being very graceful in habit and comparatively rapid in growth. They are mostly natives of the East Indies, and are of slender form, bearing long, light green, pinnate leaves, the foot-stalks of which are all more or less clothed with long brown or black spines. Among the most beautiful varieties of this genus are *C. palembanicus*, *C. adspersus* and *C. hystrix*, and a compost of two-thirds sandy loam to one of peat will be found a good one for them. *Calamus* should be given an abundant supply of water and a moist atmosphere, as when allowed to become too dry they are liable to an attack of red spider.

The *Chamædoreas* are another useful class of small growing Palms, some varieties of which are very well known, being easy to grow and not very particular as to their surroundings, provided they receive plenty of water and a reasonable degree of heat. They have been mostly introduced from Mexico and Central America, and have pinnate, or occasionally entire leaves, light green in color. An interesting feature of most of the varieties of this species are the flower-spikes, which are freely produced from the axils of the leaves even in small plants, the inflorescence being usually either orange or red. Probably the best known variety of the *Chamædoreas* is *C. elegans*, with its graceful pinnate leaves from two to four feet long. *C. Ernesti-Augusti* is one of the best representatives of the entire-leaved section of these plants. It has handsome foliage about two to three feet in length, deeply cut at the apex into two sharp pointed lobes. Other notably good varieties of this genus are *C. graminifolius*, *C. Sartorii* and *C. Wendlandii*.

Of course, such a general favorite as *Areca lutescens* is indispensable in any collection of Palms, and is too well known to need further reference in this connection.

In this brief enumeration of Palms suitable for small establishments, no attempt has been made to offer explicit directions in regard to treatment; but it may be said that no Palm should be allowed to become very dry at the root at any period of its growth, and with reasonable care in ventilating, heating and shading in summer any of the sorts mentioned may be kept in fair condition.

Orchid Notes.

Odontoglossum grande.—Dr. Lindley, when he described this fine *Odontoglossum*, for the first time, in the *Botanical Register*, would probably have found it difficult to find a more appropriate specific name than "grande" for it—a name to which it does full justice by the great size and conspicuous beauty of its flowers, which mark it as one of the very finest species of the group to which it belongs. Nowadays good specimens may be obtained at a very modest price, which appears a mere trifle when compared with the enormous sums which were willingly paid for this plant several years ago, when the culture of Orchids was a rage with the most wealthy only.

O. grande may be said to celebrate its jubilee of cultivation this year, for it was just fifty years ago that it was first introduced by Mr. George Ure Skinner from the shady ravines of Guatemala. It seems to be confined to this region, notwithstanding the fact that the traveler, Warscewicz, sent a specimen to Professor Reichenbach labeled as having been found in Costa Rica.

The chief characteristics of this fine species are its ovoid, compressed, dull green pseudo-bulbs, which, when young, are encased in strong greenish sheaths. Generally two oblong-lanceolate leaves, about six inches long, are borne on the summit of each pseudo-bulb. They are grayish green above, paler beneath, often copiously spotted with brown and distinctly traversed by curvilinear veins. The erect spikes, bearing from five to eight flowers, which often measure seven inches

across, are produced when the growth is about half over. The oblong, acute sepals are bright yellow, transversely barred with glossy cinnamon-brown, and the broader petals are of deep, shiny cinnamon-brown, except at the tips and margins, which are bright yellow. The sub-orbicular lip is, as a rule, whitish, and more or less densely covered with brownish red blotches, while the bifurcated crest is rich orange-yellow, blotched with cinnamon, and the bright yellow column is furnished with a rather large pubescent wing on each side. Some hundreds of plants have been in flower here since the beginning of September, and now, in the first days of November, there are still several in bloom.

O. grande is not hard to grow. In its native country it inhabits damp, shady places where the temperature ranges from sixty to seventy degrees Fahr. during the summer and a minimum of about twenty degrees lower in the winter. The plants should, therefore, be grown in a house whose summer temperature conforms as near as possible to that of their natural condition. When growing, water may be freely given, but when the plants have finished both growing and flowering—that is, about November—the supply should be much decreased and the plants allowed to rest for about three months with as little water as possible. The usual compost of rough peat and sphagnum in conjunction with well drained pots seem to be most suitable for this species.

St. Albans, England.

John Weathers.

Arachnanthes (Vanda) Cathcartii.—This interesting Orchid is very seldom seen in bloom, and is by no means plentiful. The growth is peculiar, scrambling, with a slender, woody stem, clothed with distichous, pale green, fleshy leaves, about seven inches long and two broad. The pendent racemes springing from the side of the stem bear four or five flowers about three inches across. In color these are white on the outside, while the interior is yellow, banded with reddish brown. The lip is divided into three lobes, the two lateral ones being white, streaked with red at the base, and the middle lobe whitish, with a yellow, crenate, incurved border. *A. Cathcartii* was introduced from the Himalayas in 1864, and grows freely in the East India house with the usual *Vanda* treatment, but should have a good exposure to sunlight with accompanying dryness after growth is finished to induce it to flower freely.

Saccolabium bigibbum, a rare and attractive little plant, is now flowering freely here. Its greatest disadvantage is the extreme shortness of its raceme, which seldom exceeds two inches, and, when more than a dozen fair sized flowers are crowded in this short space, many of them remain hidden between the leaves. The flowers are very pretty, with yellow sepals and petals, and a saccate, triangular white lip, with beautifully fringed edges and a yellow centre. It is a compact growing plant, with bright green leathery leaves about six inches long, growing and flowering very freely when accorded the usual warm-house treatment. It lasts a long time in bloom, and should be grown in a basket, to show its flowers to full advantage.

Kenwood, N. Y.

F. Goldring.

Melothria punctata.—This is a delicate and graceful plant of the Cucumber family, sometimes known as *Bryonia punctata*, and in gardens more frequently as *Pilogyne suavis*. It was discovered a century ago at the Cape of Good Hope, and is now known to be widely distributed in Africa as far north as Abyssinia. I saw it this year used with excellent effect covering the tubs of large standard plants in Herr Borsig's beautiful city garden in Berlin; and once I have seen it used to form the delicate festoons of living green the Germans are so fond of carrying along the borders of their garden walks. But it is evidently much less used now in Germany than it was twenty or thirty years ago, for a correspondent of *The Gardeners' Chronicle*, writing in 1861 about *Pilogyne suavis*, says: "It is universally employed in Germany and Belgium for hiding the bare stems of standard Roses and making little festoons between them, and for any similar purpose. As it is a very neat and pretty plant, not inclined to become a rampant grower, it is particularly adapted for this purpose; and it has become so great a favorite there that it is found in every garden."

"The treatment that *Pilogyne* requires is as simple as could well be desired. In autumn a few cuttings are struck and kept in store pots in a warm green-house through the winter. In the spring they are potted off. If there is not a sufficient number, a stock can soon be obtained, for they strike as readily as *Verbenas*; they are hardened off with the bedding plants, and as soon as the weather permits planted wherever they may be required. They need but little further

attention; a string being placed where the festoon is required, the plants attach themselves to it and very soon produce a rope of verdure. This plant has yet another good quality to recommend it; in the evening, or after a shower of rain, it emits a very pleasant, faint, musk-like perfume."

The leaves are rough to the touch on the upper surface, five-lobed, one or one and a half inches in diameter, and bright green. The flowers are small and quite inconspicuous, and as only the male plant is known, apparently, in cultivation, it never produces fruit. It is for its foliage, therefore, that this *Melothria* is used, and it is certainly well suited for making a temporary covering over any unsightly object in the garden. If it is not known in this country, it might be introduced advantageously from Germany. S.

Begonia Socotrana.—Botanically, this is one of the most interesting Begonias known. It was discovered in Socotra in 1880 by Dr. Balfour, who sent tubers of it to Kew, where it flowered the year following. Sir Joseph Hooker, when figuring it in the *Botanical Magazine*, said that "Socotra was one of the last places in the world where a Begonia would have been expected to occur." Horticulturally, it has proved exceptionally valuable, partly from its own merits as a winter-flowering species with remarkable foliage, and handsome, deep rose, large flowers, but chiefly as the parent of a race of Begonias which promise to be as useful for in-door gardening in winter as the progeny of the Andean tuberous species are in summer. I allude, of course, to the several hybrids raised by Messrs. Veitch, and named John Heal, Adonis and Winter Gem. These grow about a foot high, have bright green foliage and rosy crimson flowers, large and numerous enough to make a rich glow in the stove in winter. The most remarkable character in the flowers of these plants is that of keeping fresh several weeks in water, or if left on the plants they last a month or more before withering on the stalks. They do not fall as all other Begonia flowers do. *B. Socotrana* is represented by a large group of plants in the Begonia house at Kew, and it will be attractive until Christmas. The leaves are large, petate, cupped, shining green, and they spring almost upright from a short, fleshy stem. This plant and its offspring go to rest in spring, and start into growth again about July. They should be started and grown in a warm, sunny green-house till the beginning of October, when they require a stove temperature.

Jasminum gracillimum.—This plant ought to be in every collection of stove-plants. It is by far the finest of all the tropical Jasmines, although *J. pubescens*, an old garden plant and a near ally of *J. gracillimum*, is not much its inferior. When first introduced it was grown as a dwarf pot plant, in which form the Messrs. Veitch exhibited it for the first time in 1881. Now, however, it is known to be best when treated as a climber, and when grown against pillars or along rafters in stoves it is seen to great advantage. At Kew it is trained on pillars, and its long shoots hang gracefully all round, each one bearing a large terminal cluster of beautiful white, star-like flowers, one and a quarter inches across and sweet scented. As a basket plant this species also produces a fine effect. It is a native of north Borneo. W.

American-grown Cauliflower Seed.—Last spring two packets of Cauliflower seed, grown at Fidalgo, Washington, were sent to this station for trial. The seed was of the Erfurt and Snowball varieties. It was sown in the open ground on May 14th. In due time the plants were transplanted to the garden, and they have headed better than plants of the same varieties grown in former years from imported seed, and that, too, in spite of an extremely dry autumn. Every plant has either formed a fair-sized head or it gives promise of doing so in a few days. The heads are not large, but that is not surprising, as we have had almost no rain for the past two months. They are neatly formed, and when tied early, to exclude the bright sunshine, are white and of excellent flavor. If the seeds planted in this trial are fair samples of the Cauliflower seed that may be produced in the Puget's Sound region, there are good reasons for believing that we shall soon be able to grow all our own seed of this delicious vegetable.

Two New Squashes.—Last spring Messrs. Vilmorin, Andrieux & Co., of Paris, advertised in their catalogues two new Squashes, under the names Very Early Prolific (*Courge prolifique très hâtive*) and Missions Squash (*Courge des missions*). Like most of the varieties of the Cucurbit family developed in France, these do not appear to have qualities that would commend them in this country. The first is an early Squash, similar to our Dunlap's Marrow and Orange Marrow, but the

fruits are smaller in size and the plants less productive. The second is a winter Squash, the color of the Perfect Gem, or a shade more grayish, and of a form resembling that of our Bay State. The quality is very good, but in our test the plants were quite unproductive, and the fruits were formed so late that few of them attained their size before frost.

Wisconsin Experiment Station.

Correspondence.

Growing Timber Without Knots.

To the Editor of GARDEN AND FOREST:

Sir.—What is the best treatment of Pine-trees in a forest when the lower branches on the trunks are dying? The trees are wanted for timber.

Duluth, Minn.

S.

Your correspondent fails to state whether he has in view particular conditions, to which the information is to be applied, and as a doctor can only prescribe after diagnosis of the special case, the answer can only be general.

To grow timber free of knots, and that means a shaft free from branches, the best plan is to provide for it from the start by keeping the growth densely crowded. Close planting is recommended largely for this reason. The physiological explanation of the effect of dense growth in preventing the formation of branches, or, if formed, in soon killing them, lies in this, that leaves, and dependent upon their activity wood-growth, require for their development and life a certain amount of light. Failing to receive this, no buds are developed, and where the branches that have developed are excluded from the light, or receive insufficient light, they lose first their foliage and then die a natural death. This is the forester's natural method of growing clear timber—by timely management.

As knife and medicine become necessary, where the rules of hygiene have been neglected, so the pruning knife and saw are called into requisition to fit trees for a purpose, for which they were not managed in time. The system of pruning the branches for the purpose of producing clear timber has not, as a rule, proved satisfactory in France, where it was most strenuously advocated and practiced. Dead and dry branches can usually be removed without danger to the tree. In fact, their timely removal by a sharp cut close to the trunk reduces the danger of rot, which is apt to start in the stubs of broken branches. The removal of living or partly dead branches is practiced at the risk of inducing decay, unless done with great care. The open, unprotected wound first dries, then splits open and gapes, water enters, with the spores of fungi, which produce rot, and the disease may spread and ruin the whole shaft. If the tree is in vigorous growth, with a fully developed crown, on a favorable site, it will heal a wound made by the amputation of a branch not thicker than three or four inches by "walling over." Where the conditions are less favorable, it becomes necessary to guard against decay by covering the wound.

To avoid, then, the occurrence of knots in future sawlogs, and to produce trunks free from branches, these must be shaded out when young. Since, however, a full development of the crown is necessary for the full and normal development of the trunk—the trunk being a product of the crown and its mass proportional to it—it is evident that the right time for bringing the growth out of the dense position of its early years to the roomy position which insures proper development of crown and trunk, is an important consideration for the grower of timber. This time occurs when the maximum height-growth has been attained; that is to say, when the trunk proper has grown to nearly its full length and now requires filling out—diameter development—under the full activity of the crown.

According to species and character of site this period varies, and accordingly also the time of first thinning, its recurrence and degree require the judgment of a forester and cannot be briefly formulated.

Thinning out takes place in a dense forest growth sooner or later, more rapidly or more slowly, according to the

species which form it, the soil-conditions and several other factors. Some species, like the Beech, Fir and Spruce, have the capacity to develop their leaves, and vegetate with very little light at their command; others, like Birches, Poplars, Ashes, require much light, and therefore thin out very soon under their own shade, exerted by their crown. The former class, which may be called shade-enduring timbers, can develop in about fifty to seventy-five per cent. of the room which the latter, the light-needing, require for full development. This means that fewer individuals of the latter are allowed to live on a given area than of the former, and the natural cleaning of dead branches takes place much more rapidly, and earlier.

On the better qualities of soil this struggle for existence is brought to a close much sooner than on poorer land and in higher altitudes, where the energy of growth is less vigorous. Therefore, we can say, summarily, that in a normal, natural forest growth, the average room occupied per tree is larger in proportion as the growth is older, the species more light-needing, the soil conditions better and the locality less elevated.

The treatise on pruning forest and ornamental trees, by Des Cars, translated by Professor Sargent, contains all information necessary as to the methods of pruning. Where walling over of the wound is expected, it may be said that if the pruning is done in July rather than in the autumn the healing process will begin the first season, and to some extent the danger of frost to the wound will be avoided. The main point is to cut with a fine-toothed saw as close as possible to the trunk, taking care to make a smooth, uniform cut, and to avoid loosening the bark; this necessitates, in heavy branches, two cuts, the first lopping the branch at a distance from the trunk to relieve the weight. Conifers usually furnish the water-proof coat by the exudation of resin. Deciduous trees require artificial protection by means of coal-tar thinned with turpentine and applied with a brush.

How far pruning may be depended upon to produce timber free from knots is still an open question, and depends on circumstances often beyond our control.

Washington, D. C.

B. E. Fernow.

Ocneria dispar.

To the Editor of GARDEN AND FOREST:

Sir.—In the Boston *Evening Transcript* of October 31st there is an article headed "Save the Trees" giving some account of this European moth, which has become seriously abundant at Medford, Massachusetts. The writer of the article states that the insects were "first noticed three or four years ago. . . . For a while the extent of their work was so limited that not much attention was paid to them, but early last summer their numbers had so increased that much damage was caused."

Although there can be no doubt that the insect will commit serious ravages, if unchecked in any way, the prospect that "a great danger threatens the country unless prompt and effective measures are taken to stamp out the pest" seems remote, when it is known that over twenty years have elapsed since it was accidentally introduced by M. L. Trouvelot, a French naturalist, who made experiments in silk raising near Medford, but whose efforts in this direction were unsuccessful, partly because he also unintentionally imported one of the diseases so fatal to the silk worm. This *Ocneria* (also known under the generic names *Hypogymna* and *Liparis*) is nearly allied to the troublesome tent-caterpillar (*Clisiocampa*), and to the *Orgyia*, which is often so destructive to the foliage of many of our shade trees.

The males and females of the species differ strikingly. The former are small bodied, with dark reddish brown wings, which expand about an inch and a half, and the large bodied females have white or greenish white wings, with black and brown markings. They expand about two and one-half inches.

The egg masses are deposited on the limbs of the plants upon which the caterpillars feed. When fully grown the latter are larger than our common tent-caterpillar (*Clisiocampa*), and are dark in color and sparingly covered with small tufts of long hairs. They are almost omnivorous in their feeding habits and in Europe they eat the foliage of such differing plants as the Apple, Peach, Linden, Azalea, Oak, Larch, Juniper and White Pine.

In the article in the *Transcript* it is stated that the State Board of Agriculture "intends to ask the Legislature for an appropriation sufficient to meet the emergency," and it seems to be expected that a liberal appropriation will exterminate the pest.

Professor Fernald, the Entomologist of the Hatch Experiment Station, is also said to be preparing circulars, illustrated by plates, which "will be sent to all the residents of Medford in order that they may watch for the re-appearance of the pest and co-operate in the work of stamping it out." The outcome of these efforts will be very interesting.

It is, at least, very improbable that every specimen in such a considerable area (about one and a half square miles, according to the article quoted) can be destroyed. The insect has probably come to stay, and, ultimately, the best way to keep it in check, outside of the artificial remedies, may be the importation of the parasites and natural enemies to which it is liable in Europe.

European specimens of the insect in all its stages have been for many years on exhibition at the Zoölogical Museum, at Cambridge, Massachusetts. One of the earliest notices of its introduction occurs in the *American Entomologist*, vol. ii., p. 111 (February, 1870), and the case is also mentioned in Professor Riley's report on the insects of Missouri for the same year.

Cambridge.

Exhibitions.

The Chrysanthemum Show at Philadelphia.

GARDENERS complain that this has been a trying year for Chrysanthemums, and yet the collection of plants in Horticultural Hall last week was one of the largest ever shown there, and, beyond question, the best in quality. Not only were the plants exceptionally good, but they were well arranged and displayed. They were not placed in a solid mass, but were separated into two sections by a broad wall of green which ran lengthwise through the middle of the hall. This stretch of green began near the entrance with a remarkable collection of Ferns on a low table, beyond which towered a superb *Cibotium regale*. Then came tall Palms, with branches overarched a mound of rich foliage, while further on, the low tables, covered with Marantas, Dracænas and plants of this class, stretched toward the stage. The bank of Palms across the stage-front, like the Ferns, from the gardens of Mr. A. J. Drexel, were all good examples of choice kinds like *Pritchardia grandis* and *Livistonia Chinensis aurea*. Around the whole the walls were hung with evergreen and autumn leaves, and the galleries were wreathed and festooned with garlands of the same.

All this made an admirable frame and setting for the long double rows of flowering plants on either side of the hall. These were in great variety, including the best known of the old kinds of established reputation and a strong showing of later introductions. Among the plants and cut blooms were examples of some forty kinds which had never been exhibited before. It is worth putting on record, too, that of the plants and flowers, both old and new, which attracted most attention, at least one out of every four, and perhaps a still larger proportion, were originated by Mr. W. K. Harris. Beyond doubt the seedling Chrysanthemums of the first quality which, as the product of Mr. Harris' skill, now enrich our gardens, far outnumber those originated by any other American.

Among the plants the group of twelve, which took the prize for the best collection of that number, displayed wonderful cultural skill. These plants are naturally of different habit and time of blooming, and yet they were all at their very best on this special occasion, and while they had not been tortured into any formal shapes, they were surprisingly even in size and proportion—that is, about three feet high and five feet across, with a fully developed flower, erect on every branchlet. There were better single plants in the room than any individual of this dozen, but every one was a striking specimen, and all were so uniformly vigorous and floriferous that one looking down upon them would find it difficult to point out in what particular any one of them was more satisfactorily grown than another. As a matter for future reference, we give the names of this prize list: Mrs. A. Blanc, Gold, Mrs. Irving Clarke, Miss May Wheeler, Frank Wilcox, Mrs. Frank Thompson, Robert Crawford, Robert Bottomly, Puritan, Grandiflorum, Bride, and W. H. Lincoln. Of these all but three are American seedlings. They were exhibited by James Verner, gardener to A. J. Drexel. Of other plants, one of the most interesting was a specimen of Mrs. William Bowen, carrying about a hundred blooms, with florets of an intense crimson within and bronze reverse. Very striking, too, was a plant of Mrs. Irving Clarke,

with semi-globular flowers of immense size and a delicate pink color. *Kioto*; *Cullingfordii*, unrivaled yet in its deep crimson; *Source d'Or*, of an orange tint which has never yet been duplicated in any other flower, and many more, were shown in almost perfect specimens. By the way, Mr. Verner's collection would have been improved if *Cullingfordii* had been substituted for one of the pink flowers. Five pink varieties are too large a proportion of that color in a dozen *Chrysanthemums*.

Of flowers for the first time shown, Harry E. Weidener, a bright lemon yellow, of the *Grandiflorum* type and perfectly incurved, took the *Blanc* prize. It was raised by William Jamison and shown by Hugh Graham's Sons. The same firm gained an award for a white seedling, incurved, and also of perfect form and immense size. *Crown Prince*, grown by James Monahan, gardener to Mr. Charles Trotter, is an evident improvement on Mrs. Wheeler, much larger and of freer growth. J. T. Emler is in the way of Mrs. Carnegie, and has a better form than that fine flower. *Molly Bawn* is a white sport from the well known *Syringa*—a novel form in a white flower. Thomas A. Edison is very large and valuable for its color—a creamy lilac and quite new. *Eldorado* is of the deepest yellow—a yellow flushed with orange—and Mrs. Trotter is a beautiful flower of a novel lilac shade. John Hughes, gardener to George W. Childs, showed several fine seedlings, a firm white and a delicate rose with pale reverse, both being especially good. Mr. W. H. Graham showed one large, incurved blush white with broad florets, and another of pure white. The flower which won the premium as the best single bloom was Mrs. W. K. Harris, to which the plant prize went last year. It is a large, rich yellow, incurved, very deep, and carrying as many florets, perhaps, as any *Chrysanthemum* in cultivation.

Of many other admirable new flowers, like *Progression*, *Coronet*, E. G. Hill and *Ada Spaulding*, we have no space to speak; but it is to be hoped that by another year the National *Chrysanthemum* Society will be prepared to give certificates to such as merit the distinction. Mr. Peter Henderson's new *Louis Boehmer* would have caused a sensation two years ago, since it is almost an exact reproduction of Mrs. Hardy, except in color, which is called by some a silver rose and by others a rosy lilac. It is not a lively tint, and the pubescence, which is quite as dense as that on Mrs. Hardy, rather dulls than brightens it. The plant is interesting as a new example of downy florets, and it will prove useful to the hybridizer. The cut flowers, as a class, were good, but inferior in quality to the plants. The twelve blooms which took the grand prize were H. Cannell, *Domination*, *Compte de Germiny*, *Kioto*, Lord Byron, Mrs. Frank Thompson, Mrs. Langtry, W. W. Coles, Mrs. W. Barr, *Gloriosum*, E. Molyneux and Mrs. Houston.

Among the principal prize-takers besides those named above, were J. W. Colflesh, Gordon Smirl, F. R. Sykes, Thomas Long, E. P. Wilbur and George L. Fowler.

Philadelphia.

The Chrysanthemum Exhibition in Boston.

THE exhibition of *Chrysanthemums* of the Massachusetts Horticultural Society, which opened in Boston on Tuesday of last week, was the most successful the Society has given. The season has not been a particularly good one for the growth of the *Chrysanthemum* and several of the Massachusetts collections have suffered seriously from the attacks of a species of *Typhlocyba*, closely allied to the Rose-leaf hopper, which, unless some method for keeping it in check can be found, seems destined to interfere seriously with the successful cultivation of this popular plant.

The exhibition, however, in spite of these drawbacks, was surprisingly good, and contained a larger number of well grown plants and of cut specimen flowers than any of its predecessors. The arrangement was good; the lower hall being devoted to cut flowers, while in the larger upper hall the specimens were most effectively arranged in great groups and banks. The exhibition was varied, but hardly improved by the introduction of a number of tall, single stemmed plants with one flower, or, at most, a couple of flowers at the top of the stem. This is the favorite English fashion of growing *Chrysanthemums*, and an unnatural one it is, and not to be encouraged except when abnormally large, single flowers are wanted for exhibition purposes. The tall standard plants, with naked stems five or six feet high and surmounted with a scanty parasol-head bearing occasional tired looking flowers—wonderful examples, no doubt, of cultural patience—were hardly attractive either, and not to be compared, from an ornamental or from a useful point of view, with the compact half specimens, like those with which Mr. Walter Hunnewell took the first prize in the class for twenty named varieties. These were

models of what *Chrysanthemums* should be; compact, well grown plants, with rather short stems, covered to the pot with large, healthy, deep green foliage, and profusely flowered, with blooms not too large to appear unnatural or to lack substance. A better or more even lot of twenty well grown and well selected plants has not been seen in Boston.

The big flowers, however, attracted the masses, and a stand of eighteen cut flowers, of Japanese varieties, shown by Mr. Simpkins, of Yarmouth, was surrounded from morning till night by crowds of people, who learned here, perhaps for the first time, what a *Chrysanthemum* flower, in the hands of a first-rate gardener, can be developed into. The flowers which represented most of the new favorite varieties were simply marvelous in size and quality, and it is not easy to imagine that larger or better grown specimens have ever been produced.

An interesting feature of the lower hall was the row of tall vases occupying the end platform, containing cut flowers of many of the best varieties, with stems a yard long, and evidently grown specially for this purpose. The beauty of the flowers was heightened by the fact that only three or four specimens, always of the same variety, were used together in the same vase. This exhibition was made by Galvin Brothers, and showed how the *Chrysanthemum* can be used for the very best effect in large decoration.

The usual number of new varieties and of seedlings were shown. But it is not wise to judge of these from an acquaintance which does not extend beyond the show-table; and the number of novelties which are produced now in all countries is so great that a new variety should be subjected to the severe trial of long cultivation and to varied conditions before the public can take much interest in it. The new seedling, *Ada Spaulding*, is a case in point. This is the variety which, at Indianapolis the other day, won the cup offered by the wife of the President of the United States for the best American seedling *Chrysanthemum* for the year, and which has thus gained a sort of national reputation. The flower was, no doubt, badly shown in Boston; as seen here it was not large, and lacked substance; the color was weak and washy, as if it had been taken from a weak plant and had suffered from traveling. But due allowance being made for all this, it was no better than a dozen other seedlings of the year, which appeared here, and there were many better varieties shown in the exhibition.

The following first prizes were awarded by the Society: For a display of twenty named plants, distinct varieties, to Walter Hunnewell; for twelve plants, to Mrs. Francis B. Hayes; for sixteen Chinese varieties, to Dr. H. P. Walcott; for six Japanese varieties, to Dr. H. P. Walcott; for six Chinese varieties, four blooms each, Dr. C. G. Weld; for a specimen plant of Chinese variety, H. L. Higginson; specimen Japanese "Snow-storm," H. L. Higginson; specimen *Pompon* plant, Dr. H. P. Walcott; specimen *Anemone* plant, H. L. Higginson; best standard specimen plant, Dr. C. G. Weld; for twelve blooms of Chinese varieties, Joseph P. Melley; twelve blooms Japanese variety, John Simpkins; six blooms of Chinese varieties, E. A. Wood; six blooms of Japanese varieties, John Simpkins; for best fifty blooms, E. A. Fewkes & Sons, who received also, for fifty blooms, a piece of plate provided from the Bradley fund. A special prize, the Society's Silver Medal, was awarded to James Brydon, gardener to Mr. Simpkins, for the best seedling of 1889; Fewkes & Son and George Hollis winning the second and third prizes for new seedlings.

Boston.

D.

[The *Chrysanthemum*, *Ada Spaulding*, is rather an early variety, and it was not as good a flower when seen in Boston and Philadelphia as it was the week before in Indianapolis. It has bloomed the second season and we can now speak of it with some confidence. Its color is not the most desirable, but it has unusually good form, size and substance. Our correspondent does well to note the fact that every year brings a host of novelties, which are no better than the old kinds. But certainly no one would discourage the production of new seedlings—for this is the only road to improvement. Only a small fraction of one per cent. of the kinds raised prove worth propagating; but it is proper to offer prizes for the best *Chrysanthemum* of the year and in such contests it is plain that the new ones cannot compete with the older sorts. What we need is not fewer seedlings—but some tribunal to pass vigorous and impartial judgment on them. If our National *Chrysanthemum* Society will assume this authority and exercise it firmly and judiciously, they will place every friend of this flower under obligations.—Ep.]

Notes.

A lot of Chrysanthemums, imported from Japan by Messrs. Pitcher & Manda, have just bloomed, and one of them turns out to be the veritable Mrs. Hardy, now introduced for the second time into American gardens.

Mr. F. T. McFadden contributed 300 Chrysanthemum blooms to the Indianapolis Exhibition—twelve each of twenty-five varieties—which were pronounced by John Thorpe the best collection of such a size ever seen in America.

We are glad to know that the demand for Mr. Ellwanger's pleasant book, "The Garden's Story," has been such that a second edition has already been issued. The book appears in heavier paper, with a new and most appropriate design for the cover.

The Emperor of Brazil has recently sent to our correspondent, M. Naudin, the decoration of Commander of the Order of the Rose of Brazil, in remembrance of his visit to the gardens of the Villa Thuret, and as a token of his appreciation of M. Naudin's eminent services to botany and horticulture.

Reports from Los Angeles confirm what has already been stated in regard to the effective work of the parasite which was imported to check the increase of the Cottony Cushion Scale. The prospect now is that the *Icerya*, which threatened to destroy the Orange orchards of California, will itself be exterminated by its microscopic enemy.

A variety of the Chinese Juniper (*J. Chinensis*) with distinctly pendulous branches is one of the interesting and attractive novelties among the numerous conifers of abnormal growth which have lately appeared in European nurseries. It originated on the Continent a few years ago, and has been propagated at Knap Hill by Mr. Anthony Waterer.

The interesting History of the Chrysanthemum, which was prepared for the *Gardeners' Magazine* by Mr. C. Harman Payne, is illustrated by portraits of men who hold positions of prominence in the annals of the flower, from Sabine and Bernet down to the present time. Dr. H. P. Walcott and Mr. John Thorpe represent America in this picture gallery.

Spring is, of course, the time to see a bulb-garden in the Netherlands at its best. But from an account of a visit to one at Haarlem in the early autumn, recently published in a German journal, they must be very beautiful at that season too, gay with a multitude of Tritomas, Tigridias, Amaryllis, Gladioli, Nerines and Autumn Crocuses, and their borders adorned with a multitude of late flowering shrubs and annuals.

Among the announcements of articles to appear in *Scribner's Magazine* during the coming year we note the promise of a series dealing with American homes and their surroundings in town, suburb and country. This announcement is a cheering proof that, in the opinion of the editors, the interest which Americans have of recent years shown in the construction and arrangement of the home building is extending itself to the home surroundings, and that they are, in truth, one and indivisible.

Among horticulturists promoted to the grade of officer in the Légion d'Honneur for their connection with the Paris Exposition, may be mentioned M. Ed. André, the distinguished landscape-gardener and the editor of the *Revue Horticole*; M. Henry L. de Vilmorin, President of the Botanical Society of France and head of the house of Vilmorin, Andrieux & Co.; MM. Croux and Moser, the well known nurserymen; and M. Choisy, professor of landscape-gardening in the national school at Versailles.

A number of plants of *Cattleya Bowringiana*, including an immense mass with twenty-five spikes, recently imported, are now in flower in Mr. Ames' Cattleya-house. This is one of the handsomest of the early autumn-flowering Orchids. The flowers, of which a dozen or more are borne on a spike, vary from pale lilac to rose-purple, shaded to dark crimson on the front lobe of the lip. It is a native of Honduras, and was introduced into England by Veitch & Co. in 1884. It is considered an easy plant to manage.

The foliage of Hall's Honeysuckle continues bright and green, as it usually does at this season, and it will, no doubt, persist up to the holidays. It is rather late for the flowers, however, but they are still opening in considerable numbers where the vine has a sheltered and sunny exposure. For some days past a vine trained against the south side of the Pennsylvania Railroad Station at Marion, New Jersey, has attracted much attention for the cheerful display of bloom it is making in the face of approaching winter.

There is certainly real cause for regret that the Japanese Maples are so unreliable in the climate of this country, for some of the forms of *Acer polymorphum* especially are unsurpassed by any other plant in the beauty of the colors which their leaves assume here in late autumn after the foliage has fallen from nearly all the native trees and shrubs. They are hardy enough, and grow rapidly, and then, perhaps, at the end of two or three years, or possibly ten or fifteen, just as they begin to show their real habit and character, they often commence to die branch by branch, and then soon disappear.

On the evening of the fourteenth instant the local Florists' Club at Summit, New Jersey, formally took possession of a new reading-room and bowling alley, which had been provided for the club by Mr. John N. May, upon his grounds. There were a hundred guests present, many of them from distant points, like Boston and Philadelphia, and including the secretary and four former presidents of the Society of American Florists. A collation was served in Mr. May's long potting shed, which was converted into a veritable bower of beauty by a profuse use of greenery, with Roses, Orchids and Chrysanthemums.

Not long ago we spoke of the value of *Ceratostigma plumbaginoides*—the blue Plumbago—as a hardy, low-growing perennial plant; and in one of his pleasant letters, Mr. Nicholson lately described the dazzling effect of a mass of this plant along the top of a wall in the Via Petrarca. It is worth noting that after the flowers have been checked by frost the foliage turns to a deep red. According to Mr. Nicholson, the plant requires a rather dry and poor soil and a sunny situation. We have in mind a mass of it in deep, rich soil, partially shaded and certainly not dry this year, and the foliage is now fairly glowing with a color which is nearly a maroon.

Kerria Japonica, one of the first plants brought from Japan, and an inhabitant of most old-fashioned country gardens, has much to recommend it, especially the single flowered form, which is much less commonly seen than that with intensely double flowers. This shrub is beautiful in winter, with its conspicuous, slender, light green branches; it is beautiful when it is covered in early June with its bright yellow flowers, and just now it is particularly attractive. The foliage turns late always, but when it does turn it takes on a clear, brilliant, sunny yellow, which is unsurpassed. There is no more beautiful or distinct looking shrub during the early days of November than the *Corchorus*, the old familiar name for *Kerria*.

A law case of general interest to horticulturists is reported in a late issue of the *Gardeners' Chronicle*. The plaintiff, a nurseryman, had purchased 500 roots of what he was led to believe was *Spiraea palmata*. He took them home with him, potted them, and grew them from November until June, when the plants flowered, and it was discovered that, instead of being *Spiraea palmata*, they were *Spiraea elegans*, a comparatively worthless species, it appears, for his purpose at least; and he was able to show that the plants he had purchased possessed no commercial value. The plaintiff claimed the one shilling and three pence for each of the 500 plants, which he would have obtained for them when fully grown had they been of the kind he supposed he was buying. No charge of fraud was made against the defendant, who, evidently, was selling in good faith what he thought was *Spiraea palmata*; but the jury found for the plaintiff the full amount claimed, and judgment was given accordingly.

The Chrysanthemum has fairly captured the town of Boston. The public flocked to the Horticultural Society's exhibition of the favorite flower, which fills every florist's window to overflowing. It is sold at the street corner in profusion and excellence, and a woman is rarely seen in the streets without a bunch, big or little, in her hands or on her dress. This remarkable popularity has grown in recent years, for it appears, from an authoritative article published last week in the *Boston Evening Transcript*, that the first record of the exhibition of Chrysanthemums in this country was in 1830, when fifteen varieties were shown at an exhibition of the Massachusetts Society. The first prizes for Chrysanthemums, amounting to a total of \$17, were offered in 1861. Seven years later the fall exhibition of the Society was first called the "Chrysanthemum Show," and the prizes were increased to \$55. They were increased to \$150 in 1879, and an entire day was devoted to the exhibition. The exhibition in 1882, although planned for only a single day, excited so much interest that it was kept open two days, and this plan was continued until 1886, when three days were required, as they have been in succeeding years, to satisfy the popular curiosity. The prizes, too, have been gradually increased until they now amount, in the aggregate, to the handsome sum of \$741.

Central Park and the Exposition.

TWO or three weeks ago the committee whose duty it is to select a site for the World's Fair, to be held in this city in 1892, formally abandoned their plan to include a portion of Central Park in the exhibition grounds. This step seemed necessary on account of the opposition which the threatened occupation of the Park aroused—an opposition which grew stronger every day, and resulted at last in the resignation of several members of the committee and a public declaration by a large majority of the legislators elected from this city that they would vote against a repeal of the law which now protects the park from any invasion of this kind. We are not surprised at this result, for the park has been rescued from similar dangers many times before by the power of public sentiment when opportunity has been offered for full discussion. And yet this renewed manifestation of jealous regard for the park and intelligent appreciation of its purpose and value is an encouraging fact. If this action of the committee is final it will not only establish another precedent against future assaults upon Central Park, but it will give additional security to every acre of park area in every city of the United States for all time to come. On the contrary, if our chief city should allow the most famous park in the country to be desolated when it is only approaching mature development and has hardly begun its career of usefulness, there would be little hope that parks in other cities would be able to withstand the pressure for admission constantly brought to bear upon them by all sorts of enterprises foreign to the purpose for which they were created.

It is well to remember that the conversion of Central Park into an exhibition ground would be more than a mere local calamity. Public-spirited men in other cities who are helping by their moral support to avert such a calamity are strengthening the barriers which protect their own parks against intrusion. They are helping to give security to every public pleasure-ground, national park and botanic garden in the country, and they are encouraging the establishment of other institutions which must live and grow for long years before they attain the full measure of their usefulness. And the people of this state should remember that they can bring their influence to bear directly to this end by instructing their representatives in Albany to oppose

any relaxation of the law which now protects the rights of the people in the park against invasion.

The recent wise action of the Site Committee is no guarantee that some scheme to capture a portion of the park for the Exposition will not be revived. If the fair is held on the site now designated, it will reach out for room in every direction. Even now it is proposed to change the law so as to include the Museum buildings and Harlem Mere. But no amendment to the statute should be tolerated. The law was passed deliberately, not only with the sanction but in accordance with the urgent demand of every reputable paper in this city. It was passed just after the park had been threatened by one World's Fair, and for the express purpose of protecting it in precisely such an emergency as the present. The more imposing the proposed fair, the greater the danger to the park. The fiercer the rivalry and the wilder the enthusiasm, the more need of safeguards erected in quiet times and with cool judgment. The law will never be able to do better service than it is doing on this particular occasion, and certainly this is not the time to repeal it, when the first opportunity is offered to prove its value. It is no time to open it for amendment, for one exception will make room for another. There is absolute safety while the law stands as it is—and absolute safety is what every friend of the park should insist upon.

Mr. Nicholson describes on another page his visit to Pallanza, on the shore of Lake Maggiore—a spot which has perhaps no equal in Europe for the rare and beautiful trees, especially coniferous trees, which abound in its neighborhood and thrive in a manner quite unknown in less favored regions. Here may be seen growing side by side, in perfect health, species from the Alps of Europe and the Andes of South America; from the mountains of northern Africa and the hills of southern China; from the plateau of Mexico and the plains of Canada; from the Himalaya and the Sierra Nevada; from our southern Pine-belt and from Japan; from Asia Minor and the mountains of Brazil. The best specimen in Europe of the curious Keteleeria of southern China is growing in Signor Rovelli's garden near a plant of the hardly less curious Pseudolarix, which has no rival in cultivation, except in the finer specimen still to be seen in the old Parsons Nursery at Flushing. Across the bay from Pallanza, on Isola Madre, is one of the most perfect natural gardens, in which our White Pine, with a robustness of growth and depth of color almost unknown in its native forests, towers high above Yews and Evergreen Oaks of extraordinary dimensions. There are Canadian Hemlocks in this Borromean garden which it would be difficult to match anywhere, growing among Himalayan Rhododendrons, Mexican Yuccas; and here, perhaps, is the finest Californian Incense Cedar in Europe, and a Himalayan Fir unsurpassed in its loveliness. On the curious but far less attractive and interesting Isola Bella the tree-lover will find in the court-yard of the palace a plant of the American Persimmon, of a size almost unheard of in Arkansas even, where the Persimmon attains to its best estate; and on the terrace not far from the group of great White Pines, which make every American feel proud, is a remarkable specimen of the Evergreen Carolina Cherry of our southern states.

Large specimens of several Mexican Pines are interesting features in many of the gardens on the shores of Lake Maggiore, where they find apparently the congenial conditions necessary for their growth. Here the variable *Pinus Montezume*, always healthy and sometimes handsome, appears under many grotesque and unfamiliar names. *Pinus patula* displays the beauty of its slender, graceful, pale green foliage, and in the garden of the Grand Hotel of Pallanza, *Pinus Ayacahuite*, the White Pine of Mexico, produces freely its enormous cones. A short hour's drive from Pallanza will carry the lover of trees to the garden of the Villa Ada, in which Prince Trubetskoy planted his remarkable collection of conifers, rich in specimens of Retinospora of remarkable size, in

many Mexican Pines, in a wonderful plant of the Lacebark Pine of China (*P. Bungeana*), in a great collection of Cupressus of many interesting forms, and in a number of specimens of the bright blue variety of the Mt. Atlas Cedar, so vigorous in health, so graceful in outline and of such brilliant coloring that one may well exclaim in looking on these trees for the first time, "I have never seen a beautiful conifer before." Not far away are the grounds of the Villa Franzosini, rich in fine trees, and the best example, perhaps, of a well arranged and well planted garden, simple and convenient in treatment and uninjured by any gaudy horticultural innovation, which can be seen on the shores of the Italian lakes, a region famous for beautiful gardens.

The great botanical establishment which the people of New York are still talking about vaguely is to be realized in St. Louis. It is provided for under the will of Mr. Henry Shaw, who died during the past summer, having for many years devoted his leisure and a considerable part of his income to the establishment and care of a public garden in his adopted city. The whole of his estate, with the exception of a few small legacies, is now left to a board of trustees for the benefit of this garden. It has been appraised at nearly \$3,000,000 and produces a net income of about \$50,000; but as a large part of Mr. Shaw's property is invested in unimproved real estate within the city limits of St. Louis, the income of his estate may be expected to increase enormously with the growth of that city; and Professor William Trelease, the newly appointed director, will, in all probability, soon find himself at the head of a better endowed establishment than any other of its kind which has ever existed. There is no botanical garden in the world, with the exception of that at Kew, where the annual expenditures are not far from \$100,000, which enjoys an income of anything like \$50,000, and a vast amount of good and useful work can be accomplished every year with that sum of money. Professor Trelease, with the income now at his command or which will be available for his purpose in a short time, will be able to lay the foundation of an establishment of such scope that it will soon make St. Louis the botanical centre of the New World and draw to it students from every quarter of the globe. His early efforts, very properly, will be devoted to elucidating the botany of North America; and he is fortunate in possessing as a nucleus of the St. Louis herbarium the collections of Engelmann, which, in certain groups of plants, are of inestimable value.

Of special interest to young men who desire to become gardeners is the plan, not yet entirely matured, of offering, in connection with the Shaw Garden, six scholarships for garden pupils, for the benefit of young men between fourteen and twenty years of age, who are to be taken for six years, and who will be expected to work in the different departments of the garden, receiving, besides, theoretical instruction in botany, horticulture, economic entomology, and as much land surveying and bookkeeping as is necessary for a gardener having the charge of a large estate. It is proposed by means of these scholarships to make gardeners, and not botanists, and a taste for the manual work of the garden will be insisted on in the young men who hold them. They will receive pay for their work, and be given, free of cost, plain and comfortable lodgings near the garden, as well as free tuition in the School of Botany of Washington University, and such other instruction as may be necessary. Never before has such a chance been offered in this country to young men desiring to become thoroughly educated and trained gardeners, and the influence which Mr. Shaw's munificent bequest will exert through these scholarships upon horticulture in the United States can hardly fail to be great and lasting.

The Trustees of the Shaw Garden have it in their power to build up a great and useful institution of science and learning. Their opportunity is magnificent, and their responsibility is correspondingly great.

The Exhibition Grounds, Paris.

AS the question of a World's Fair to be held in New York is being so generally discussed, it seemed desirable to publish for our readers the best view that could be obtained of the grounds of the great exhibition recently closed in Paris, although, of course, no single picture can give any adequate idea of the skill with which they were disposed, or of the gay, yet monumental, effect they presented. The illustration on p. 571 is from a photograph taken from the first platform of the Eiffel Tower, looking southward, away from the Seine, toward the largest buildings. In the centre we have the Palace of Industry, with its chief entrance, and the great central dome, that rose above the vestibule. Behind this is the higher mass of Machinery Hall. In the buildings to right and left the industrial display was continued; and could we see those which followed them, nearer the tower, we should see the Palace of the Fine Arts and the Palace of the Liberal Arts. The smaller structures near the great entrance held the exhibits which illustrated the history and condition of the city of Paris. The long tents on either side of the walks were for protection from the sun or rain, covering nothing but chairs and small booths where light refreshments were sold. The fountains in the centre are those which, when illuminated at night, proved the most popular attraction of the exhibition. The main jet then rose from the circle of bronze plants near the foreground, and not only beneath the tents, but up to the edge of the grass, spectators were massed in the densest lines. Between the four great feet of the tower was a lawn with a central fountain; on either side of it were gardens containing many small pavilions; and to the north, opposite the present point of view, was a large open space; then the bridge across the river, covered for the time with a red and white tasseled awning, and then the rising ground on the Trocadéro side, with a great cascade in the centre falling from beneath the Trocadéro Palace on top of the hill. Of course, the grounds were much larger than this description implies, extending along the *quais* for a great distance, and running back from the river again, nearly a mile further east, to fill the broad *Esplanade des Invalides*. But the present view shows their most effective portion, and though the horticultural exhibition was accommodated on the Trocadéro slope, there was much here of interest to the lover of plants and of gardening design. The harmonious contrast between the formal central walks and the more naturally disposed paths on either side should be remarked, and it should be remembered that the various pieces of statuary were not makeshift decorations, but admirable works in marble, produced for their especial purpose by well known artists. The hardy trees were set out when the design was made a year or two years in advance. Particularly effective were certain large, isolated specimens of *Phoenix Canariensis*, planted on the lawns, which, with the other isolated plants and flower-beds, were most appropriate to the semi-formality of the design. The terraces in front of the Palaces of the Arts were banked with fine Rhododendrons, exhibited by M. Moser and by Croux & Son; and here, too, were some admirable specimens of *Chamærops excelsa*. The little kiosks and pavilions had been carefully designed, and, in short, in every detail one saw the hand of the skillful artist disposing of the most excellent horticultural material. A particularly pretty idea was the encircling of the grass plots with rows of small electric lights set close to the ground. As viewed from the tower at night, these starry bands had an enchanting effect in contrast to the flashing splendor of the illuminated fountains, which in their turn were relieved against the transparent masses of the façades beyond, crowned by the great dome, with its tasteful festoons of lights, where the yellow of gas was effectively mingled with the whiter light of electricity. These gardens seemed then a fairyland indeed, and one was filled with admiration for the good taste which could produce so dazzling an effect, and yet

not fall into extravagance or mere glare and show. Nothing more impressive could be imagined than the view at night from the tower when great bodies of people filled all the open spaces, and the murmur of their voices added to the gaiety of light and color. During the day-time on Sundays every one was allowed to walk, sit and eat on the grass; and the sight was then equally amusing and attractive, a myriad white napkins and bright spots of color enlivening every green expanse.

Among the Pines of Northern Michigan.—II.

THE view of a country from the car window is not always satisfactory. We are often provoked by a curiosity to search some parts of a region over more in detail. It is better to walk or drive, with plenty of time at command. To enjoy such a trip most keenly, one should be accompanied by one or two others—seldom more—and all should be botanists, with an interest in gardening. If they are interested in collecting living plants for the garden, monstrosities and nice specimens for a museum, and plants for a herbarium, with a view to making a report, the enjoyment will be much enhanced. The person who is merely hunting for game or looking for the best trees for lumber knows little of the pleasure realized by the naturalist.

It is not an uncommon thing to see Hemlocks, Birches and sometimes other trees growing on low land with the roots next to the "stump" part of the tree all above the ground, like a spider on the tips of its long legs. Such trees were started as seedlings on a decaying log, which has since all disappeared in decay. In one place near Kingsley we found ten or a dozen small Hemlocks of this kind all in a row, where the log had only partially decayed.

Toward the south of the district we are considering are some very fine specimens of the Hornbeam. Especially are they beautiful in moist, rich soil, with plenty of room. I never fully appreciated the beauty of a well grown Hornbeam till I saw, for the first time, some well grown specimens in Central Park. The smooth-fluted gray trunks, the dense, clean foliage and the peculiar drooping fruit surrounded by a pair of mitten-shaped bracts, distinguish it from everything else.

Occasionally, where the soil is thin and the forests have been mainly cut away, may be seen villages which are now nearly deserted. Such a village is Cheeney, in Crawford County, and Fife Lake, in Grand Traverse County, is likely to reach the same condition. The mills burn down, are removed or the machinery has been taken out, while the shabby old building remains on guard near the piles of saw-dust, and a few worthless old logs never cut into lumber. The dwelling-houses can scarcely be given away, and there they stand fast going into decay. No one sees much beauty in a dead village, not even the botanist.

Akin to the above are the deserted homesteads and farms often found on the Jack Pine-plains. There remains the neat house made of logs or rough boards. The barn and out-buildings, the fences and gates, the remains of orchard trees and small fruits, of shrubbery and perennial herbs and the introduced weeds—all remain to tell of the culture and wasted capital and energies. There might have been some mismanagement, but the energy and care bestowed would, under more favorable circumstances, have won eminent success. It is to test such lands and give assistance to the owners that experiments are now being conducted by the Agricultural College.

The beautiful and the picturesque are often strangely blended. The dead trees and black stubs and logs, the ragged thistles and fireweeds, perhaps help to add interest to things that are beautiful. There is nothing to admire in the dead tree-tops and rubbish left where the trees have been felled, cut into mill logs and drawn away. The rubbish courts a fire which it is most sure to burst out on the arrival of the first very dry weather.

Railways require the removal of earth, cutting and filling, exposing much bare surface. In places there are irregular depressions sunk near the road to procure earth for the road. It is surprising with what rapidity kind nature begins to repair such damages as these. The remaining charitable old Hemlocks and Pines and Maples vie with each other in producing bountiful crops of seeds which, by the aid of the wind, they scatter on the bare slopes and in the naked places; and where enough moisture and shade are found, such spots are quickly covered by a crop of beautiful young trees.

In the newly exposed places, plants vie with each other to see which can do the most. Hanging over the crest of the

banks, or some of the pits from which earth has been taken, are many beautiful plants from which lessons may be learned.

The Wintergreen, Bearberry, Trailing Arbutus, Dwarf Blueberries, Dwarf June Berry, Violets, wild Asters, the Sweet Golden-rod, Anemones, the Andropogons and bunchy Panicums among Grasses, and Dwarf Sedges, are among the most common and attractive plants in such places.

I must refer to the three-toothed cinquefoil, *Potentilla tridentata*, which is common in many sandy places in northern Michigan. The leaves are wedge-oblong, coarsely three-toothed, evergreen and glossy; the petals white. The plant spreads readily by root-stocks, and is perfectly at home in poor, sandy soil. It is attractive and good to use in patches, or when mingled with other small perennials.

Agricultural College, Mich.

Holiday Notes in Southern France and Northern Italy.—VI.

AT Luino we took steamer and passed a succession of picturesque villages charmingly situated amidst the Olive groves, vineyards and luxurious vegetation of the mountain slopes. Our destination was Pallanza, a thriving little town of some repute as a winter resort, built on the warmest and most sheltered spot on the Lago Maggiore. From the landing stage a row of *Magnolia grandiflora*—the Big Laurel of the southern states—attracted our attention; this is not often used as a street tree. My companion, however, informed me that he had seen it so employed at Angers, in western France. The nursery of Messrs. Rovelli, situated on a tongue of land jutting out into the lake, is now one of the show places of the district. Thirty-five years ago it was not adorned with a single tree, but the firm having bought out a considerable number of small proprietors, and then planted fine exotic conifers and other rare plants, many visitors with no special love for plants are attracted to it because guide-books, etc., announce it as one of the sights. To real lovers of trees there is much to instruct and delight, some of the specimens being probably unique in Europe as regards beauty and size. The following notes by no means exhaust the objects of interest; lack of space alone compels me to select the most striking features and to leave alone much that is wonderful to a traveler from more northern regions.

Amongst the conifers, perhaps the most remarkable is a large, handsome tree of the Chinese Golden Larch (*Pseudolarix Kämpferi*); this cones very freely, and thousands of healthy seedlings carpeted the ground beneath the spreading branches; it has been found advisable to allow the seed to germinate where it falls, much better results being thus obtained than by collecting the seed and sowing it in pans under glass. Next comes a Chinese Abies, *A. Fortunei* (*Keteleeria Fortunei*), with large numbers of round, broad-scaled cones; a photograph of the tree itself, of the male catkins, cones and curious corky bark, have been published in the *Gardeners' Chronicle*. In England, and then solely in sheltered spots, this appears to be able only to keep alive. Other Firs are represented by examples of *A. Nordmanniana*—upward of fifty feet in height—*A. Cilicica* and of *A. bracteata*, both very beautiful specimens, and a curious columnar form of the common European Silver Fir (*A. pectinata*)—which the courteous proprietor informed us passed under the name of *A. laxa* in southern nurseries—in all probability it is Carrière's variety *Columnaris*. *Pinus Canariensis*—more than forty feet high—is here a fine object, and on the hot, dry limestone rocks of the Riviera it also grows apace. The Mexican *P. patula* does well, a striking species from the same country bearing the name of *P. Russelliana*. *P. longifolia*, a graceful, long-leaved Himalayan tree which must be cultivated under glass at Kew, has here attained tree dimensions, and the Georgia Pine, *P. palustris*, is at home in its company. The Japanese *P. Koraiensis* was bearing its first crop of cones, which, in addition to the habit, indicated clearly enough its relationship, from a systematic point of view, with the Arole (*P. Cembra*) of Switzerland. As might have been expected, the Monterey Cypress (*Cupressus macrocarpa*) does well at Pallanza, and we afterward frequently saw it along the Riviera. The Californian White Cedar (*Libocedrus decurrens*) had attained a greater size here than ever we had seen it before; the trunk was three feet in diameter. Trees of *Cryptomeria Japonica* showed how picturesque this species is under really favorable conditions, and so did one of *Cunninghamia Sinensis*—nearly fifty feet high. *Araucaria Brasiliensis*, bearing cones, came as a surprise to us who had only seen it grown under

glass. *Fitzroya Patagonica*, fifteen feet high, a beautiful mass of *Podocarpus Chilina*, with its long, narrow, dark green leaves, and two small growing conifers which have originated in the Pallanza establishment, must conclude my list of the Pine and Fir tribes. One of these—here called *Thujopsis nidifera*—is a dwarf plant with gracefully curved branches, suggesting a bird's nest; it is said to be a hybrid between *Chamaecyparis Nutkaensis* and the Oregon Cedar (*C. Lawsoniana*). The other is *Retinospora Trubetzkoyana*, named in honor of Prince Trubetzkoy, whose famous garden we, unfortunately, had no time to visit.

Camellias are a great feature at Rovelli's; they grow as freely as do the Cherry Laurels in England, and are cultivated in great numbers, from small stuff in pots to big bushes in the open ground. A goodly proportion are exported to other countries, the bushes selected for dispatch in autumn (as early as the beginning of September), being transplanted in spring. *C. Sasanqua* and its varieties are the first to flower; they begin in November; the others commence to blossom in January and continue until April. Other members of the Camellia family deserving of notice are Tea-plants, both from Assam and China; from his fine bushes of these Signor Rovelli—who has traveled a good deal and knows what tea is—told us that he had manufactured tea of fairly good quality.

The Camphor tree (*Cinnamomum Camphora*) grows as freely at Pallanza as a Willow or Poplar in many countries, and gives some trouble in pruning to prevent its exceeding the limits assigned to it; the trunk measured between two and three feet in diameter. The East Indian *C. glandulifera* also thrives equally well; here, however, the name under which it is grown is *Laurus glandulifera*, a title now incorrect and somewhat misleading, as there are no true Laurels in India, the Sweet Bay—the Laurel of the classical writers—being confined to the Mediterranean region, and the only other species of *Laurus* being a native of the Canary Islands. The California Olive (*Umbellularia Californica*) also grows to tree size and is everywhere known in the regions visited by us as *Laurus regalis*. In England it requires to be treated as a wall plant—except, perhaps, in such favored spots as Cornwall, and a few others.

Palms were not represented by many species, and of all of them much finer examples are to be seen along the Riviera. *Phoenix Canariensis* is hardier here than the Date Palm, and the Japanese Fan Palm (*Trachycarpus* [*Chamaerops*] *excelsus*) is more robust and hardy than *Chamaerops humilis*, which is a native of the Mediterranean region. *Cocos campestris*, a graceful species, is hardy, but it grows much more slowly here than along the Riviera. A fine example of *Jubæa spectabilis*, with a trunk two feet in diameter, is the most remarkable Palm at Pallanza.

Cycas revoluta is the only Cycad which thrives in the open air here. *Viburnum Awafuki*—met with in southern gardens under the name of *V. lucidum*—thrives wonderfully well; one grand plant, at least twenty-five feet in height, was bearing a crop of coral red berries. The most noteworthy Oak was the Portuguese and north African *Quercus Mirbecki*, a tree upward of fifty feet high, which bears acorns annually. Bamboos were very beautiful and vigorous; it is sad that the garden nomenclature of these graceful plants is in such a state of utter confusion. *Bambusa Simoni*—more correctly, *Arundinari Simoni*—is worth particular mention, not only on account of its merits as an ornamental plant, but because it does not die after flowering, as do many of its relatives. The Climbing Fig (*Ficus repens*), so popular in its small-leaved condition for clothing bare walls of plant houses in England, had here overtopped its wall, and developed large-leaved, rigid branches, which bore a crop of fruit.

Leaving Pallanza, where we had a fine view of the snow-clad glaciers and peaks of the Simplon group, we sailed past the far-famed Borromean Islands, which were converted in the seventeenth century by Count Vitalio Borromeo from barren rocks into gardens which now have a world-wide reputation. Unluckily, we had no time to go to Isola Bella, which boasts of many fine American trees. Gardening proper can, however, hardly be said to exist in this beautiful spot, terrace upon terrace with bewildering array of statues, vases, fountains and grottoes making a formal, unlovely combination, quite distressing to those who hold that a garden should exist primarily for plants and that the work of the sculptor should be a secondary consideration. Oranges and Lemons clothed the terrace walls, and fine Oleanders and other flowering shrubs somewhat relieved the monotony of stone-work.

George Nicholson.

New or Little Known Plants.

Yucca elata.

THE two large arborescent Yuccas of the valley of the lower Rio Grande, *Y. Treculiana* and *Y. filifera*, were figured in the early issues of this journal. The illustration upon page 569 of the present number represents a plant of the tall Yucca peculiar to the dry, desert region west of the Rocky Mountains, situated on both sides of the boundary between the territory of the United States and that of Mexico. It is the *Yucca elata* of Engelman, who, at the time his classical monograph upon the genus Yucca was written, considered this plant a southern, and arborescent form of the stemless *Y. angustifolia* of northern New Mexico and Colorado (*Y. angustifolia*, var. *elata*). He was fortunate enough to see it growing, however, during a journey which we made together to the Santa Rita Mountains in southern Arizona, during the autumn of 1880, and became convinced that it had best be considered a distinct species.* The Arizona plant may be distinguished from the allied Colorado species by the tall, stout trunk, ten to twelve feet high, with a diameter of eight to ten inches at the ground, and by its long flowering scape, seven to ten feet high, naked below, and bearing a much branched panicle often five feet long. The perianth is spreading, three and a half to four inches wide when fully expanded (those of the allied species are more globose), with oval-concave segments, which are waxy white and deliciously fragrant. Young plants begin to flower before they form a trunk, but even these are easily distinguished by the tall, naked scape and by the shape of the flowers.

A full panicle of flowers of this Yucca is an object of surpassing and surprising beauty. Our illustration is from a photograph made by Mr. C. G. Pringle on the dry plains between the town of Tucson and the Rincon Mountains in Arizona. It shows an old plant with two flower-panicles, the ends of the branches bearing green and living leaves, while a third branch and the upper half of the trunk are covered and armed with the reflexed dead leaves of many previous years.

Yucca elata was first detected by the botanists of the Mexican Boundary Survey more than thirty years ago, but it is probable that it has not been introduced into cultivation until quite recently. Seeds have now, however, been distributed among several European gardens, through the agency of the Arnold Arboretum. C. S. S.

Acanthopanax ricinifolia.

THIS great tree Aralia of northern Japan promises to become one of the most striking and remarkable ornamental trees which can be grown in the climate of the northern states. It was introduced several years ago into the Arnold Arboretum, where the largest of the two specimens which the Arboretum possesses is now nine feet high, having grown at the rate of about one foot a year. Although planted in low ground and in an exposed situation, they have shown no sign of suffering during the most severe winter they have experienced here. Flowers have not appeared yet, but the deeply divided and sharply lobed leaves fully a foot across, and borne on petioles nine or ten inches long, serve to give an idea of what this tree will look like if it ever reaches in this country the size which it attains in Japan. There is no plant in the collection which presents, even in its young and undeveloped state, an appearance so dissimilar to our native vegetation.

The following popular account of this plant, extracted from Rein's "Industries of Japan," may interest the lovers of rare trees who have not access to the work itself:

"This beautiful tree is distinguished by its great, lobed, shiny leaves, its white flower-umbels and black fruit of the

* "*Yucca elata*.—Trunk, three to five feet, or more, high; leaves, linear, rigid, sharp pointed, filamentose on the white margins; with white, oval, acute or acuminate bracts as long as the pedicels; flowers white; segments, ovate-acute; ovary attenuated into a whitish style; capsule, cylindrical-ovate, obtuse, short cuspidate; seeds, large, one-half inch wide, narrowly wing-margined."—Engelman in *Botanical Gazette*, vii. 17.

size of pepper corns, resembling, like its flowers, the *Aralia* and Ivy. Like *Magnolia hypoleuca* and *Esculus turbinata*, it is scattered in the high mountain forests of Japan from Kiushiu to Yezo, but is most numerous in the north. In Yezo, trunks of from nine to twelve feet circumference and ninety feet height may be seen. I often found them in Hondo quite as high, but generally not so thick. In high forests the trunks are often somewhat bent, and do not branch until they are sixty feet high. Their dark, thick, rugged bark makes them as noticeable as their beautiful foliage. The white wood shades often into brown, and is moderately light, rough fibred and more or less porous. Cross cut, it shows year-rings, but no pith-rays. The pores are of two kinds: one sort microscopic and scattered about in the thick summer-wood; the other apparent to the naked eye, and denoting the spring girdles. According to Böhmner, the Ainos make their canoes out of the large trunks from eighteen to twenty-seven feet long.

Acanthopanax ricinifolia is sometimes found in gardens under the name of *Aralia Maximowiczii*. C. S. S.

Cultural Department.

The Pecan Tree.

(*Hickoria Pecan*.)

ALTHOUGH this tree demands attention chiefly for its nuts, which form one of the valuable products of the Atlantic forest-region throughout all its southwestern section, it also has merits as a timber-tree. I venture to reply to many inquiries from all parts of the country concerning the character of this tree, the method of cultivating it, and the profit to be derived from it, the more readily because I have some new

experience to report since I read a paper on these subjects before the Mississippi Valley Agricultural Society in 1883. For the latest information in regard to the propagation of the Pecan, I am indebted to Mr. J. J. Delchamps, of Mobile, an energetic cultivator of this tree, who has given it his attention during nearly forty years.

DISTRIBUTION.—The Pecan is found growing from northern Louisiana and Mississippi through the alluvial lands of the Mississippi River and its larger tributaries, as far north as southern Indiana, southwestern Kentucky, and along the Missouri to eastern Kansas, as well as in the Indian Territory, Arkansas, Texas and the adjoining regions of northern Mexico.

SOIL AND SITE.—Naturally, this tree is confined to the rich, cool and damp soil of the river-bottom lands, with a sub-soil which offers to its long tap-root a constant supply of moisture. This water supply and abundant plant food are essential to the perfect growth of the tree and the production of nuts of the best quality. The Pecan shuns a dry, silicious soil, and the attempts to raise it on the sandy rolling Pine lands have resulted in disappointment, the highly porous soil rendering the application of fertilizers of little benefit to the tree. It fails, also, on lands with a rocky subsoil, which impedes the growth of its tap-root.

RATE OF GROWTH.—The Pecan grows rapidly, reaching a height of from twenty to twenty-five feet within ten years. It begins to bloom and produce a few nuts in its seventh or eighth year. Trees three years old, when taken from the nursery in 1873, began to bear in my garden six years later, and the crop of less than half a bushel to the tree in 1883 has increased steadily until this year, when it was two and a half bushels of nuts of a quality that would command fifteen cents a pound. Another tree in my immediate neighborhood, from a nut planted in 1867 and left undisturbed, yields at present from three and a half to four bushels of nuts of a higher grade, commanding a price of twenty cents a pound. This tree is fully seventy-five feet high, with a girth of about sixty-six inches. I lately had the opportunity to measure several trees which have never been transplanted, but stand where the nuts were planted in 1866, in the sandy loam of the coast plain of Mobile, where the subsoil is a damp clay. By actual measurement they were found from seventy to seventy-five feet high, with a circumference of fully five feet breast high, and a crown varying from sixty to sixty-six feet in greatest diameter, yielding crops of good quality and quantity and coming true from seed. According to Mr. Delchamps, trees, undisturbed in their growth by transplanting, bloom several years earlier and produce remunerative crops of nuts correspondingly sooner than seedlings brought from the nursery; while it is not until the tenth year that the latter can be depended upon under the best conditions of soil and methods of cultivation to produce fruit. The crops increase every season for a long series of years, extending most probably over more than a century.

CULTIVATION.—The practice generally adopted is to plant the nuts early in the fall in drills two or two and a half feet apart in a generous, loamy soil, enriched, if necessary, by well rotted compost, and to keep the seedlings for the following two or three years under good cultivation. Having by the end of that time reached a height of from four to five feet, the young trees are carefully taken up, and, without delay, transferred to their permanent position. Care is taken not to expose the long tap-root, which is provided with only a few lateral rootlets, to the dry air. The fall of the year, after the first frosts, is considered the best time for transplanting. In the poorer and lighter soils of the coast of the lower Atlantic and Gulf states the soil should be from the outset enriched by a liberal application of well-rotted stable manure, repeated from year to year, particularly after the tree begins to yield large crops. To insure the best development of the tree and the production of nuts of good quality on the lands of the class described, annual mulching and manuring are absolute necessities. A mixture of stable manure and pure bone meal is the best compost. The Pecan is a strong feeder. It soon exhausts the plant-food in a naturally poor soil and shows the want of more by an immediate failure to produce perfect seeds. In the deep, rich soils of the Mississippi silt, manuring can be dispensed with for a long period. In such localities, under the sunny skies of lower latitudes, nuts of the finest quality are produced almost without failure every year, and by trees far beyond the first half century of their existence, provided the land is above the line of protracted overflows.

THE TAP ROOTS.—The theory that earlier fruiting is secured by shortening the tap-roots leads many nurserymen to cut off these roots of the young seedlings with a sharp spade. Mr. Delchamps asserts that in no instance within his knowledge

has any such root-pruned and transplanted tree proved an early bearer; that, on the contrary, such trees do not bear fruit until they are twelve, and even fifteen, years old. Experience, of late, leads more and more to the planting of the nuts where the tree is to stand. Several nuts, soon after their gathering, are placed in a hill well supplied with rotted litter. The following season the strongest of the seedlings is left standing. The hills are placed at a distance of from thirty to forty feet. Judging, however, from the diameter of the crown, as displayed by trees long before they have reached the fullness of their growth, it is evident that they should stand at least fifty feet apart.

QUALITY OF FRUIT.—The nuts from different individuals of spontaneous growth or under cultivation present an endless variation in size, shape, thickness of shell and plumpness and flavor of kernel. The nuts of the trees growing in the alluvial forests east of the Mississippi River are somewhat spindle-shaped in form, small, hard shelled and of scarcely any value for marketing. West of the Mississippi River, in the open belts of timber fringing the streams in Texas, west of the valley of the Trinity, the nuts are more oval, with a thinner shell and of better size and flavor. Nowhere else are such fine, natural crops of nuts produced as in western Texas. These are of no small importance to the settlers of that section. Many hundreds of thousands of pounds of nuts annually reach the markets of San Antonio and Austin, where they sell by the wagon-load at five to six cents a pound, and where they are assorted according to their quality before they are shipped to distant markets. Nuts of highest quality, oblong-ovate in shape, one and a half inches long, with shells so thin that they can be crushed between the fingers, and unsurpassed in richness of flavor, are grown with cultivation throughout Louisiana west of the Mississippi River. The earlier settlers along the so-called Mississippi coast parishes, in the Red River district of Bayou Têche, have given attention to the improvement of the Pecan-nut, and, of late, similar efforts have been made successfully in Mississippi, Alabama, Florida and South Carolina.

HYBRIDS.—The influences which cause the variations in the quality of the Pecan nuts, outside of those depending upon climate and soil, cannot be discussed at present. There can, however, be no doubt that in these deviations from the original type, much is due to cross-fertilization between individuals possessed of slight variations, originally mere sports. It is a fact that scarcely any other tree is more subject to hybridization by the crossing with other individuals of its kind. Such hybrids are met with in the forest and also among cultivated trees, to the great dismay of the planter, yielding fruit as unsightly as it is unpalatable. Crosses between this species and the Water Hickory (*Hickoria integrifolia*—*Carya aquatica*, Nutt.) are frequently met with. The fertilization in the case of these trees being entirely left to the agency of the wind, it is clear that intercrossings between the different species of Hickory, hybrids, variety hybrids, and the forms presenting slight deviations from the original character, must lead to the production of a multitude of variations, and that to keep a desired race pure, individuals bearing fruit of inferior grades growing in the immediate neighborhood of the grove should be removed.

PROPAGATION BY SEED.—The opinion held by many that the fruit does not always prove true to that of the parent tree, and that the propagation by seed of trees bearing the finest nuts cannot be depended upon with certainty, receives confirmation every year. Mr. Delchamps, convinced of the uncertainty of producing fruit in every respect equal to that of the parent tree, holds the opinion that there is a limit to the improvement of all fruits, and that if this limit is once reached, the tendency is strong to revert to the original type. According to his experience, this tendency is well marked in the Pecan, and repeated observation shows that trees grown from the finest nuts often produce fruit of very inferior quality. In the selection of nuts for planting he would reject the very finest as well as the poorest, and limit his choice to medium sized nuts, well shaped and of good flavor. He is confident of obtaining in this way a greater percentage of fine nuts and fewer inferior ones.

PROPAGATION BY GRAFTING.—To obtain just such nuts as are desired—that is, to propagate and multiply extra fine qualities—as in other fruit-trees, grafting must be resorted to.

The cultivator quoted states that, in the face of the bold assertions to the contrary made years ago, he succeeded without failure in whip-grafting or tongue-grafting the Pecan on a common Hickory (the Mockernut), the stock being sawn off close to the ground. He would layer well shaped and well flavored nuts in sand until January and February (in the latitude

of Mobile), and plant them where the tree is to stand permanently. Under good cultivation, in a year most if not all the young trees will be stout enough to tongue-graft. The cions, taken from choice trees, should be cut some time before they are used, say about Christmas, and kept in sand until needed. As soon as the stock trees show signs of swelling the buds, say about the beginning of February, they should be cut to the ground and the cions grafted on them. If any are still too slender, the grafting can be deferred till the next year.

PECANS AT THE NORTH.—The possibility of propagating successfully trees bearing nuts of finest quality in the territory north of the southern states is yet a question to be settled by experiment. This is the only way that it can be decided whether late frosts in the spring prove an obstacle by causing injury to the flower-buds, or whether the earlier frosts near the close of the season will interfere with the full maturing of the fruit.

INSECT ENEMIES.—The Pecan-tree has some insect enemies which endanger its health and life. Amongst those are the larvæ of a cerambycid beetle, which bores into the very heart of the tree, and a species of tent caterpillar, which causes less injury to the tree, but gives it an unsightly look from the numerous nests infesting the crown.

POSSIBLE PROFITS OF CULTIVATION.—The Pecan-tree yields its crops of nuts almost without failure every season; however, not in equal abundance, one year of fruitfulness being generally followed by one of considerably shorter crops. From numerous inquiries made it can be asserted that a tree, after having reached the twentieth year, will for generations to come yield an income averaging from fifteen dollars to twenty dollars a year at ruling market prices. Considering the facilities with which the shipping and marketing of the Pecan-nut is attended and its possible transportation to the most distant points without any injury—considering, too, the increasing demand for this fine dessert nut in this country and in foreign markets—there can be no doubt about the profits to be derived from the establishment of a Pecan-grove. No part of an estate will prove of greater and more permanent value as a bequest to posterity.

In the southern states, in the region best suited to the cultivation of the Pecan-nut, lands of the required conditions are easily obtainable, abundant and cheap, particularly on the lower Atlantic or the Gulf coasts. As the trees come into bearing those found to yield nuts of inferior quality, and therefore of little market value, should be immediately taken from the grove and replaced by grafted trees of vigorous growth.

Mobile, Ala.

Charles Mohr.

Rose Notes.

THE dull, cloudy weather which has prevailed for the past month has plainly affected both the size and color of many of the best forcing Roses, and in some varieties it has also caused many malformed flowers, a trouble not usually met with so early in the season. There are some good flowers to be found, it is true, but there are also many poor ones.

This was quite noticeable at the recent exhibition of the Pennsylvania Horticultural Society, in Philadelphia, where few superior blooms were seen among the cut Roses. Dull colors and in many instances comparatively small size was the rule among these flowers, and beyond question this was due rather to lack of sunshine than to lack of intelligent care on the part of their growers.

Very prominent just now among the newer Roses is the so-called dark La France, the Duchess of Albany, a flower which has attained much popularity, for its first season, in some localities. It is very similar to La France in general appearance, the chief difference being in its color, which is a deep pink. Perhaps, even, it may be termed a rosy red. There are, however, decided differences of opinion as to the comparative attractiveness of the new color, and it will probably be hard to persuade some persons that the newcomer is really better than a good La France.

Madame Hoste is to be seen in good quality, and some buds are as large as those of Cornelia Koch, although not furnished with so stiff a stem. Madame Hoste seems free of habit both in growth and bloom, and may prove very useful, for it forces well. Its greatest drawback is its undecided color, the lemon yellow of the centre fading to white in the outer petals, and there is apparently considerable density in its shades of color.

A Rose, not often seen in quantity now, is Ma Capucine, but at the Philadelphia Exhibition before alluded to, a glass filled with blooms of this pretty little Tea attracted much notice. Ellwanger describes its color as "nasturtium yellow." It is of slender growth and not large enough in bud to satisfy the popular demand for big Roses; and yet Ma Capucine is much

used in Europe as a button-hole flower, and it was thoroughly tested as a forcing Rose in this country some ten or twelve years ago.

A nice bunch of Meteor, in one of the exhibition collections, reminded one that, when in good condition, this is a remarkably pretty, dark variety, but, unfortunately, it is such a shy bloomer during the winter that it can hardly be considered a profitable sort for commercial growers.

The flowers of Souvenir of Wootton thus far have hardly met the high expectations it had raised, but the season is young yet and much better results may be produced later on. The bold looking foliage and sturdy growth give promise of better flowers. It seems to have the fault of producing its blossoms in clusters, and it will, therefore, be found necessary, when this is the case, to disbud it to a single flower. By this means larger blooms may be secured.

Pansies in recent years, a race of intermediate plants has been secured which is hardy, vigorous, free blooming, with most charming flowers, pure in color, and in many varieties having a very distinct perfume. As they have a more tufted habit than the ordinary Pansy, Mr. Robinson, of *The Garden*, an enthusiastic admirer of the race, has suggested that they be known as "Tufted Pansies." A recent issue of *The Garden* contains a plate of the variety Ariel—with a delicate mauve and white flower. This supplements two previous colored figures of other dainty beauties, and the series shows well the types of perfection in this flower. In comparison with the modern Pansy, the Tufted Pansy is a flower of moderate or even small size, but beside its more free blooming character, its tufted habit and somewhat less succulent stems, it is pleasing for its great purity and delicacy of color, with no trace of coarseness. The self-colored sorts are very beautiful, and a

Grounds of the Paris Exhibition from the Platform of the Eiffel Tower.—See page 566.

There are such wide differences between the climates of Great Britain and of the United States, that an opinion, based on European experience, cannot safely be offered in regard to the merits or demerits of a new Rose (or an old one, for that matter) in this country until it has been thoroughly tested here. An illustration of this was seen in the discussion that took place a few months ago in the columns of an English horticultural journal, as to whether the Rose Madame Lambard was or was not one of the most generally useful of the entire Tea class. A majority of the correspondents seemed to think it was decidedly the most useful; while on this side of the ocean a very different opinion prevails, and it is but little used.

Holmesburg, Pa.

W. H. Taplin.

Tufted Pansies.

AMONG charming and desirable hardy spring-blooming plants the Hybrid Violets must take a foremost place. By judicious hybridizing of various alpine Violets and fine

mass of one of the good whites, as the "Countess of Hopton," is a charming floral picture. As bedding plants Tufted Pansies are most desirable, coming into flower very early and blooming freely and continuously. Much attention has been paid to this race by the best English and Scotch florists, especially the latter, and numerous named varieties are offered. And it is to be hoped that some of our growers will interest themselves in these plants, which apparently have excited little attention here, but which will certainly become popular when their merits are known. It may seem a retrogression to cultivate Pansies of less than the standard three inches and upward; but the increase in size of the modern Pansy has been accompanied by an unpleasing tendency to coarseness, and there are still flower-fanciers who do not look upon big blooms of everything as of first importance, a fact which seems to require emphasis in these days. These Pansies may be had from seed, which is offered by English seedsmen, though finest varieties do not reproduce themselves truly.

However, a packet of seed will produce many charming varieties and good kinds may be selected from these if named plants are not obtainable. The culture is the same as for Pansies—a good, deep, cool, well enriched soil and frame protection in winter.

Orchid Notes.

Cape Orchids.—During the last few years an effort has been made to popularize some of the elegant little terrestrial Orchids of the Cape of Good Hope in British gardens, and the movement has been attended with a certain amount of success, though much remains to be done if they are to take a permanent place among our cultivated Orchids. Beautiful as some of them are, their successful cultivation is by no means such an easy matter as is that of the majority of the epiphytic species, and even when they appear to be doing well some of them have a way of taking French leave during the resting season that is particularly irritating. One cause of failure is, doubtless, the difficulty of imitating, under cultivation, the conditions under which they exist in their native homes, and when these conditions are understood and successfully imitated, these plants may become more familiar to us. A few years ago it was considered quite a feat to grow the beautiful *Disa grandiflora* successfully, and for the simple reason that its requirements were not understood. A writer in the *Gardener's Chronicle* has recently described the Disa-house of Messrs. James Backhouse & Son, of York, and shown what can be done when the task is set about properly. It is ninety-eight feet long by twelve and a half feet wide, partly sunk, and the sliding lights are taken off in fine weather from early spring to late autumn, while they are always left open at night. The tubers are planted out in a prepared compost and liberally watered. Under this treatment over five hundred spikes were produced which bore over a thousand flowers, and one spike was nearly three feet high and bore nine large flowers. Such a sight must have been worth going a long way to see.

Other species which have been successfully grown are *Disa crassicornis*, *D. lacera*, *D. racemosa*, *D. tripetaloides*, *Satyrion carneum* and *S. coriifolium*, with several others of considerable interest. Speaking of *Satyrion*s, a recent writer recommends that the tubers should be potted much as Hyacinth bulbs would be, and remarks that they are not more difficult to flower when properly grown.

The blue flowered group of Disas have long been sought after by cultivators, but hitherto they have been grown with very little success. During the present year several plants of *D. lacera* have flowered, and one of them has been figured in the *Botanical Magazine*; but, in spite of its novel color, the figure seems to suggest that only when grown in strong clumps would it make a very showy garden plant. Whether this is practicable remains to be proved, and at present appearances seem rather against it, unfortunately.

Cultivators of Cape Orchids will doubtless welcome a little work entitled "The Orchids of the Cape Peninsula," by Mr. Harry Bolus, F.L.S., which appeared some little time ago, in which much interesting matter relating to this subject is to be found. It appears that the majority of the species flower in early summer, yet there is no month (excepting, perhaps, April, in some unfavorable year) in which some Orchid may not be found in flower on the Cape Peninsula. Beginning in April the flowers of *Disa tenuis* and *Liparis Capensis* may be found. These continue in various situations until June, and are succeeded in July by *Disperis Capensis*, scattered everywhere over the Flats. These all have green or dull colored flowers, but a note of brighter color is struck when *Satyrion coriifolium*, with its orange flowers, and *Disa obliqua*, with flesh colored flowers striped and blotched with purple, appear. Several others quickly follow, until in October the maximum is reached. In November and December the Orchids on the Flats have disappeared, though they are still abundant on the mountains. "After December the number rapidly diminishes, yet the peerless *Disa uniflora* is in its glory on the rivulets of Table Mountain in February. The last to linger are the lovely blue *Disa graminifolia* and the flame colored *D. ferruginea*, which may often be found until late in March. The three last named are the brilliant product of the unclouded summer sun; and with them Nature gloriously closes, as in a gorgeous and many-colored sunset, the splendid array of these beauties of the floral year."

The *D. uniflora* here mentioned is none other than *D. grandiflora*, being an earlier name of the species, and we may conclude with the following remarks upon it, from the pen of Mr. Bolus: "This beautiful flower is the object of universal

admiration, and the name which has been given to it, the 'Pride of Table Mountain,' indicates the honor in which it is held. It is indeed the queen of terrestrial Orchids in the southern Hemisphere, as *Cypripedium spectabile* may be said to reign, though with less magnificence, in the northern. . . . It is still abundant on Table Mountain, although of late years large quantities of the tubers have been annually exported to Europe, and much needless destruction, arising from wasteful gathering by unskilled hands, resulted. But the summit of the mountains being Crown land, the government has recently intervened and restricted the removal of tubers within reasonable limits, so that, if this supervision be continued, there will be little reason to fear the extinction of this truly noble species."

London.

Calypto.

***Zygopetalum Burkei*.**—This is quite a handsome plant, and not at all common. It was introduced from Guiana in 1883, where it was found growing among the grass in swampy places and also on the drier uplands. It should be placed in the warmest house; indeed, we could do nothing with it until we placed it in the warmest corner of the Phalænopsis house, in company with *Phajus tuberosus*, *Odontoglossum Roezlii* and other so-called "miffy" Orchids. It now grows like a weed, potted in a mixture of loam, sand and decayed leaves, kept very wet, and syringed overhead at least twice a day. After growth is finished a little less water may be given. This species has a clustered habit, with oblong, lanceolate bulbs about three inches long, and two lanceolate, acuminate leaves about one foot long. The scapes, which appear with the young growths, are about twenty inches long, bearing half a dozen very attractive flowers, with greenish sepals and petals prettily mottled and barred with brown. The ovate, acuminate lip is pure white, faintly tinged on the margin with yellow; the crest, or ruff, has crimson colored folds. The flowers last quite a long time in perfection, and are found valuable for cutting.

Kenwood, N. Y.

F. Goldring.

***Urceolina aurea*.**—A group of a dozen pots of this plant, and comprising nearly forty spikes of its elegant brightly colored flowers, is very ornamental at this time of year, or indeed at any time. This species is an old garden plant, but it is not much cultivated nowadays. To be effective it should be grown in quantity and massed when in flower, and as the bulbs yield offsets very freely, there is no difficulty in soon obtaining a good number of flowering bulbs. The erect spikes are a foot long, and each one bears from three to five pendent flowers on thin pedicels, hanging like ear-drops. The corolla is urn-shaped, two inches long, the lower half bright yellow, the upper emerald green. The flower-spikes are developed after the leaves have withered. The plants should be potted in fibrous peat and sand and grown on a shelf in a stove. They do not like bright sunshine, being accustomed to the shade of woods, where they grow wild in the Andes of Peru. During growth they require a regular supply of water, but after the leaves change color no water should be given. There are two other species, viz., *latifolia*, which is larger in bulb and bears about eight flowers on a scape; and *miniata*, generally known as *Pentlandia*, which has bright scarlet flowers, and thrives in a green-house. It flowered at Kew in July last. The most useful of the three, however, is *U. pendula* (syn. *U. aurea*).

Kew.

W. Watson.

Work in the Vineyard.—The frequent rainy days this fall have interfered seriously with working the soil, especially where it is of a clayey nature, but opportunity has thus been given for early pruning of the vines. This work is more easily and expeditiously and more comfortably done in mild weather than in the winter when the ground is frozen or covered with snow. A few grape-growers hold to the antiquated notion that no pruning should be done except in February, but experience has proved that no harm comes from early cutting. The work of the plant is not completed with the ripening of the fruit and the fall of the leaves. The wood continues to harden, and meanwhile the sap does not cease its movements. This sap, which in spring will follow the cut of the knife or shears like water, is much thicker at this season of the year, and exudes, if at all, in a thick gummy condition. If, as some suppose, the ripening of unnecessary wood is a tax on the plant, its removal now certainly must be a relief and a benefit to the remaining wood. Whether this theory is correct or not, autumn pruning of the Vine is on the increase, and constantly growing in favor. It not only gives the plants a neater appearance, but affords much better facilities for clearing up the ground and putting it in good condition for passing the winter. If the plants need laying down for protection it is

more easily accomplished. My Vines were all pruned last month much earlier than usual, and whatever the happening of the winter, the job is out of the way and causes no apprehensions.

Montclair, N. J.

E. Williams.

Brussels Sprouts.—This delicious vegetable is grown quite extensively in the Cauliflower districts of Long Island, and is proving a profitable industry now that its cultivation is getting better understood. It is grown in the same manner as the Cauliflower, the seed being sown early in June and the plants set about the 1st of August. The usual custom is to set the plants in the same field as the Cauliflower, as they require the same treatment in all respects, and are followed by the same crop, which is usually Corn. The crop of Brussels Sprouts comes in conveniently, as it need not be sent to market until the Cauliflower season is past, as ten or twelve degrees of frost does not in the least injure it, while a few degrees of frost is beneficial, having the same effect as it does on the Ruta-baga. Some of the growers have found by experiment that the seed grown on the island does far better than that which is usually sown, the plants being more vigorous and more productive. The crop is far more remunerative than Cauliflower, as it is more sure, and the prices better, while there is a great saving in freight. A bushel of sprouts will bring as much, usually, as a barrel of Cauliflower, while the yield per acre will not be materially less. It is surprising that Brussels Sprouts are not found in every private garden, as they are among the most palatable of vegetables and easy to grow.

Floral Park, L. I.

C. L. Allen.

The Japan Persimmon.—A neighboring gardener has just brought me some excellent fruit of the Japanese Persimmon, to show what a small bush in close quarters can produce. His plant is in a box but eighteen inches square, and it is but three feet high. During the summer a place is found for it under the shade of a Grape-arbor, and in the winter in a cool cellar. There are about a dozen ripe fruits on it now and last year fourteen were gathered. The possessor of this Persimmon says that it requires less care than any plant he has. As the fruit of some varieties is delicious, I think it should be more generally known that its cultivation is very simple. Would it not be a good addition to the list of fruits for cultivation under glass?

Correspondence.

The Abandoned Farms of New Hampshire.

To the Editor of GARDEN AND FOREST:

Sir.—Mr. N. J. Bachelder, the Commissioner of Agriculture and Immigration, sends me a price list of more than one hundred abandoned farms in this state. An accompanying note says that these farms have been reported by the selectmen of the various towns to have fairly comfortable buildings, and that they comprise but a small part of the abandoned farms of the state, a full description of which will be given in a forthcoming catalogue, if the necessary facts are reported by the owners. The Commissioner observes that "in most instances these farms have not been abandoned because the soil has become exhausted, or from the lack of natural fertility, but from various causes appearing in the social and economic history of the state, which will be more fully discussed hereafter."

This is an interesting and important undertaking. The law authorizes the collection of necessary information in regard to the opportunities for developing the agricultural resources of the state through immigration, and the facts obtained and the advantages offered to immigrants are to be circulated where the Governor and Council may consider it for the best interest of the state. The inquiry and discussion which will result cannot fail to be of great interest and value, and I hope that everybody will co-operate with Mr. Bachelder in his purpose to make the investigation as thorough as possible. At this stage I submit some notes of observations made while living here during the last ten years.

Some of the abandoned farms belong to men who left them in early life and have established occupations and homes elsewhere. There is nothing mysterious or remarkable in their having remained away; the point of interest is in the fact that nobody has cared to buy and work these farms, as many of them have long been for sale on extremely easy terms. One of the chief reasons why men who could have bought such farms have not done so, is that they have preferred to go west and take the chances of bettering their condition there. I have seen many of them, in all the regions from western Iowa and Minnesota to the Pacific coast; most of them working

harder than they would have to work here, and having a much poorer living, the life of the women a long starvation from homesickness and hunger of mind and heart. But a few of these emigrants have grown rich, and they all leave their old homes in the hope of being among the few fortunate ones.

The conditions of soil and climate in this state are such that farming will yield a living on most of the land that has been brought under cultivation, if the farmer and his family do all, or nearly all, of the work, and practice reasonable economy. Some accumulation would be possible, but the gain would be slow. Some of the best farms would admit of the employment of a hired man, during a part of the year, at least, if he would work faithfully and efficiently for moderate wages, as in earlier times; but, in general, the farmer and his wife and children would have to do nearly all the work. The return for their toil, the prospect or outlook for them, would be the possession of a home of their own, with the same steady hard work kept up till age unfits them for it, when they may hope to have laid by something for the support of their later years.

Now the race of men and women who will go on thus toiling patiently and practicing small economies all their lives for the sake of a mere living, is very nearly extinct in this region. The young men and women will not stay here under such conditions; they will go elsewhere for the chance of doing better. Illusion is an important element in the life of most Americans. We do not value security very highly, but prefer the possibility of splendid fortunes to the certainty of moderate gains. Usually the possibility is only imaginary, but the fascination of the game lures young men on, and there is still an element of inflation and romance in the practical life of our country.

It is also to be noted that the growth of manufacturing industries has brought about great economic and social changes. In many instances the former town-organization has been modified by the development and dominance of the manufacturing villages, with their population of operatives, often largely a floating or changing one, in the employ of the proprietors of the mills; and it is often apparent that the farmers have less interest and prominence in town affairs than they had under the old order of things. One effect of the change is that the sense of community, of a common interest in the welfare of the town, has been to a considerable degree eliminated. There appears to be less of public spirit, and, at any rate, what remains is not distributed among so many citizens as formerly.

The truth is that the old New England civilization and organization of society has here mostly come to an end. It has run its course, has completed its cycle, and we are beginning again with new and very different materials. We have already large populations of French Canadians and other foreigners, and it is plain that for a long time to come we shall have, in the principal communities of this state, the civilization and the intellectual and social life which these people and the Roman Catholic Church will produce under the new conditions of life in New England. The farmers still stand by the churches of the earlier time, but the bond which they formerly supplied for the social life and public spirit of the towns has become less vital and efficient with the decline of the rural population.

Many people here advise the encouragement of immigration from the north of Europe; and I have no doubt that Swedes and Norwegians could make a living on these abandoned farms, because they would do more work and consume less for their living than native New Englanders, and the value of taxable property and the volume of business in the towns would be increased. But the gain would be temporary. If the new inhabitants send their children to our schools we shall soon Americanize them to such a degree that they will not stay on the hills, and in twenty or twenty-five years the farms will be more abandoned than they are now. I think there can be no permanent restoration of farming in this state without some considerable changes in the methods of it, and in the thought and methods of life of our people; and beginnings in such things are apt to be difficult.

Natural conditions are favorable for stock-raising, and many of our leading citizens have done much to promote the general welfare by improving the character of farm animals. The state is adapted, in a peculiar degree, to the growing of sheep. I have eaten mutton in every part of our country which produces it, but have never anywhere else found any that approached the excellence of that which is grown in New Hampshire. If the people of the cities were aware of its quality there would be a great demand for it at the best prices, but there is not enough to supply the few people who use it in the

villages here. The dog is a kind of sacred animal with us, and dominates the community. He is the object of a personal affection, a sentiment of romantic regard, which rises far above such sordid considerations as the possible profits of sheep raising. Our best people—and some others—keep dogs, and when the instinct of the chase awakens in them and they go forth upon the hills and hunt down the sheep, and have to die themselves for their frolic, we all mourn their fate. The sheep can be paid for out of the public treasury—there is a tax on dogs—but nobody has any sentiment about sheep. We are in that stage of development in which we grow dogs and delight in them, but not sheep.

There is considerable land in farms in this state which, if properly managed, would be more profitable for the production of timber than for any other crop, and which would be worth more than it is to-day if forest-conditions had always been maintained on it. But timber land here needs to be handled with judgment and foresight. It has to be protected against fire and pasturage, of course, and unless the timber, when it has grown, is cut off intelligently, forest land is not always a good permanent investment. It is the opinion of many of our intelligent lumbermen that much of our timberland might be made more profitable by improved methods of management.

The results of our system of cultivation, as shown in many of the farms in all the older parts of our country which have not been abandoned, and the inclination of so many of our people to seek their fortunes by leaving their early homes, point to the fact that a considerable proportion of our material success has been achieved by the partial exhaustion of our capital in the fertility of the soil. We have amassed wealth by robbing the future, and we are transmitting our impaired and damaged heritage to those who come after us. Whatever may be the fertility of the abandoned farms of this state, the methods of culture widely followed in our country have seriously diminished the productive capacity of the soil, and many farms in other parts of the United States would in time be abandoned if there were still, as formerly, a boundless area of virgin land for our people to appropriate. Perhaps we may in time come to understand that the earth is adapted to yield a living to a considerable number of men if they will wisely till it and husband its capacities; but that its resources are not profuse enough to sustain indolent luxury or careless waste, and that toil and scant indulgence are, in the long run, inevitable for the mass of men. Thus far in human history slavery and war have been pretty constant conditions. The forms change, but the essential facts abide hitherto, and perhaps they may still do so.

In my judgment, existing conditions co-operate to make an opportunity for an important change in the economic and social elements in the life of the state. I think that many of the abandoned farms, and many of the hill farms which have not been abandoned, would be good investments for men of means who live in the cities, and who would like to have summer homes for their families in the country. The climate of our state does not suit everybody, of course. But for those whom it does suit, it would be hard to find anywhere on the planet a more salubrious and delightful region than this is for the time between the first of June and the last of October. No other mountain country that I have seen has such expanses of uncontaminated and vital air. I think that, looking far ahead, as a few men at least should try to do, looking at all conditions and relations comprehensively, the best and wisest thing for all concerned would be a considerable movement of men of wealth from the great cities of our country to the hill farms of this state. They should be men of intelligence, with adequate knowledge and judgment for the management of their woodlands, so that the growing of timber as a crop would be profitable. There is no ground of hope for the future prosperity of our people unless forest-conditions are permanently maintained on a large proportion of the land of the state. At the same time a system of highly concentrated farming should be followed on whatever land is kept in cultivation. The ownership of farms here by men from the cities would render such methods of culture possible, would give profitable employment to many laborers, and would increase the value of land and the amount of business in every part of the state occupied by the new summer homes. It would be the establishment of better conditions, the beginning of a new order of things which would be permanently favorable to the interests of our entire population.

I should be glad to stimulate public interest in the investigations which are now in progress under the direction of the government of this state, and I am sure that the reports of the New Hampshire Commissioner of Agriculture and Immigra-

tion will deserve the attention of all students of American civilization.

Franklin Falls, N. H.

J. B. Harrison.

Native Shrubs.

To the Editor of GARDEN AND FOREST:

Sir.—I was much pleased with your article calling attention to the *Viburnum lantanoides* and speaking of its great beauty. It may not flourish in the dry, sunny garden of the nurseryman, as you say; I have found it, however, very easy to transplant into places shaded by deciduous trees. Small bushes taken from the neighboring woods in the fall, and even when in flower in the spring, not only survive but grow luxuriously. Some of these thus transplanted are now ten feet high and are very delightful in their striking and beautiful foliage as well as in their blossom.

The name of Moosewood, given by you as the common nomenclature, is also applied to the Striped Maple (*Acer Pennsylvanicum*), though not so commonly as the Viburnum. The Striped Maple is more of a tree, and is very graceful and pleasing, and also easy to transplant.

There are other of our native shrubs of great merit, which can easily be transplanted. The Ground Cedar or Savin (*Juniperus communis*), with its vigorous, close growing, shining foliage and hardy habit, can be used with good effect in rocky, sterile places where it is difficult to get other shrubs to grow.

Nothing, however, is finer than the Mountain Laurel (*Kalmia latifolia*); nor is it difficult of cultivation, as many suppose. In preparing places for this plant I have found that it grows and blossoms best in beds made like those used for Rhododendrons, of a depth of about two and a half feet, and filled with one-half peat mud and the other half loam and manure and some sand. The peat I suppose is useful in retaining moisture. The Laurel has many small roots that do not extend a great way from the bush, but permeate every inch of the soil they reach in ground prepared in this way.

Beverly Farms.

C. W. L.

Forest Fires.

To the Editor of GARDEN AND FOREST:

Sir.—The Nemadji River drains, in Wisconsin and Minnesota, very little land except deep beds of clay with some layers of fine sand.

The surface rises, westward from Lake Superior, some 400 feet by terraces, and through these the streams have cut deep ravines. The banks of these ravines are now held in place by a dense growth of Dogwood, Hazel, Elm, Poplar and Balm.

If, with the settlement and clearing which will soon come, these banks are stripped by escaped fires (no thoughtful person would clear them), land-slides into the streams will be frequent and much earth will be washed into the bay; and thus not only will valuable farming lands be destroyed, but navigation will be obstructed.

The situation can be indicated by the simple statement that many homesteaders have killed their own standing Pine by setting fires they could not control.

Practically we have no law to restrain any person from setting fire as he may choose.

Duluth, Minn.

H. B. A.

Recent Publications.

Die Natürlichen Pflanzenfamilien, conducted by A. Engler and K. Prantel, Leipsic, Verlag von Wilhelm Englemann, 1889. This book is indispensable to the library of every working botanist, who will discover in it vast stores of exact information which, thanks to small but clear typography and a system of abbreviation, is compassed in a wonderfully small space. It is copiously and handsomely illustrated with exceedingly well chosen and well executed figures, which display the structure of the different families and genera discussed, as well as their larger aspects, as the species appear growing in their native haunts. The first volume is devoted to *Cycadaceæ* by Professor Eichler; *Cordaitaceæ* and *Coniferae* by the same, the last most carefully and elaborately worked up and admirably illustrated; Professor Eichler has also elaborated the *Gnetaceæ*. The *Angiospermae* are by Engler, the *Potamogetonaceæ* by Ascherson, the *Najadaceæ* by Magnus; the *Juncaginaceæ* by Buchenau and G. Hieronymus, the *Gramineæ* by Heckel, the *Cyperaceæ* by Pax, the *Palmae* by Drude, the *Araceæ* and *Liliaceæ* by Engler, the *Antiarthlidaceæ* by Pax, the *Orchidaceæ* by Pfitzer. This bare enumeration serves to show that several of the largest and certainly some of the

most difficult families of plants have received fresh and careful treatment at the hands of some of the most distinguished specialists of the day. This great work is being continued with regularity, and, considering its character, with wonderful and commendable rapidity.

The *Annual Administration Report for the Forest Department of the Madras Presidency, 1887-88*, has reached us, and shows that no less than 564 square miles of reserved forest and 1,498 square miles of reserved lands have been added to the areas under the control of the Forest Department during the year. Some remarks upon the Madura district, by Colonel Campbell Walker, Inspector-General of the Forest Presidency, which appear in this report, are as applicable to our western forests as they are to those of the whole of the dry regions of India; and as they are spoken by one of the most capable and experienced forest-officers of the age, they may well be weighed carefully by persons in this country who see no danger in the destruction of the forests on our western mountains. "It takes a long time to reclothe the denuded slopes; but nothing struck me more, after a long and intimate knowledge of the district, than the good results apparent from conservancy and protection, which the villagers themselves admit. It cannot be too clearly borne in mind that we just stepped in in time to prevent utter ruin, for not only had all trees and shrubs been cut, but the very roots rubbed up, and the hilly slopes were fast approaching the last stage, in which remedial measures are all but impracticable, except at very great cost; the soil having been washed away and all seed-bearing trees and shrubs exterminated, nothing being left beyond bare and arid slopes seamed with mountain torrents and ravines, which carried off the rain immediately it fell."

The financial results of protecting the Indian forests are most gratifying. Twenty-five years ago they produced nothing whatever to the government. They began to yield a considerable net income, however, in a few years after forest-conservancy had been established, and it has increased steadily every year since, now amounting to from \$5,000,000 to \$6,000,000 annually.

Report of the Progress and Condition of the Botanic Garden of Southern Australia during the year 1888. Dr. R. Schomburgk, Director.

The operations of the garden were considerably interfered with by the unprecedented droughts of the year. The amount of rain was only 14.543 inches, or nearly the lowest average ever recorded, and 6.446 inches below the general average of the forty-nine years preceding. Excessive heat, with the thermometer rising to 170 and 177 degrees in the shade, added to the difficulties of conducting horticultural or agricultural operations in the colony; but unfavorable as this condition of things was, it adds to the value of a series of experiments carried on in the garden to determine the value for dry regions of various Grasses and fodder plants. Dr. Schomburgk reports that among these the most successful in withstanding the drought was a newly introduced Grass, a native of South America, *Paspalum dilatatum*. "This valuable Grass has maintained its luxuriant growth without irrigation during the disastrous drought. It grows in tufts, attains considerable size and makes a good leafy growth and roots strongly. Prairie Grass (*Bromus unioloides*) proves one of the best and most nutritious of Grasses, and is little affected by our driest season. The drought did not seem to have the slightest effect upon it. One good characteristic of this Grass is that the self-sown seeds grow freely, and the Grass extends. It is one of the best Grasses for hay." The dry weather made no impression on the California Bunch Grass (*Elymus condensatus*), and *Panicum Crus-galli* stood the severest drought, growing vigorously during December, January and February, supplying nourishing feed for cattle. The Japan Clover, so called (*Lepedeza striata*), does not succeed in the dry climate of South Australia, a fact which confirms the experience of persons who have tried this plant in dry Mediterranean countries. It is evident that moisture is essential for its rapid growth, as is proved by the way this plant has spread in a comparatively short time over a large part of our south Atlantic states.

The value of this report is increased by the addition of a number of colored portraits of specimen trees growing in the garden. Of these, the most interesting to Americans is the so-called Pepper tree, a native of Peru, and of late years largely planted in California for shade and ornament. The specimen in the Adelaide garden was planted in 1863, and has attained the height of sixty-four feet seven inches. The spread of its branches is fifty-four feet, and the girth of the trunk three feet from the ground is nine feet nine inches, a remarkable development for a tree which does not often attain such dimensions.

A specimen of *Pinus Sabiniana*, the Digger Pine of California, planted in 1868, has grown to the height of fifty feet, with a spread of branches of thirty-five feet, while the trunk four feet from the ground is seven feet in circumference—certainly a satisfactory growth.

Recent Plant Portraits.

BILLBERGIA VEXILLARIA, *Revue Horticole*, October 16th; a beautiful hybrid obtained by M. André by crossing *B. thyrsoidea* and *B. Moreli*, the latter being the pollen parent. It is a striking plant, with compact habit and showy inflorescence, the scarlet bracts making a strong contrast with the white stem and ovaries and deep dark purple corollas.

Botanical Magazine, November.

CARLUDOVICA ROTUNDIFOLIA, *t.* 7083; a noble species from Costa Rica, nearly related to *C. palmata*, from the leaves of which are manufactured the well known Panama hats, but with larger leaves, borne on petioles sometimes nine feet long.

IRIS BAKERIANA, *t.* 7084; under this name, Professor Foster describes a slender new Iris from Armenia. It is one of the bulbous species, not unlike *I. reticulata* in general appearance, but the cylindrical leaves separate it from that species. It flowers in England in February and March, and some of the flowers are delightfully fragrant with the odor of Violets.

XYLOBIUM LEONTOGLOSSUM, *t.* 7085.

PHAJUS PAUCIFLORUS, *t.* 7086; a native of Java, belonging "to a section of the genus with small flowers which are produced upon the stem, and not amongst the leaves or on tall scapes from the base of the old pseudo-bulbs, as in others of this genus. In this respect, as also in the form of the lip, it approaches those Indian species of *Calanthe*, in which the lip is at the base of the column, and which render it very difficult to give technical characters for the separation of the two genera."

GERBERA JAMESONI, *t.* 7087; the first representative of this South African genus of *Compositæ* introduced into European gardens; a showy plant, the ray-florets represented as dull yellow on the lower side and bright orange or flame-colored above.

Notes.

Mr. George W. Childs was chosen President of the Pennsylvania Horticultural Society at the annual meeting for electing officers held on Tuesday, the 19th instant.

Five books dealing with the pleasures of contemplative outdoor life and the minor beauties of nature as thereby revealed were recently reviewed in a single issue of the *Atlantic Monthly*.

No plant is prettier in a hanging-basket than the common wild Strawberry. In France one often sees it, used alone, falling in graceful, long tendrils, and equally charming whether in blossom or in fruit.

The hardwood trees of Maine are yearly becoming of more importance in the sum of its lumber exports. As one item we may note that during the past year seven million spool-bars of birch have been shipped to Scotland.

A bibliography of French publications on forests and forest-science, prepared by one of the Professors of the National Forest School, at Nancy, for the exhibit of the Forest Department at the Paris Exposition, contains 8,000 titles, a fact which shows the value placed on forests by the most civilized nations.

Mrs. Mary E. Schenley, a lady of Pennsylvanian origin who has long lived in England, has recently given 300 acres in the city of Pittsburgh for use as a public park, and when it is conveyed to the city there will be granted the privilege of purchasing, at current rates, 100 additional acres which adjoin it.

On Saturday last the *Detroit Journal* gave to each one of 2,000 little girls under twelve years of age a potted Hyacinth bulb, with instructions how to care for it. The flowers are to be exhibited at a charity festival next spring and it is hoped that the children's display will be an attractive feature of the affair.

Among the plants introduced into this country from Japan by Mr. Thomas Hogg is a dwarf, compact, pyramidal variety of the Japanese Hemlock (*Tsuga Sieboldii*), which does not seem to be much known yet beyond the borders of the Flushing Nursery. It is an attractive and interesting plant, nevertheless, well suited to occupy a place in a small garden, and well worth cultivating in any collection of conifers.

The handsome new Brazilian Cucurbitaceous plant recently described by M. Naudin, under the name of *Sicana odorifera*, has this year set fruits for the first time in Europe in the gardens of the Villa Thuret, where it is expected that they will ripen and perfect seed.

Upon a few small plants of *Syringa oblata* which have come under our notice near this city the leaves still remain fresh and green. There is no mildew, nor is there any sign of turning to bright autumn colors, which is said to distinguish this Lilac from others. From other species and varieties near these plants the leaves fell weeks ago.

Among the Chrysanthemums which competed with Ada Spaulding for the cup offered by Mrs. Harrison, Mistletoe, raised by Mr. Frederick Dorner, is said by *The American Florist* to be remarkable for a shade not before seen in Chrysanthemums. This is described as a deep wine color on the upper side of the florets, with a showy mauve reverse. The flower is incurved.

According to the *Pacific Rural Press*, the Sugar Pine-region on the Georgetown divide has been fired in twenty places by the sheep-herders to improve the pasture next year. The mountaineers complain bitterly of the herders, who have destroyed, as is asserted, hundreds of acres of the finest timber. It is claimed that nearly all the destructive forest fires in that vicinity of late have been deliberately kindled by the sheep men.

At the close of the Philadelphia Chrysanthemum Exhibition a committee was appointed for the selection of the finest plant in the hall, to be presented to Mrs. Elizabeth Schaffer, the lady who presented the valuable hall building to the Philadelphia Horticultural Society. The plant selected was one of the two specimens of Mrs. A. Blanc, both prize winners, exhibited by Mr. James Verner, gardener to Mr. A. J. Drexel, who kindly consented to the presentation. This variety was sent out last year by Messrs. Craig & Bro., of Philadelphia.

Professor Bailey, in a recent Bulletin on Tomatoes, from the Cornell Experiment Station, says that out of 200 varieties tested, six could be selected which would combine the desirable market qualities of the entire list. These would be Ignatum, Beauty (or Acme), Mikado, Perfection, Favorite, and Potato Leaf; for very early, perhaps Advance, or Salzer, or Prelude might be added. Of recent varieties especially valuable for amateur cultivation, Dwarf Champion, Lorillard, Peach and Prelude are mentioned. Good varieties seem to run out in about ten years. It is impossible now to get a sample of the Tilden Tomato, once very popular. Trophy is becoming inferior, and Paragon begins to show the same weakness. Frequent transplanting of the young plant and good tillage are essential. Liberal manuring, too, is good practice, although there is a prevailing notion that strong feeding encourages an unprofitable growth of the plant at the expense of the yield of fruit.

The great horticultural exhibition to be held in Berlin next spring will differ from its predecessors in the paramount attention paid to the decorative side of the art—that is, to the employment of plants and flowers in in-door decoration. Only a small part of the exhibits will be shown out-of-doors, the majority of them finding place in a large, permanent exhibition palace, to which green-houses are attached, and in a temporary building to be erected near by. The decoration of ball-rooms, living-rooms, banqueting tables, winter-gardens, etc., will be displayed in appropriate apartments; fountains of various sorts will be shown amid varied groupings of plants; window and balcony gardening will be illustrated, and garden sculpture shown; one immense hall will give room for the erection of arbors and pavilions; decorations for christenings, for weddings and for funerals will be displayed, and all these branches will be open for competitive essays. Of course, with all this, the usual features of a horticultural exhibition will be found, and, moreover, a display of gardening literature and landscape-gardening designs. According to the full descriptions and the numerous plans published in a recent number of *Gartenflora*, this exhibition promises to be of singular interest. It is called a "General Exhibition," but whether it is to be an international one or not we have not seen distinctly stated.

Several large collections of trees and shrubs formed an important and interesting feature in the permanent arrangement of the gardens of the Trocadéro at the Paris Exposition during the past summer. The broad-leaved evergreens and then the conifers were naturally the most conspicuous and satisfactory features in these exhibits, because these plants

recover from the effects of transplanting and push out new growths sooner than plants with deciduous leaves, which often do not get hold of the ground fairly for two or three years after they have been transplanted. The number of new plants in these collections, or even of very rare ones, was surprisingly small; and many species of North America, and of eastern Asia, now comparatively well known in American gardens, were entirely unrepresented at the Exposition; although nearly all such plants may be confidently expected to flourish in central Europe. The naming of plants in these collections was not, on the whole, satisfactory; but certainly it was not less so than the nomenclature in commercial establishments everywhere. The largest collections were those of Croux & Fils, of Val d'Aulnay, near Sceaux, and of Honoré Defresne, of Vitry. In both collections there were fine series of specimen plants of our evergreen Magnolia (*M. grandiflora*)—deservedly one of the popular trees in western and southern France, and for many years a specialty in several of the great French nurseries—of Ivies, and of standard, and half specimen of Rhododendrons in many varieties. In the Croux collection were gathered together from the gardens of southern Europe many evergreens, rarely seen at the north. These added interest to the collection, of course, although hardly to be placed among so-called hardy plants. M. Croux showed three conifers which were described as "new." These were a White Pine (*P. Strobus*), with leaves faintly marked with transverse bands of yellow; a dwarf variety of the Norway Spruce (*Picea excelsa*), with a globular head, out of which a few straggling branches grow up irregularly; and a dwarf, compact growing form of the Scotch Pine, called *P. sylvestris columnaris compacta*. This is a feathery and a rather striking looking plant, which, until closely examined, would hardly be taken for any form of Scotch Pine; it was the only one of the three plants of any real value; and perhaps the most interesting novelty in its class shown at the Exposition.

On the 29th of September last the centennial of the birth of Peter Joseph Lenné was celebrated by a gathering of German landscape-gardeners at the village of Bornstedt, near Potsdam, where he lies buried. Holding for many years the position of Director of the Royal Gardens in Prussia, Lenné is considered, by his fellow-countrymen at least, the greatest landscape-gardener of his time. The son of a court-gardener at Bonn, he studied first at home and then in Paris, and later traveled widely in Europe, being greatly influenced, as he confessed, by the example of Kent. Thoroughly versed in horticulture, architecture and engineering, as well as in the principles of landscape-design, he was charged, while still a young man, with numerous tasks in Potsdam and its vicinity, building the so-called "Russian Village" at Potsdam, and restoring the royal gardens, which had suffered from grievous neglect during the long wars with Napoleon. Frederick the Great's gardens at Sans Souci were remodeled, and, we must believe, greatly improved by his hand, and the work was very quickly done, for he had previously established government nurseries, whence he could draw an abundance of material, and preparatory schools, which supplied him with efficient assistants. In 1832, he transformed the Thiergarten, in Berlin, originally a royal hunting-park, into a public garden, which, improved by his successors, is now one of the most beautiful in Europe. It was an idea of Lenné's that it should be ornamented with memorials of national significance. In 1845 he laid out another park, the Friedrichshain, in Berlin, and transformed many squares within the city into blooming gardens. In 1848 he turned a flat kitchen garden at Potsdam into the Marly Park, which has been called "an ideal work in the English style," and later designed the "Sicilian" and "Northern" gardens, with their contrasting forms of vegetation. These are but a few of Lenné's chief undertakings. In speaking of their number and variety a recent writer in *Gartenflora* says: "In all his works, which were conceived on broad, vigorous lines and with a masterly power of in-grouping, he took creative Nature as his guide and developed thereby his own creations in a personal style which found many followers." But any one who remembers the stately terraces and plant-houses at Sans Souci, for example, or the effect of the great central avenue in the Thiergarten, will recognize that his following of Nature did not mean servile imitation, but that he knew what differences of treatment were required in different situations, and could work well in a semi-formal as well as in a thoroughly natural way. He died in 1866, and is commemorated by a bust of Rauch's in the garden of the new palace in Potsdam, by a portrait in the Town Hall of Berlin, and by a street in Berlin and one in Dresden, which have been called by his name. *Magnolia Lenné*, the handsomest of the hybrid Magnolias, recalls his name to all lovers of trees.

Forestry in the Agricultural Colleges and Experiment Stations.

A BULLETIN on the subject of Forestry has lately been issued by the Agricultural Experiment Station at Brookings, South Dakota. When we consider how young this station is, and how much time is necessary to determine and prove the substantial facts in relation to forestry; and when we consider further that a climate in which the rainfall from the first of September, 1888, to the thirty-first of August, 1889, was less than ten inches is rather a discouraging one for the tree-planter, we need hardly expect to find in this record much that is of general interest and application. And yet every reader will be pleased to note that so far as they go, these experiments indicate that fruit-growing and forest-planting can be made successful on some of the Dakota prairies.

The bulletin goes into particulars as to planting and cultivation, and gives in detail just such information as the tree-planters of that region stand in need of. The problems discussed, however, are not all of merely local interest, for no one can read without profit the testimony in favor of shallow cultivation as a means of mitigating the effect of drought, for it illustrates a principle of universal application. Even in sections where the annual rainfall is much greater than it is at Brookings, it is important in our hot, dry summers to husband the supply of soil water. The records of the Dakota Station show that but a fraction more than three inches of rain fell during the three spring months of this year, and that a hot June followed with a rainfall of less than one and a half inches. It is not surprising that the prairie grass seemed dead for want of water, but it is instructive to read that, even then, moist soil could be found anywhere in the plantation of young forest-trees by brushing away a little of the surface with the foot. This condition was due to frequent shallow stirring with harrow-tooth cultivators, and it is another evidence that a thin layer of loose earth—a "dust blanket"—is a most efficient mulch in any climate, and that if "there is a remedy short of irrigation for long seasons of drought, it will be found in deep plowing and thorough shallow cultivation."

The purpose of this article, however, is not so much to

discuss the matter of this particular bulletin as to call attention to the fact that the country has a right to expect from the agricultural colleges and stations a good deal of substantial work in forestry, even if it is elementary. At the late meeting of the American Forestry Association in Philadelphia, Mr. N. H. Egleston, of Washington, offered a resolution "that our agricultural colleges should regard it as one of their most manifest duties to give the subject of forestry a prominent place in their curricula of instruction, and that every experiment station should engage in investigating those branches of forestry which have special importance in the localities in which they are situated, or which are of general interest to agriculture and the arts." This resolution was adopted without reference to a committee, and the facts of the case seem to give ample justification for it.

The forests of the country have, beyond question, important relations to agriculture and the mechanic arts, and it was for the promotion of these that the colleges were founded by the general government. The experiment stations were endowed for the purpose of research in the sciences connected with agriculture, and this purpose would naturally include investigations in the field of forestry. The colleges have an endowment of about \$15,000,000, with some 700 professors and 12,000 students. There are forty-six experiment stations, with eleven branch stations, employing 370 observers, a large portion of them trained in the prosecution of experimental inquiry, and in addition to \$125,000 a year given by individual states, besides fees for analyses and the like, these stations receive from the general government \$600,000 a year. Institutions manned and equipped with such care and at such cost ought to be able to give some attention to so important a subject as that of forestry. Some of the colleges and stations have begun forestry work in earnest, as this Dakota bulletin testifies, and perhaps preparation for the work is going on in all of them. In the great majority of them, however, neither catalogues, reports nor bulletins make mention of the subject.

In a country where there is no systematic forest practice, and therefore no trained foresters, we cannot expect the colleges to give instruction in the refinements of the art, nor would it be profitable for the stations to make such investigations as are carried on in the older forest experiment stations of Europe. But much work of immediate practical utility can be prosecuted in the nursery, the field, the laboratory and in the natural forest, where there is one within reach and under the control of the station or college. This is not the place to state the problems which can be hopefully attacked in this way, but an admirable outline of the general field of research is given in Mr. Fernow's report for 1887, which was reviewed in these columns at the time it appeared. What is first wanted is a realization by the colleges and stations of the necessity for work in forestry and a determination to undertake it. The particular course to be pursued by each will be matter for after consideration.

Peter Kalm, a Swedish naturalist and a pupil of Linnæus, visited America in 1748, at the instigation of the Swedish government, for the purpose of examining the natural resources of this country. His journal, afterward translated into English, gives one of the best accounts of the natural features of the northern states, in which Kalm traveled extensively, and of the agricultural resources of the people that appeared during the last century. The following quotation from this journal is as true to-day as when it was written 130 years ago. The same wasteful methods of treating forest-property are still in force over a large part of the territory of the United States. They have wrought inestimable damage to great areas of country, and must sooner or later destroy the productiveness of this land. That this habit of annual burning has not done already greater damage than it has, shows the wonderful fruitfulness of this country and the recuperative powers of the

forest in the moist and salubrious climate of eastern North America. It can be a question of time only, however, when the annual burning which Kalm lamented in the following passage, will exterminate the forests and destroy the reproductive strength of the soil:

"The leaves which dropt last autumn had covered the ground, in depth three or four inches. As this seems to hinder the growth of the grass, it was customary to burn it in March, or at the end of that month (according to the old stile), in order to give the grass the liberty of growing up. I found several spots burnt in this manner to-day; but if it be useful one way, it does a great deal of damage in another; all the young shoots of several trees were burnt with the dead leaves, which diminishes the woods considerably; and, in such places where the dead leaves had been burnt for several years together, the old trees were only left, which being cut down, there remains nothing but a great field, without any wood. At the same time, all sorts of trees and plants are consumed by the fire, or at least deprived of their power of budding; a great number of plants and most of the grasses here are annual; their seeds fall between the leaves, and by that means are burnt: this is another cause of universal complaint, that grass is much scarcer at present in the woods than it was formerly; a great number of dry and hollow trees are burnt at the same time, though they could serve as fuel in the houses, and by that means spare part of the forests. The upper mould, likewise, burns away in part by that means, not to mention several other inconveniencies with which this burning of the dead leaves is attended. To this purpose the government of Pennsylvania have lately published an edict which prohibits this burning; nevertheless every one did as he pleased, and this prohibition met with a general censure."

It would be interesting to know whether the people of Pennsylvania have acquired sufficient intelligence and self-restraint during the last century and a half to submit willingly to the enforcement of the act which met with such general censure at the hands of their ancestors.

Professor Shelton, of the Kansas Agricultural College, explains in a recent number of *The Industrialist*—a bright little paper edited and published by the faculty of that institution—a new irrigation project for the western or "arid" section of that state, which will be watched with interest. It seems to have been known for a long time that at almost any point in the wide valley of the Arkansas River, water can by drilling be reached at a very shallow depth, usually from four to nine feet. This water is found in a stratum of sand so thoroughly saturated that enormous quantities can be pumped up without diminishing the supply in any appreciable degree. This subsoil water is supposed to have a distinct movement, flowing along as the river flows, and it is argued that the river itself is but the visible and superficial outflowing of the great underground stream. Professor Shelton adds:

With these facts in view, Judge Gregory, editor of the Garden City *Sentinel*, has advanced the idea that, by tapping this underflow with a ditch of suitable size and depth, a permanent supply of water for irrigation may be led to elevated regions, just as water from the river is ordinarily led away for use on the uplands. This original plan has been brought to the attention of the public with great persistence and force by means of circular addresses and newspaper articles. As a result of this agitation, conducted by Mr. Gregory, the attention of practical irrigators has been drawn to the subject, and measures have been taken to give the new scheme a practical test upon a large scale. The corporation owning the great Dodge City ditch—a canal twenty-five feet wide and nearly 100 miles long—is already at work upon an extension of their main ditch which will intercept a full mile and a quarter of this sub-flow. This, with the number of powerful steam pumps planned for use another season, will certainly prove to what extent the underflow of the water of the Arkansas River is available to the husbandman.

No doubt these enterprising men realize that a permanent water supply is quite as necessary to sustain the even flow of an underground current as it is in the case of an ordinary stream. While they are tapping this hidden river, therefore, the projectors of this scheme should use every effort to save the forests where it takes its rise.

Holiday Notes in Southern France and Northern Italy.—VII.

MY note-book was next brought into requisition in the picturesque situated and beautiful city of Genoa, where there is abundance of interesting things to note for the benefit of the stay-at-home gardener.

Immediately after leaving the large, handsome station we come upon the Columbus monument, surrounded by Date Palms and other members of more or less tropical floras, which we were destined to see in great number, vigor and beauty for some distance along this beautiful coast. The Cape of Good Hope, Mexico and Australia are centres of plant life, which seem to find their counterpart in the hot, almost rainless, summers and the very mild winters of Genoa and its neighborhood. At any rate, large numbers of shrubs and trees from these countries thrive in the Riviera so well that it is difficult to imagine their succeeding any better even in their native habitats. Acacias, Myoporums and Pittosporums of large size, fine *Dasyliirions* and enormous *Agaves* combine to produce a strangely exotic effect. Here, as well as elsewhere, we were somewhat disappointed to find little or no use made of such beautiful native shrubs as the Myrtle, Terebinth and the like.

Acqua Sola, a small park at the north-east end of the city, and about 140 feet above the level of the sea, is a favorite promenade. It occupies the site of part of the old ramparts, and was laid out in its present form about half a century ago. Then we pass on to the Villetta di Negro, a well kept garden with winding promenades, which ascend to a bastion about 150 feet above the level of Acqua Sola. Fine views of the harbor, city and neighborhood are obtained from this spot. The old walls have allowed plenty of space for climbers, and such things as the yellow *Bignonia Tweediana*, *Solanum jasminoides* and other plants of similar character have thriven exceedingly. The common Ivy (*Hedera Helix*) clothed some of the steep, sunny banks, and here and there *Convolvulus Mauritanicus*, with its slender shoots bearing a profusion of pale blue flowers, grew out of the Ivy carpet, seemingly quite satisfied with its quarters. *Fluggea Japonica* was here also used for forming a turf in dense shade, just as we had seen it in the gardens on the north Italian lakes, and so far we have seen nothing which produced such satisfactory results. Very tall Date Palms, with thick stems, were, in the opinion of my companion and myself, spoiled by training Ivy and other creepers round them. A sort of ravine, with a small watercourse, provided suitable places for *Colocasias*, and other moisture-loving, fine foliage plants. *Melia Azedarach* (laden at the time of our visit with panicles of small round fruits about the size of peas) is a Genoa shade tree, as is also the Carob (*Cerotonia Siliqua*), with its handsome, leathery, black-green, pinnate leaves.

Cycads were only represented by *Cycas revoluta*, and Palms by scarcely half a dozen species. The common Date Palm (*Phoenix dactylifera*) and a dwarf species (*P. reclinata*), the South European *Chamærops humilis*, the Japanese and Chinese *Trachycarpus excelsus*—or, as nurserymen mostly prefer to call it, *Chamærops excelsa*—and the Californian Fan Palm, *Washingtonia filifera* (better known as *Pritchardia filifera*), conclude the list as far as the public gardens of Genoa are concerned. The last-mentioned Palm is a remarkably quick grower, and magnificent examples of it are to be seen along the Riviera—some before long will become the rivals of the celebrated pair in the Californian city of Los Angeles. The Director of the Public Parks and Gardens at Rio de Janeiro told me a week or two ago that a specimen in one of the Rio gardens has attained huge dimensions and produces fruit in abundance. In a small pond, too much shaded by trees for the perfect happiness of sun-loving aquatic plants, we noticed *Nelumbium speciosum* in flower.

Leaving Genoa, the railway skirts the Mediterranean coast line, and affords the traveler a succession of enchantingly beautiful views. The train carries him past bare, frowning, lofty rocks, with their bases washed by the sea and their summits crowned with ruined towers erected in former ages for protection against pirates; then extensive, terraced Olive groves—gnarled and picturesque—Citrons, Oranges, etc. Here and there between the railway and the sea are small patches of flat ground, and these are generally utilized for growing fruit and vegetables. Constant irrigation is, however, necessary, and we became quite familiar with the sight of water being raised from a well by a donkey working in a circle under a thick, vine-clad roof, and then conducted along small channels to the slightly sunken beds. Not a weed was visible in these gardens, and very fine crops of Tomatoes, Aubergines, Lettuces and other vegetables were the rule.

Bordighiera, a few miles from the French frontier, is specially famous for its Palm groves, and presents an exceedingly picturesque aspect. According to Dean Alford, there are more Palms here than in the whole of the Holy Land. A considerable trade in Palm leaves is done in Bordighiera; in fact, that town may be said to possess the monopoly of supplying blanched Palm leaves for church purposes. The young growths are tied up tightly in order to make them the requisite color, and plants so treated are anything but ornamental in appearance. Fortunately, however, a comparatively small proportion of the Bordighiera Palms are undergoing such treatment at one time. The Date Palm is said to have been introduced to this coast more than a thousand years ago, and in the garden (of the French Consul at Bordighiera) which now occupies the site of a Dominican monastery, there are huge trees which are believed by their present possessors to have been planted by the Dominicans upward of ten centuries ago. All along this district, too, the Olive is seen in its full beauty—and a fine Olive tree is a really beautiful sight. It is not pollarded, as in southern France toward Marseilles, and in Languedoc, but allowed to attain tree size and grow in a perfectly natural way. *George Nicholson.*

Pinus Banksiana on the Maine Coast.

IT has been known for some years to a few botanists and others that the northern Gray or Scrub Pine (*Pinus Banksiana*) grew abundantly on the coast of Maine much farther south than had ever been supposed, but until recently no statement of the fact has ever been published. Those who are curious to know how the discovery occurred will now find in the November number of the *Bulletin of the Torrey Botanical Club* (vol. xvi., No. 11) some notes relating to the fact written by Mr. John H. Redfield and myself.

The station is on Schoodic Peninsula, in the town of Gouldsboro, Maine, lying opposite the eastern shores of Mount Desert Island across the expanse of Frenchman's Bay, and is well marked by the bare, flat-topped mass of Schoodic Mountain, 417 feet in height. Apart from this elevation the surface of the peninsula is for the most part level, and often boggy, overgrown by an uninteresting growth of low deciduous trees and the common conifers of the coast, with here and there, especially on the mountain slopes, great Alder patches. Throughout this region, from within sound of the sea to the interior of the peninsula, and stretching at intervals miles beyond its limits to the northward, grows *Pinus Banksiana* in its most southern home now on record, the latitude being about forty-four degrees twenty minutes. In the lowlands this Pine here attains a height of twenty to thirty feet, forming a slender, graceful tree, well distinguished from the Spruces, in spite of its short leaves, by its less conical form, by the bunching of its leaves toward the extremity of the twigs in the manner of Pines generally, and by its peculiar cones curved at the tip. On the east it forms almost a forest, nearly displacing the usual conifers of the Maine coast. Toward the west, however, the growth becomes thin—although this may be due to a free use of the axe—and decreases until only scattered trees appear here and there. On the mountain-top it again appears, but in a much changed form. There it is a true Scrub Pine, dwarfed, weather-beaten, twisted into many a strange shape, along the bare, exposed and wind-swept summit. On the peninsula it certainly is the prevailing Pine, almost to the exclusion of the other species. Beyond here its extent northward and inland is not well known. As Mr. Redfield remarks, it would be interesting to know what degree of continuity there may be between this station and the larger areas in northern Maine.

The presence of this interesting Pine on the Maine coast appears to have a certain appropriateness. Despised as it may be elsewhere in comparison with the beauty and value of the other Pines, here its whole character is in keeping with the rugged, storm-swept surroundings. As a tree for cliff or shore planting on this rocky coast I am convinced it would have great worth, for it appears able to adapt itself to the most exposed situations. To me, I confess, it has as a tree a peculiar beauty of its own, and even as a dwarfed shrub it appears to greater advantage than the other conifers of the coast.

Boston.

Edward L. Rand.

In a lawn of small dimensions the losing of the turf under the shrubs is of the utmost importance, as it gives an appearance of extent to its limited proportion. To help this, Periwinkle, St. John's-Wort and other ground creepers may be planted with the shrubs, and by uniting them with the lawn will tend to diminish the hard line of the border, a thing that cannot be too strongly insisted on, as essential to continuity and repose.—*W. S. Gilpin's "Practical Hints,"* 1832.

The Kauri Pine.

OUR illustration upon page 583 represents a fine specimen of the Kauri Pine of New Zealand, one of the giants of the vegetable kingdom, and, economically, a tree of very great value.

It belongs to the small genus *Agathis* (Dammara of many authors, who have adopted for these trees the name applied by Rumphius indiscriminately to several resin-bearing trees of different families), closely related to *Araucaria* and *Cunninghamia*, and characterized by diœcious flowers; the male in short, cylindrical, extra-axillary heads, with numerous stamens with short, eight to fifteen celled anthers; the females terminal, maturing at the end of the second year into short, cylindrical cones, with thick, coriaceous, densely imbricated scales; and by sub-opposite, ovate-oblong or lanceolate thick, leathery leaves, one to three inches long, and an inch or more wide.

Eight or ten species of *Agathis* have been described, but it is not impossible that the number can be considerably reduced when they are better known; they are found in the Malay Archipelago, in the Fiji Islands, New Caledonia, New Zealand and east tropical Australia. The best known of the species is the Kauri Pine (*A. australis*), a native of New Zealand, where, in the Auckland district of the northern island, in sheltered mountain valleys, it often forms extensive forests, reaching a height of 150 feet, with a trunk sometimes fifteen feet in diameter. The wood of this tree is probably not surpassed in value by that of any other coniferous tree. It is pale straw-colored, moderately hard, straight-grained, sound and remarkably durable. It works easily with a beautiful silky lustre and takes a fine polish. It is an admirable cabinet-wood, and is largely used in New Zealand for railroad-ties and piling; for all sorts of building purposes and for cooperage, and is now somewhat exported into Great Britain.

The Kauri Pine produces also one of the most valuable gum-resins known, now largely used in making varnish. This resin is exported annually from New Zealand to the value of nearly two million dollars. It is not obtained, however, in great quantity from the living trees, but is dug out of the ground from the sites of old forests, where none of these trees have been known to exist since the earliest discovery of the island. This semi-fossil resin, however, which is far softer than amber, does not greatly differ from that which exudes from the living trees, which are productive only when they have passed their prime and are becoming decrepit.

It is not improbable that the Kauri Pine, and possibly some of the other species of *Agathis*, may thrive in different parts of California, although it is doubtful, perhaps, if any of the conifers of the southern hemisphere will ever attain anywhere north of the equator the age and size which they reach in their native countries, or produce as valuable material. They are, nevertheless, well worth trying in southern California, and it may well be one of the aims of the managers of the new Arboretum which is soon to be planted in connection with Mr. Stanford's University, to collect there all the most valuable timber trees of the south temperate zone. They can be grown in no other part of the United States, and among them, as we know already in the case of various species of *Eucalyptus*, are many trees apparently fairly well suited to the climate of California and of Mexico.

The Art of Gardening. An Historical Sketch.

XIV.—Suburban Rome.

CHATEAUBRIAND aptly compares the present aspect of the Roman Campagna to the desolation of Tyre and Babylon, "a silence and a solitude as vast as the noise and tumult of the men who formerly occupied the same soil." Scarcely a tree is visible, and the only product seems to be the "ruins which appear like a forest of indigenous plants, the growth of a soil composed of the skeletons of the dead." As it looked to-day, so—except for its crop of ruins—the Campagna looked in the early days of Rome, and its climate was as malarious then as now. But, in the imperial time, drainage and cultivation, an enormous supply of water brought from distant hills, and the making of multitudinous well-built roads, had redeemed it from barrenness and disease and had turned it into one vast garden. For miles around Rome lay the villas of its wealthy citizens, the richest patrician families owning not one but several, "planned and arranged on a different principle in accordance with their destination as winter, spring or

summer residences.* Some stood in extensive domains—the ruins of the various buildings belonging to one cover nearly a square mile of ground; others were of smaller size, but all were planned with a regard for comfort and surrounded with a care for systematic beauty that are nowhere paralleled on a similar scale to-day. The most common practice was to use the suburban villa in spring, spending the midwinter in Rome, and escaping to sea-side or mountains during the greatest heat of summer. The Roman citizen did not abandon the service of the commonwealth or the management of his private affairs until the decadent days of the empire; thus, when the short winter was over, he could not immediately desert the city, but spent vast sums instead on a suburban residence. Six or seven miles from the metropolis meant nothing to him, mounted on a Numidian pony or whirled along in a hooded carriage to the gates, where he was obliged, by the crowded state of the narrow streets, to transfer himself to a litter. “The number of these villas is really incredible. . . . In the golden age of the empire, before the transformation of Rome into an intrenched camp, accomplished by Aurelian, it was impossible to define, even approximately, its extent. . . . To the houses adjoining one another succeeded a second ring of houses separated by small gardens, a third ring of houses separated by larger estates, and lastly, a fourth ring of great villas and huge *latifundia*, each one constituting a populous and flourishing village. These groups of rustic dwellings were laid out in the town fashion, with the shrines of the compital or domestic gods at the street corners, and with local festivities and solemnities. . . . Great care was bestowed on the drainage of the house, which was always carried to a great distance and forced through its channel by a permanent jet of water. Remarkable, also, were the arrangements for the supply of water, which, when not actually needed, . . . was stored in huge reservoirs or cisterns, ready for any extraordinary emergency. At the crossing of the roads . . . there were fountains for the accommodation of travelers and their horses,” and seats were set under the trees for the comfort of weary pedestrians. The great arcaded aqueducts, the temples, shrines and altars, with their marble sides and roofs of bronze, the “endless marble cemeteries, shaded by the ilexes of the villa and by the Olive-trees of the farm,” followed one another in orderly succession. The villa† itself was, as a rule, “divided into two distinct and independent portions. The first comprised the lord’s manor, with more or less spacious gardens surrounding it; the second comprised the farmer’s house, the various stables and barns, the dwellings of the slaves, orchards, Olive-yards, vineyards, corn-fields, woodlands and so forth.” On the hill-sides the villa rose “in steps and terraces from the foot of the hill, each terrace supported by huge foundation walls ornamented with niches and *nymphææ*. The lower terraces never contained buildings; they were simply laid out in gardens, and less frequently in an orchard; the mansion of the landlord was perched on the very top of the hill and within the area of the highest terrace.” The type was an excellent one, affording the best possible outlook and permitting that lavish use of ornamental water which the Romans loved above all else. “But it is incredible how ingenious and clever ancient architects proved themselves to be in adapting the general type of villa to the natural conditions of the special tract of land which had been selected,” and in placing the house so that it would best serve the owner’s desire to use it as a winter or a summer residence. “The characteristic of an ornamental Roman garden was the entire absence of natural beauty. Its style can be compared, to a certain extent, to the French and Italian villas of the sixteenth century.” Topiary work was practiced (as we saw when Pliny’s far-off country-seat in Tuscany was described) to an extent so great that Lanciani ventures to say “no tree or shrub dared to grow in its own natural fashion.” . . . The *allées* were shut in by walls of green Box or Laurel with windows, doors and niches imitating the architecture of palaces. Here and there appeared threatening forms of wild beasts, bears and lions, serpents winding themselves around trees, “all cut by the skillful hand of the *topiarius* out of the green Cypress, Box, Yew-tree, Myrtle and Laurel. . . . Grounds laid out in this style, in which . . . every vestige of Nature’s free dominion is annihilated, are not only described by ancient writers . . . but actually painted, I might almost say photographed, in the frescoes

* Lanciani: “Ancient Rome in the Light of Modern Discoveries.” From this recently published and very valuable work most of the facts in this chapter have been gathered.

† *Villa urbana*, *villa pseudo-urbana* or *prætorium* was the suburban residence of a more elegant, *villa rustica* of a more simply utilitarian sort. It is the former, of course, which concerns us here, and it got its name because the disposition of the town house was closely followed, though often on a more splendid scale and always with a greater regard for external effect.

of Pompeian dining-rooms, in those of the green-house in the gardens of Mæcenas on the Esquiline, and in those found in the villa of Livia. . . . An excuse for such absurdities can be found in the fact that the means afforded by Nature in those days were but small in comparison with the abundant resources of our time. Foreign countries had not as yet unfolded their rich treasures of rare and splendid vegetation, nor their thousand shrubs and flowers; restricted to a barren flora, but little improved by culture, the Romans sought to create by artificial means a striking contrast to the free forms of nature. This is, at all events, the excuse given by Becker.* But it hardly seems a sufficient excuse. The comparatively few plants native to central Italy would have sufficed for combination into lovely “naturalistic” effects, had the taste of the time run in that direction. It is not the born lover of natural landscape beauty who asks, first of all, for endless variety in the items which the prospect supplies—it is, rather, the sophisticated horticulturist, or the scientific student, or the man in whom curiosity is stronger than the æsthetic feeling, or a delight in single objects is stronger than admiration for a general effect. The Romans loved formal gardens because their taste in all things was architectonic. In art, as in all other forms of activity, they proved themselves great organizers, practical constructors, lovers of system, regularity and usefulness, not men of poetic imagination or of purely æsthetic impulse. They were far more remarkable as architects than as poets, sculptors or painters, and their gardens were naturally those which an architect, rather than a poet or landscape-painter, would admire. But I have said that there were exceptions to the general rule of formality in the suburban gardens of provincial towns and in the imperial pleasure-grounds of Rome; and Becker believes that such was likewise the case among the villa-gardens of the Campagna. The hero of his “*Gallus*” owns a *villa urbana*, where, in addition to the symmetrical clipped garden, there is another of natural loveliness.

We are not surprised to find that these luxurious yet practical Romans were the inventors of the green-house. It is not mentioned before the first century of our era, but was then extremely common, and, as in modern times, was roofed with glass and heated by pipes. Here such exotic plants as could be obtained were carefully tended, and fruits, vegetables and flowers were assisted to early development or even forced to perfection during the winter months. Great aviaries and *viridaria* or preserves for animals were likewise common—indispensable, indeed, in places of any pretensions; and the former were often large enough to contain trees of considerable size. Huge fish-ponds, as useful as they were ornamental, were walled around with marble and kept pure by constant streams of water from the exhaustless aqueducts.

Although the poorer classes of Roman citizens were buried pell-mell in great heaps on the hill-sides near the city, much pains and money were lavished on the tombs of wealthier citizens, whether their bodies were interred or cremated. In either case the relics were enshrined in sumptuous buildings, placed along the suburban highways, greatly to the increase of their magnificence of effect. No traveler need be reminded of the remains of such monuments which are still visible on the Appian Way. The so-called Castle of St. Angelo, at Rome, is the central building of the mausoleum of Hadrian, once surrounded by a wide garden, and covered, up its terraced sides, with rich plantations; and across the river stood a similar construction which was the resting-place of Augustus.

In the Roman cemetery still preserved at Arles were long lines of small monuments overshadowed by the inevitable Cypress-tree. †

New or Little Known Plants.

Chrysanthemum Mrs. Fottler.

THE Chrysanthemum illustrated on page 581 is the variety Mrs. Fottler, sent from Japan two years ago in the famous Neesima collection, which included such notable kinds as Mrs. Hardy, Lilian Bird, W. H. Lincoln and Kioto. The flowers of Mrs. Fottler are borne on long, stiff stems, and they are of large size, very full, and of a distinct tint of pink. The petals are long, feathery, and very persistent, so that the flower will remain perfect for a long time. The plant not only gives fine blooms for exhibition, but it has proved very satisfactory

* See Becker’s “*Gallus*.” This book and the same author’s “*Charikles*” are romances, but were written by a learned German student of antiquity for the purpose of portraying, as accurately as possible, the life of a young aristocrat, in the one case in imperial Rome, in the other case in Athens. Their explanatory notes are much more voluminous than the text itself, and even Lanciani quotes from Becker with a lavish hand. Both works have been translated into English.

† McGibbon: “*Architecture of Provence*.”

for market purposes, and in the neighborhood of Boston it has been the most profitable pink variety grown.
 Newton Highlands, Mass.

Foreign Correspondence.

London Letter.

WE are in the midst of the Chrysanthemum season, and the so-called centenary of the introduction of this plant into English gardens is being duly honored by exhibitions, conferences and publications of all kinds. The value of the Chrysanthemum as a decorative plant is second only to that of the

These are decorative plants which may stand alone and form a picture by themselves. The exhibition plant here is a totally different thing. The cut flowers are many of them really wonderful productions, and this year they are, perhaps, better than usual, though the exceptional mildness of the weather this month and last has not been favorable to Chrysanthemums, the flowers being somewhat weak and flabby.

The Conference held at Chiswick was a great success in papers by specialists and a general comparing of ideas and opinions relative to the plants. Mr. Hemsley, a member of the Kew staff, dealt with the botany and literature of the Chrysanthemum. We are not much concerned with the name

Fig. 147.—Chrysanthemum Mrs. Fottler—See page 580.

Rose. Easily grown, inexpensive, yielding splendid results in a short time, accommodating as regards size and habit, almost endless in the variety of shade, size and form of its flowers, the Chrysanthemum is indeed a magnificent garden-plant. Exhibitions such as these teach a great deal, and so also do conferences; but the real beauty of the plants is rarely revealed at either. I confess to a weakness for a plant natural in shape, well-leaved and full of flowers, not large and mop-like, with their crutch-like props, but medium in size, and plenty of them. I have seen a few such plants, their names Val d'Andorre, Alice Bird, Edwin Molyneux, Queen of England and such like. They were plants of various heights, perfect in foliage, and each bearing not three or four, but twenty or thirty, blooms.

of the species from which the garden plants originated; otherwise Mr. Hemsley's discovery that by right of priority *C. morifolium* is the proper name for the plant hitherto known as *C. Sinense* would alarm those who object to the disturbance of old names which have become as household words. Mr. Shirley Hibberd, Mr. Harman Payne and Mr. E. Molyneux, three men whose names stand first amongst admirers and growers of the Chrysanthemum, also contributed interesting papers on its history and development.

The exhibition of the National Chrysanthemum Society, which was held this week at the Aquarium, was remarkable for the display of good standard sorts rather than for anything new. The principal exhibitor of new kinds was Mr. Cannell.

Such sorts as Avalanche, Edwin Molyneux, Mr. R. Brocklebank, Boule d'Or, Princess of Wales, Lord Alcester and Mrs. H. Cannell were in splendid form, nothing among the new kinds approaching them. I have a weakness for the Japanese sorts, and Avalanche as a cut flower I consider is the purest and most beautiful of all Chrysanthemums. Amongst colors the king of all is Edwin Molyneux. The most striking of the newer sorts is Etoile de Lyon, of which Mr. Cannell showed a large number of magnificent blooms. It was certificated last year. The flowers sometimes attain a diameter of fourteen inches, and not one of the many exhibited by Mr. Cannell was less than ten inches across. The color varies from white and rose to deep rosy purple and silver. It is a broad petaled and rather flat variety of the Japanese section. The new kinds certificated were Lady Dorothy (incurved), a large flower; color deep bronzy cinnamon and gold. Mr. Cannell, who exhibited it, declares it to be one of the best and most lasting of the section. Miss Margaret (large Anemone), with rosy ray florets and sulphur centre; John Doughty (incurved), a sport from Queen of England, with the base of flowers pink and a buff centre flushed with pink; Madame A. Carrière (Japanese reflexed); Mrs. S. Coleman (incurved), pink, with pale yellow centre; Alice Stevens (Pompon), golden yellow, a fine flower; Madame Baco (Japanese), remarkable for its size, the narrowness of its petals and its delicate color—a rosy lilac. Amongst those which did not obtain certificates were several of considerable promise, but not in the best condition. One, named Admiral Sir Thomas Symonds, a very fine yellow Anemone, and fragrant, was shown by Mr. Cannell, to whom the Admiral had presented a plant which he had brought from China. Evidently much greater development in size, variety and color has resulted from the manipulations of English and French breeders of the Chrysanthemum than in the hands of the Chinese, who are said to be a long way behind. What we want now is hardier kinds, such as will flower well outside in an ordinary season. There is also a tendency to breed taller plants than is desirable.

The injurious effects of London fog on plants and flowers have been so very marked of late years that the Royal Horticultural Society has decided to collect information on the subject, with a view to discovering, if possible, some means of counteracting it. At present we are unable to decide whether the injury done is due to absence of light or to direct effect of some of the components of the fog, though, so far as my observation goes, it is almost certainly the latter. A heavy yellow London fog is a terrible demon. We do not get the worst of it at Kew, but at Chelsea it is often very bad. The Orchids there suffer much from it. Messrs. Veitch and Mr. Bull find it almost impossible to get flowers, especially white ones, in winter. I have seen a whole houseful of *Phalænopsis* spikes destroyed in a single day by a fog at Clapton. Not merely expanded flowers, but buds even as small as pin heads, are withered and reduced to pulp, as if they had been dipped in boiling water. The large flowers of *Angracum sesquipedale* suffer just as much as those of the delicate *Phalænopsis*. It is not the fact of the flowers being white that causes them to suffer, as *Masdevallia candida* and *Odontoglossum crispum* were apparently unharmed at Clapton. Bouvardias, both leaves and flowers, turn black, as if they had been scorched; the leaves of many plants wither and fall off; even such Orchids as *Vandas* suffer at Chelsea, their lower leaves turning yellow when the fog is severe. Plants under glass suffer a great deal more than those out-of-doors. The fogs in the country do not do any appreciable harm, so far at least as I have been able to ascertain. Gardening in the immediate neighborhood of the metropolis is growing more and more difficult in consequence of these dirty fogs in winter. The Messrs. Veitch have been compelled to remove the whole of their seedling Orchids to Slough, out of the reach of the London smoke, and Mr. Seden is now able to continue his work of hybridizing and plant-breeding in an atmosphere much more congenial than that of Chelsea.

Pleiones have been very good here, in spite of early fogs. A delightful bank of *P. lagenaria* was for a time the most charming feature of the Orchid-house. The plants are grown in pans a foot across, and on some of the pans I counted over eighty expanded flowers. Some plants of *Adiantum cuneatum* were arranged with the Pleiones, producing a pretty effect. These have been succeeded by equally good pans of *P. Wallichiana* and *P. maculata*. After these come *P. humilis* and *P. Hookeriana*. The Pleiones are amongst the easiest of plants to manage. As a rule, they fail through excessive heat. They are alpine plants, requiring cool or green-house treatment, except during the period when growth is most vigorous. This is usually about the end of March or in April and on until June, an intermediate temperature with an abund-

ance of moisture being then most suitable for all of them.

We are promised a considerable increase in the number of great plant exhibitions to be held next year in London. The Royal Aquarium, Westminster, caters for the public by providing attractions of a very varied nature, from white kangaroos to cannibals and Samsons. The success of the Chrysanthemum exhibitions held there has no doubt determined the authorities to compete with the Crystal Palace, the Botanical Society and the Royal Horticultural Society next year in the matter of exhibitions of plants generally. They propose to hold an exhibition on each month from March to November, and offer substantial prizes. Flower shows are supposed to foster a spirit of emulation among the crowds who go to see them, and perhaps they do a little good to horticulture by showing what has been or can be done—a kind of reporting progress. But it is easy to overdo this kind of thing; and we are not quite sure that shows which have gate money as their sole object are not to be condemned on that account. You do not appear to hold many plant exhibitions in America. Is it because the people do not believe in them, or because you have not time?

CHATSWORTH.—The very interesting notice of this famous ducal residence which appeared in a recent number of GARDEN AND FOREST has been read with pleasure here. English horticulturists are proud of Paxton and his works, and Mr. Downing did not say one word more in praise of Chatsworth and its gardener than they deserved. You may be interested to learn that Paxton was what is known as a "Chiswick lad," for it was at Chiswick that the Duke of Devonshire saw and liked him and finally engaged him as gardener. I believe his wages started at twenty-five shillings per week. After he was knighted, Paxton was member of Parliament for Coventry. Chatsworth is still a grand garden; but it is not the only one, as it was, perhaps, when Paxton was its head. So far as I could judge when I saw it a year or two ago, the keep of the gardens was first-rate, and the cultivation of some things exceptionally good. The present gardener, Mr. Owen Thomas, is known as a man of exceptional ability. Chatsworth may be looked upon as a kind of Kew for the Midlands, as it is open to crowds of visitors at almost all times. Cheap trips to Chatsworth from Sheffield, Chesterfield, Lincoln, Derby, and other towns, are often arranged, and many hundreds of people are allowed to walk through the grounds, the houses and the palace on certain days.

Copper Sulphate against Fungi.

EXPERIENCE during the summer of 1889 encourages the belief that we have in the solutions of copper sulphate a defense against many of the fungus pests which so seriously threaten the prosperity of our agriculture. In 1888 the efficacy of what is known as the Bordeaux Mixture as a preventive of mildew and Black Rot of the Grape was fully proved. This year experiments have taken a wider range, and many of the so-called diseases of plants have been successfully treated. The Apple-leaf rust (*Rastelia pyrata*) succumbs to an occasional spraying with the Bordeaux Mixture. The Quince blights (*Morthiera Mespili* and *Hendersonia Cydoniæ*) are likewise prevented, and the fungus which causes the blight of leaves and cracking of fruit of the Pear may now be regarded as under the control of the copper solutions.

The prevention of this Pear fungus, *Entomosporium maculatum*, is, perhaps, of greater advantage in the nursery than in the orchard. Where the disease is epidemic in the nursery it places a veto upon the budding and grafting of young Pear stocks. The leaves are destroyed just when their aid is essential to the vitality of the bud or cion. By spraying the nursery rows every three weeks during the season of growth with the Bordeaux Mixture the leaves are preserved in health and the success of the grafter's labor is assured.

But in addition to this use of the copper solution it is found to be preventive of the Tomato blight (*Macrosporium Solani*), and (which is of far wider importance to our agriculture) it prevents the Rot of the Potato, *Phytophthora infestans*. In treatment of this disease of the Potato-plant some of our experiment stations have this year been quite successful. My experiments in this line have had gratifying results. For many years in this region of southern New Jersey every attempt to grow the Peachblow Potato has been a failure. At about the time the plant is in blossom and the tubers are say one-fourth grown, this deadly blight invades the Potato field and sweeps over it like fire. I have had an acre of Peachblows showing every sign of thriftiness and giving

promise of a heavy crop, and in one week from the time of the appearance of this blight every plant was dead or dying. It is the prevailing opinion here that the Peachblow Potato is a variety which is "run out," and its culture has been generally abandoned.

Happening to see, last autumn, a few bushels of small Peachblow Potatoes for sale, I bought them for the purpose

When the plants were a foot high, and before they blossomed, I began to spray some of them with the Bordeaux Mixture, and repeated this operation every two or three weeks thereafter until nearly the last of September. The times of treatments were regulated somewhat by the weather and the frequency of heavy rains. At any rate, I aimed to keep leaves and stalks on the sprayed plats pretty thoroughly whitewashed

Fig. 148.—The Kauri Pine.—See page 579.

of giving them another fair trial under the protection of the Bordeaux Mixture. Last June I plowed a clover sod between the tree-rows of an orchard, and there planted these Potatoes in five equal plats of three rows each, manured in the row with the Mapes Potato Manure at the rate of half a ton per acre. The plats lay side by side, running north and south.

with the copper sulphate solution, so that its presence was always visible all over the plants. Whenever a drenching rain washed off the application it was renewed as soon as possible. I made the treatments with the portable Eureka spraying machine. I thus sprayed Plats 1 and 2, left Plat 3 (the middle plat) untreated, and sprayed also Plats 4 and 5.

About the time the plants blossomed the middle plat (No. 3) was, as usual, struck by the blight, and in two weeks all of the potato tops on this plat were dead and dry. The plants on the other plats were green and growing as vigorously as could be wished. They remained green and growing until killed by frost in November.

I then dug and weighed separately the total product of each plat. Plat No. 1, sprayed with Bordeaux Mixture, yielded 346 pounds of fine, large, marketable potatoes, which were sold as soon as dug for a dollar a bushel. Plat No. 3, not sprayed, yielded only 164 pounds of small-sized tubers, scarcely one of which was marketable.

The diameter of the largest tuber on the untreated plat was three inches. The diameter of the largest on the treated plat was five inches. There is a marked difference in the cooking of potatoes from the unsprayed and from the sprayed plats. Those from the plat not treated are immature and "soggy." Those from the treated plats are mealy and have all the excellence for which the Peachblow potato was formerly esteemed.

I have saved ten or fifteen bushels of these Peachblows to plant next year, in the confident expectation of a crop of 350 bushels of potatoes per acre. Under the unfavorable conditions in which these experimental plats of potatoes were grown (between rows of trees twenty feet apart and twenty years old) I did not expect a large crop. Yet the yield of the treated plat (No. 1), 346 pounds from 225 hills, is not bad, under the circumstances, being about 125 bushels per acre.

Of the Bordeaux Mixture employed the formula is: six pounds of pulverized sulphate of copper (blue vitriol), dissolved in four gallons of hot water; four pounds of fresh lime, dissolved in four gallons of cold water; mix the two solutions and dilute with cold water to make twenty-two gallons of liquid.

I believe, however, that the ammoniacal solution of carbonate of copper will be found as efficient a fungicide as the Bordeaux Mixture, and it has the advantage of being more readily prepared and more easily distributed in spray. Its formula is: carbonate of copper, three ounces; ammonia, one quart; mix. The copper carbonate will dissolve almost at once in the ammonia liquor. Then dilute this mixture with cold water to make twenty-two gallons of liquid.

From sundry experiments which I have made this year, and which I have reported in detail to the United States Department of Agriculture, I conclude that it is the copper in solution which is specifically antidotal to fungus germs, and not the other component, sulphuric acid, of the sulphate. In experimenting on treatment of the Black Rot of the Grape I tried quite extensively a mixture made similarly to the Bordeaux Mixture, only substituting sulphate of iron (copperas) for the copper-sulphate. This mixture had no effect whatever in prevention of Grape Rot. I saw some benefit from its use, however, in prevention of leaf mildew, and it is quite likely that it may be found sufficiently effective for treatment of the blights of the Potato and Tomato. It is much cheaper, pulverized sulphate of copper costing about eight cents per pound, while copperas costs only seven-eighths of one cent per pound.

Further experiments are required to teach which of these fungicides may be the preferable one, and for what uses. Certain fungi will endure with impunity applications under which others will perish, and certain varieties of plants are damaged by chemical solutions which do not harm others. Thus, the Tomato plant will not tolerate a spraying with Bordeaux Mixture as it is used for the Potato. The mixture for the Tomato must be reduced in strength at least one-half. Nor will *Vitis aestivalis* endure spraying with copper sulphate mixtures, which do not injure the vegetation of *Vitis Labrusca*.

My counsel to those who purpose engaging in these vegetable therapeutics is to go slow. When all ready for spraying try only a few patients at first, and wait to note the effects of the medicine. Otherwise there is great danger of learning pathological wisdom as did the quack doctor who found out in his practice that "what cured the shoemaker killed the tailor."

Vineland, N. J.

A. W. Pearson.

Bleaching and Keeping Celery.

THE Dwarf Celeries now used by most cultivators are grown on a level surface in rows four to six feet apart. Handling is the first work toward bleaching. I use cotton cord, and tie it loosely around the first plant, and then passing the string to the next, take a turn around this, tying it the same way, and continue through the row without breaking the cord, which is tied to the last plant. In this process all the leaves are gathered and tied firmly enough to hold the plant erect and compact. If tied too tightly the Celery, as it grows, will double back when the string is reached and injure the ap-

pearance of the heart. After the Celery is banked with earth, the string rots under the ground and gives no trouble at the time of digging.

Many methods of bleaching are practiced. During the past season I saw heavy paper tied about the plants by one grower, and earth was then drawn up against the paper. Another grower placed corn-stalks against the plants to hold them upright, and then banked against these. A third tied each plant separately with tobacco cord, and left them without banking and exposed to all weather till November 1st, when they were carried into deep hot-beds to bleach under leaves and boards. Another banked the plants half way up, and still another covered Celery almost to the tops. This last lot bleached in from two to six weeks, according as the weather was warm or cool.

The warmer the place in which Celery is kept, the quicker the bleaching will be complete. In early fall, bleaching causes little trouble, whether it is done by tile, paper, boards or earth.

The great difficulty is to keep Celery through the winter into late spring. That intended for late keeping ought to be left out-of-doors in the rows until severe freezing is threatened, and it should be banked half way up at least. The part out of ground should be protected from hard frost, for this makes the stalks hollow. After the plant has been taken from the ground it will still continue to grow. If the leaves are green when stored, they will remain green, and a growth from the centre will appear, which will always be white. Celery partly bleached when brought in will be better in quality than if the whole process of bleaching be left till after digging from the garden.

Darkness with a temperature of sixty degrees in the cellar will fit celery for the table quickly. If it is to be kept until spring, then a temperature as near forty degrees as possible should be maintained. Last season I saw 100 roots brought in before a hard frost and set on a cellar floor and against the wall, in a space ten by four feet and filled in with dirt half way up the stalks. The hatchway-door above was open daily, and the winter air drifted down upon the Celery, which kept until April, when more than half of each bunch, as put in, in the fall, was eatable. The tops were kept cool and often frozen, while the dirt between kept the stalks crisp; there was no furnace in the cellar. I see no advantage in trimming the roots before bringing them into the cellar.

West Springfield, Mass.

W. H. Bull.

Winter Flowering Plants.

AT this dull season of the year some change in arrangement and a few bright flowers make a great difference in the appearance of the plant-house. As it is rather early for many of the most showy flowers, as, for instance, Primulas in variety, Narcissi, Calceolarias, Cinerarias and Azaleas, we must look elsewhere for the glow of color which is needed. It is true that some of these plants may be had in bloom during the winter by a little forcing, but they are more often looked upon as spring flowers only.

For winter flowering some of the *Eranthemums*, though considered by many as rather too old-fashioned, will be found very useful and effective, and they have the additional merit of being among the easiest to cultivate. This is an extensive genus of plants, many of which are natives of the East Indies, and, although some of the species are rather weedy, yet there are a number of very pretty ones among them, and it is to a few of these that attention is now directed.

Perhaps the oldest, and certainly one of the prettiest, of the *Eranthemums* is *E. pulchellum*, its flowers being of a rare shade of vivid blue. It is a rapid grower, and if generously treated will give an abundance of bloom, and though the individual flowers do not last long, yet, as they open in succession on the spike, the plant continues to make a show for a considerable time. *Eranthemum tuberculatum* is another fine species. It is of slender growth and shrubby habit, the branches being more or less marked with small, knotty tubercles. Its nearly white flowers are produced from the axils of the leaves in great profusion. *Eranthemum Andersonii* is also a notably pretty member of this family, though perhaps less frequently seen than the two previously mentioned sorts. *E. Andersonii* forms spikes of bloom from six to eight and sometimes even ten inches in length, while the flowers are quite showy, the upper lobes being pure white and the lower one dotted with dark crimson.

While speaking of *Eranthemums*, it may be well to state that one kind, at least, *E. atropurpureum*, is a useful plant for bedding out in summer, its dark, glossy foliage being somewhat similar in color to that of *Achyranthes Lindenii*, though rather broader and more showy than the latter.

Either of these *Eranthemums* may easily be rooted as cuttings, and will flourish in almost any moderately light soil,

though, to make shapely plants, they should be pinched occasionally as the growth proceeds.

Another group of pretty dwarf growing plants are the Aphelandras, which are not only ornamental in flower, but also have handsome foliage. One variety in particular, *A. nitens*, is specially noticeable in this respect, the upper surface of the ovate leaves being a very glossy olive green, while the under side is dull purple, and this, contrasted with the brilliant scarlet of the flowers, gives a very striking effect. *Aphelandra Ræzii* is also a good variety, and its foliage offers a great contrast in coloring with the preceding species, the leaves of *A. Ræzii* having a silvery appearance. The flowers of this species are bright orange in color, and are produced in terminal spikes in common with the other members of the genus.

Another Aphelandra of rather more recent introduction is *A. fascinator*, also prettily marked in foliage, and a rapid grower, though the leaves have less substance than those of the last, and are consequently more subject to the attacks of red spider unless grown in quite a moist atmosphere and fairly well shaded. In addition to the above there are several other Aphelandras in cultivation, though some of them may be less easily procured than those to which special reference has been made. *A. aurantiaca*, *A. Liboniana* and *A. variegata* are all interesting.

The Aphelandras will make satisfactory progress if potted in good loam, rather sandy, to which may be added a small proportion of peat if convenient, although it is not absolutely essential to their welfare. Their propagation is easy, either by cuttings or from seeds, the latter being preferable, as seedlings not only make the best shaped plants, but there is also less trouble from insects when they are grown by this method, because old plants kept for stock are very liable to become infested with mealy bug and scale. As to temperature, sixty to sixty-five degrees will be found to suit the Aphelandras, though a somewhat lower temperature will not specially injure them. In the winter, full sunlight should be given, while some shading is necessary in summer.

Orchid Notes.

Oncidium varicosum.—This showy Orchid is one of the most valuable for cutting. Its golden yellow flowers are borne on large branching panicles, often three feet in length and bearing 150 to 200 flowers at one time, and these will remain in perfection nearly two months if the atmosphere is kept dry and cool. It is advisable, however, not to allow the flowers to remain on the plant so long, for it is liable to be considerably weakened, and it will eventually be killed if this course is persisted in. There is a fine variety named *Rogersii*, in which the lip measures two and three-quarters inches across; but this plant is exceedingly scarce, though many inferior varieties are sold under this name. A part of the typical plant is in the collection here. *Oncidium varicosum* was introduced about twenty years ago from Brazil, where it has a wide distribution, and, under varying conditions of climate, varies a good deal in size and habit. It grows freely in the intermediate house, requiring liberal treatment during the growing season. It should be shaded from the sun no more than necessary to keep the leaves from being burnt, and it dislikes much potting material around its roots—a thin layer of moss is sufficient; baskets are preferable to rafts or blocks. I find the plants deteriorate rapidly after being a year or so on the blocks.

Odontoglossum Kramerii.—This very rare and attractive little plant is now in flower with us, and is doing fairly well in a basket of moss in one corner of the Phalænopsis-house. It is said to be found in only one locality on a mountain-slope in Costa Rica, and was introduced from there in 1868 by Kramer. It is a small growing plant, with compressed ovate bulbs with one oblong-lanceolate leaf about seven inches long. The ascending scape bears three to five flowers one and a half inches across. These are white, shaded to violet in the centre. The clawed and half-round lip is two-lobed at the apex, dark violet, with bands of white and reddish brown at the base. The general appearance of the flower reminds one of the better known *O. citrosum*.

Kenwood, N. Y.

F. Goldring.

Cattleya Walkeriana is a splendid dwarf species, with bulb-like stems from two and one-half to four inches high, bearing an oblong-elliptic, obtuse, leathery leaf, with one, and sometimes two, beautiful rose colored flowers, the lip of which is of a richer rose than the other parts and has a very slight tinge of yellow. The flowers often measure from four and a half to five inches across. We generally have our plants bloom in November and they make a very fine display at this dull

season. The large flowers from such a small, leafless bulb always excite surprise. The blooms last from four to five weeks when kept rather cool and dry. They are very sweet scented and fill the house with their fragrance. Our plants are suspended from the roof in rather a light place, in small pans, with a small quantity of sphagnum moss and charcoal, and they flourish fairly well in this way. They do not like much sunshine.

Cattleya maxima Backhousii is a very distinct and desirable variety. The bulbs are rather short and plump, with stout, erect leaves. The sepals and petals are bright rich rose, and the lip is elegantly variegated with very dark crimson veins down the centre, and it has a beautiful yellow throat. This is, no doubt, the most beautiful of the *Maxima* type and should be found in every collection. It nearly always blooms here in October or November. We grow it both in pots and pans suspended from the roof; it likes abundant light, and a little sun appears to ripen up the bulbs and induce it to flower much more freely. Our plants are kept rather dry after flowering until they show signs of growing, and then a copious supply of water is given.

Staatsburg-on-Hudson.

F. Atkins.

Autumn Flowers.—Much has lately been written on the various shades of color to be seen in the Autumn Anemone, *A. Japonica*, ranging as they do from deep rose to pure white. In their way these plants are unquestionably without rivals for autumn decorative use. We wish to call attention, however, to a plant that flowers at the same time as the Anemones, lasts fully as long, and the color of which is a beautiful dark blue. The plant is known as *Aconitum autumnale*, although we are now informed that this is only one of the plant's many specific synonyms. It is often sold under the name of *A. napellus*, and, indeed, this is the title under which it came into our own possession; but it is very distinct from *A. napellus*, which flowers in early summer, and is not so showy as *A. autumnale*, or *A. Fischeri*, as we are to call it in future. The plant grows about three feet high, the spike is often branched so as to form a panicle, and these branches prolong the flowering period for a considerable time, and when planted with the Anemones, the combination of colors, red, white and blue, is very striking during the latter part of October. *A. Fischeri* is a native of China and is perfectly hardy. The roots are tuberous and readily admit of division for the purpose of increasing the stock, and, in addition to this means of propagation, seeds are produced abundantly, which germinate readily when sown and placed in a gentle heat.

Passaic, N. J.

O.

Gaillardia hybrida grandiflora.—Stray blooms of hybrid Gaillardias in the last week of November remind me to note that these are the most persistent bloomers among hardy plants. My plants came into bloom early in June, since which time they have flowered constantly and in profusion, and now have many buds which will not mature. This very ornamental genus has been worked up in recent years, and probably from hybridizing *G. aristata* and *G. picta*—the former giving hardiness and the latter coloring. The English florists offer constantly many new varieties, but there is a great similarity among most of them. They are usually yellow, with a more or less distinct zone of deep red, though some yellow selfs are offered. The petals are usually flattish, though sometimes quilled and fringed. A package of seed will produce many pleasing kinds, quite satisfactory to the ordinary cultivator. They bloom freely the second season from seed. The plants are entirely hardy, in this section, and rapidly increased by cuttings of the roots. Owing to this readiness to increase from pieces of roots, Gaillardias are rather difficult to eradicate from borders, unless care is taken to lift with the roots entire. They certainly may be classed among the most useful of hardy herbaceous perennials, either for show or for cutting.

Polygonum amplexicaule, var. *oxyphyllum*.—This is a Himalayan Knot weed, introduced to cultivation by Messrs. Hall-ock, of Queens, New York, under the more poetic name of Mountain Fringe. This variety, which is said to have been brought to this country several years since by Professor Gray, is a very vigorous one, too vigorous for small places, as it grows, with numerous branches, to the height of five feet. With me it came into bloom in October, bearing clusters of small creamy white flowers, which are attractive on the plant, but which soon fade after they are cut. As a sharp frost ruins the plant, shelter will be needed for it in this climate. Where bold masses are needed—in large places and parks south of this latitude—the plant will be very useful, and for persons who enjoy the foliage of Smart weed it may be used in more modest collections. But since it does not give a specially large

crop of flowers, the space it fills in small gardens can be more profitably occupied. My plants are curiously unlike the figures in the catalogues, in which they appear of a different habit and with a much larger ratio of bloom to the amount of the foliage.

The Forest.

Forestry in Great Britain.

DR. WILLIAM SOMERVILLE will deliver during the session of 1889-90 a hundred lectures on the Principles and Practice of Scientific Silviculture before the University of Edinburgh. The following extracts from the first of the series, which are taken from a report published in the *Gardeners' Chronicle*, are of general interest, and deserve careful reading and wide circulation in this country.

Dr. Somerville, in opening his lecture, referred to the great attention that was paid to forestry in Germany, India and other countries, and showed how the state forests in these countries were made an important source of revenue, and had a most important bearing on the welfare of the nation. He then proceeded: It is undoubtedly true that we have lost much through the scarcity of our state forests, for had they been present in greater numbers the regrettable condition of many of our private woodlands would not now have existed. This would have been a great gain to the country in general; but if the same improvements could have been brought about by some other means than the extension of government forests, the gain would have been still greater.

The experiences of other nations, however, tend to show that no other means have ever had very much effect. It is true that we have always managed to get along fairly well in other departments with the very minimum of state interference and example, and, undoubtedly, the independent spirit which has thus been developed has stood us in good stead in carrying us over many difficulties. But the peculiar conditions and circumstances consequent to the ownership of forests, all point to the state as being in a more favorable position to make the best use of land stocked with trees than the private individual can be. It is a great question, and one whose discussion in all its various ramifications would lead us far beyond our limits of time. Suffice it to say that the experience of nations and the investigations of political economists point to the conclusion that, although the state proves a bad farmer, it makes an excellent forester. But apart altogether from the purely economic bearings of the case, many circumstances may be present to compel a state to interfere with forest management in order to secure the public welfare. Extensive denudation near the head waters of rivers has often been followed by destructive floods, affecting not the owners of the cleared areas, but the inhabitants of districts situated, it may be, hundreds of miles away. This has been strikingly exemplified in many parts of Austria, where the wholesale removal of trees from large areas in the Tyrol, without any steps being taken to restock them, has resulted in widespread inundations and immense loss of life and property. The cause of these Austrian floods has, within recent years, been made the subject of government inquiry, with the result that the state has purchased large areas of private land in the Tyrolean valleys in order to preserve the existing forests and to restore those which have been spoiled. America can also furnish many cases of flooding following denudation. Besides the dangers of inundation, those arising from avalanches are also increased by denudation, and many valleys in Switzerland, the Tyrol and the north of Italy are comparatively safe only through the preservation of large masses of wood on the mountain-slopes. In these cases, and in many others which will readily occur to your minds, state interference in the management of forests is entirely justifiable on the grounds of public safety. None of them, however, apply with much force to our own country. At one time the maintenance of a supply of oak for the navy was a question of great national importance, but it is now only historically interesting. It would thus appear that in this country the state might very well refrain from meddling with forestry as an important department of national finance, were it not for the beneficial educational influences which would be started. On this account the state forests which we already possess should be made models of good management, and others should be obtained in important centres—care being taken to select places where the extra work would be a decided benefit to the rural population.

Dr. Schlich, in his recently published *Manual of Forestry*,

directs attention to the fact that Canada is the only British colony which supplies us with an appreciable quantity of wood. At any moment, however, these imports may cease, for even now the United States is able to take all the timber which Canada can spare. As a matter of fact, our wood imports from that colony have decreased thirty-two per cent. within the last five years, and, as they may be extinguished before other five years, we will have to depend entirely for our imported timber upon countries over whose policy we have no control. Dr. Schlich says that we import £13,000,000 worth of forest produce which we could grow at home, for which purpose the afforesting of 6,000,000 acres would be necessary. This land he believes to be all available in Scotland, and strongly urges the desirability of extended sylvicultural operations.

We have now touched upon two of the factors which have exerted their influence upon British forestry, namely, scarcity of state forests and our insular position; a third is to be found in our fortune in possessing such rich and extensive coal-fields. No country in Europe can approach us in this respect. Whereas wood is still the most important article of fuel in wide regions of the continent, it is but little appreciated for heating purposes in this country. Had the case been different, we should have been compelled to look to our forests to furnish an appreciable supplement to our supplies of coal fuel, and necessity would have forced us to bestow more care upon our forest management. Those who have given their attention to the subject tell us that we are now within measurable distance of the time when we shall have to face a diminishing coal supply, and, finally, exhausted coal-fields. Although it is probable that the question of providing a substitute for coal will not urgently demand a solution in our time, still it is undeniable that, sooner or later, it must be faced. Some enthusiastic foresters press the desirability of more extensive tree planting, so that a store of firewood may be laid up against the evil day. That there is some wisdom in the suggestion no one will deny; but Professor Heflerich's calculations with regard to the matter do not afford us a large measure of comfort. He says that if we take two and seven-tenths pounds of wood as giving the same quantity of heat as one pound of coal, and one acre planted with Scotch Pine trees as capable of yielding annually eighty-six and one-third cubic feet of wood, equal to twenty-eight hundredweight, without the capital stock of timber on the land being encroached upon; then, in order to yield the equivalent of the coal output of England and Wales, it would take a fully productive forest area more than six times the total extent of these countries, even supposing our present imports of timber to suffer no diminution. From this it is evident that, even with a largely extended area, our forests cannot be expected to furnish a complete substitute for coal, although undoubtedly they could assist to a considerable extent.

Correspondence.

Chrysanthemum Ada Spaulding.

To the Editor of GARDEN AND FOREST:

Sir:—Referring to the remarks of your Boston correspondent on the appearance of the *Chrysanthemum Ada Spaulding* at the recent exhibition in that city and to your note upon the same subject, allow me to say that I have no doubts as to the merits of this variety, but consider it one of the very best of the new kinds.

It is a robust grower, with short-jointed, heavy wood and foliage of the thickest texture. I have yet to see a single leaf attacked, either by white mildew or black rust. The flowers are of the largest size, distinctly globe shaped—that is, the lower half of the petals recurve to the stem, the upper ones incurving to the centre, thus forming a nearly complete sphere. The lower part of the flower is of a pleasing blush rose, the centre being pure white.

The flowers shown at Indianapolis were seven and three-fourths inches deep by six and three-fourths inches in diameter. It is plainly a mistake to exhibit seedlings or new varieties when not in good condition; which was evidently the case with this flower when shown in Boston. First impressions have much to do in determining whether one will ever fancy a new-comer. The flowers of *Ada Spaulding* which I saw at Orange and Philadelphia were small and not at all characteristic, and therefore they did injustice to a really valuable acquisition.

If it is the proper work of the National Chrysanthemum Society to determine which plants shall and which shall not be distributed, the task will be a difficult one. To condemn a

plant is a serious matter in many cases. It not only discourages the tyro from persevering, but the judgment may be unsound. It is easy to pass by varieties that are not at their best when shown before a committee, and as the legitimate season of the *Chrysanthemum* extends now from the 20th of September until the 20th of December, varieties may be neglected which may be very good either early or late. There are few *Chrysanthemums* in which I can see no beauty, but for the best interests of all there must be a limit to the propagation of varieties which are at best duplicates of existing kinds.

Pearl River, N. Y.

John Thorpe.

A Lesson in Transplanting Evergreens.

To the Editor of GARDEN AND FOREST:

Sir.—During the month of August last I witnessed the transplanting of several hundred Austrian and Scotch Pines. The result was the loss of nearly the whole lot; and it was such a surprise to me that I think the facts in regard to it worth recording. The weather was all that could be wished for, being warm and moist, and the soil was in the same condition. The Pines had been growing close together in rows and were from four to five feet high. As they were not as bushy as could be wished, we thought best to prune them in well, and, after the transplanting, a man was sent with shears to clip them closely. This he did, cutting off all the latest growth, taking from six to ten inches from the branches. Out of 300 plants all were so trimmed except some half dozen, which were purposely left unpruned to see which would do the better. At that time I confidently expected that the pruned trees would show the benefit of the work. However, they soon began to turn brown, and in the end every one died, while every one of the few left unpruned are alive to-day.

As soon as it was observed how the matter was going to end, another row was set out, unpruned, and all the plants in it are thriving to-day. No doubt the severe pruning was the cause of this failure. All the younger or active foliage had been cut away, leaving only that which was past its usefulness and which was about ready to drop off. The trees were, in fact, in just the same condition that a deciduous tree would have been if stripped of all its leaves in the middle of summer. It was a costly but a most valuable lesson and one worth putting on record as a warning to others.

Germantown, Pa.

Joseph Meehan.

Variegated Wild Plants.

To the Editor of GARDEN AND FOREST:

Sir.—I found in 1888, near here, a prettily variegated form of *Polygonatum biflorum*, and it has kept its variegation during two years of cultivation. In the garden of a friend there is a plant of *Symplocarpus fatidus*, the foliage of which is suffused with large white blotches, and he tells me this is the second he has found in his wanderings. Variegated plants of *Capsella Bursa-pastoris* and *Portulaca oleracea* are frequently to be met with here in the summer months. These instances are offered in response to the suggestion of Dr. Sturtevant.

Passaic, N. J.

E. O. Orpet.

To the Editor of GARDEN AND FOREST:

Sir.—In your issue of November 6th a correspondent asks for additions to the list of variegated wild plants, which he gives.

Rudbeckia hirta.—On marshy land near Klinger Lake, Michigan, I noticed for the first time, in 1887, a number of plants upon which the yellow rays were variegated with brown. This year more regularity and deeper coloring was observable, and in one instance, at least, a distinct circle at the base of the cone.

Dorcas E. Collins.

Klinger Lake, Mich.

Recent Publications.

Annual Report of the Royal Botanic Garden, Trinidad, 1888. By J. H. Hart, Superintendent. Handsomely illustrated with a series of views of several of the most interesting trees in the garden, including a fine specimen of the Traveler's tree (*Ravennala Madagascariensis*), of the great Bamboo, the Palmyra Palm (*Borassus flabelliformis*) and of other Palms.

As a scientific station the value of the Trinidad garden is very great, and much of its present success is due to the energy of the new superintendent, who is doing wonders in his efforts to develop the material prosperity of the British West Indies, by the publication of bulletins on various useful plants, and by the introduction of others from different parts of the tropics. The Trinidad garden, too, is the richest and

most beautiful probably in the tropics of the New World, and there is no spot where so many interesting plants of the tropics can be seen growing together which can be so easily reached from this country. It is gratifying, therefore, to read in Mr. Hart's report that the number of Americans who take advantage of this opportunity and visit the garden is steadily increasing, and that "the amount of energy and enthusiasm shown by visitors from the north is something surprising—certainly eclipsing anything seen from the European side of the world."

Department of Agriculture, 1888. The Report of the Botanist, by Dr. George Vasey, contains a description, with figures, of a number of Grasses of economic value, to which are added accounts of the western Plantain (*Plantago Patagonica*), a native of South America, but now spread into various parts of North America, and extending as far north as British Columbia on the Pacific side of the continent, and to New England on the Atlantic; of *Lygodesmia juncea*, a perennial weed common in the Rocky Mountain region, especially pernicious in vegetable gardens; and of *Solanum triflorum*, a wild Potato found growing from New Mexico into British America. A paper upon the *Pastoral Resources of Montana*, from the pen of Mr. F. W. Anderson, is appended.

The Bulletin of Miscellaneous Information from the Royal Gardens, Kew, for October, contains articles on the *Bahia Pissava*, a valuable fibre obtained from the leaf-stalks of the Brazilian Palm (*Attalea funifera*), largely imported into Great Britain, and on *Seedling Sugar-cane plants* at the Barbadoes; on the cultivation and production of the very successful *Cinchona* plantations in Jamaica; on *Gambier*, largely used in tanning and obtained from *Uncaria Gambier*, a climbing plant, native of and largely cultivated in the Strait Settlements of the East Indies, and on *Fibre Industry* at the Bahamas.

Hooker's Icones Plantarum. The October issue completes vol. xix. of the entire series and contains figures of several of the small Orchids of the Indian flora now in process of elaboration, by Sir Joseph Hooker, for his *Flora of British India*; and a continuation of the remarkable new Chinese plants which Dr. A. Henry has discovered in the western provinces. The most interesting of these are *Tetracentron Sinense*, a new genus of *Magnoliaceae*, a tree twenty to fifty feet high, with the habit of *Cercidiphyllum*, but with the flowers in long spikes; *Toricellia angulata*, the Chinese representative of a genus known previously in the Himalayas only, and belonging to *Cornaceae*; *Cercis racemosa*, an exceedingly handsome shrub or small tree, well marked by its loosely racemose inflorescence; no less than eight new species of Maples; a new genus in *Sapindaceae*, *Dipteronia Sinensis*; and several other plants which need not be enumerated to show the richness of the flora of western China in new forms, and the service to science which Dr. Henry has performed in making them known.

Notes.

The fifteenth annual meeting of the New Jersey State Horticultural Society will be held at Trenton, on Wednesday and Thursday, the 18th and 19th instant.

At one of the horticultural exhibitions held in the Exposition grounds at Paris last summer, eighty-five new varieties of Potato were shown by M. Rigault, of Croslay.

Lilium Harrisii is already found in quantities in our flower markets. This is five or six weeks earlier than usual, and it shows that florists have learned how to force these flowers more rapidly.

The Yellow Chrysanthemum, H. E. Widener, which received the Blanc cup for the best new seedling at the Philadelphia Exhibition, has passed into the hands of Mr. E. G. Hill, of Richmond, Indiana, who will send it out.

A novelty at the World's Fair in Paris was the exhibition of a group of Orchids, chosen simply for the beauty of their foliage. With the exception of *Odontoglossum Alexandrae foliis variegatis* all were natives of eastern Asia.

Barnard College, the new institution for women connected with Columbia College in this city, recently opened with a Freshman class of twenty girls, nine of whom will devote themselves exclusively to the study of botany.

An illustration of *Pilogyne punctata* was published in the *Illustrirte Garten Zeitung*, of Vienna, for November last, with a brief note highly commending the plant. A fuller description of it, with directions for cultivation, was given in GARDEN AND FOREST on the 18th of November.

M. Bruant, of Poitiers, writes to the *Revue Horticole* that he has obtained some hybrids by crossing *Rosa polyantha* with the common Bengal Rose. The plants begin to bloom early and continue to bloom a great part of the summer, when the flowers are succeeded by persistent fruit of a bright red color. A cluster of the fruits was said to make an interesting ornament.

According to *Gartenflora*, the well known variegated *Tradescantia* (*T. zebrina*) is an unfailling in-door weather prophet, if grown where it can receive the sun even for a short time daily. In the flowering season it will be filled with a multitude of buds, but these will expand into the delicate lilac flowers only when a storm is near at hand. *T. viridis* is said not to exhibit this peculiarity.

A correspondent of a German periodical writes that he possesses a variety of the common blue Chicory with white flowers, and finds that it is often thought by those who admire it to be an exotic novelty. He suggests, therefore, that horticulturists would do well to keep their eyes open in the woods and fields, as they might find other pretty things that would repay cultivation even in a commercial sense.

Flowers were in great demand in New York for the Thanksgiving holiday. Fine American Beauty Roses retailed for a dollar each, and the same price was paid for the very best Grandiflorum Chrysanthemums. Violets retailed at five dollars a hundred. They are very scarce, owing to the disease, which seems more prevalent and virulent than ever this year. The unusual number of damp and rainy days may account for the increase of the disease.

The last number of the *Bulletin of Miscellaneous Information* issued by the Director of the Royal Gardens of Kew (that for November) contains articles on *Phylloxera Regulations* at the Cape; on *Collecting and Preserving Fleshy Fungi*; on the attempt to promote in Labuan the cultivation of the plant which produces palm oil (*Elais Guineensis*), and on the different machines, lately exhibited in Paris, for the preparation of the fibre of the Ramie or Rhea-plant (*Bahmeria nivea*).

Our readers know that the *Victoria Regia* has been cultivated out-doors in Massachusetts, for an illustration of a successful result was shown in these pages some months ago. It was not until the past summer, however, that the experiment was made in Europe. Near the Mexican Pavilion, in the Exposition grounds at Paris, was a small tank where three plants flourished, and in the middle of August produced their immense flowers. They had been brought from their native home in boxes, and sunk, boxes and all, in the basin, which was warmed with water drawn from the elevator machines in the Eiffel Tower.

From 1,000 Prune trees, five years old, Captain Guy E. Grosse, of Santa Rosa, California, has this season dried five tons of fruit, which he is delivering at the Southern Pacific station for eastern shipment at four and a half cents a pound. The rapid maturing of a Prune orchard, after arriving at the fourth year, is shown by the increase in the crop of this year over that of last year, when the yield was but 1,200 pounds. Next year it is expected the crop will be trebled. At four and a half cents a pound, the proceeds from the 1,000 trees this year equals \$450. In two years more it should be nearly \$3,000.

One hundred and twenty-nine thousand eight hundred persons visited the Niagara Reservation during the months of July, August and September last. A new stairway to the Horseshoe Fall has been built; the old art gallery has been turned into a library; an iron railing, 200 feet in length, has been carried around on the steepest shore of Goat Island; the stone foundation of Prospect Park has been rebuilt, and many walks have been repaved or macadamized. Money has been appropriated for the establishment, at the "Old Garden," of a nursery, whence material for planting can be drawn in future years.

Floral decorations are taking their place among advertising expedients. At the recent opening of a large retail store in Washington, the interior of the seven-story building was almost covered with groups of Ferns and Palms and large "set pieces" of brilliant hue, and with wreaths of Asparagus and Smilax, while the great show-window was arranged as a sort of conservatory—banked with Ferns and filled with flowering plants surrounding a small glass lake in the centre, the firm's stock of furnishing goods being illustrated by an intermingling of lace curtains, rugs and ornamental seats. It seems doubtful whether the effect can have been very artistic, but one can well believe that it served its main purpose by "attracting great attention."

Mr. Peter Henderson exhibited in his windows in Cortlandt Street, last week, a selection of Chrysanthemum flowers, including a number of new importations from Japan. Besides the new pink one in the style of Mrs. Hardy (Louis Böhmer), there was also shown another numbered 22, with large tubular florets, with coarser glandular hairs. Mr. Henderson's new collection comprises a number of fancy kinds, quilled and tasseled. One of these, number eight, has very narrow florets, which are so tightly twisted that they look like long, slender tubes, the lower half of which are crimson and the upper half bright yellow. They are gathered in a cluster like a plume, the florets curving gracefully outward. There are three others of this type, a pure white, a crimson and white, and a pink. They are dwarf and bushy in habit, very floriferous, and quite distinct in character from any other Chrysanthemums that have come under our notice.

The color and texture of rocks, especially when they rise in almost perpendicular walls, form a noteworthy feature in many landscapes. The soft, mellow tints of the buttresses of the Natural Bridge in Virginia will occur to many persons as an illustration of this, and all who have traveled among the northern Rocky Mountains have observed the rich color-effects upon the cliffs of that region. Writing of Lower California, Mr. C. R. Orcutt, in the *West American Scientist*, says: "No small factor in producing a pleasing effect in the scenery here is the great variety of rock-lichens everywhere prevalent. Red, yellow, gray and white are the prevailing colors observable, and the whole side of a cliff is often covered by lichens of the same tint. How many valuable mines may be hid from the prospector's keen eye by these deceptive colorings? Quartz, however, is not a favorite rock with the lichens and consequently is seldom concealed, while the lichens also frequently imitate, in coloring, the natural color of the rocks on which they are found."

One of the most interesting and valuable results of recent French horticultural effort is found in the new race of dwarf Cannas, with large and brilliantly colored flowers, produced by M. Crozy, of Lyons. A large bed of these plants in the garden of the Trocadéro, in Paris, was surrounded all summer by crowds of people. Too much has not been said of the beauty of these plants and of their value for decorative purposes, whether planted in the open ground or grown in pots or tubs. The colors of the flowers of some of the varieties are surprisingly brilliant. There seems no good reason, however, for calling the plants "dwarf," except that they begin to flower when they are not more than twenty inches high, for they grow, especially in this country, when generously treated, to a height of six or eight feet. Seventeen of the new varieties exhibited at Paris for the first time, which, on the whole, are no better than those sent out by M. Crozy during the past two years, are described in a recent issue of the *Revue Horticole*. No one who has not seen a collection of M. Crozy's Cannas in good condition, can form the faintest idea even of the beauty and the brilliancy of the flowers of the plants.

A recent writer in the *New York Sun* says that the name of Maine should be changed from the Pine-tree to the Spruce-tree State. "In the early days of lumbering," he explains, "pine made up the greater part of the cut, and little else than pine and spruce was sought for. The pine was mostly sawn into boards, and a large part of it was shipped to the West Indies, where it was exchanged for Spanish gold, molasses and sugar. While this traffic lasted Bangor's foreign trade was lively. A big fleet of the old-fashioned brigs and schooners found employment in a trade which paid good freights. Cargo after cargo of the wide, clear, White Pine boards went out to Cuba, Porto Rico and the Windward Islands, and other cargoes of the sweets of the Antilles came back. Loggers and river-drivers earned great wages; the big pine was rapidly cut away and began to grow scarce. Then came a change, the decadence of the pine and the ascendancy of the spruce, the decline of the West India business and the opening of a new era in the lumber trade. In 1855 123,000,000 feet of pine were surveyed at Bangor, and only 78,000,000 of spruce. Ten years later things had changed about, for in 1865 the survey was: spruce, 107,505,867 feet; pine, 48,296,222 feet. In 1889, out of a probable survey of 150,000,000 feet, less than one-sixth of the amount will be pine, and that mostly second growth. There are lots of big Pine trees left in Maine, but they are far away to the north, and no great operations are now carried on for that kind of lumber. Some pine is cut to supply a limited demand, mostly local, but the large markets are now supplied from Canada and Michigan. This is the age of spruce in Maine."

Trees in Winter.

TREES, to many persons, are attractive only when they are clothed with leaves, and many people whose interest in them is considerable do not notice those peculiarities which make it easy to recognize one tree from another after the leaves have fallen. But to the real lover of trees, they are equally beautiful and interesting at all seasons of the year; and no one can pretend to know trees well who cannot distinguish the different species as quickly and as easily in winter as in spring or summer. If trees are considered from an ornamental point of view only, almost every one of them has some special and peculiar beauty which is only displayed in winter. The fine spray of the Beech is seen only at this season of the year, and there is no more beautiful object in nature than the delicate ramifications of the American Beech seen against the clear blue sky of a brilliant winter day. The sturdiness of the Oak is only realized in winter, when the knotted strength of its limbs is not disguised under their covering of leaves. The Birch is a far more graceful and attractive object in winter than at any other season of the year; and what is there more stimulating to the imagination than to stand on a clear winter's day and look up into the marvelous structure of one of the great Elms which, here and there, still grow near some of our northern rivers? The bark of all trees appears, at least, more beautiful in winter than at other seasons, because the eye, undisturbed by the contemplation of masses of foliage, can then take in all the details of its varied texture and wonderful colors.

The artist and the mere lover of beauty will be well repaid by constant visits to the woods in winter; but for the student of trees—that is, for one in search of accurate knowledge concerning them—it is as important to study trees in winter as in summer. It is not easy to imagine that there are educated people in a community like this who can mistake a Birch-tree for an Oak in winter; and yet there are thousands of people who drive or walk in the parks every winter of their lives and never see the slightest difference between one mass of naked branches and another. And yet the differences between the various families of trees are clearly enough defined to make their recognition easy

and fairly certain. Nor is it difficult to determine the various species when once the characters peculiar to each are fixed in the mind of the observer; and such characters are often more constant and stable than characters derived from the shape of the leaf or from the size and shape of the fruit upon which people, who are not scientific botanists, depend generally to identify any given tree. Each species of tree has its peculiar habit, which may be seen at a glance in winter, and which it retains always, unless the individual has been subjected to some abnormal conditions. The character of the bark rarely changes on individuals of the same age, although the bark of old trees is often very different from the bark of young trees of the same species. The color of the branchlets and the character of the winter-buds often afford certain means of determining closely related trees. The winter-buds are quite distinct on each of the six or seven Magnolias which grow in the American forests, and no one who has studied these trees has any difficulty in distinguishing one species from the others by a glance at a winter-bud. The winter-buds of our Hickories are all different on the different species and always constant, and as individuals of the species vary greatly in their leaves and fruits, botanists are sometimes obliged to fall back on the winter-buds in order to be certain of their determinations. And in every tree there is, in addition to its general appearance, which is in itself sufficient to make its recognition easy with a little practice, some special character which will enable the lover of trees to confirm his first impression, and to distinguish a particular species of Oak, or Hickory, or Poplar from every other.

A knowledge of trees, the ability, at least, to recognize and identify them, adds vastly to the pleasure of every one who walks abroad where they grow. One meets and greets them like old friends. Every season invests them with a new charm, and the more we study them, the greater will be our admiration of the wonderful variety and beauty which they display in winter.

The handsome Silver Fir, *Abies Veitchii*, was discovered on Mt. Fusi Yama, in Japan, in 1860, by Mr. J. G. Veitch, and was described by Dr. Lindley in the *Gardeners' Chronicle* of January 12th, 1861. Mr. Veitch, who was instrumental in introducing at that time many Japanese plants into England, did not succeed in bringing home living specimens of the Fir which commemorates his services as a botanical explorer; and *A. Veitchii* remained unknown in English gardens until 1879, when Maries, a collector sent to Japan by the Veitches, succeeded in introducing it. Mr. Thomas Hogg sent, in 1876, a number of Japanese plants to the Parsons Nurseries in Flushing, New York, and among them was a Fir to which Mr. Parsons gave the name of *Picea Japonica*, under which name he has propagated and sold it. We are able now to identify Mr. Hogg's plant with the *Abies Veitchii* of Lindley, so that the irregular and unpublished nursery name may be disposed of finally. The interesting feature in this matter is, however, that this tree, which was particularly desired in England, and for the introduction of which special efforts were made, was cultivated in this country for three years before it reached Europe, and that no one knew anything about the Flushing plant, or took the least trouble, apparently, to find out what it was.

It is, of course, too early to speak of the value of this species as an ornamental tree in this country. Mr. Hogg's plant, still in the Flushing Nursery, is fifteen or sixteen feet high, with a spread of branches twelve feet across on the ground. The foliage is thin and poor, and the lower branches are failing. The ornamental value of the species, however, cannot be judged fairly by this specimen, as it is planted in poor soil, and has evidently been starved and neglected. The smaller specimens in Mr. Hunnewell's Pinetum at Wellesley, imported from England, and in Mr. Dana's garden on Long Island, are in excellent health, deeply colored, and promise to develop into handsome

specimens. As *A. Veitchii* is a species which grows only at high elevations on the mountains of central Japan and far north on the other islands, there is no question of its hardness. It is, according to Rein, distinguished by its red bark and by the brilliant bluish white color of the two bands of stomata on the under surface of the leaves, which give it a peculiar and striking appearance. It grows in its native forests sixty to ninety feet high, with a diameter of trunk which rarely exceeds two feet. The wood is described as moderately fibrous, splitting easily, and as being lighter and less elastic and firm than that of the Momi (*A. firma*), and therefore not as highly prized.

The result of a suit brought by the Government in the United States Circuit Court, against John R. Hite and John W. Snyder, shows the difficulty which exists in protecting the forests on the public domain of the United States, and the feelings of the people in western communities on subjects relating to forest preservation. The defendants in this suit are wealthy residents of Mariposa County, California, who had, it was claimed, been engaged in cutting timber unlawfully on Government land during the ten years between 1877 and 1887. The amount of damages claimed by the officers of the Government was \$91,000. The stolen timber was sawed in a mill owned by Hite, situated about fifteen miles from Mariposa. There seems to have been no great difference of opinion on the facts in the case, and the Government had little difficulty in establishing the existence of the depredation and the employment of the timber. The jury, after deliberating for five hours, returned a verdict in favor of the Government, fixing the damages, however, at only \$5,000. The letter of Mr. Shinn, on another page of this issue, should be read in the light thrown upon it by such incidents as this if we are to appreciate the full dangers to which our western forests are exposed.

"Ornamental Planting" in Paris.

SO frequent is the inappropriate use in our public and private pleasure-grounds of formal flower-beds, isolated exotic plants and bright-hued shrubs and trees, that the untraveled observer may be pardoned if he concludes that Americans must be exceptionally devoid of a feeling for true landscape-art. But, no matter where his landing-place on European soil may be, the American soon discovers that his countrymen are not alone in their sins. There, as well as here, he finds some parks, where the original "natural" scheme has been kept free from inharmonious details; but many others will be found where such a scheme is ruined by the tasteless devices of so-called "ornamental planting." Indeed, certain mistakes in treatment are common abroad, which have not been introduced here, and injudicious planting is more conspicuous to-day in the pleasure-grounds of France and England than in those of America. Perhaps the most striking instance in point is that of the Parc Monceau in Paris—the most striking because the park itself, if freed from its deforming details, would be the loveliest of the smaller urban parks of the world.

The Parc Monceau lies directly north of the Rond Point of the Champs Elysées. When first laid out in 1778 by the landscape-gardener, Carmontel, it was well outside of the city and was then considered one of the most beautiful "English gardens" in France. What remains of it to-day leads one to believe that its reputation was well deserved. A decree of the Convention in the first years of republican rule ordered the establishment, within its limits, of various buildings of public utility, but its distance and lack of easy communication with Paris preserved it from actual injury. After some changes of ownership, in 1852 it was constituted public property. In subsequent years the development of the now splendid quarter in which it lies necessitated the reduction of its area to about twenty-two acres, something less than one-half of its original size; but the reserved portion was carefully respected, and to it were transferred certain interesting architectural features that had stood elsewhere. The wide Boulevard de Courcelles now runs along its straight northern side, where a gateway, in its tall iron railing, opens between two porters' lodges. The other three sides are curved in outline, and the southern, where there are two smaller entrances, is encircled by a row of fine residences each having its small garden opening on

the outer alley of the park. But what gives especial beauty and character to the Parc Monceau is the design of the two chief approaches—on the east where it is entered from the Avenue Velasquez, and on the west where the Avenue Van Dyck leads out into the wide Avenue Hoche and thus directly to the Arc de Triomphe. Each of these short avenues is planted with double rows of fine Plane-trees, and flanked by sumptuous private houses, set back in large and shady gardens. They form, therefore, approaches of much stateliness, where the effect is semi-architectural, semi-verdurous, and make an admirable transition between the rigidity of the ordinary streets beyond and the "natural" design of the park itself. Where each avenue meets the park, moreover, there is an elaborate high barrier of wrought iron, profusely gilded, with great central gates—works of the forger's art, which have become famous as among the very best produced in modern times. Between these approaches runs the main roadway of the park, gracefully curved, yet not so sinuous as to render it inappropriate as a portion of one of the main routes taken by persons driving to and from the Bois de Boulogne. About midway of its length it is crossed by another driveway running between the northern and southern gates. Otherwise there is no provision for carriages, but a sufficient number of paths open up all parts of the domain to the pedestrian, for whose use it is primarily intended. These paths are most gracefully, yet simply, laid out, and, passing now by open lawns and again under groves of tall trees, offer a grateful alternation of sun and shade. It is no wonder that the nurses and babies of the neighborhood should crowd the park on pleasant days in winter as well as spring; and there is no spot where the lover of landscape-gardening would be better content to saunter, were it not for the superfluity of minor "decorative" features which the taste of recent years has seen fit to introduce. No area of its size could be more beautiful in the modeling of its surface, sinking here into wide sloping lawns, between which runs the main drive, and rising there in gentle banks crowned by thickly planted trees, among which Planes, Horse-Chestnuts and Maples are most conspicuous. No trees of remarkable size or conspicuous beauty, as individuals, can, perhaps, be found in the Parc Monceau; the planting seems to have been done with a view to the contrasting of broad, open stretches with masses of foliage, rather than to the development of fine individual specimens of tree-growth. But, given the area of the ground and its special purpose as an umbrageous retreat in the heart of the town, the scheme is a wise one; and here and there, where the lawns are largest, some isolated groups of three or four large trees of the same kind stand where they are most effective. Through the thickly planted part of the park runs a little stream, which, near a pretty grotto and rockery, feeds an oval pond partly encircled by a Corinthian colonnade. This once formed part of a rotunda begun by Catherine de Medici at St. Denis; and not far away from it is the fragment of a straight colonnade which once formed part of the old Hotel de Ville of Paris. These architectural relics do not injure the natural effect of the park, for, thickly shaded and draped with vines, they look like the remains of charming pavilions or covered walks designed for the repose of the pedestrian. They add, indeed, to the romantic effect of the scene and cannot be called inappropriate, since it is confessedly an urban and not a rural pleasure-ground.

But how the hand of the gardener has defaced this charming park! All along the borders of the roads and paths formal flower-beds of large size and crude color are thickly distributed; the rising banks are spotted over with little specimens evergreens, Palms and exotic flowering plants of many sorts; the bases of the trees which stand on these banks are smothered in big beds of Geraniums or tuberous Begonias; an immense bed of purple-leaved shrubs, surrounded by sickly white-leaved Negundos, lies on one side of the main drive, forming a discordant spot; the isolated trees on the lawns are encircled by flower-beds, and even the isolated exotic plants which are placed near them—as if they were not obtrusive and discordant enough in themselves—are surrounded in the same way. A tuft of Pampas grass, which would be far better away, is rendered doubly bad by its ring of Geraniums, or a wide-leaved Palm overshadows a circle of crimson Coleus.

But worst of all, perhaps, is the way in which the shrubberies are treated. Instead of the shrubs being allowed to droop naturally in a varied outline upon the grass, they are trimmed to allow a flower-bed about a foot wide to run in a straight line along their base, and this bed is filled with rigid rows of gaudily colored plants. Nothing could be more uncalled for than this intrusion of "ornamental" plants between the grass and the shrubs, which, if left to themselves, might effect a beautiful union; and nothing could be worse than the look of

he stiff line of color between the soft green masses above and the soft green expanse below. Not only on the path side of the shrubberies, however, but even on the lawn side this feature is constantly introduced; and we see the same thing to-day almost everywhere in France and England, and in private as well as in public gardens. Fortunately the fashion has not yet been taken up in America, and it is to be hoped that it will never cross the sea.

As the Parc Monceau was designed it was a spot of the utmost unity of effect, restfulness, gracefulness and charm. There are a score of spots within its borders from which might be obtained vistas of sloping greensward and feathery shrubbery and overarching tree-tops that could not be surpassed for harmony and loveliness in any park in the world; and the aspect of breadth and openness secured in so small an area, with so entire a concealment of the surrounding streets, must have seemed indeed a triumph of art. The practiced eye can still read these charms under the disfigurements of to-day; but it reads them with perpetual irritation and protest; for there is no standpoint whence the prospect in every direction is not marred by obtrusive spots, lines and solid masses of color, and by inharmonious plant forms; not a nook so rural that the spade of the potter-out has respected it; not a fair stretch of lawn which is not broken and speckled with "specimen" plants of a dozen sorts; not a shrubbery, and scarcely a conspicuous tree, which is allowed to spring naturally from the turf at its base. The most exacting landscape-painter might once have found many subjects for his pencil here in the heart of Paris; the least exacting could not paint a bit of the Parc Monceau to-day without omitting a hundred offensive details. The effect is all the worse because nothing needs to be planted, nothing permanent needs to be altered. The simple rooting out of a myriad ephemeral plants would at once restore the domain to perfect beauty.

The River Birch.

THE charm of the banks of many streams in the United States is due in large part to the presence of the River Birch, which graces them with its peculiar beauty, and which is not only one of the most beautiful trees of the American forest, but one of the most interesting. It is interesting because of all the Birches, a family of trees widely scattered over all the colder parts of the northern hemisphere, it is the only one which grows in a warm climate. There are Birches, perhaps, which grow nearer to the equator than our River Birch, like some of the East Indian species, but these are found at great elevations only on high mountains, and, therefore, in boreal climates, while the River Birch flourishes in the damp, semi-tropical lowlands of Florida, Louisiana and eastern Texas. It is peculiar, too, among Birches in the season of the year when its seeds ripen. The seeds of other Birches ripen in the autumn, fall to the ground, and do not germinate until the following spring. The seeds of the River Birch mature in June, or often earlier in the southern states, and germinate at once as soon as they reach the ground; and the young seedlings are often a foot or more high before the coming of cold weather stops their growth.

Several of our trees which grow in wet places naturally have acquired this habit of early ripening of the seed. It is the habit of nearly all the Elms, and of the Poplars, and of the Red and White Maples, although the other Maples, which grow naturally on dry ground, do not ripen their seed until late in the autumn. This early ripening of the seeds of certain species only of particular genera can be accounted for by the situation in which such trees grow. The River Birch is found on the borders of streams or swamps which are covered often with water to a depth of several feet during a part of every year. The Red Maple and the Silver Maple and the Poplars grow only in swamps or other wet places. If the seed of these trees ripened late in the autumn, when streams and swamps are full, they would fall into the water and would be washed away or destroyed, and this particular species of tree would have been exterminated gradually; but falling as they do in early summer, when the soil which receives them is neither covered by water nor dry and baked by the droughts

of the hot months, they are placed in the most favorable situation possible for germination; and the young plants are able to acquire sufficient height and strength before autumn to bear, with a good chance of survival, the effect of being flooded during their first winter.

There is an interesting fact, too, and one which is not easy to explain, connected with the geographical distribution of the River Birch. It is found on the banks of the Merrimack and of the Spicket Rivers in north-eastern Massachusetts. Here it grows luxuriantly and abundantly, but it grows nowhere else in New England, or anywhere else as far north as Massachusetts. It grows on the banks of one small stream on Long Island, but nowhere else in New York, and it only becomes common in the lower part of New Jersey; but from southern New Jersey to Iowa on the west, and to northern Florida and eastern Texas on the south, it occupies the banks of almost every stream, excepting those in the high Alleghany Mountains, which have a gravelly bed and banks which are not marshy. There is no tree so rare and local in New England and the northern states, and none in the particular situations it selects more common in the middle and southern states.

The River Birch is a tall tree, eighty or ninety feet high when it is at its best, with a ponderous trunk three or four feet in diameter. The bark on the trunks of old trees is thick, dark brown and deeply furrowed, while that on young trees, with a trunk diameter of not over ten or twelve inches, and on the branches, is light red or cinnamon colored, dividing readily into thin, transparent, papery layers. It is this color of the bark of the branches, peculiar to this species, which has caused it to be called also the Red Birch, although by a curious misapplication of names this tree is known to botanists as *Betula nigra*. The ultimate divisions of the branches, as is the case with all Birches, are slender, pendulous and graceful, giving to this tree in winter that light and feathery appearance which makes it such an attractive object at this season of the year, as it pushes its branches out over some deep, swift flowing stream. The leaves of the River Birch are large, sharply toothed and pointed; they are bright and lustrous on the upper surface and pale on the lower, and in autumn turn bright yellow before they fall from the branches.

The wood produced by the River Birch is light and strong; it is easy to work, of good color, and well suited for furniture of the best quality, which has of late years been made from it in large quantities in some parts of the country. As an ornamental tree for the decoration of parks, the River Birch has much to recommend it. It grows rapidly when removed from the banks of its native streams to drier soil, and may be depended on to develop in a short time into one of the most beautiful of deciduous trees. It is not a common tree, however, in cultivation, in spite of the fact that it was one of the first American trees cultivated in Europe, having been planted in England as early as 1736, and its value and beauty are not known or appreciated by the present generation of tree-planters. Large specimens may be seen occasionally in some of the old European parks, especially in those of northern Germany; but it is practically unknown in those of this country or of England; and yet there is no tree better suited to place on the borders of ornamental water, and there is none which, in such a position, is capable of adding more grace and beauty to the landscape.

The picture of the group of River Birches in Massachusetts in winter, which appears on page 593 of this issue, shows the beauty of this tree at this season of the year, and serves to illustrate the fact, already stated on another page of this issue, that trees are as beautiful in the eyes of the real lover of trees in winter as they are in summer, and that there is much to learn by studying them at this season of the year, when their whole anatomy is made clear by the absence of their leaves.

Our illustration is prepared from a photograph by Dr. William Herbert Rollins, of Boston, to whom we are indebted for permission to reproduce it. C. S. S.

New or Little Known Plants.

The Last Addition to the Shrubs of Eastern North America,

(*Croton Alabamensis*.)

THIS plant, the rarest and most beautiful of the *Crotons* found within the limits of the United States, was first brought to the notice of botanists by Professor Eugene A. Smith, who found it in the summer of 1877 near Pratt's Ferry, Bibb County, Alabama, not far from the eastern bank of the Little Cahaba River, the principal upper tributary of the Cahaba, where it forms dense and almost impenetrable thickets, many acres in extent, in the Oak forest covering the base and flanks of the old-silurian limestone hills which skirt the valley. The soil and the rocks, scattered widely over this valley, are covered under the deep shade of shrubs and trees with a cool, dark carpet of mosses, studded with numerous Ferns, the sombre green relieved in some exposed spots by the pale purple flowers of the delicate *Sedum Nevii*, the rare *Gatesia late-virens* and several shade-loving *Desmodiums*. When I first visited this locality in the fall of 1882, in a vain search for seeds of the Alabama *Croton*, I was repaid by the discovery, among the White and Chestnut Oaks overshadowing it, of the then little known *Quercus Durandii*, first observed in this state in 1840 by Mr. S. T. Buckley, who subsequently described it from specimens gathered by him in Texas. The exact habitat of this rare tree east of the Mississippi River had remained, however, unknown up to the time of my rediscovery of it in the valley of the Little Cahaba River.

There are only at this time a few of these thickets of the Alabama *Croton*, called by the inhabitants of the region "Privet brakes," known, and these are all found close together; and it is probable that it does not extend beyond a territory a few miles square.

Croton Alabamensis,* when fully grown, reaches a height of six to ten feet, with upright, or slightly bent, stems one and a half to two inches in diameter, covered with grayish white bark. The rigid, widely spread branches are rather naked, the foliage being confined to the terminal branchlets, which only appear at some distance from the ground. The stem and branches of young plants, however, are covered with leaves and flower-bearing lateral branchlets, and are then almost hidden with their dress of silvery white and brilliant green foliage. The leaves are destitute of glands and are subtended by small exceedingly deciduous stipules; they are oblong-lanceolate, obtuse, entire, deep green on the upper surface, the lower covered with a dense tomentum of shining silvery scales, as are the short petioles, young shoots and the inflorescence. The leaves are persistent, remaining on the branches through the winter, and are then gradually replaced during the succeeding season by a new crop produced from early spring to the end of autumn. The flower-buds begin to appear soon after the ripening of the fruit in early summer; they are placed in axillary racemes from an inch to an inch and a half long at the time they open, which is from early February to the middle of March. The small whitish flowers are short pediceled, with a calyx of five broad acute sepals, a little longer than the five narrow petals, and alternating with the oblong glands at their base. The deep yellow anthers of the fifteen or twenty stamens, arranged in alternate sets of five in the crowded male flowers, make the inflorescence somewhat conspicuous. The female flowers, fewer in number, occupy the lower part of the raceme, their hairy ovary bearing three small, flat, somewhat emarginate stigmas. The male flowers soon fall after pollination, when all parts of the female flowers increase rapidly in

size, the racemes growing to more than double their original length. The fruit ripens from the latter part of April to the end of May; the carpels, when fully mature, separating by the slightest touch, splitting dorsally and discharging their seeds with some force. This habit will account for the difficulty I have experienced in procuring a supply of seeds, for which I have made two fruitless excursions.

The Alabama *Croton* is not a rapid growing plant. According to Professor Smith's observations, seedlings of the second season, and about eighteen inches high, transplanted from the forest in 1880, have now attained a height of seven feet, having made a growth of about five feet and a half, the largest stems having a diameter of one and a half inches. These plants began to flower when they were two feet high, and at that time were covered with numerous lateral branches. During succeeding years the growth was principally upright, and the plants at present have no lateral branches on the lower part of the stem. No effort has been made to propagate this plant by layers or by cuttings.

The original forest-growth, which still covers the limited area upon which the Alabama *Croton* is found, is, in this day of rapid development of the timber and mineral resources stored up in this secluded part of the country, liable to early destruction, and the survival of this typical Alabama plant in its native home is, at best, uncertain, and will, in all probability, be of short duration. It is only by cultivation, therefore, that the continuation of this species can be secured; and to this it is entitled, not only as a rare production of the vegetable world, possessing many points of scientific interest, but also for its value as an ornament for the garden and the park. There is little doubt that its cultivation, with slight protection during the winter in higher latitudes, can be made successful, and that it will thrive in the Atlantic states as far north as New England.

Croton Alabamensis belongs to the sub-genus *Eluteria*, and its nearest relative in the United States is *Croton argyranthemum* of the south Atlantic states, and, as Dr. Chapman has pointed out to me, it is very closely related to an extra-tropical species of southern Brazil, which differs from it slightly in specific characters.

Mobile, Ala.

C. Mohr.

Chrysanthemum, Mrs. Andrew Carnegie.

THIS is a seedling raised from Duchess, with Cullingfordii as the pollen parent. Out of twenty-five seedlings from this same cross, several had distinct crimson flowers, but were not of sufficient merit to justify their distribution, while the one in question I consider the best crimson variety of the type known as Japanese. The Mrs. Carnegie requires particular treatment to bring out the true shape and coloring of the flower. It should never be forced into rapid growth, but should be grown slowly from the start. The plant should be exposed to the sun after the 1st of September and should not be removed to the green-house until freezing weather threatens, and after that it must not be subjected to more artificial heat than is necessary to protect it from frost. A dry atmosphere, too, is of the greatest importance, as the least moisture on the florets after they begin to unfold causes them to damp or mould.

The Shrub-Garden in November.

THE garden in November is not always destitute of interesting or beautiful objects, as is commonly supposed, and, under ordinary circumstances, there are many plants which well repay examination at this season, when nearly all vegetation seems to have lost activity and life. In the latter part of the month, or Thanksgiving week, in New England many a pretty bouquet can often be made from the flowers and fruit which may be found in the open garden or in sheltered corners.

It is at this time that the value of woody ornamental plants

* "C. ALABAMENSIS, E. A. Smith (ined.).—Stem tall, woody, much branched; leaves thin, short petioled, oblong-lanceolate, mostly obtuse, smooth or nearly so above, the lower surface, like the branchlets and racemes, coated with silvery scales; racemes often unisexual, few or many flowered; calyx-lobes five, acute; petals of both sexes scarcely shorter than the calyx, woolly-margined; stamens twenty or more; styles simple, truncate or emarginate; capsule much longer than the calyx; seeds glabrous. Central Alabama, flowering throughout the year. Stem, six to ten degrees high. Leaves, two to three inches long." Chapman, *Fl. S. States*, Suppl. 648.

Fig. 149.—The River Birch in Winter.—See page 591.

shows to advantage when compared with the annuals or perennials. It is true of our woody plants that the flowers which several species bear at this season are usually not due to appear before April or May, but a few blossoms are almost invariably produced at the time when the leaves are falling or after a succession of mild days in winter. An exception to this rule is the Witch-Hazel (*Hamamelis Virginica*), the normal blooming season of which is in October and November, the time varying greatly, according to situation and exposure, so that flowers may be found in winter or very early spring.

This plant, which should be in every shrub-garden, has

fragrantissima and *L. Standishii*, occasionally open before all the leaves have fallen, and they are just as fragrant as they would be if not developed until spring. These two species retain their leaves longer here than any others of the genus except *L. Japonica* and its varieties, which are almost evergreen. Among other spring blooming shrubs a few yellow flowers of the Forsythia can be found, and in the *Ericaceæ* open blossoms of *Andromeda floribunda* and *Erica carnea* may be discovered during the late autumn and under the snows of winter, while the last species is one of the first shrubby plants from which bees collect nectar in the spring. *Daphne Cneorum*

Fig. 150.—*Croton Alabamensis*.—See page 592.

1. Flowering Branch. 2. Fruiting Branch. 3. Male Flower, enlarged. 4. Female Flower, enlarged. 5. Pistil cut across, enlarged.
6. Fruit, enlarged. 7. Ventral view of a Coccus, enlarged. 8. Seed, enlarged.

an added interest from the fact that it well illustrates one of Nature's many beautiful ways of scattering seeds. The fruit ripens as the plant comes into bloom and the woody capsules open and disclose the oblong shining black seeds. As the capsule dries the lower edges contract and press against the sides of the tapering seed, which, suddenly breaking loose from its attachment at the base, is thrown with the velocity of a bullet for a distance of ten or twenty feet or more from the parent plant.

Against sheltering walls flowers in considerable numbers may still be found on Hall's variety of *Lonicera Japonica*, and a very few blossoms of the spring flowering bushy species, *L.*

bears a second crop of small clusters of blossoms during the autumn, and, if with *Vinca minor* it is somewhat protected from severe early frosts by sheltering trees or buildings, a bunch of the purple flowers of the *Vinca* and of its white variety, may be made fragrant by stray sprigs of the *Daphne*.

Spiraea Thunbergii is the last of its genus to lose its bright autumn foliage and its early spring flowering habit is often indicated by a profusion of small white blossoms during mild periods in November.

But it is those species of shrubs which, having lost their foliage, retain their fruit in its original plump and bright condition, that give the most satisfaction at this season.

Some of the bunches of fruit of *Lonicera Sullivantii* (commonly grown as *L. flava*) still retain much beauty, although many of them have become dry and shriveled. The Cranberry-bush (*Viburnum Opulus*) holds its fruit, which is somewhat duller than before frost; and the long, slender stems of

Among all the conspicuous fruit-bearing plants, the Japanese *Berberis Thunbergii* seems one of the handsomest and most satisfactory. The bright red fruit, thickly set along the branches of this Barberry, remains full and fresh-looking until spring, and well laden branches, if cut off and dried for in-door decoration,

Fig. 151.—Chrysanthemum, Mrs. Andrew Carnegie.—See page 592.

Lycium Chinense remain covered with bright scarlet ovate fruit.

The bright red fruit of our native Black Alder or Winterberry (*Ilex verticillata*) can hardly be surpassed in some respects, but in some districts it is liable to be eaten early by birds, while in other places it may remain on the plants all winter.

retain their beauty for a long time. The plant is now becoming well known and commonly advertised, and it is likely to be quite popular as a low hedge plant. The fruit of some other Asiatic species or varieties still retain a little beauty, but most of it has become much shriveled and lost its early brightness.

Crataegus pyracantha, the Evergreen Thorn of southern Europe, which is not very hardy in this latitude, still retains all of its shining green leaves, and the birds have not yet devoured the bright scarlet fruit, which is quite pleasant to the taste. The Washington Thorn (*C. cordata*) is almost the only other species whose fruit retains its brightness and is persistent through most of the winter. The fruit of the European Spindle tree (*Euonymus Europæus*) ripens late, and just now the orange colored arils are very showy, although the pods have dried and lost much color. This species is more showy at this time than the native Burning-Bush (*E. atropurpureus*). No list of bright fruiting plants is complete without the Waxwork or climbing Bitter-sweet (*Celastrus scandens*), with its bunches of bright scarlet fruit, which often take a conspicuous part in New England Thanksgiving and Christmas decorations. It should be propagated from plants which are known to fruit abundantly. *Celastrus punctatus*, a Japanese species, is also very ornamental, although the fruit is small and is borne in small, loose, scattered cymes, a character which gives it quite a different aspect from the close, raceme-like bunches of our native species.

The Rose family also contains many plants well known for their showy fruit of late autumn and early winter. Perhaps the most valued of these is the large-fruited Rowan-tree (*Pyrus aucuparia*) of Europe and our own Mountain Ash (*P. Americana*). A dwarf species of the same genus, *P. arbutifolia*, var. *erythrocarpa*, still holds its very dark red fruit in a firm and fresh state. Some of the native and foreign wild Roses still retain their fruit in an attractive condition, varying in color from red to brown or black. Several species of Cotoneaster are deserving of more general cultivation, either for their showy fruit or evergreen habit. The Snowberry (*Symphoricarpos racemosus*), so common in all old-fashioned gardens, is interesting for its large, white fruit, which is unique at this season. The Indian Currant (*Symphoricarpos vulgaris*) has considerable ornamental value, and its long, slender branches, covered with small, fresh, dark red and magenta colored berries, are in their best condition at this date.

The evergreen Bearberry (*Arctostaphylos Uva-ursi*), with its deep red fruit, and the Aromatic Wintergreen or Checkerberry (*Gaultheria procumbens*), have not yet become thoroughly domesticated, although the Bearberry grows and thrives very well in some situations under cultivation. The bright scarlet, spicy berries of the Checkerberry are commonly found in the market at this season.

Shrubs which have bright colored stems and branches also contribute greatly toward lighting up the landscape at this season, but mention of them has been omitted from this list because the colors of most of them become more intense after the snow falls and as the winter advances.

Arnold Arboretum.

J. G. Jack.

The Roses of the Year.

THE list of new Roses for 1888 and spring of 1889 was an unusually large one, about equally divided between the Hybrid Perpetuals and those known as Ever-bloomers in this country, including Teas, Polyanthas, Hybrid Teas, Noisettes, Bourbons and Chinas. It is impossible to determine the value or quality of a Hybrid Perpetual with a single summer's trial, but my notes made in England and on the Continent during August last may indicate varieties that will probably prove useful in this country. Oscar II., King of Sweden, was introduced by Soupert et Notting, of Luxembourg. Color is the remarkable feature about this Rose, it being a maroon-brown; or, to put it another way, a brown-crimson. A strong, vigorous grower, with large leathery foliage, it produces flowers quite double and of fair form. It has a rival in Sir Rowland Hill, an English introduction of the previous year. This is a fine, erect grower, and, if vigorous enough when grown on its roots, will be much sought after when known in America. It, too, is a maroon-crimson, with just enough lustre to light the flower up nicely. It is similar to Duke of Edinburgh in habit and form. Both the above Roses are decided departures in color, and from what I saw of them they appeared very free in the production of flowers. Caroline D'Arden, raised by Dixon, of Langport, Ireland, is a Rose of much promise from its sturdy habit and fine, open-faced flowers, which are produced in abundance when the size of the flowers is taken into account. It is of a bright cherry-rose, one of those appealing tints that one cannot help liking. Countess d'Eu (Verdier) is a fine globular flower of a bright cerise-rose color, flushed with vermillion. It is a Rose of excellent shape and a fascinating color. Marquis of Salisbury, raised by Levéque, is of a bright rose-crimson, shaded with silver. Its attractive color, with its fine shape and great masses of flowers, impressed me greatly.

Duchess of Albany and Duchess of Leeds, both English-raised Roses, are classed as Hybrid Perpetuals in Europe, but they are both bred like the well known La France. The first is a Rose of decided value. As seen growing with the originators, Messrs. William Paul & Son, it was all that could be wished for, being larger in size, deeper in color and stronger in growth than its parent, La France. Duchess of Leeds, at certain stages of its development, is finely colored, and has a bright, crisp appearance. Its weak point is its slaty or dead pink color when fully expanded. The outer or reverse side of the petals is always of good color. To my notion it is a good, useful Rose, but would not please the fastidious on account of its short petals and ashen color when fully open. The two sports from Lady Mary Fitzwilliam, White Lady (Paul) and Maid of the Mist (H. Bennett), are very fine as seen growing and flowering in the genial climate of England, but are of no use here on account of their inability to withstand the fungoid disease commonly termed Black Spot. One of the finest Roses in England is the parent of these two white sports, but it is valueless here on account of the disease mentioned. Cheshunt Scarlet (George Paul) is a brilliant crimson-scarlet, and the nearest approach to a pure scarlet of any Rose we know. It is from that splendid race of Roses beginning with Duke of Edinburgh and running through most of the seedlings raised at the Cheshunt Nurseries. It is semi-double, with broad petals, and will make up in color for deficiencies in other directions. Marchioness of Lorne, as grown at Waltham, is very nearly an ideal Rose; splendid in form, bright crimson-rose in color, sweet-scented, producing its buds and bloom with a lavishness unknown to most Roses of its class. Unfortunately, it does not maintain its perpetual flowering character when transplanted to American soil, as plants introduced last spring behave like all other Remontants. The Roses mentioned above are likely to prove valuable, and are distinct enough from existing kinds to warrant a trial on this side the water.

Count Henri Rignon is a fine, distinct Hybrid Tea, raised by Pernet, of Lyons—a grand Rose, as seen in the gardens in the south of France; and it gives much promise on this side of the Atlantic. It is equal to American Beauty in size, but of a light, silvery flesh tint, which is decidedly pleasing. Our growers might try forcing this variety in the way that American Beauty is grown. It would sell if well done. Ernest Metz, a large silvery pink flower, tinged with flesh color, of extra large size, and Madame Pierre Guillot, a rose of the Watteville type, are the two most promising Teas of the year; and for bedding purposes in the open ground they will please the fancy of critical rosarians. They are the product of that cautious and conscientious man, M. Pierre Guillot, of Lyons, who has done more, perhaps, than any other one man to enrich our gardens with good varieties.

We are expecting other varieties of Tea Roses, but the propagator's knife has despoiled them to such an extent that they must wait until we can judge them properly. I might mention The Queen, raised in this country, a sport from that old favorite, Souvenir d'Un Ami, and a fine Rose for bedding in the open ground; Clotilde Soupert, said to be a hybrid Polyantha, is, perhaps, the Rose of most value on this side, out of the many introductions of 1889. It is nearly the size of the fine Hybrid Noisette, Boule de Neige, but differs from that variety in being short-jointed and truly perpetual, as much so as any of the common Chinas. It also promises to be hardy in our northern climate, and if so it will be of great value. Whether it is a Polyantha or a Hybrid Noisette, matters little if it continues to do as it has done the past summer. It was raised by Soupert et Notting, Luxembourg, who declare it a true descendant of the Japanese Fairy or Polyantha Roses.

E. G. Hill.

Chrysanthemums in 1889.

THE record of the year, so far as the introduction of new varieties of great promise goes, has not been an encouraging one.

A larger number of new kinds than has ever before been offered appeared in the spring catalogues of growers in America and Europe; and, with very few exceptions, the experience of this season will probably strike from the list nine-tenths of them as not having sufficiently distinct qualities to justify their propagation. Some allowance should be made for the unfavorable influences of an exceptionally bad season for plants grown in the open ground. But the new flowers are not, in themselves, either in form, color or substance, marked improvements on those already in existence.

Mrs. A. Hardy, the principal novelty of the year, notwithstanding its apparently great vigor of growth, has not done

well; not a plant of it was shown at the Chrysanthemum Exhibition of the Massachusetts Horticultural Society. The flowers, however, were shown, and have the same attractive qualities that excited so much enthusiasm last year. There has also been exhibited this season, under the name of Louis Böhmer, a flower having the hairy petals peculiar to Mrs. Hardy; the color of the flowers, however, is a dull pink, not at all pleasing, at least in the specimen shown at Boston. Whether Louis Böhmer is a sport from Mrs. Hardy or an original seedling imported from Japan was not stated.

Messrs. Pitcher & Manda have received, in a recent importation from Japan, among some very promising Chrysanthemums, another specimen of Mrs. Hardy. Among the seedlings of this variety raised by Mr. Manda, and shown by him during the season, there has been no appearance of the hairs. One of the seedlings, named Bohemia, is a large, dark flower of decided promise. Strangely enough, there does not appear to have been any sport from Mrs. Hardy, though the unusually large numbers of that variety, which have been grown this season, would lead one to expect this not unusual occurrence.

Of the varieties of recent introduction the following may be noted: Alcyon, Délie, Superbe Flore, Madame Pépee, Val d'Andorre, Ed. Audiguier, W. H. Lincoln, L. B. Bird and John Thorpe, all Japanese, have done well; Mrs. G. Wright, Avalanche and Condor are three good whites of the reflexed Japanese type; Mrs. H. Cannell, white, incurved Japanese, has not done well, while Mr. H. Cannell, though not a very free flowerer, appears to be a real addition to the large yellows of the old Grandiflorum class; Mrs. N. Davis, a yellow sport from Princess of Teck, has all the good qualities of one of the best of the large incurved Chinese kinds; Marie Ouvray has not shown itself to be a valuable addition to the long list of early flowering varieties of more or less distinct violet shade; M. Garnier, a Japanese, with yellow ground, shaded and striped brown-red, is a fine variety; Souvenir d'Alfred Motte, reflexed Japanese of a peculiar color, magenta and buff, is worth adding to a large collection, and so too is Mrs. Falconer Jameson, one of Cannell's new varieties, a flower colored buff and red, with yellow points; La Tosca, Japanese, fiery crimson, striped brown, though a small flower, is good and distinct; Cythere, of the same class, purple-amaranth and shaded dull red, is also good; Magicienne, Japanese, color chamois with light rose tints, is a large and early flower; Vieil Or, though very rich in color, is too flimsy in substance to be useful; Etoile de Lyon, a deep lilac-rose, margined with silver, of large size, though it has not done well here, has succeeded so well on the other side of the ocean that it should be given a second trial.

The incurved Chinese flowers have fallen into undeserved neglect in later years here, and the few valuable additions to this class have not attracted the attention due them. One of the best of these new-comers is M. Roux, a seedling raised by Boucharlat and introduced in 1884. It has retained, even this year, its good qualities of a low habit of growth and well shaped, closely incurved flowers of a bright chamois yellow. Ralph Brocklebank, a yellow sport of the old variety Meg Merrilies, has the same serious defect, a dark centre.

The seedlings of the year, of American production, are not very numerous, nor are they, as a whole, very promising. They have generally been exhibited as single large flowers grown to the fullest size that high cultivation can give them. It is not easy, therefore, to say how valuable they will prove for general cultivation. It is, unfortunately, true that many of the best new seedlings have been plants of bad constitution, capable of yielding, in the hands of expert gardeners, wonderful results, but comparatively valueless for the average grower. Some most remarkable flowers, exhibited at the Boston show by Mr. Brydon, gardener to Mr. Simpkins, were largely of this class. Better flowers were never exhibited here, and, probably, better could not be seen on any exhibition table in the world; but if the ordinary grower should select these plants for his own collection he would inevitably be disappointed in the results of his cultivation.

Mrs. Andrew Carnegie, one of last year's seedlings, was shown by Mr. Brydon, in good form and bright color, but the same flower, as exhibited by other growers, was dull and unworthy of its reputation. Ada Spaulding is not attractive in color, at least was not so at the Boston exhibition, and is no better in size and form than many more highly colored flowers already in the market.

The other conspicuous seedlings of 1889, so far as they have been seen, must, in my opinion, await the results of another season's cultivation before they can be awarded a very high place on the list.

Cambridge, Mass.

Orchid Notes.

Trichosma suavis.—This is one of the most attractive Orchids in flower during the months of October and November. From a botanical point of view, it is allied to *Eria* and *Cœlogyne*, but more closely to the former genus than to the latter, and we find that it was formerly known under the names of *Eria suavis*, *E. coronaria* and *Cœlogyne coronaria*. It is a native of the Khasya Hills, where it was discovered, and from thence introduced, in 1837, by Gibson, who was traveling in that locality for the Duke of Devonshire, whose place at Chatsworth was interestingly described in this volume of GARDEN AND FOREST, on p. 506.

This species, which, by the way, is the only one yet known, grows vigorously and flowers freely. Its green and succulent terete stems are about two-thirds as thick as an ordinary lead pencil and about a foot high, with two oblong-elliptic, acute leathery leaves at the summit, whence emerges the peduncle, bearing from five to eight fragrant flowers, each borne on a pedicel about an inch long. The creamy white sepals and petals are about an inch long and broadly lanceolate in shape, the two lateral sepals being connate at the base, forming a kind of pouch. The white lip has three lobes, the lateral ones being erect and handsomely striped with dark reddish crimson, which circumstance reminds one of its relation to *Cœlogyne*. The middle lobe is recurved, bright yellow, with from five to eight narrow, undulating, elevated keels in front of two pure white raised crests, which run parallel to the base; and the column is greenish white behind, streaked with dark crimson in front. I have seen a so-called variety, *Bella*, in nurseries, which is supposed to have richer colored flowers than the type.

This plant is somewhat scarce, but it is well worth a place in every collection on account of its masses of dark green foliage, which form an excellent background for the trusses of creamy white flowers. It may be grown in the cool end of the Orchid-house, in a compost of fibrous peat and moss, and the pots must be well drained. When in active growth the plants may be liberally watered, and at other times require more or less attention in this respect, according to atmospheric conditions; but it will be found necessary never to let the plants get too dry at the roots, as they have no pseudo-bulbs to serve as a reservoir for moisture.

St. Albans, England.

John Weathers.

Dendrobium bigibbum is a very handsome species, much resembling *D. superbiens*, and certainly one of the handsomest of the Australian kinds. It is a rather dwarf growing plant, producing slender fusiform stems, about nine inches long, from which spring peduncles bearing racemes of rich, rosy purple and very broad-petaled flowers. They oftentimes continue to throw out these racemes from the same stems for several successive years. We grow this plant in *Cattleya Trianae* house, suspended from the roof, where it gets abundant light and sunshine. It does best here in small cribs, with a little sphagnum moss and charcoal and a good supply of water when growing. We never allow it to become dry enough to shrivel, as it is with difficulty restored; but it likes a period of rest, as it appears to grow much more freely afterward.

Staatsburg-on-Hudson.

F. Atkins.

Begonia octopetala hybrida Lemoinei.—This plant was introduced in the spring of 1889 by M. Lemoine, of Nancy, with the statement that it is the result of a cross made some years since between the white flowered *B. octopetala* and some of the best of the tuberous section. The corms do not differ materially from those of *B. octopetala*, and start into growth naturally in June, throwing up numerous rather coarse leaves of a character intermediate between the parents and nearly radical. The flowers, borne on rigid foot-stalks twelve to eighteen inches long, in clusters of four or five, on my plants are about two inches in diameter. Varieties sent out were pink, white and magenta. Each plant throws up five to eight flowering stems. The variety *Anemone* came into bloom in October, followed by *Fleur d'Automne* in November, but at the end of the month the variety *Ville de Nancy* shows no sign of blossom, though apparently as strong as the others. The flowers have all been males on my plants. As the leaves and flowers, thrown well above the foliage, have a distinct and pleasing port, this cross is likely to prove of some value in the fall when the hybrid tuberous kinds are about over, though one regrets the absence of female flowers, so that with the vigor of the *Octopetala* parent we might infuse more size and substance into the blooms. Such further crosses might also refine the foliage. *B. octopetala* is somewhat impatient of root confinement, and perhaps this hybrid could be successfully cultivated planted out on a green-house bench, though in such a position

it would occupy valuable room in return for a comparatively short season of bloom. If the varieties of new winter-blooming hybrids of *B. Socotrana* continue to improve and increase in variety, the Begonia season for large blooming tuberous kinds will be so extended that there will be little difficulty in securing a continuous display of these showy flowers during the entire year.

Elizabeth, N. J.

J. N. Gerard.

Forcing Asparagus.—I prefer roots three or four years old for forcing; but the age is immaterial, provided a vigorous growth has been made the previous season. The roots are originally planted out in rows five feet apart and a foot apart in the row, covered with three inches of soil, and cultivated as for an ordinary crop. When wanted for forcing the roots are plowed out, with as little damage to them as possible. In neighborhoods where Asparagus is grown for market, farmers will often plant as above, and then, in the third or fourth year, will plow out every other row to be used for forcing, leaving permanent rows ten feet apart. At this distance the ground can be thoroughly tilled, and abundant light, warmth and air will make strong crowns, so that an early crop of the first quality can be expected. Roots to be forced are placed in a pit under the benches and heated with hot water. They are placed on two inches of soil, and covered with four to five inches to blanch the shoots. Cutting will be in order about fifteen days after the roots are put in, and the same roots will produce profitable shoots for six weeks. Asparagus can be forced on greenhouse benches, in frames or in hot-beds, where the manure is not too fresh, so as to generate too much heat and steam. I have seen the best of "grass" grown in a common frame, with eighteen inches of leaves and manure, to ferment and give heat, and a covering thrown over the frame at night. It should be remembered that Asparagus starts with very little heat, forty-five degrees being sufficient to start it in the soil.

Jobstown, N. J.

J. G. Gardner.

The Forest.

Among the Siskiyou Forests.

I HAVE just returned to San Francisco from a visit to the Mount Shasta region, which, as I should explain, is north of Shasta County, in Siskiyou. Although it was the middle of November, there was no snow in Strawberry Valley at the foot of Shasta, the air was dry and warm, the roads were excellent, and the Indian summer was in its lovely prime.

I am told that the sales of timber land made this year are greater than for any previous three years. Three new saw-mills will begin operations next spring. A broad gauge railroad is being built from Anderson, Shasta County, about twenty miles north, to meet a thirty-mile flume, tapping the heart of the finest forest of *Pinus Lambertiana* in northern Shasta. It is said that the four or five San Francisco gentlemen who are pushing this enterprise own 30,000 acres of the best Pine-lands of the district lying between Mount Shasta and Mount Lassen. Four or five years ago it was considered perfectly inaccessible and worthless. Hardly a word of opposition would have been raised if it had then been withdrawn from sale. I was offered five thousand acres of Sugar Pine and Yellow Pine, in 1887, for two dollars an acre in this district. Now it could not be bought for ten times the sum.

Californians have had dreams of a great Mount Shasta Park, some fifty or sixty miles square, including the head waters of the Sacramento, McCloud, Trinity, Shasta and other great rivers. But it was merely a subject for table discussion, and was never taken up and made a living issue on which men had to take sides. And now, if not already too late, it soon will be. The Southern Pacific Railroad Company, whose Oregon line passes through these forests, has the greatest individual interest in their preservation. There is no forest district in California more interesting to the fisherman, the hunter, the botanist, and the lover of nature; no district of more importance to the city dwellers; no region more closely connected with the agricultural prosperity of the great central valleys; but no one in California is "making a fight" for the Shasta Park. Senator Stanford is reported as saying, recently, that he had not known how fine the Pines of Mount Shasta were, and that he had thought of buying 1,200 acres, and keeping axe and fire out of it; but the saw-mills were already in the tract he wanted, and nothing has yet been done in the matter.

In the forest near Sissons, the leading trees are *P. Lambertiana*, *P. ponderosa*, *Pseudotsuga taxifolia* and *Libocedrus decurrens*; of these the *P. ponderosa* is most numerous. Among the young trees springing up in the forest, the Douglas Spruce seems most abundant, the *Libocedrus* next, and the *P. ponderosa* third, while the *P. Lambertiana* is hardest to find. The

trees grow in little groups, no two alike, but all attractive in the highest degree. Where the sheep have been kept out, as in the largest tract I saw, there are millions of seedlings visible to a close observer, and their roots are so fibrous in this rich soil that I should believe in their easy removal. The proportion of Douglas Spruces is even greater among these yearlings than among those of five or ten years of age; when the Pines are destroyed, this will be chiefly a Spruce forest.

On the edges of the valley and on the lower mountain slopes, where the lumbermen are doing their heaviest work, the forests are largely of the Red Fir of California (*Abies nobilis*), with the *A. grandis*, and the great Pines before named. Pines, Firs, Spruces and all the magnificent conifers of the district must soon disappear. The groups of small *Cupressus McNabiana*, discovered by Jeffreys many years ago, some fifteen thousand feet above the valley; the alpine Pines, higher up to the snow line, *P. monticola*, *P. Balfouriana*, and the graceful *P. albicaulis*, dwarfed to a mere white-stemmed shrub, will probably escape destruction because of the comparatively small amount of actual timber they can furnish.

There are thousands of cords of two-foot wood piled up along the railroad track. It sells at two dollars and a quarter a cord, delivered at the siding. It is not from refuse, or stumpage, or Pine-tops; it is clean, straight pine from the best part of the trunks. The wood-chopper takes every large tree just as surely as the lumberman does. These immense piles of cordwood are all "No. 1" white and yellow pine. The stumps stand in the valleys and on the slopes, the trees having been cut off at a height of from five to ten feet above the ground, much valuable wood being wasted; the whole top of the tree is considered worthless.

A California saw-mill is always run on a large scale. Labor is high priced, transportation is difficult, owing to the size of the logs, and so the only way to make money is to rush things. Every two or three minutes a log comes in, is squared, sliced into planks, ripped into laths, turned into broom-handles, shaved into shingles or split into scantling. It is gigantic work from dawn to dark, and sadly, strangely impressive. I have visited many of the most famous saw-mills of the coast, from the Navarro Redwoods—a million-dollar estate in Mendocino, where I have seen logs fifteen feet in diameter turned into railroad ties—to the great mills of the Pine-belt of the Sierras, and I know of nothing more calculated to make an American citizen pause and ask himself where it will end. I asked a mill-owner about it the other day, and his answer was: "When we have cut it all off we will go to Alaska."

"But the people want these forests left."

"The people don't care. Every settler within ten miles of my mill wants to sell me trees at a dollar apiece. The state doesn't care or it would have been saved, at least the school sections. The country don't care or we should hear from it. There is money in the lumber business, and every tree has got to go. Sorry for the feelings of the fellows who didn't know enough to get timber-land when it was cheap."

In the Mount Shasta region there are twenty-two species of conifers, and an observer from the Smithsonian listed 103 species of birds. There are great glaciers, hot, cold and mineral springs, mountain lakes, extinct craters, and all that goes to make the region "the keystone mountain mass" which upholds the northern arch of coast range and Sierra. The "Shasta Park" idea was a fine conception, but no one has taken a step towards its fulfillment. Is it indeed true that "nobody cares," and that nothing can be done to save these forests until another generation has been educated by hard necessity to a knowledge of the issues involved?

Correspondence.

Trees in the James River Valley.

To the Editor of GARDEN AND FOREST:

Sir.—A recent visit to the James River region, in Virginia, afforded me the chance of seeing and measuring some of the most remarkable trees of the valley.

Dr. Mohr's interesting paper in a late number of GARDEN AND FOREST calls to mind a Pecan-tree I saw at Lower Brandon, on the south bank of the James. It measured, at four feet above the ground, sixteen feet and four inches in girth. For a station so far north and east this seemed unusual, especially when I remembered that there is a reasonable assurance that the tree grew from a nut planted but a little over a century ago by an ancestor of the present owners of the estate.

Towering above all its associates, it had ample room for expansion, and the result was a vast spreading mass of limbs and foliage instead of the narrower spire-like top seen in the forest

specimens. It bears well, and the nuts are regularly expected as one of the spontaneous products of the place. On the same ground were several smaller trees (by comparison), though considered in themselves they were large. These all came from the seed of the older tree. The soil is a rich sandy loam.

Ulmus alata is very common at the water's edge near Lower Brandon. So far as my observations there convinced me of anything concerning the corky wings on the branches of the tree, I thought that these excrescences were much more common on the specimens whose growth had in some way been interfered with. I sought in vain for them on the branches of two vigorous individuals which grew on good soil and in abundant sunlight; but, on the other hand, in the trees which grew in the thicket, or in places where they had been exposed to mutilation, corky wings were quite conspicuous.

Pinus Taeda, of course, grew commonly enough in suitable places. What most struck me was its vigorous growth and the size it attained so far north. Judging from the plant life, I should say that the valley of the James was disproportionately warm as compared with Philadelphia. Harvest is over there, and the grain under shelter, or in the bags, before we on the hill-sides of southern Pennsylvania have commenced to cut it. I am convinced this somewhat abrupt change to a more southern appearance of the trees is testimony in the same direction.

University of Pennsylvania, Philadelphia.

J. T. Rothrock.

Melothria pendula.

To the Editor of GARDEN AND FOREST:

Sir:—The article on *Melothria punctata* in GARDEN AND FOREST of November 20th reminds me that it may be interesting to some northern readers to learn that our native Wild Gherkin (*M. pendula*) is a very handsome climber bearing yellow flowers of small size, followed by a profusion of black fruits resembling tiny cucumbers. This plant is common in clearings, more especially in rich soil, where, in some cases, it entirely covers the ground with a dense mat, producing quantities of fruits, which are made into most delicate pickles. Although usually running on the ground, this plant will climb a trellis, or any object placed for its use. In rough land the vine covers small objects, hiding their unsightliness. The leaves are "cordate, with from three to five angular-toothed lobes," being as handsome as those of *M. punctata*, and, as seed is freely produced, they can be had in any desired quantity. The plant is an annual, and lasts throughout the summer.

Recent Publications.

Scientific Papers of Asa Gray, selected by Charles Sprague Sargent. Vol. I., Reviews of works on Botany and related subjects, 1834-1887. Vol. II., Essays: Biographical Sketches, 1841-1886. Two volumes octavo. Vol. I., pp. viii, 397. Vol. II., pp. iv, 303. Boston and New York: Houghton, Mifflin & Company, 1889.

The writings of Dr. Gray may be roughly divided into three classes, viz.: Contributions to systematic botany, instruction books for students, and miscellaneous papers. By the first class of writings, principally, he won his place among the princes of that branch of learning which its votaries affectionately call "nostra scientia amabilis;" by the second he has educated a generation of botanists in a wider field than his own native land, and by the third he achieved high rank and wide reputation among literary people outside of the realm of natural history. The present volumes contain a large and judicious selection of these miscellaneous papers, beginning at a time when the Natural System, as illustrated by Lindley, was beginning to displace the purely arbitrary and artificial system of Linnaeus, and continued down to the day when the victory had been so long won that the strife was forgotten, and men were now seeking to know what system and structure may teach of vital truth, rather than to pit one system against another. For as the chemistry, the geology and the electrical science of half a century ago are remembered to-day only as leading up to what men now know and do, so the botany of that time is replaced by broader and more intensely interesting principles, facts, theories and researches.

This progressive change in the scope and aims of botanical science becomes very evident to any one who will read these volumes with even only careless haste, while the more careful reader will find more than enough to interest and instruct him in the arguments and facts presented, and will, moreover, be charmed with the clear and simple style of a master of English prose. Dr. Gray's "Reviews" were seldom confined to an account of the book under consideration; but he usually took up the subject presented, brought out new or forgotten

facts to illustrate or to confute the theories of the writer, and rarely failed to say a good deal which the author reviewed could read with profit. This is especially true of his reviews of the successive writings of Mr. Darwin, and of De Candolle's works on phytography and on the origin of cultivated plants.

The second volume of these selected papers contains fourteen "Essays" and thirty-eight biographical sketches. The first of these essays was published in 1841, and is an account of the chief European herbaria as they then existed, when the great herbarium at Kew was yet to be founded by the transfer of the collections of Sir William J. Hooker, at that time residing in Glasgow. Several of the later essays were addresses delivered on particular occasions, as that on "Sequoia and its History," which was the address of the retiring President of the American Association for the Advancement of Science, and was delivered at Dubuque, Iowa, in 1872. Among the subjects of the biographical sketches are the names of Robert Brown, Alexander Humboldt, William Jackson Hooker, Darwin, George Bentham, and our own Torrey, Sullivan, Agassiz, and Dr. Gray's intimate associate and neighbor, Jeffries Wyman.

We found but few typographical errors in reading these handsomely printed volumes and made no note of them at the time. Still they do exist, and the Riverside proof-readers ought not to have let such slips as *Helorageæ* and *Hibridization* escape their attention.

It is to be hoped that this series of "Selections" will be continued. Some of Dr. Gray's earlier papers descriptive of new plants are not now to be obtained, and to reprint them would be a great favor to working botanists.

Periodical Literature.

Mr. Bradford Torrey has never written a more charming essay than "December Out-of-Doors," published in the current number of the *Atlantic Monthly*. It begins with a word of praise for November mildness and sunshine, referring, naturally, to the November of 1888, not to the gloomy, pouring month of 1889. The December of 1888, which Mr. Torrey then chronicles more at length, was almost as favorable to out-door rambling, for at its end, he says, he found that, "omitting five days of greater or less inclemency, I had spent nearly the entire month in the open air. I could hardly have done better had I been in Florida." The greater number of the pages in which the charms and the *trouvailles* of the month are recorded tell us of birds and their ways. But a few at the end speak of the December flowers on the northern Massachusetts coast. We are not surprised to hear that their number was "limited." It is more unexpected to be told that so many as sixteen different sorts of plants were then and there found blooming in the open air. The hardiest of all local plants, Mr. Torrey thinks, is the common Chickweed (*Stellaria media*), and the next a Groundsel (*Senecio vulgaris*). Another kind of Groundsel (*Senecio viscosus*, a recent emigrant from Europe, very locally established) was likewise counted in bloom, and the thirteen remaining heroes were Shepherd's Purse, wild Pepper-grass, Pansy, Mouse-ear Chickweed (*Cerastium viscosum*), Knawel, common Mallow, Witch-Hazel, Cinquefoil, Many-flowered Aster, Cone-flower, Yarrow, Fall Dandelion and Jointweed. The Cinquefoil was *Potentilla Norvegica*, not *P. argentea*, as Mr. Torrey thinks might more reasonably have been expected. Knawel kept on flowering till the middle of January, and *Senecio vulgaris* "all through December and January, and I know not how much longer." One-half the sixteen were plants that have been introduced from Europe, and six were members of the Composite family. The author's description of his experience with the Witch-Hazel is too pretty not to be quoted entire: "Such Witch-Hazel blossoms as can be gathered in December are, of course, nothing but belated specimens. I remarked a few on the 2d, and again on the 4th; and on the afternoon of Christmas, happening to look into a Hamamelis-tree, I saw what looked like a flower near the top. The tree was too small for climbing, and almost too large for bending, but I managed to get it down; and, sure enough, the bit of yellow was a perfectly fresh blossom. How did it know I was to pass that way on Christmas afternoon, and by what sort of freemasonry did it attract my attention? I loved it, and left it on the stalk in the true Emersonian spirit, and here I do my little best to embalm its memory."

We should be glad if our readers in various parts of the country would follow Mr. Torrey's example and catalogue such plants as they may find in bloom in midwinter; and if the coming season should prove more inclement than the last, their lists, although shorter, would be even more interesting.

Notes.

The fourteenth annual meeting of the Iowa State Agricultural Society will be held at Glenwood on the 10th, 11th and 12th instant.

On one of the coldest days of last week we received from the gardens of Dr. George Thurber, of Passaic, New Jersey, some large and perfect flowers of *Helleborus niger altifolius*, which had grown out-of-doors with no protection.

It is a fact significant of the present tendency of horticultural fashion that the receipts from visitors at the Chrysanthemum exhibition held at Boston last month exceeded the receipts taken at all the other exhibitions combined held by the Massachusetts Society during the year.

The illustration of the Chrysanthemum Mrs. Carnegie, on another page of this issue, is taken from a photograph of one of a collection of remarkable flowers exhibited at the late Chrysanthemum show in Boston by James Brydon, gardener to Mr. Simpkins, of Yarmouth, Massachusetts.

According to specimens received from Professor Gerald McCarthey, of Raleigh, and from Mr. G. W. Lawrence, of Fayetteville, North Carolina, it appears that hogs of that state are fond of the fungus, *Clathrus columnatus*, Bosc, a species which has the repulsive odor found in nearly all the order *Phalloidea*. Several hogs have been killed by indulgence in this unæsthetic, and, to human taste, nauseating diet.

All foreign journals notice the fact that the taste for single flowers is rapidly growing. Single Dahlias, Chrysanthemums, China Asters, Cinerarias and Pyrethrums are now in demand, whereas a while ago only the double varieties were liked. So unfamiliar, indeed, was the single Dahlia a few years ago in Germany that florists who displayed it in their windows were constantly asked its name. Now it is one of the most popular of flowers.

Plants of *Croton Alabamensis*, described in another column, were sent last spring to the Arnold Arboretum by Professor Smith. They are now well established, but have not, of course, been tested yet in the open ground in winter. The contrast between the brilliant green on the upper surface of the leaves with the silver whiteness of the young branches and the under surface of the leaves makes the Alabama Croton an exceedingly attractive plant, and its cultivation desirable.

Work has been begun on the Memorial Arch, at the entrance of Prospect Park, which is to commemorate the citizens of Brooklyn who fell in the war of the rebellion. The design selected from the many competitive essays presented last winter is the work of Mr. John H. Duncan, architect, of this city. It is the same which was then pronounced in GARDEN AND FOREST to be not merely the best for the purpose, but so far above all its rivals that there was no room for discussion with regard to it. Who is to execute the groups of statuary which should adorn it we have not yet learned.

Those elegant Cape bulbs, the Freesias, deserve their growing popularity, both on account of their graceful growth and their delicious fragrance. There are some plants of remarkable vigor just now in the green-houses of Mr. John Thorpe. They are in five-inch pots, with five bulbs in each pot, and each plant is twenty inches high, with leaf-blades three-fourths of an inch wide and sheaths of the same width at the base. They were potted on the 6th of July in soil of sandy loam, with a quart of bone flour to each half bushel of soil, and there is little doubt but that the plant food in the bone did much to nourish them into their unusual growth.

One of the best forms of *Elæagnus umbellata* in cultivation is that introduced into this country from Japan by Mr. Thomas Hogg. The largest specimens of this plant in the Flushing Nursery, where it was first planted, are now twelve or fifteen feet high and form stout, wide spreading bushes. It is almost the last deciduous plant to lose its leaves in the autumn, and the fruit, which is freely produced at Flushing, is high colored and attractive in appearance, and possesses rather an agreeable sub-acid flavor. The Indian form of this widely distributed and variable species, known in gardens often as *E. angustifolia*, is a far less hardy and in every way a less desirable plant.

An interesting and attractive form of *Cattleya Bowringiana*, with pale mauve colored flowers, is now blooming for the first time in Mr. Ames' garden at North Easton. In the same collection two plants of *Vanda Kimballiana* are in bloom, and with them a plant of *Vanda Amesiana*. The flowers of the latter plant, although less showy in their contrast of colors than those of Mr. Kimball's *Vanda*, are deliciously fragrant, a single spike

of bloom perfuming a whole house. This delightful fragrance and the fact that this species blooms at a season of the year when comparatively few Orchid-flowers are seen, make *Vanda Amesiana* a most desirable plant.

The first of the twelfth course of the free Michaux Forestry lectures was delivered by Professor Rothrock, in the hall of the Philadelphia Academy of Natural Sciences, on the evening of the 4th instant. The subject was "Civilization as Related to Surroundings." The other lectures of this course will be given on the succeeding Wednesday evenings, and will treat of "Some Neglected Trees," of "Some Famous Trees," of "Trees Along Our Roadsides," of "Trees In Our Yards," of "Trees We Are Exterminating," and of "Practical Forestry." These lectures are given under the auspices of the American Philosophical Society, and are provided for from the income of the fund left to that Society by Francois André Michaux, the distinguished historian of American trees.

The new vegetable, *Stachys affinis* (or *S. tuberifera*), which is called "Crosnes" in France, seems to be winning its way in Germany. It was put to proof in the proverbial way at a recent meeting of the Society for the promotion of Horticulture in Berlin, being eaten both boiled and roasted. Some who tasted it pronounced roast potatoes much better, but the majority, says a German journal, declared that the *Stachys* tubers have a "fine, peculiar taste, and should be highly recommended to the epicure." An official of the Berlin Botanic Garden stated that a rumor to the effect that the new vegetable was being propagated there brought hundreds of requests for it, and that he was obliged to have hectographed circulars prepared explaining that the report was untrue.

We must listen to foreigners to learn about American manners and customs. Here is an example, quoted from a German horticultural journal of the most serious character: "The love for oranges in America has led to the introduction of picnics that are called 'Lemon Parties.' Each attendant at such a picnic brings a lemon or orange and gives it to the general 'squeezer.' This official cuts the fruit in two, collects and counts the seeds and then prepares a bowl of lemonade. Each person then guesses the total number of seeds collected, he who is nearest right receives a prize, usually a costly lemon, a goblet; he who is furthest wrong is called 'the Bubi' (booby?) and given a lemonade squeezer. Those whose lemons have contained the most and the fewest seeds likewise receive prizes, and the ladies present are always adorned with yellow Roses and ribbons."

The rare *Cypripedium Fairieanum* is now in flower in Mr. Ames' collection. This species, although it has been known for thirty years, is one of the rarest plants in cultivation. All that is known of its origin is that it was obtained at a sale at Stevens' auction rooms, in London, of a lot of East Indian Orchids sent from Assam. It has never been seen in its native country, although various efforts have been made to rediscover it, one enterprising English dealer having expended, it is claimed, no less than \$25,000 in a vain attempt to obtain a supply of native plants. The flowers are not large, but they are exquisitely colored and penciled, and are among the most attractive of the genus. *Cypripedium Fairieanum*, although it has been considered generally a delicate plant, and difficult to manage, has impressed itself on several hybrids, of which the best known is *C. vexillarium*, obtained by a cross with *C. barbatum*.

The English journals announce the death, in his ninetieth year, of Robert Marnock, the foremost landscape-gardener who has appeared in England during the second half of this century, and one of the best exponents of the 'natural style.' He served his apprenticeship as a gardener and found his first public employment in designing the Sheffield Botanic Garden, of which he became the first curator, not a bad training for a landscape-gardener, and one which led to his selection, in 1839, to lay out the garden of the Royal Botanic Society in Regent's Park in London. This established his reputation, and he has since been kept busy in the practice of his profession until his retirement a very few years ago. Marnock was strong in artistic feeling and in his practical knowledge of plants; and here was the secret of his success. The artist and the gardener worked together, and his creations were gardens gracefully and tastefully arranged, but gardens in which plants were always the principal and controlling feature. It never fell to his lot to make any great urban pleasure ground, or to design one of those broad landscapes which tax the highest creative skill of the artist, but in his particular field Robert Marnock was, in his day, without a rival. As a man he was singularly modest and attractive.

Our Forest Interests.

WHEN forestry is first brought to their attention many persons think chiefly of tree-planting, of the effect of forests on rainfall, and other things which are not essential or of the greatest practical importance. Their first impressions are likely to be superficial and inadequate. The question of the effect of forests on rainfall has not been determined. It is a matter for accurate and continued scientific investigation, without which all opinions and theories regarding the subject are alike worthless, because they cannot be verified. The point of general practical interest here is the function of forests, especially of mountain forests, in the distribution of the water that falls upon them as rain or snow. The doctrine of rational and practical forestry regarding this matter is, that forests retain the water in the spongy mass of their floor, retarding its descent to the channels of streams, and thus prevent or modify both freshets and drought. This effect of the forests upon the streams which have their sources in them is of great practical value; it is not beyond the range of popular appreciation, but can be verified, without special scientific training, by any observing person who will go into the woods in a hill-country during a heavy rainfall. This is one of the essential facts or fundamental principles of forestry, and it should be urged upon popular attention until it is "in the air" everywhere, a part of the universal thought and established knowledge of the time.

Tree-planting on a small scale, if intelligently and carefully done, would be useful almost anywhere as an educational experiment. It would help to awaken and increase interest in subjects connected with the care and uses of trees, and it should everywhere be encouraged. But it is not forestry, is not necessarily any part or feature of it, and it is not best that people should take one thing for another without knowing it. In all the eastern part of our country the trees will come in again, and the forests reproduce themselves, if they are cut off in the right way, and the land is afterward guarded from fire and pasturage, and this natural perpetuation of the forest is of far greater importance here than planting trees.

Looking at forest interests in this country in a practical way, it is plain that the care of individual holdings of timber-lands, and the methods best adapted to perpetuate the growth and production of timber on the farms of the United States, are matters of great and increasing importance. The existing condition and practice are unsatisfactory, because there is, generally, very little system, plan or management. The future is largely left to chance, or to take care of itself. This branch of forestry is obviously a part of agriculture. It is chiefly an economical subject, and there is not much need or room for sentiment or mystery connected with it. It has not yet begun to receive adequate attention among the farmers of our country. The diffusion of knowledge and propagation of sound and practical ideas regarding the care of farm woodlands, and the value of timber as a permanent crop, should be a prominent feature of the work of the Granges and other organizations of farmers, as well as of local and state forestry associations.

The value of mountain forests, and the necessity of maintaining forest-conditions permanently on lands around the sources of mountain streams, are most vital and important features of scientific and practical forestry. They urgently require attention in this state, in Pennsylvania, New Hampshire and the other states intersected by our eastern mountain-system. The effects of the permanent destruction of forest-conditions over large areas of mountain country are so far-reaching and fatal that indifference and inattention constitute a crime against civilization and the nation's life. The fate of the mountain forests on the lands which still belong to the nation is one of the most momentous of all the problems now presented to the American people, and its decision will determine the future of vast areas in the western part of our country, whether they shall be fertile, populous and prosperous, or irreclaimably barren, and, in large degree, uninhabitable. The danger, and the necessity of prompt action in withdrawing the forest-lands of the public domain from sale, and of guarding them effectively from spoliation until a competent commission decides what portions should be kept permanently in forest, and presents a plan for national forest-management, should be urged upon Congress and the President by the people and press of the entire country in the most direct, clear and forcible manner.

The herbariums entered for the prize offered by Mr. Peter Henderson made one of the most interesting features of the exhibition at the last meeting of the Society of American Florists. The collection which won the first premium was the work of a young gardener, and it is described by a correspondent of *The American Florist* as consisting of good, typical specimens, carefully mounted, correctly named, neatly tied in folios marked with outside labels to indicate the natural orders, arranged in botanical sequence and with a full index, and placed in an attractive and serviceable cabinet. Now, herbariums in themselves are of little practical value unless they are large and are used systematically. But when a young man sets out in serious earnest to make a good collection of well-preserved plants, the training which he receives in cultivating habits of observation, order and accuracy, and in acquiring a general knowledge of plants, will be of immense value to him all the rest of his life. In some of the establishments of Europe the making of herbariums has been long considered a valuable aid in the education of gardeners. In the article referred to we are told that Mr. Henderson himself received two medals for similar work before he was eighteen years old, and he testifies that the interested and careful preparation of these specimens did much toward developing methodical habits and laying the foundation for business success. There are many indications of a growing belief that the prosperous gardener of the future will be a man who has made some progress in the sciences related to horticulture, and who has enjoyed some special training in the art. The collection and

care of dried specimens is not enough to make a good gardener; but it is one means of developing a love for plants, of increasing a knowledge of them, and of inculcating lessons of orderliness and accuracy which will prove of lasting value to every one who expects to be a gardener or florist.

There appears in the "Annals" of New York city for the year 1786, compiled from the newspapers of the day, joined to the reprint of the New York Directory for 1786, recently issued by the Trow Directory Co., the following item:

April 14th, 1786.

"Mr. Michaux, botanist to his most Christian Majesty, having purchased a lot of ground at Wehocken, near the Three Pigeons, is erecting a garden there which for magnificence, etc., will exceed anything of the kind in America. In it will be introduced many exotic and domestic botanical curiosities."

This Mr. Michaux is the distinguished French botanist, André Michaux, who resided in America from 1785 to 1796 as an agent of the French Government for exploring the natural resources of this country, and for the introduction of useful trees and other plants into France. An account of this garden, from the pen of Mr. H. H. Rusby, was published in the *Bulletin of the Torrey Botanical Club*, in August, 1884, from which it appears that when Michaux finally left America it was transferred to a Mr. Saunier, and later to a son of the latter, who continued to send plants to France for many years. Michaux's garden now forms a part of the Hoboken Cemetery, and all traces of the plants brought here by Michaux from his long journeys in remote parts of the country have now entirely disappeared.

Abraham's Oak.

THE old Oak at Mamre in Syria, or, as it is known everywhere, "Abraham's Oak," is one of the most famous and venerable trees in the world. It is revered alike by Jew, Christian and Mahomedan, for it is supposed to mark the spot where the patriarch pitched his tent in the desert. There is a superstition in Jerusalem, and in all the country about, that whoever shall cut or injure this tree will lose his first-born son. So for centuries it has been allowed to toss its gnarled and contorted limbs in the gales which sweep from the Mediterranean over the Syrian plains.

This tree was visited by Sir Joseph Hooker in the autumn of 1860; and in his paper upon Syrian Oaks, read the following year before the Linnæan Society (*Transactions*, xxiii.), he gave a description of it and a portrait drawn by his own hand.

Abraham's Oak was found to belong to *Quercus pseudo-coccifera*, which, to quote from Sir Joseph's paper, "is by far the most abundant tree throughout Syria, covering the rocky hills, of Palestine especially, with a dense brushwood of trees eight to twelve feet high, branching from the base, thickly covered with small evergreen rigid leaves, and bearing acorns copiously. On Mt. Carmel it forms nine-tenths of the shrubby vegetation, and it is almost equally abundant on the west flanks of the Antilebanon and many slopes and valleys of Lebanon. Owing to the indiscriminate destruction of the forests in Syria, this oak rarely attains its full size." The circumference of the trunk of "Abraham's Oak" is given as twenty-three feet, and the diameter of the spread of the branches as ninety feet.

Quercus pseudo-coccifera is an evergreen species with the general appearance of the Ilex of southern Europe, and closely related, botanically, to *Q. coccifera*, a common and widely distributed scrub Oak of southern Europe, and of Algeria; indeed, Hooker was of the opinion that the two plants were merely geographical varieties of the same species.

Our illustration of "Abraham's Oak," upon page 607, represents the tree with much less foliage than appeared in Hooker's picture taken nearly thirty years ago, when it was apparently in a more vigorous condition than at the time

when the recent photograph from which our illustration is made was taken. We are indebted for this photograph to Mr. Francis Skinner, of Boston.

The Art of Gardening—An Historical Sketch.

XV.—Rome.

(Concluded.)

IN his catalogue of trees, the elder Pliny names many varieties—eighteen kinds of Chestnut, for instance, eleven kinds of Myrtle, thirteen Laurels, four Elms, three kinds of Box, twenty-nine Figs and forty-one Pears. But even if such numbers represent garden varieties which we should now call distinct, they are not, in most cases, very imposing compared with the riches of to-day; indeed when we consider the number of distinct kinds, it is very apparent that in trees and shrubs as well as in flowers the wealthiest Romans could not command a hundredth part of the material that is easily procured to-day. Yet many of them were passionate horticulturists and such exotic plants as could be procured were highly prized. The Plane, according to Pliny, was among the first trees to be introduced, simply, as he is careful to explain, for its ornamental value. It came from the Levant by way of Sicily, and the Cypress and Cedar were likewise foreigners, though they now grow apparently wild in many parts of Italy. The Balsamum, "a plant that has been bestowed by Nature only upon the land of Judea," where "in former times it was cultivated in two gardens only, both of which belonged to the kings of that country," was "exhibited in Rome" by Vespasian and Titus; and its cuttings were so valuable that "the fifth year after the conquest of Judea these cuttings, with their suckers, sold for the price of 800,000 sesterces." The Balsamum got this extraordinary value as the source of a favorite kind of incense,* but many other shrubs "were introduced for ornamental gardening," and after the time of Pompey it was the custom to carry foreign trees in the triumphal processions. On the walls of the villa of Livia, the Laurel, the Pomegranate, the Stone Pine, the Ilex, the Plane, the Myrtle, the Cypress, a species of Cherry and three different kinds of Firs are accurately portrayed. Ivy and other evergreen vines, as well as the Acanthus and the Grape, were everywhere trained upon walls and trees in the most ingenious ways, and Grapes, Gherkins and Watermelons are named among the fruits forced under glass. Olive-trees, of course, were everywhere, and Plums and Apples, as well as Pears, were cultivated in manifold varieties. Pliny asks us to believe that there stood at Tibur a tree which bore every known kind of fruit, and it is certain that grafting was constantly and skillfully practiced. The Peach had been introduced from Persia, as is shown by its name—*Persicum*. Vitellius, who had been legate in Syria, introduced many Syrian varieties of the Fig into his country-seat at Alba. The Ash, the Oak, the Mulberry, the Quince, the Walnut and the Almond were other familiar trees, and the Palm was planted here and there, but as a rule seems to have been imported from Syria and Egypt and grown in pots. I may say again that neither in Greece nor in Italy was a distinction made between ornamental and useful trees. Any tree of pleasing aspect was thought appropriate to the pleasure-ground, and was but the more highly valued if it served utility as well as beauty.

An amusing anecdote told by Pliny the Elder shows the estimation in which exceptionally fine trees were held. Cneius Domitius publicly rebuked Crassus for living in a house so magnificent that he himself would be willing to pay ten million sesterces for it. Crassus replied that, deducting six trees only, he would accept the offer. Domitius declared that on those terms he would not give a single denarius, whereupon Crassus exclaimed: "Well, then, which of us sets a bad example and deserves the reproof of the censors—I, who live like a plain man in a house which has come to me by inheritance, or you, who estimate six trees at a value of ten million sesterces?"

These trees, adds Pliny, "were of a Lotus kind, and by the exuberance of their branches afforded a most delightful shade."† They must have stood in an urban garden, for "they were in all the freshness of youth when Nero burned them."

* Unguents, says Pliny, were not known in the West until Alexander captured the perfume chest of Darius. But in imperial times their use was so common that a score of spots on the Mediterranean coast and islands were famous for their manufacture, and the love for them gave a great impulse in Italy to the cultivation of plants with sweet-scented leaves.

† It was this Lotus-tree and not the aquatic plant called by the same name which furnished the *lotophagi* with the food which obliterated memory. Some writers have thought it the Celtis, but modern authorities identify it with the *Rhamnus Lotus* of Linnæus, now known as *Zizyphus Lotus*.

In the most distant northern countries conquered by the Romans—all along the Rhine, all through France, and in many parts of England—lie the remains of great villas, the architectural magnificence of which must have been supported by pleasure-grounds of corresponding beauty. No excavations can help us to recover, in the art of gardening, a single relic of the designs of days so long gone by. We can easily imagine, however, how the Roman horticulturist consoled himself in his exile, now by forcing the products of an alien clime into a likeness with the garden effects that he had loved at home, and now in devising new effects which should display these products in a characteristic way, appropriate to the more northern climate and the wilder landscape. And a sign of his labors everywhere persists in the presence of many trees, now apparently native to the soil, which history or tradition tells us he was the first to introduce.*

In the history of the eastern and southern provinces the work of the Roman gardener is constantly recorded. Of course it was often modified by those ideas of Greek or Persian origin which he found already prevalent, but there can have been no town in the civilized world during the first three centuries of our era which the combined influence of Persia and Rome had not richly ornamented. Ephesus, Smyrna, Miletus and Antioch were especially famous for their gardens, and at Pergamon, where the ruins of the magnificent temple commemorating victories over the invading Gauls have recently been unearthed, the main structure was encircled by vast pleasure-grounds, where stood the library and other public buildings. Even the bitterest enemies of Rome in Asia felt the common impulse. Strabo mentions at Cabeira "the palace of Mithridates, the water-mill, the park for keeping wild animals and the hunting-ground in the neighborhood;" and Pliny tells us that the great Parthian king and his people used their utmost efforts to grow the Myrtle and the Laurel, plants everywhere desired for use in religious ceremonies.

The fullest description of an Oriental pleasure-ground of this period which I have been able to find is the one which Diodorus gives of Panara, in the island of Panchæa, off the coast of Arabia Felix, where, of course, Persian influence had been at work. I quote it as an interesting contrast to the younger Pliny's account of his Tuscan villa:

"The fields round about the temple are planted with all sorts of trees, not only for fruit, but for pleasure and delight, for they abound with tall Cypresses and Plane-trees, Laurels and Myrtles. . . . Near the temple there's such a mighty spring of sweet water rushing out of the earth that it becomes a narrow river; thence it divides itself into several currents and streams, and waters all the fields thereabouts, and produces thick groves of tall and shady trees, amongst which, in summer, abundance of people spend their time. . . . Here are many gardens, sweet and pleasant meadows decked with all sorts of herbs and flowers, and so glorious is the prospect that it seems to be a paradise worthy of the gods themselves. . . . Here are likewise large and fine Palms and abundance of Walnut-trees, . . . and a multitude of vines of all sorts spiring up on high, and so curiously interwoven one amongst another that they are exceedingly pleasant to the view and greatly advance the delights of the place."† The temple stood in the middle of this park, with the dwellings of the priests around it. The spot was evidently one which nature had especially marked out for man's delight; yet it must have been carefully arranged and tended to fit it for permanent habitation by the priests, and a certain measure of formality is indicated by Diodorus' mention of a great fountain which was "lined on both sides and flagged at the bottom with stone at vast expense."

New York.

M. G. Van Rensselaer.

"In making islands we must follow nature very carefully. It is noticeable, generally speaking, how very seldom this is done; I hardly remember to have seen anywhere a made island, whose artificiality was not obvious at the first glance. This I found to be the case even in the small royal garden at Buckingham House, where the island looked more like a pudding in its sauce than like any nature ever produced."—*Pückler-Muskau*, 1834.

* "Cæsar found, in Britain, apples of indifferent quality and a very poor catalogue of other fruits, such as the Hazel, Bullace, wild Raspberry, Sloe, Elder and Blackberry. The generals who succeeded him left us, at quitting, the Pear, Peach, Cherry, Vine, Fig, Mulberry, Damson, Medlar and Walnut, with many ornamental shrubs. They were men of taste and luxury, and some of those who resided long in this country sent to Rome for any novelty suited to the climate, planted, probably, the first orchards—at least of superior fruits—the earliest Rose-gardens, and, among other trees, the Bay, the English Elm and the Plane, which had passed from Asia into Italy, and had reached the northern shores of Gaul, as Pliny states, about A.D. 79."—"The Migrations of Plants," *Edinburgh Review*, April, 1889.

† Blake's translation.

Holiday Notes in Southern France and Northern Italy.—VIII.

MENTONE must be a dreary spot to the ordinary tourist, except during the winter and spring months, when the place is crowded with visitors, attracted by its mild climate and natural beauties. Full details about the climatology of the district are to be found in Dr. Henry Bennett's charming book, "Winter and Spring on the Mediterranean," a work which has run through several editions and is pretty well known in the United States. Without studying the climate it is impossible to understand such a wonderful array of vegetable forms, such a strange mixture of tropical, sub-tropical and temperate plants growing side by side as are seen here. Nowhere in Europe have experiments on the hardness of tropical plants been conducted on so large a scale as on the Riviera, and consequently the northern gardener finds much to learn from both the failures and successes of his brethren in the south.

On steep slopes near the station at Mentone are groups of such very fine Agaves (or Aloes, as they are called in Italy and elsewhere) that they attract the attention of every passer-by of a horticultural turn of mind. *Schinus Molle*, the Pepper tree or *Poirrier* of the French, is a favorite street tree here, as well as elsewhere along the Riviera; it is of very graceful habit, when not too much cut in, the long, slender branches—clothed with dark green, pinnate leaves, and bearing panicles of red fruits about the size of pepper corns, and about as hot to the tongue—droop much in the manner of those of our common Weeping Willow.

A short avenue, going at right angles to the Avenue du Careï, is planted with Date Palms and *Washingtonia filifera* (at the present moment probably the most popular Fan Palm along the Riviera) in alternate pairs. The bed of the Careï—at the time of our visit quite dry and dotted here and there with annual weeds of a southern and unfamiliar type—is flanked by roads, along the sides of which are planted such trees, etc., as Oleander, big Ligustrums, *Photinia serrulata*, *Senecio Petasites* and *Myoporum latum*. In one garden a bush of *Wigandia Caracassana* some fifteen or twenty feet high, with enormous panicles of fruit, was a very conspicuous object from the foot-path.

The public garden of Mentone is unworthy of the place; it is small, and the flowering shrubs are simply clipped with shears, and are neither pruned nor cultivated in any rational way.

As a weed on roadsides leading from Mentone to Grimaldi we noticed the Squirting Cucumber (*Ecballium Elaterium*), a plant which in some parts of England is cultivated for medicinal purposes. On dry, sunny banks Rosemary seemed quite happy, and here and there the Caper (*Capparis spinosa*), with its long, slender branches, hung down the face of the hot rocks. Fine groves of Olives and Lemons flank the highway, from which beautiful views of the sea and coast line are constantly appearing. Sometimes Wild Pines (*Pinus Halepensis*) and the so-called Umbrella Pine (*P. Pinea*) clothe the face of rocky, barren slopes almost down to the water, and add not a little to the beauty of the scenery. Part of the side of a hill before Grimaldi is reached is the site of the garden of Dr. Bennett, whose name has already been mentioned at the beginning of these notes. What can be done, even under very adverse circumstances, by the enthusiastic gardener is obvious here, for a considerable collection of plants has been gathered together, and is cultivated on a site where previously few even native plants could find a living. Magnificent views are obtained from Dr. Bennett's garden, particularly from the top of the Saracen tower on the height behind the house—a building in the Florentine style of the fifteenth century. Among flowering plants noticed was a fine specimen of *Brunsvigia Josephina*, with its red flowers arranged in an umbel more than forty inches across and surmounting a scape nearly two feet high. Amongst the South African farmers who are familiar enough with *Brunsvigia* in a wild state it is known as the Candelabra-flower. Several, however, to whom I had given the dimensions above mentioned had never seen in the native habitats of the plant any inflorescences nearly so fine as that I have described in the gardens of Torre di Grimaldi.

In a small piece of water on one of the terraces, high up the side of the hill, is a colony of the White Water Lilies (*Nymphæa alba*); this affords abundance of cut flowers until December, when the Cape Pond Weed (*Aponogeton distachyum*), which has been at rest during the hottest part of the year, gets into vigorous growth and continues the supply throughout the winter and spring.

LA MORTOLA.—Across the Italian frontier, about an hour's walk from Mentone by the famous Corniche road—and at about the highest point of the road between San Remo and

Monaco—brings us to La Mortola, a small village in the midst of Olive-groves. Here Palazzo Orengo, the residence of Mr. T. Hanbury, is finely situated, and is surrounded by a beautiful garden containing an extraordinary collection of plants. Just twenty-two years ago its present owner found it covered with Olive and Lemon-trees, some of which still remain; the area of the garden is about fifty acres, and there is a difference of level of considerably more than six hundred feet between the lower portion and the highest part. Some fifteen years ago a couple of illustrations, representing views in the gardens of Mr. Hanbury, appeared in the *Gardeners' Chronicle*, but these fail altogether to do justice to the exquisite beauty of the place and its surroundings; the letter-press, however, accompanying the illustrations in question, recalls vividly to my mind the impressions received at La Mortola. A few sentences covering some of the points I find recorded in my note-book. I herewith copy from the *Gardeners' Chronicle* for July 11th, 1874: "Our business lies not so much with the village as with the grounds round the Palazzo Orengo, now occupied by Mr. Thomas Hanbury. Placed in a situation very similar in character to the projecting cape on which Monaco is situated, and almost equally lovely in its surroundings, this garden is one of the most interesting, from the richness and variety of its contents, that can be seen in any country. It occupies the slope of a hill trending toward the sea, is protected in part by the mountains which rise behind it, but must be exposed to certain winds which rush from the north down a deep gorge on the western side of the garden. This gorge, from the side of which our illustration is taken, descends from the top of the mountains to the sea, and its sides are planted with Olives and Pines. This ravine adds greatly to the picturesqueness of the garden, and, together with the rocks in its vicinity, furnishes a perfect treasure-house of wild plants. Fancy the delight of gathering Wild Myrtle with one's own hand, and Wild Oleander, and yet in Europe! *Coriaria myrtifolia* is also a characteristic plant, and so is the pretty *Smilax aspera*, whose spotted leaves and zigzag clusters of pink berries are of a very ornamental character. Lavender, Rosemary and Thyme grow abundantly on the rocks. *Convolvulus althæoides* is one of their greatest ornaments. The Caper flourishes on the walls. A species of *Moricandia* comes up everywhere in the neighborhood as a weed, but is one of those plants whose distribution is entirely confined to a narrow area on this coast, it not being found elsewhere. A species of *Asparagus* (*A. acutifolius*) is by no means inelegant; *Daphne Gnidium* grows here in some profusion; the *Alaternus*, so familiar to us at home, fruits abundantly; *Globularias* abound on the rocks; *Euphorbias* are very characteristic, in particular a little spiny species, *E. spinosa*, and a really grand shrubby species, *E. dendroides*, which forms large bushes, not only under the Olives, but also springing from the clefts of the rock close to the sea, where little else will grow. An admirable selection from these native plants—admirable not only from the judgment with which they have been selected, but also for the faithfulness with which they have been represented, and the interest that has been thrown around them—is given in (the late) Mr. J. Traherne Moggridge's "Flora of Mentone." An account of some of the more remarkable exotic plants in Mr. Hanbury's garden will be given in my next series of notes.

Entomological.

A Tulip Tree Leaf Destroyer.

(*Cecidomyia liriiodendri*.)

IN the *Monograph of the Diptera of North America*, Part I, (1862), p. 202, Baron R. Osten-Sacken gives the following brief account of the insect to which this notice and the accompanying illustration (see page 605) refers.

"*Cecidomyia liriiodendri*, n. sp., Brown spots with yellow or greenish aureole on the leaves of the Tulip tree (*Liriiodendron tulipifera*). These spots, about two-tenths or three-tenths of an inch in diameter, indicate the presence, inside of the leaf, of a leaf-mining larva of *Cecidomyia*. It is about one line long, orange, the exserted portion of the breast bone is truncated heart shaped; the tip of the body has two short, horny points, directed upward. (Similar spots on the same tree are produced by a lepidopterous larva.)"

No further observation is made. Baron Osten-Sacken had evidently not seen the imago, and I have not been able to find any other record or account of the insect or its injuries. During the past two years, at least, the beauty of the foliage of many large Tulip trees about Boston has been destroyed by

the work of these little leaf-miners, or, more properly, spot-makers, belonging to the large genus *Cecidomyia*, which includes the destructive Hessian fly. Many people who have always counted upon their Tulip-trees as belonging to one of the few species free from serious insect-attacks, have, by midsummer, been disgusted to find the leaves filled with large brown and yellow blotches. In some instances the foliage, by the end of August, has become so brown and twisted from the effects of numerous spots in every leaf that it has had the appearance of having been scorched by fire, and many of the leaves having thus become dead and dry fall to the ground.

There are several (three or more) broods of the insect during the season, and the broods so overlap each other that some larvæ may almost always be found. The first eggs are probably laid on the young leaves as they unfold in the spring, and the last lot of larvæ reach full growth about the end of September, when they make a slit on the under side at the edge of their mine, and escape to the ground to pupate and remain through the winter. The pupa skin is very thin and transparent. The species of *Cecidomyia* are so numerous, and so similar in most of their characters, that it is generally not easy to identify the flies without a knowledge of their early stages and habits. In the present case the body of the small, delicate fly is light brown in color and sparingly covered with hair. The length of the female is about eight-hundredths of an inch (two m. m.), and of the male considerably less. The head is black; the antennæ are dark brown and in the female apparently thirteen-jointed. The joints of the antennæ of the female are on short pedicels, and they are cylindrical and of even length. The basal joint is thicker and much shorter than the others. Each joint has a whorl of hairs around it near the base, and a few near the other end, and some of the basal hairs are longer than the joint.

The antennæ of the male are much longer and apparently twenty-four-jointed, with two additional very short and indistinct joints at the base. The pedicels between the joints are long; the joints are simple, short, and bulb-like, every alternate joint being slightly smaller; and the connecting pedicel is somewhat thicker and shorter than the next, which is slender and cylindrical. Each joint is provided with a whorl of very long hairs, thus giving the male antennæ a feathered appearance.

The legs are long, with femora and tibiae of equal length, and tarsi much longer. They are banded by light yellow and brown, and are dark or black at the joints.

Like most of the genus, the surface and margins of the wings of this species are hairy, the hairs being longer and more numerous toward the base. The wings of the largest specimens (females) expand about two-tenths of an inch (five m. m.).

The poisons appear light brown.

The dark spot in the leaf is the part occupied by the larva, and the "yellow or greenish aureole," which is represented within the light outer lines in the figure, is probably caused by the disturbance of the tissues, or more likely by the absorption of the nutritive sap by the larva. As these larvæ cannot devour the tissue, but simply live upon the sap, the diameter of the spots occupied by them is usually little greater than the length of the inmates. In addition to the brief description of the larva given by Baron Osten-Sacken, it may be noted that when removed from its mine and placed upon a flat surface it has the power of springing an inch or two into the air. This is done by doubling up the body and suddenly extending it again, and probably the large spines on the last segment are made use of for this purpose. Some other species are known to possess the same power of springing, and in the monograph referred to (p. 183) it is remarked that "all such larvæ belong to the sub-genus *Diplosis*." The venation of the wings corresponds with the venation given for the sub-genus *Diplosis*, and the number of joints of the antennæ also agree with the characters as drawn up by the late Dr. H. Lœw. But without referring to Dr. Lœw's arrangement, I should have been inclined to describe the antennæ of the male as thirteen-jointed, each joint being very deeply and widely constricted in the middle and forming two bulb-like divisions.

No thorough, cheap, and easily applied remedy can be given for this pest, because the larva, living between the epidermal layers of the leaf, is safe from the action of poisons. Showering the trees with a very fine spray of kerosene emulsion or whale-oil soap when the flies are active or ovipositing might destroy many of them; but, where the trees are large, this would be difficult and expensive, and would have to be repeated, and the result then could only be a partial success. As the larvæ fall to the ground and probably pupate directly beneath the trees on which they live, they might be best and

most easily destroyed by thoroughly turning over and rolling the soil in the late autumn or very early spring. Thus buried deeply and with the earth pressed firmly about them, the delicate flies would either be crushed in the pupa state or would not be able to push their way to the surface. This might destroy a large proportion of them. These remedies are merely suggested; they have not been tried, and may not be practicable or efficient. Very injurious attacks are often quite local, and on some estates about Boston the trees have been comparatively free from damage by the insect, although its presence may be everywhere detected.

Foreign Correspondence.

London Letter.

THE end of November may be termed a kind of close season for horticulture. There are Chrysanthemums, of course, and they are everywhere, crowding exhibitions, filling the papers, and occupying the attention of almost every horticulturist. In the houses we have little except Chrysanthemums. Hope of better things soon is encouraged, however, by the development of the Poinsettia, Euphorbia, Linum, Luculia, winter-flowering Acanthads and the Ericas; but they

Fig. 152.—*Cecidomyia liriodendri*.—See page 604.

It is quite possible that on account of unfavorable seasons or other causes, there may be years when its disfigurement of the foliage will not be noticed, and it will only occur in injurious numbers at irregular intervals.

The accompanying illustration, from a drawing by Mr. C. E. Faxon, shows a leaf well filled with spots, although there are frequently two or three times as many in a single leaf. It may be added that the "similar spots" made by a "lepidopterous larva," mentioned by Baron Osten-Sacken, have so far not been detected here; but leaves with long, irregular, winding mines are not uncommon.

Arnold Arboretum.

John G. Jack.

are only coming. Out-of-doors the near approach of Christmas is heralded by the beautiful white cups of the Hellebores, and there are still left the spikes of Schizostyles, notwithstanding three successive nights of about nine degrees of frost and a slight fall of snow. The Sea-buckthorn (*Hippophae rhamnoides*) is heavily laden with its bright orange berries, and the yellow Jasmine is beautifully in flower on a sunny wall. Until the frost came our trees and shrubs were richer in autumn colors than they have been for many years. All of those mentioned by Mr. Jack in his interesting notes on the autumn colors of leaves in American gardens were brilliant here, besides many others not mentioned by him. Indeed, so

favorable to the development of autumn tints has the past season been that scarcely a tree or shrub out-of-doors was lacking in attractiveness of this kind. Here we require a mild, moist, sunny autumn to make the leaves of deciduous trees and shrubs assume beautiful colors before falling. If we could be ensured of this, then English landscapes might be made as glorious as the best in America by the use of those trees which in a favorable season put on these glowing colors. But next year and the next may be as unfavorable as this has been favorable. Some plants never fail even here, as, for instance, some of the Maples, the Oaks and Ampelopsis; but it is only rarely that we get such pictures as hardy vegetation generally presented this year.

GYMNOGRAMMAS.—The illustration of *G. schizophylla*, var. *gloriosa*, published in GARDEN AND FOREST for November 6th (p. 533), is a beautiful representation of a Fern which must be extremely difficult to represent on paper. The species is popular with Fern-growers in England, as indeed are a considerable number of the hundred or so species at present known. Forty of them are represented at Kew, and of this number about two-thirds are sufficiently ornamental to rank among the choicest of garden Ferns. *G. schizophylla* was known in Jamaica a long time before it was successfully introduced into England, although many attempts were made to get it to Kew. The plant is so very delicate that it soon perished when subjected to the adverse conditions of a long sea voyage in a Wardian case. It came at last in surprising condition, luck having favored it all the way, and we had the pleasure of opening the Wardian case, which contained about a score of beautiful plants in fair health. It arrived about the same time at the nurseries of Messrs. Veitch, who soon afterward distributed it. The variety *gloriosa* was distributed in 1885. It is not of garden origin, as stated in GARDEN AND FOREST, but is an exceptionally strong form which was imported from Jamaica. The species is somewhat variable in the size, form and substance of the fronds, some of the forms being as weak and attenuated as that named *gloriosa* is strong and full. The cultivation of Gymnogrammas is not difficult, if their liking for direct sunlight is remembered. I know from experience that a position which is shaded is much less agreeable to these plants than one which is not shaded at all. The Kew collection is placed on a side stage with a south exposure, and when all the rest of the house is shaded with the blind this is left unshaded. The difference in the vigor and health of the plants thus treated and those grown in a shaded house is most marked. Of course the atmosphere is kept saturated and the plants are freely watered at the root, except in winter, when the soil is kept moist only.

Amongst the rarer species, which are sufficiently ornamental to rank with the most select garden Ferns, the following are noteworthy, viz.: *G. Mulleri*, fronds erect, pinnate, about a foot long on well grown plants; pinnæ roundish or oblong, an inch long, rather leathery in texture, and covered on both sides with silvery scales. It is a native of Australia. *G. vestita*, something like the last, but with more flaccid fronds and stalked pinnæ. It is a native of the Himalayas, and thrives in an ordinary green-house. *G. rufa* is another of the same section as the two already named. It is distinct, covered with soft, silky hairs rather than scales; the fronds, too, are longer and more herbaceous. *G. Pearcei*, var. *robusta*, is an exceptionally strong and attractive variety which we owe to the Messrs. Veitch, who distributed it last year. The type, also introduced by Messrs. Veitch in 1864, is an elegant Fern, but too delicate to find much favor; whereas this new form of it develops into a strong, well furnished plant under ordinary treatment. All the forms of *G. calomelanos*, including several new ones, are first-class decorative Ferns. *G. trifoliata* may be called a climbing species, the fronds sometimes attaining a length of five feet by six inches in width, and requiring to be supported. Except as a very extraordinary species of Gymnogramma, it has little to recommend it.

Ferns do not receive as much attention in England now as they did a few years ago. It is only rarely that anything like a collection of them is formed, a few of the most useful for decorative purposes being grown in great numbers. The example set by Kew about seventy years ago, when the then curator, Mr. John Smith, commenced to form a collection by means of spores taken from specimens of Ferns sent to Kew by collectors, was followed in all large gardens in England, and Fern-collections were almost as fashionable as Orchid-collections are now. Although not in fashion, yet the whole order is one of the most delightful among garden plants, and few occupations could be more fascinating than the cultivation of a good collection of Ferns, beginning with spore-sowing and ending at big specimens.

ORCHIDS.—At this time of year the Orchid-houses are much gayer with flowers than the rest of the in-door department. Already *Odontoglossum crispum* is well in flower. A very fine variety, not yet named, is in bloom at St. Alban's, in Mr. Sander's nursery. It is remarkable for the size of its flowers and for a large chestnut colored blotch on each of the segments. Another new *Odontoglossum*, probably a natural hybrid, and of which *O. luteopurpureum* may be one of the parents, is also in flower with Mr. Sander. Its most striking character is in the labellum, which is rather long and narrow, crisped, white, with blotches of rosy violet, and the raised lines in the throat terminating in a thin filament. *Vanda Amesiana* is flowering freely in the nursery of Messrs. Low & Co., of Clapton. The principal fact now to be recorded in connection with this fine *Vanda*, noted by me last year, is that it appears to thrive better in a cool house than in a tropical one. Such, at all events, is the result of experiments made in the Clapton Nursery, where there are some thousands of it in cultivation. Its near ally, *V. Kimballiana*, is also coming into flower. A plant at Kew has a spike two feet high, but the fogs have proved fatal to most of the buds. It is remarkable that fog proves to be more injurious to *Vandas*, *Saccolabiums* and *Angræcums* than to other Orchids. *Lælia autumnalis* is in flower, as also is *Cattleya Bowringiana* and *C. bulbosa*. Several species of *Platyclinis* (*Dendrochilum*) are flowering in the cool house. It appears from a note which accompanied the picture of *P. filiforme*, recently published in GARDEN AND FOREST, that these plants are successfully grown in a tropical house, such as suits *Phalænopsis*. But here they are grown in a cool house along with the cooler *Cattleyas*, and they are in perfect health. Some Orchids thrive in a wide range of temperature, and, apparently, *Platyclinis* should be numbered amongst them.

MASDEVALLIAS.—The publication of Messrs. Veitch's beautifully executed monograph of Garden Masdevallias occurs at a time when it is likely to do some good by rousing Orchid-fanciers to the merits of many of the species as ornamental flowering-plants, and to the interesting nature of the genus as a whole. For it has to be admitted that in England at all events the Masdevallias have fallen out of favor, or, adopting the expression in the Orchid market with regard to them, there is nothing like the money in the majority of the species that there was a short time ago. This is a sordid view; but when one observes a glut in the market of established healthy plants, it is a safe conclusion that they are not much in demand. Next year may bring a revival of the love for Masdevallias. Certainly there is no genus in the whole Orchid-family which is so peculiarly suited to the ordinary cultivator, as well as to the specialist, as this; and for the following reasons: they are, as a rule, easily procured; they may be kept in health much more easily than most Orchids; they flower freely, many of them being rarely out of flower, and their flowers are extremely varied in size, in color and in form. If fantastic flowers are wanted they are abundant among Masdevallias, while richly colored, elegantly formed or "microscopically beautiful" flowers are equally well represented. Possibly the fact that these plants are not difficult to keep in gardens accounts for their depreciation in value here. But in your country I suspect they are not so abundant, nor so cheap, and to any one in search of an interesting and delightful specialty, the Masdevallias may be recommended. "Calypso" has called attention to the botanical and artistic merits of Messrs. Veitch's manual; permit me to add that the cultural directions are equally excellent, and that for any one wishing for directions as to what is best worth growing and how best to grow it, this book contains everything that is necessary.

FICUS ELASTICA VARIEGATA is a handsome stove plant which was introduced into English gardens about five years ago and is now popular. It is simply the well known "India rubber plant" with the outer half of the leaves colored clear shining cream-yellow—not a smudge-like variegation, nor yet a sickly pallor such as one sees in many new variegated plants, but a healthy, attractive yellow. Plants at Kew three feet high have leaves down to the pot and every leaf has the variegation well developed. It is much admired and will certainly become a general favorite. The plant was not received at first with much favor, and this was owing to there being two forms of it, one much inferior to the other. It is just as easy to multiply and cultivate as the green form. Possibly, however, the variegation would not be so marked if the plant were grown in a green-house; I am only able to speak of it from its behavior when treated as a stove-plant.

LILIUM AURATUM.—The number of bulbs of this *Lilium* which are imported, sold and killed in the gardens of this country is incredible. Weekly sales, commencing long before Christmas and ending about March, are conducted in London,

and every week from ten to twenty thousand bulbs are disposed of in this way alone. In addition there are the thousands of bulbs which the nurserymen import direct from Japan and distribute. Apparently the Japanese are as successful in the multiplication of this Lily as the Dutch are in that of Hyacinths and Tulips, otherwise the annual supply would not increase as it has done. The treatment to which the large majority of the bulbs of *L. auratum* are subjected in England must be very wide of what is right, for when properly treated no Lily is more easy to cultivate nor increases in the ground more rapidly. It should be planted six inches deep in beds in which Rhododendrons, Azaleas, Kalmias, or other peat-loving plants are grown, protected from severe frosts by a cone of ashes or cocoa-nut fibre about six inches high, and otherwise let alone. Treated thus at Kew a single bulb has in three years multiplied so as to produce eleven stems with an aggregate of one hundred and twenty blooms.

• London.

W. Watson.

in cultivation, all would be well; but instead of this, one receives amongst a mass of almost worthless varieties only a few with distinct characters, and a whole year, perhaps two, will be lost before they can all be determined. If seeds from selected varieties be sown at the same time, many of them will bloom the second year, and the raiser will be able to make his selection not later than the third year after sowing if the seedlings have been well treated. This means of procuring new forms is certainly the best, especially when we take into account the fact that one, at least, of the old varieties is well known to grow and flower freely on heavy, clayey soil where the other varieties totally refuse to grow at all. By means of seedlings the number of varieties for heavy soils may be increased and the characters made more pronounced. We are not at all sure that the best treatment for the Christmas Rose, whether in heavy or light soils, is fully understood, for a really fine plant can rarely be found in any of our nurseries, but this in a measure may be owing to the practice of

Fig. 153.—Abraham's Oak.—See page 602.

Cultural Department.

Christmas Roses.

BESIDES the annual importations from the native countries of *Helleborus niger* and its varieties, much is being done in a quiet way at home in raising seedlings from the best of the old established forms, and many of these are already showing characteristics which give the raisers every encouragement to redouble their energies in this good work of improvement. Although it is quite true that from these native habitats, chiefly Italy, the Tyrol and other parts of Austria, we occasionally get a really handsome form, it becomes a very doubtful question if the expenses of collecting, freight and other dues can be realized in the face of the many good forms raised at home. If one was always sure of procuring, in quantity, some form not already

breaking up the clumps for propagation. The prevalent idea seems to be that the Christmas Rose loves an unmanured soil, whereas our experience points rather to the most liberal treatment. Their first requirement is a deep, rich, well drained, but moist, soil. Then they need liberal top-dressing early in autumn, with stable manure, leaf soil and soot, if procurable; this given early in autumn feeds the plants at a time when they most need it—when the buds are being formed. The dressing may be lightly forked in late in spring. The last requirement is complete shelter from cold, drying winds. The same treatment for this handsome group of winter flowers will, no doubt, be applicable in the United States.

These Hellebores are sure to attain a high perfection in the United States. This is especially true of *H. niger altifolius*, which does exceedingly well in Scotland, where it perhaps attains its greatest perfection in the United Kingdom. Hellebores also do

well in Ireland, especially the pure white, *H. niger angustifolius* and the St. Brigid form, both of which are largely grown there. To-day, November 16th, we gathered the beautiful *H. niger maximus* or *altifolius*, the first to remind us of the approach of Christmas, and lasting in full beauty until the snowy white forms above named greet us early in the new year. *H. niger altifolius* is always the first with us here, beginning toward the latter end of October and continuing until January. Excepting, perhaps, the Riverston variety, which is a truly handsome flower, *H. niger altifolius* is the tallest and largest flowered of all known varieties. When grown under shelter the flowers come almost pure white, but when in the open air they have a warm, rosy tint, very attractive when grouped. The leaves grow from twelve to twenty inches high, of a fine dark green, and when liberally treated remain in perfection all through the flowering season. This is probably the only form amongst the old ones that flourishes in a cold, clayey soil, which is found fatal to most others; and it will prove a boon to those living in low-lying or cold districts. *H. niger angustifolius* comes next in order, and of this variety there are at least three distinct forms: The Wardie Lodge form, which is an exceedingly valuable one; St. Brigid, which is also a free, handsome kind, and the Riverston form, which is one of the best kinds we possess. The Brockhurst form, which we take as being nearly the type, is not the least valuable of the four, and is an exceedingly free and easily grown plant. The leaves are bright green, the segments very narrow, and the flowers, which are pure white, form a pretty, snowy nest in the centre of the plant. These plants are not so liable to damage, owing to the protection afforded by the foliage, both at the sides and above them, as when full open they are still well below the leaves. Of the variety Major there are also several forms, the Irish one being, perhaps, finer than the Bath one, but both are certainly exceptional; indeed it is from this class we get some of our best Christmas Roses. The very large, snowy white flowers are produced with almost certainty about Christmas-time. There is also a fine Continental form, probably selected from Austrian plants, called Madame Fourcade. The flowers are cup-shaped, snowy white; the leaf-stalks bronzy, with a tinge of the same running through the pale green leaves. It has a neat though spreading habit and is an excellent plant for pots. An almost intermediate form called Caucasicus is one of the most useful for rockeries; the flowers out-of-doors being slightly tinged with rose, but when grown under glass, snow white, of beautiful form. It has a most vigorous constitution and stands severe weather well, the flowers being protected like those of *Angustifolius* and its forms. Most of these varieties and forms stand slight forcing very well, but if too hard driven they will certainly take a rest the following season.

Kew.

D. Dewar.

Helleborus niger and its varieties are just now supplying many beautiful flowers in the open ground, which would otherwise be destitute of anything in the way of flowers, owing to the several severe frosts that have been experienced recently. Frost seems to have no injurious influence on these beautiful flowers, whose popular name, Christmas Roses, is, in this instance, a happy one, for with us they often last until the festive season has come and gone. The cultural needs of these plants are so few, and, in most cases, easily supplied, that no one with a garden need be without flowers even at this dull season; but these wants, though few, are imperative.

The first of them is a soil of a naturally retentive nature, so that they may at no time suffer from lack of moisture at the roots, especially during their season of growth, when this is most likely to occur. Another essential to their successful culture is shade from the scorching rays of a midsummer sun. To obviate this we plant them under deciduous trees, where they get the benefit of the shade in summer, while the fallen leaves of autumn provide an acceptable protection to the crowns of the plants in winter. Hellebores like a rich soil, and, as their thick, fleshy roots penetrate deeply, plenty of manure should be added when planting them, for, when once planted, they should not be disturbed again until the soil has become impoverished; this is best done in spring as soon as the frost disappears, as these plants commence leaf-growth very early, and if shifted after this has fairly commenced it seriously affects the development of the large, shining foliage, itself an ornament at all times. *H. niger* is best known, but cannot be compared with the varieties of it now in commerce. Of these, we find the one called *H. niger altifolius* to be the best; its flowers are three inches across, pure white inside and pink on the outside of the sepals, and borne two and

sometimes three on stems twelve inches in length. *H. niger major* and *H. niger maximus*, with us, are identical, and rank next in beauty, while *H. niger angustifolius* is another desirable form, with leaves the segments of which are narrower than the type, and the plant produces more flowers, and these are almost pure white. The beauty of the blossoms is often marred by heavy rain-storms bespattering them with soil. This can easily be avoided by placing a sash or handlight over the plants while in bloom, or they may be carefully lifted, potted and placed in a cool house or frame and planted out again in spring. So far we have noticed only *H. niger* and its varieties; the cultural remarks apply equally well to the whole genus, and there are many other species, but they all flower in spring, the flowers being produced with the young leaves. *H. orientalis*, *H. Caucasicus*, *H. Abchasicus* and others belong to this section, and are the parents of the many fine named hybrids now offered in trade-lists.

Passaic, N. J.

Leading American Apples.

THOUGH we received the Apple from Europe (the improvement of our native American Apples never having been attempted), yet it must be noted that on this continent a large number of the best varieties have appeared as seedlings from the original stock. American apples take the lead in every market where they have appeared; and they stand at the head of the list, with very few local exceptions, wherever this fruit is sold. Each section of the Union (except, perhaps, the Pacific Coast and Rocky Mountain regions) has produced its own varieties, having merits and adaptation which give them more or less preference near the place of their origin. To the older sections, where fruit-growing, as a business, has been longest pursued, belong the best known varieties for the general market; yet the south and south-west have many Apples of all seasons, native to the soil, the commercial merits of which have only to be made known in order to be acknowledged. It is only among the summer and fall Apples that any foreign sorts find acceptance with our fruit-growers, and the list of these hardly extends beyond five named varieties—Yellow Transparent, Red Astrachan, Oldenburgh, Alexander and Gravenstein. The Astrachan is a most remarkable fruit, in the fact that it is equally at home, valued and productive in Canada and Louisiana, and from the Atlantic to the Pacific.

In the north-eastern and middle Atlantic states the four leading native early market Apples of American origin are Sweet Bough, Early Harvest, Williams' Favorite and Summer Pippin. Some persons would replace the Williams' Favorite with American Summer Pearmain, which is popular also southward along the Atlantic Slope, with the Early Harvest, the Summer Queen and Summer Rose. Farther south, Carolina Red June comes into this list. For home use, Primate and Early Joe must be added; while, south and westward, Early Red Margaret is popular. It is not certain, however, that this is an American variety.

The fall Apples are extremely numerous; and, as the latitude varies, many sorts among them will rank as summer fruit. In the north and east, Fall Pippin, Porter, Munson Sweet and Maiden's Blush are most commonly seen. Westward, and in Canada, St. Lawrence is added; while, as we go south we note in addition, Buckingham, Fallawater and Rambo. In the north-west Fall Wine, Haas and Saxton appear.

The early winter Apples of the north-east are very numerous. Fameuse (in southern New England a late fall Apple), Jewett's Red, Bellflower and Hubbardston are abundant. Southward the Baldwin falls into this list, with the Striped Winter Pearmain, Smokehouse and Smith's Cider. In the north-west the Wealthy is now becoming the leading early winter Apple. Northern Spy is not a long keeper in the Ohio Valley. Wagener is popular in the milder parts of the north-west.

Late winter Apples in the north-east include Baldwin, Rhode Island Greening, Northern Spy and Roxbury Russet among the most prominent and profitable; but there is a long list of others well known and salable, especially in the smaller local markets. The King of Tompkins must be included for New York, while westward Limber Twig and Golden Russet, of western New York, are very prominent, though Ben Davis leads all of this class in the Mississippi Valley from Iowa and Illinois southward. Of winter sweet Apples, Talman easily leads in market value. In the south and south-west, aside from Ben Davis, Pryor's Red, McAfee and Nickajack are probably the most widely known.

Orchid Notes.

Cypripedium Spicerianum.—This lovely species may be looked upon as a harbinger of autumn, for as the months of October and November approach the flowers of *Cypripedium Spicerianum* appear, and last until the beginning of the New Year. Native of India and Assam, it was first introduced to cultivation in 1878 by Mr. Herbert Spicer, of the Woodlands, Godalming, England, among a mixed collection of Orchids. Since that time it has gradually gained on the popular favor, and is now to be found in almost every collection, so much admired are its flowers, which present a unique appearance. The upper sepal is very large and slightly arching forward, of the purest waxy white, with a broad, deep crimson-purple band running from apex to base, the latter portion being stained with green and covered with minute reddish spots. The lower sepal is much smaller and greenish white, being ovate-acute in shape. The ligulate petals, which are bent a little forward and slightly depressed, have crinkled margins and a yellowish green surface, thickly covered with small, dull red spots on each side of the crimson mid-line, while the helmet-shaped lip is purple brown, often suffused with crimson. The staminode is very conspicuous in this species; its margins are wavy and pure white, inside of which the remaining surface is crimson-purple. The leaves are oblong, six to twelve inches long, dark green above and spotted with dull purple underneath, toward the base; from their centre springs the slender, dark purplish hairy scapes, each of which bear, as a rule, only a solitary flower, although instances have been recorded where two flowers were borne on a scape.

C. Leeanum is now also in flower. It is a most popular hybrid, being the result of crossing *C. insigne* and *C. Spicerianum*, between which it is intermediate, although the characteristics of the latter species are more predominating. The upper sepal is very large, pure white, with a bright grass-green blotch at the base, which is traversed by lines of dark purple-brown, while on the white portion are a few mauve-purple spotted lines, on each side of the broader median line which runs to the apex. The lower sepal is pale green, and the petals, which resemble those of *C. Spicerianum*, have an undulated upper margin and a yellowish green surface, with a dull purple mid-line running from base to tip and traversed by spotted veins of purple-brown. The lip is pale green behind, and glossy purple-brown, of a more or less intense hue, in front, while the staminode partakes of the shape of that of *C. Spicerianum*, but is devoid of its rich color, except for a very dull tinge of mauve, which encircles the green and yellow tooth so conspicuous in *C. insigne*. The variety known as *Superbum* is recognized by its larger upper sepal having brighter purple spots.

C. Leeanum was raised in the collection of Sir Trevor Lawrence, Burford Lodge, Dorking, and the variety *Superbum* in Messrs. Veitch's establishment, about the year 1885.

Both of these Lady's Slippers grow freely, and may be treated in the same way. *C. Spicerianum* has been found in its native habitat growing on steep and perpendicular rocks in rich loam and in moist places. The former fact is well authenticated, for when imported plants arrive they are often smeared with mud. Under culture they may be grown in a compost of loam and peat, and as the roots grow quickly and vigorously, pots large enough to enable them to develop should be chosen, and these should be well drained for about two-thirds of their depth with clean crocks. The plants may also be grown with equal success in fibrous peat and sphagnum. A warm, moist atmosphere is best, and care should be taken never to let the roots become dry; but the amount of water to be given must be regulated according to the growth of the plants and the time of year, and during the hot summer days it will also be found best to shade them.

St. Albans, England.

John Weathers.

Cattleya Percivaliana.—Large quantities of this beautiful Orchid are now in full beauty with us. The many hundred flowers, as well as an immense number of *Lælia anceps*, now also in full bloom, will furnish a perfect blaze of bloom until the coming of larger flowers of *C. Triana*. *C. Percivaliana*, though possessing the smallest flowers of the Labiata group, is a very valuable species, both for cutting and decorative purposes, as its season of flower is fully a month earlier than the winter kinds and it fills the gap between these and the autumn blooming kinds. In addition to this, it proves to be one of the easiest of this extensive genus to cultivate and flower. It was introduced about six years ago from the Cordillera of Venezuela, at an elevation of about 4,000 feet, where

it is said to grow on rocks in very wet places and where there is a full exposure to the sun. That this does not apply to all is shown by the great disparity in the size and shape of the imported bulbs and leaves. Some of these are of immense size, the bulbs ten inches in length and proportionately thick, and would easily pass for *C. gigas*. In the other extreme the bulbs are only three inches long and almost globular in the centre, denoting a slow, cool growth without much water or with considerable exposure. Between these two extremes almost any variety of growth may be seen. The coloring of the growths also varies from a deep green to a reddish brown. Almost as much variety may be seen in the coloring and size of the flowers. In the type these are four to five inches across, with deep rose sepals and petals. The lip is convolute and of the same color externally. The front lobe is of a deep crimson purple, with a pale lilac-frilled margin, the throat being of a rich, tawny yellow. Some of the larger varieties measure seven to eight inches across, and cannot be distinguished from the old *C. Mossia*, of which this may only be a geographical form. As with almost every Orchid there is an albino form, which is called *Alba*, but this is at present very rare. One great drawback to *C. Percivaliana* is a somewhat disagreeable odor, similar to that of *Lælia autumnalis*, but, happily, this defect is not constant in the species, but is noticed more especially in the small flowered type. To grow this species successfully, it should be given plenty of heat and water during growth. Use fibrous peat and moss, well drained pots, and let these be as small as possible. As soon as the flowers are over the plants should be rested by withholding water, except sufficient to keep the bulbs plump.

Kenwood, N. Y.

F. Goldring.

Heating Green-houses.

THIS is a subject to which much study and experiment has been devoted, and yet reliable data for general practice are very hard to find, and this is mainly because in each instance special conditions of latitude, exposure and so on must be taken into account. Attention, however, is not now invited to any particular method of heating, but a few suggestions are proposed which refer to the heating of houses in a general way. In the case of brick-set boilers, an examination should be made at proper intervals to ascertain the condition of the flues, that they may be kept thoroughly clean and free from cracks, as a small accident may do much damage by permitting the escape of gases injurious to plant life. With all such boilers any portions of the flue that are near the fire or exposed to strong heat should be thoroughly lined with good fire-brick, a precaution sometimes omitted through a mistaken idea of economy. Another point in the construction of smoke flues is to have soot doors and dampers as well, conveniently arranged. Fuel can always be economized by the convenient arrangement of the regulating apparatus. In plant-houses one of the most important points to be observed is regularity in temperature; the careless method of permitting a high temperature one night and a low one the next is too often responsible for the sickly appearance of plants which may have been properly treated in other respects. In extremely cold weather it is better to allow the temperature of a plant-house to fall a few degrees below the usual standard. This will be less enervating than a forcing temperature, with its rapid evaporation. For instance, a Palm-house that is usually kept between sixty and sixty-five degrees at night, may be allowed to fall to fifty-six or fifty-eight degrees without any appreciable injury, and a Rose-house that is generally run at a night temperature of fifty-six degrees, may drop to fifty degrees in very severe weather without materially affecting the Roses. During sharp weather, when hard firing is necessary, it will be beneficial to damp down warm houses by sprinkling the walks, and the surface under the benches, especially in the morning and evening; but this operation is not so often required in houses in which there are vapor pans of some description placed on the pipes.

In regard to fuel, the location of the green-house has much to do with it, though it is probably hard to find a better material for this purpose than good anthracite coal. In some localities coke is used profitably, but, naturally, does not last so long, without attention, as a good solid fire of coal, though the coke produces a very strong heat for a short time. As to the proper size of coal, much depends on the style of boiler. A stronger draught and a shallower grate is necessary to burn small sized coal to advantage, and, though cheaper, it requires more attention in using. For a lasting fire, in a majority of boilers, coal of egg-size, or the next larger size, known as "broken," usually gives entire satisfaction.

Holmesburg, Pa.

W. H. Taplin.

Propagating.—More or less work of this character is to be done during the winter months, and therefore it is well to make preparation for it by laying in such supplies as may be needed. Attention given to such details now will save much labor and inconvenience later in the season. For instance, a good supply of clean, sharp sand should be put under cover, so that the weather may not interfere with future operations. Some Cocoa-fibre, or sphagnum, should be secured, in which to plunge cutting-pots. The Cocoa-fibre is preferable, because more lasting. Potsherds or cinders for drainage should also be provided, and if cinders are used they should be sifted out as clean as possible. A little charcoal will also be found useful, particularly where the cuttings require a considerable time in the cutting-pots or pans, for the soil in such cases often becomes sour.

Among these slow-rooting plants may be classed the *Terminalias*, *Theophrasa imperialis*, some of the *Aralias*, and *Rondeletia gratissima*, all of which and many more take a long time to develop roots.

The cut flower supply of the next season must also be provided for, and, with this in view, the first crop of Rose-cuttings may soon be put in. To secure satisfactory plants, the cuttings should be taken from healthy shoots of medium size, such as rather weak blooming shoots, these being usually of firm wood which will root quickly. Between blind wood and flowering shoots for Rose cuttings I have found no material difference, although the question is still discussed. I saw, this autumn, two houses of American Beauty, the plants in one having been raised from cuttings of flowering shoots, while a second house of the same size and under exactly the same treatment was planted with Roses raised strictly from blind wood. When I saw them I was unable to discern any appreciable difference, either in strength of growth or floriferousness of the plants in the two houses, both being in first-class condition.

Carnation-cuttings should soon be put in, for early-struck cuttings usually make the best plants. A good method with these plants is to prick them off from the cutting-bench into flats filled with soil, in which they may remain until the time for planting out. The advantage of this plan is that the plants so treated seldom become starved and root-bound, and they may be readily separated with a trowel, so that each plant, when planted out in the spring, has a good ball of earth attached to it. Bouvardias should also be put in about the beginning of the year, as the root-cuttings generally used take several weeks to make growth enough to fit them for potting off.

Holmesburg, Pa.

W. H. Taplin.

Chrysanthemums for Stock.—I find from experience that it is quite as important to give close attention to stock-plants after blooming as before. Last year I took care to have my plants in as cool a place as I could give them, free from frost. I kept them in the Violet-house. They were kept free from insects, and watered moderately. Not one of my own stock failed me, but many of the new varieties, or others obtained outside, did poorly. Another experience was that a foul cutting produced the only infested plant I had. Late struck cuttings did as well as early ones. Next season, therefore, I shall not take cuttings until the end of February. Cuttings will strike if the temperature of the propagating bed is not above fifty degrees. The bed is better kept moderately dry so long as the cuttings do not wilt.

Wellesley, Mass.

T. D. H.

Carnations.—Now that Chrysanthemums are nearly over, there is nothing more interesting to the amateur than a collection of Carnations, and if in a light and airy, cool greenhouse, they do equally well in pots or planted out. If allowed to become waterlogged or are subjected to too much heat they are injuriously affected. A temperature of fifty-five degrees is about right during the night-time. Occasional waterings with liquid manure and tobacco fumigation against the green fly seem to be all the special attention they demand. There has been a steady improvement in American seedlings, so that we not only have varieties of many hues and large, finely scented flowers, but the flowers are borne on long stems, and the calyx does not split and give the ragged look which was so often seen among the sorts grown a few years ago. There are now so many good kinds that it is hardly worth while to make a list of them. First rate kinds can be selected from the catalogues of any of the leading florists.

Pearl River, N. Y.

John Thorpe.

Kalanchoe carnea is a new introduction from South Africa. It was received in England in 1886, and seeds have been offered for the first time this season by Messrs. Veitch & Co. Plants are now in bloom here from early sown seeds, and

prove to be very attractive. The plants are fleshy, nearly resembling the scarlet *Kalosanthus* in size and form of flowers and character of inflorescence. The flowers are four-petaled, delicate pink, shading to deeper pink on the margins, and appear in corymbose cymes. They are slightly fragrant, with a honey-like odor. The leaves are light brownish green, fleshy and smooth. The plant flowers from the termination of the main stem, also from the axils of the leaves. It is now pushing new growths from the base, and, no doubt, it will continue in bloom for a long season. As this is an attractive dwarf-growing succulent of the easiest possible culture, rapidly propagated by seeds or cuttings, and giving handsome bloom in early winter, it seems a desirable addition to the green-house and probably will prove a good window plant. Aside from needing little pot-room and requiring a mixture of sandy loam and brick rubbish or similar material, it seems to require no special treatment or extra care.

Elizabeth, N. J.

J. N. Gerard.

Correspondence. December in California.

To the Editor of GARDEN AND FOREST:

Sir.—Owing to the heavy rains in October, and the warm weather, with showers, ever since, the gardens and orchards show some interesting freaks. The double *Spiraea prunifolia* usually sheds its leaves, in this locality, about November 1st, and blooms, on the bare branches, in spring. It is in full bloom now, December 1st, while the beautiful leaves, red and yellow, are all on the branches, and show no tendency to fall! A neighbor has Lilacs in bloom now—not large clusters, but small bunches of flowers. They never bloom from any other buds. The crimson Japanese Quince hedge shows a great many blooms at present, fully two months before the usual season. The beautiful *Magnolia stellata*, which is a great favorite here, is blooming freely in the midst of its leaves, a thing which I never saw before in fifteen years of watching its fragrant blush pink flowers. They do not usually show until New Year's or later, and then on leafless stems.

The Persian Walnut-trees, the "Kaghazi," imported from Cashmere, still retain all their leaves as if it were August. The English Walnuts have lost their leaves. The foliage of the Cherry-trees in the orchard is, for the most part, as green as it was three months ago. The *Paulownia imperialis*, forty feet high, shows, as yet, no sign of dropping a leaf. The Italian Chestnuts have lost only a few leaves from the upper branches, but many are still green and closely adherent. The general aspect of over 100 acres of orchard and ornamental grounds is that of late summer, except for the leafless Apple, Pear and Peach-trees.

Judge Blackwood, of Haywards, eight miles from here, told me to-day that he had an Apple-tree in full bloom, and that his Cherry-trees would be in blossom in a week. Professor E. W. Hilgard, of the State University, told me that several Apple and Pear-trees are in bloom in the grounds there. Some Apricot and Almond-flowers are reported from other districts. Here, at Niles, the Cherry-buds appear almost ready to come out, but other fruit trees are more backward than in the cases mentioned. The opinion among fruit-growers is that all the orchards will be in bloom two months earlier than usual.

The brilliant orange *Eschscholtzias* are in full bloom in a field near by—hundreds of them. February is their usual season here. The California wild Mustard is also in bloom by the roadsides. The grass on the hills and in the pastures is as tall and thick as it is in ordinary seasons by the end of March.

Niles, Cal.

Charles H. Shinn.

Trees and Telegraph Wires.

To the Editor of GARDEN AND FOREST:

Sir.—In passing along one of our streets the other day I was shocked to find that a row of fine shade trees had been used for telegraph or telephone attachments, and that the linemen had ascended them as they do the poles, by means of sharp spikes in the heels of their boots, mutilating the bark, of course, and inviting attack from the rot fungus. Two well known citizens who were passing said in reply to some questions that nobody seemed to have any power to stop such outrages.

Are we, then, wholly at the mercy of any corporation who cares to peril our lives, or destroy our shade trees, or drive us crazy by wires vibrating against the tin roofs of our houses? I am growing callous to many things, but for the trees there is "a corner of my heart that is sorry still." What we are going to do I do not know, but I send this growl where I think it may meet with sympathy.

Brown University, Providence.

W. Whitman Bailey.

To the Editor of GARDEN AND FOREST:

Sir.—During a recent visit to the Island of Santa Cruz, one of the islands forming the southerly wall of the Santa Barbara Channel, on the coast of California, I found *Polypodium Scouleri*, H. & G., growing on the basaltic rocks of which the island is largely composed.

This Fern, so far as I know, has not been heretofore noted from any locality within a distance of perhaps 200 miles north, and not at all from the south, except by Dr. Palmer, who reported it from Guadeloupe Island, off the coast of Mexico.

Santa Barbara, Cal.

Lorenzo G. Yates.

To the Editor of GARDEN AND FOREST:

Sir.—Allow me to call your attention to the desirability of *Baccharis halmifolia* for cultivation as an autumn-blooming plant in shrubberies. It occurs somewhat abundantly on Buzzard's Bay, along the west shore of the Town of Dartmouth, and the fertile plants are very attractive in September. I do not remember to have ever noticed this shrub in cultivation, although we have few more attractive ones in its season. From its habit it would appear better if planted among other shrubs than strictly alone. Although a plant of the lands adjoining the sea, yet I have seen occasional specimens along the roadsides several miles inland.

South Framingham, Mass.

E. Lewis Sturtevant.

Periodical Literature.

In a recent number of the *Cornhill Magazine* is an article on "Weeds" so amusingly written that it is a delight to receive the information it imparts. "As dirt," says the author, "is matter in the wrong place, so, I take it, a weed is simply an herb or flower which grows where the agriculturist does not want it." Humble ugliness does not make a weed, nor does beauty prevent the name from being deserved. An instance in point is cited: the blue Ageratum, which is a cherished border flower in England, but which, transported to Ceylon by an English lady, has there become, in truth, a weed, so rapidly running wild in the island that it now costs over a million and a quarter dollars annually to keep it down in the Coffee plantations. Again, Clover "is a 'crop' where it is deliberately sown; but when it comes up lawlessly of its own mere motion in a flower-bed on the lawn," then it is a weed. "Hence, it also results that a weed, wherever it shows its weedy nature, belongs to what Darwin used to call 'a dominant species'—that is to say, one that then and there can take care of itself and live down or kill out all feeble constitutions. It is this vivacious peculiarity that constitutes the original sin of all weeds; they are plants that you don't want to grow, but that, nevertheless, possess qualities and attributes which enable them to oust and overshadow those that you do. . . . Therefore, cultivation . . . consists essentially in the suppression of weeds, or, in other words, the restriction of free and natural competition." But, as the author goes on to explain, this refers merely to competition in "free, open situations." A forest or woodland herb is not a weed, because it does not compete with our crops or garden plantations. Such plants may be "weeds at heart"—that is, pushing monopolists—but they are not weeds in fact. "Man tills only the plain; and, therefore, it is only the wild herbs which naturally grow in the full eye of day that can compete at an advantage with his Corn, his Turnips, his Beet-root or his Sugar-cane. Hence arises a curious and very interesting fact, that the greater part of the common weeds of western Europe and America are neither west European nor American at all, but Asiatic, or, at least, Mediterranean in type or origin. . . . The reason is obvious. Western Europe and eastern America, in their native condition, were forest-clad regions. . . . Now, the wild flowers and plants that grow beneath the shades of the forest primeval must bear the open heat of the noonday sun. The consequence is, that whenever the forest primeval is cleared, a new vegetation usurps the soil, a vegetation which necessarily comes from elsewhere." Any one who has even glanced through Gray's "Manual" knows how true this is of our eastern states; but it is a less familiar fact that, in recent years, certain American plants are running wild as weeds in Europe. "A return wave," as our author expresses it, "from west to east is actually in progress; and . . . promises in the end to assume gigantic proportions. Many years ago the great Boston botanist, Asa Gray, prophesied its advent, and his prophecy has since gone on fulfilling itself at the usual rapid rate of all American phenomena, social or natural." This new class of emigrants, be it noted, come chiefly from the far west—from those parts of our continent which have always been a vast stretch of treeless prairie land,

clothed with plants habituated to the open sky. From the western they have begun to pass to the eastern states, and thence across the Atlantic. Our author believes that they will soon, "in virtue of their sturdier and stringier prairie constitution, habituated to long drought or broiling sunshine, live down those damp-loving and dainty cis-Atlantic weeds" which now occupy the soil of eastern America, and, once on the other side of the ocean, "will, in many cases, almost entirely swamp our native vegetation. In fact, I think there can be little doubt that, with the increase of intercourse all over the world, a few hardy cosmopolitan weeds must tend in the long run to divide the empire of life and map out the cultivable plains of the globe between them. . . . I don't doubt that in time these picked weeds of all the open lowland regions, but more especially of the pampas, the steppes and the veldt, will overrun the greater part of the habitable globe. They are the fittest for their own particular purpose, and fitness is all that nature cares about. We shall thus lose a great deal in picturesque variety between country and country. . . . *Toujours perdrix* is bad enough, but *toujours lait-d'âne*—always Sow-thistle—is surely something too horrible to contemplate."

Three American weeds are then cited as having already made good their hold in England. "One of them, the latest comer, is spreading visibly every year under my own eyes in my own part of Surrey. Thirty years ago Mr. Brewer, of Reigate, noted with interest in his garden at that town the appearance of a small exotic Veronica; the 'interesting' little plant is now by far a commoner pest in all the fields of southern England than almost any of our native Knot-weeds, Thistles or Charlocks. The Peruvian Galinsoga . . . has spread immensely in Italy and the Riviera and now grows quite commonly wild on the road-sides about Kew, whence it will sweep in time with devouring effect upon the surrounding countries." Of course, man can almost always succeed in the fight against weeds, "but his commercial and agricultural success will be but a small consolation, after all, to the lover of nature for that general vulgarization and equalization of the world's flora, which universal culture and increased intercourse must almost of necessity bring in their train to every quarter of the habitable globe."

It is interesting also to note that many plants which spread with a new rapidity in a new soil likewise develop as individuals in an unprecedented way. For example, the "petty English Knot-grass, which at home is but an insignificant roadside trailer, thrives in the unencumbered soil of New Zealand so hugely that single weeds sometimes cover a space five feet in diameter and send their roots four feet deep into the rich ground." And the Water-cress of our breakfast-tables, "in Europe a mere casual brook-side plant, chokes the New Zealand rivers with stems twelve feet long, and costs the colonists of Christ Church alone £300 a year in dredging their Avon free from it." As a proof that the battle is not always to the seemingly strong, we may quote the instance of the White Clover, which "has completely strangled its immense antagonist, the New Zealand Flax, a huge Iris-like Aloe, with leaves as tall as a British grenadier and fibres powerful enough to make cords and ropes fit to hang a sheep stealer."

Journal of the Royal Horticultural Society, edited by G. D. Morris and the Reverend W. Wilkes.

The high standard of the recent numbers of this journal show how real and successful the efforts of the friends of horticulture in England have been in restoring to this Society the character it enjoyed, and the usefulness it exerted fifty years ago. The best work such societies can perform in the present stage of horticulture is in promoting investigations and discussions on subjects of practical importance; and then in making the results of such discussions available to the world by publication in cheap and convenient form. That the Royal Horticultural Society is now doing this, a mere glance at the list of papers, and the names of their authors, published in this last part which has reached us, will make abundantly apparent.

There are three papers on Saxifrage, which are treated both from a scientific point of view by Mr. J. G. Baker, of the Kew herbarium, and culturally by Mr. George Paul and Mr. G. Reuthe. These are followed by three papers on the Hyacinth; Mr. Burbidge contributes a paper on the Narcissus, which is followed by a discussion of seedling Daffodils by the Rev. G. H. Engleheart, and by observations on Portuguese Narcissi by Mr. Alfred W. Tait. The Rev. Mr. Horner discusses the Auricula; and the number concludes with Mr. Veitch's admirable paper on Orchids, past and present, to which reference has already been made in these columns.

Notes.

Good hot-house grapes are retailing in New York at two dollars a pound.

On several plants of *Clematis paniculata*, observed near this city, the foliage remained green through the hard frosts of autumn and well into December.

The business of forcing bulbs for the market was so much overdone in this country last year that florists have bought more cautiously this fall. On the other hand, a combination of growers in southern Europe compelled importers to pay high prices for these bulbs, and as a consequence many Roman Hyacinths and other bulbs have been sold at less than cost.

At a ball given lately in Providence the three débutantes, in whose honor it was made, received from their friends 110 hand-bouquets. The money value of these flowers must have been, at current retail prices, not far from \$1,800. The fact is worth noting, as an indication of the lavish use and tremendous demand for flowers in this community.

In the *Bulletin de la Société Botanique de France*, M. Doumet Adanson describes a Fir which he considers a hybrid between *Abies Pinsapo* and *A. pectinata* as the pollen parent. The plant shows the distichous arrangement of leaves which characterizes *A. pectinata*, while the leaves themselves resemble those of *A. Pinsapo*.

William H. Moffett, United States Consul at Athens, reports the impossibility of making any official statement as to the agriculture of Greece, because "agriculture is here in the most undeveloped condition. Even in the immediate neighborhood of Athens it is common to find the wooden plow and the rude mattock which were in use 2,000 years ago. Fields are plowed up or scratched over, and crops replanted season after season, until the exhausted soil will bear no more. Fertilizers are not used to any appreciable extent, and the farm implements are of the very rudest description. Irrigation is in use in some districts, and, as far as I can ascertain, the methods in use can be readily learned by a study of the practices of the ancient Egyptians. Greece has olives and grapes in abundance, and of quality not excelled; but Greek olive oil and Greek wine will not bear transportation."

The northern suburbs of London will shortly be enriched by a fine park, presented by Sir Sydney H. Waterlow. In a letter addressed to the London City Council, the donor writes: "On the southern slope of Highgate Hill, in the parish of St. Pancras, I own an estate of nearly twenty-nine acres in extent, which was for many years my own home. This property, if judiciously laid out, would, I think, make an excellent public park for the north of London. The grounds are undulating, well timbered with Oaks, old Cedars of Lebanon, and many other well grown trees and shrubs. There is also one and a half acres of ornamental water, supplied from natural springs. The land is freehold, with the exception of two and three-quarters acres held on a long lease, of which thirty-five and a half years are unexpired. It is bounded almost entirely by public roads and a public foot-path."

A Cotoneaster, which has not flowered there yet, received at the Arnold Arboretum some time ago from the Veitchian nursery, under the name of *C. bacillaris floribunda*, is a remarkable and interesting plant at this season of the year. The foliage on the 1st of December was fresh and bright green, and on the 6th of the month, when all the deciduous leaved plants in the collection, with the exception of *Elæagnus umbellata* and two or three others, on all of which they were already much wilted and disfigured, had lost their leaves, those of this Cotoneaster, although they had been subjected to a temperature as low as ten degrees above zero, were just turning to a deep, rich wine color. This shrub, whatever its name and origin may be, is certainly worth growing for its late autumn and early winter foliage. It is vigorous and very hardy, of good habit, with large, acuminate, membranaceous leaves, and slender, spreading branches, covered with bright green bark, which at this season of the year turns claret color on the side toward the sun. It has the appearance of growing to a large size.

Professor Comstock, in a late Bulletin of the Cornell University station, gives an interesting account of a saw-fly borer which attacked the Wheat on the station ground in great numbers this year. The insect (*Cephus pygmaeus*) is well known in Europe, where it has been considered a serious pest. This is the first time, however, that it has ever been observed in this country. European entomologists describe parasites which infest this insect, but Professor Comstock found no trace of any among those in the station Wheat field. Artificial means for checking the spread of this species must,

therefore, be depended on. The burning over of the stubble or plowing it under after harvest would destroy the larvæ, but either remedy would also destroy the Grass or Clover usually sown with Wheat. It seems probable, therefore, that if the insect becomes a serious pest it will be necessary in badly infested regions either to sow Grass seed with Oats and burn or plow all Wheat stubble, or to suspend the raising of Wheat for one year, in order to destroy the insects by starvation.

A correspondent sends us the following note upon *Magnolia glauca* in its isolated northern station in Essex County, Massachusetts: "Magnolia Swamp contains several hundred acres, and it is one and a half miles in length and from ten to over 100 rods in width. I am of opinion that this swamp has furnished the shrub to all the others. In regard to three of the smaller swamps I know that this is a fact, the Magnolia shrubs having been transplanted by men. The inhabitants of Gloucester are firm in the belief that *Magnolia glauca* is a native shrub, but I cannot think so. I believe it was introduced by the old settlers, some of whom may have lived in and removed from a more southern state. 'The old Salem road,' deserted by the traveling public for over 100 years, skirts the eastern side of Magnolia Swamp. Along the line of this road are the ruins of old cellars, and in the swamp opposite one of the cellars, near a spring, may be found Magnolias which appear the oldest in the region. The root-crowns below the moss are often found to be two feet in diameter. In no other place can I find such a growth, and it is here, I think, that the shrub first started. It must be evident to any careful observer that *Magnolia glauca* is struggling here in an unnatural climate. The primary roots grow straight down into the muck, and in the fall are thickly covered with rootlets, snowy white in color. In the spring these rootlets are mostly dead, and a greater part of young shoots die down to the moss, and a certain per cent. of the old plants are winter-killed, which indicates that there is no harmony between shrub and climate."

The fruit of the Japanese Persimmon or Kaki can still be found in the markets of this city in great abundance, and of extraordinary beauty and excellence. It is raised in Florida and Georgia, where the Kaki has been planted in large quantities. It is by far the handsomest dessert fruit which the market affords at this season of the year; but it is a question whether the kaki really possesses as good a flavor as one of our thoroughly ripened and frosted native persimmons from Georgia or Virginia, a fruit which some people consider about the best that grows. A cross between the American and Japanese species might be expected to produce a fruit of larger size and finer color than that of the former, and with a richer flavor than any of the cultivated forms of Kaki. The Asiatic Persimmon, according to Rein, is "undeniably the most widely distributed, most important and most beautiful fruit tree in Japan, Corea and northern China. In Japan it endures night frosts at a temperature of from twelve to sixteen degrees C. It can be cultivated high up in the valleys and far beyond the limit of the Bamboo cane. It is a stately tree, after the fashion of a Pear-tree, with beautiful deciduous leaves, almost as large as those of some Magnolias, but of bright green color and resembling those of the Pear in shape only. The new leaves come in May; it blossoms in June; the season of ripe fruit is late in autumn, from the middle of September to the end of November. There are many kinds of Kaki, ranging in size from a small hen's egg to a big apple. Some are nearly spherical, others oblong, others heart-shaped. In color of the outer skin they run from light orange-yellow to deep orange-red. They are distinguished also by their taste, which is pleasant in its way and reminds one of tomatoes, as does the color also. They are eaten not only in a soft, doughy condition, in which those of the Migako-no-djô, in the province Hiuga, are prized most highly, but the fruit is gathered while still hard, to ripen afterward. The best in Japanese estimation are *Tarugaki*, that is, 'Tub Persimmons,' which have been converted from astringent into sweet fruit by being kept in an old saké tub. The bitter, astringent taste of all green kaki remains, even in the ripe fruit, in the case of most varieties, and it is from these that, during the summer, an astringent fluid, rich in tannin, is prepared (called Shibu), an acid of considerable importance in several industries. When over-ripe and dried in the sun, pressed somewhat flat, and then put away in boxes, the sweet kaki get to look and taste, in a few months, when skinned, like dried figs, and are used like them. The white powder which covers these dried persimmons in boxes is natural sugar that has exuded from the fruit. "In September the Kaki tree, laden with large, orange colored fruit, is a great ornament to the landscape. This beauty it preserves till it loses its leaves in October."

Christmas.

ALL through western Europe, even before it had been Christianized, the winter solstice was regarded as the beginning of renewed life in nature, and was celebrated with joyful observances, and the origin of almost all the secular features of our modern Christmas festival may be traced to one ancient people or another. From the Romans, for instance, we get our practice of making Christmas gifts, such gifts being a feature of their Saturnalia, celebrated at the winter solstice. As conspicuous as the Saturnalia in Rome were the Yule-tide festivities of the ancient Teutons. Between the 25th of December and the 6th of January, they believed, their great gods walked the earth, and their footsteps might be traced by those wise enough to see. The memory of these dates still survives in England, even though the time has passed when the "Lord of Misrule" reigned from All-Hallow Eve till Candlemas, and the land gave itself up to the eager pursuit of jollity. Many plants are mentioned by old writers as figuring in these Christmas celebrations. Chief of all was the Mistletoe, excluded from the church edifice, as its Druidic significance was too clearly remembered, but used profusely elsewhere, and the great joy of mischievous youths when pretty maidens were about.* Almost as high in favor stood the Holly, which to the ancient Germans had been "a sign of the life which preserved nature through the desolation of winter, and was gathered into pagan temples to comfort the sylvan spirits during the general death." Holly was used as a dream-plant on Christmas Eve as well as at certain other anniversaries. The same idea which consecrated the Holly as an emblem of persistent life sanctified other evergreens too, and from time immemorial many sorts were used for the Christmas decoration of church and home.

* In Irving's "Christmas Day" he speaks of "the parson rebuking the sexton for having used Mistletoe among the greens with which the church was decorated. It was, he observed, an unholy plant, profaned by having been used by the Druids in their mystic ceremonies; and though it might be innocently employed in the festive ornamenting of halls and kitchens, yet it had been deemed by the Fathers of the Church as unhalloed, and totally unfit for sacred purposes. So tenacious was he on this point, that the poor sexton was obliged to strip down a great part of the humble trophies of his taste before the parson would consent to enter upon the service of the day."

But the great feature of the old-English Christmas was the Yule-log, often called the "Yule-clog," and described as a block rather than a log. This, too, was an inheritance from paganism, having been considered to sanctify the roof-tree and protect it against evil spirits. It was a sign of ill-luck if the "clog" went out during the festivities; and a brand from it was always preserved to light its successor at the next year's celebration. Tall "Christmas candles," wreathed in evergreens, were another feature of the English Christmas.

It seems a singular fact that amid the variety of entertainments provided and rites observed in England, the Christmas-tree should not have figured, for it is the heart and soul of Christmas in modern Germany and is a legacy of ancient Teutonic paganism. However, the main idea which inspired most of these rites seems to have been the use of evergreen plants and of lights in some shape as symbols of the renewal of life; and while the English Teuton retained the Yule-log, the tall, green-wreathed candle, and the evergreen decoration of the wall, his continental cousin clung to the evergreen tree with its myriad sparks of light. In "Round About our Coal Fire," an amusing little book on Christmas customs published in 1740, no mention is made of the Christmas-tree, although in the middle of the eighteenth century many German customs had been imported into England through the advent of her Hanoverian rulers. And even to-day, although occasionally seen in England, it cannot be called at home there.

In all parts of Germany, on the other hand, Christmas would not be Christmas without the tree—one could as soon fancy our Independence Day without powder and noise. The festival is strictly a family one, and Christmas Eve, not Christmas Day, is its culminating point. Where the modern Englishman thinks of his Christmas dinner, the modern German thinks of his tree instead. He likes it as tall as his ceiling will permit when it is placed on a table. He does not hang gifts upon it—nothing but lights and pretty ornaments and a little figure of the Christ-child at the top; but the gifts should lie beneath its sanctifying shade, so he rarely sets it on the floor. But if he cannot have it large and stately he must have what he can, no matter how poor he be—at least a tiny shrub lit with two or three cheap candles. Cheaper even than this is the artificial tree which can be preserved from year to year, made of a central stick with radiating wires, all covered with fluffy green paper, the candles being stuck on the upturned ends of the wire. As an example of the affection in which the Christmas-tree is held by all Germans, high and low, young and old, we may recall that when in 1870 King William and his army were beleaguering Paris, a vast evergreen was set up in the great salon of the palace at Versailles. The gifts which had come from home for the officers invited to make merry with their king were kept until it had been lighted, and the military decorations they had deserved were taken from its branches to be pinned on their breasts.

When Washington Irving describes an English Christmas he mentions no Christmas-trees; but he does not comment upon their absence, as an American would to-day. Popular as they now are, it is only of late years that Americans have known them. Indeed, the first Americans, at least in the northern states, gave up the observance of Christmas as a rite savoring too much of that ecclesiastical tyranny which they had crossed the ocean to escape. William Bradford wrote of the first Christmas the Plymouth Pilgrims spent in the New World "Ye 25th day began to erect ye first house for comone use to receive them and their goods." And of the succeeding year he wrote "One ye day called Christmas-day, ye Gov'r caled them out to worke (as was used.)" Thanksgiving Day took the place in New England which Christmas had held in Old England; and in the Dutch settlement at New York, New Year's Day was the chief festival of the year. But gradually the claim of the great December festival reasserted itself, until it has been

recognized by all denominations. The English Christmas dinner, the Roman custom of gifts and the German Christmas-tree have become familiar facts in every part of our land. We, too, decorate church and home with evergreens. Our chief dependence, next to the boughs of Spruce, of Fir and of our beautiful indigenous Hemlock, are plants which seem to have been made for the purpose and which Europe does not know—the so-called Ground Pine and other Club Mosses, which are easily woven into garlands. Our Holly is not so handsome as the English, but it is rapidly growing in favor, and of recent years Mistletoe has been brought from New Jersey and the south to our northern towns. The scarlet fruit of the Black Alder, Mosses of several kinds and colors, the evergreen foliage of the Kalmia and the Rhododendron, the bluish gray berries of the Juniper, dried grasses, and the handsome, parti-colored fruit of the Bittersweet—all these are now lavishly used at Christmas, although it is not half a century since the first “Christmas green” was sold in New York.

From the vast numbers of Germans who within this period have landed on our shores we have learned to know and love the Christmas-tree. Middle-aged Americans can remember a time when they had never seen one, and the trade in them began in New York in 1851, when two sled loads of young Balsams were brought from the Catskills and sold at the corner of Vesey and Greenwich Streets. At least 150,000 trees have been sold in this city this year, about half of them coming from Maine, and the rest from the Berkshire Hills, the Adirondacks and the Catskills. The Balsam Fir is the favorite, and the Black Spruce is next in demand. The great west naturally gets its supply at home, and there the Blue Spruce is the chief dependence, the trees being sold at wholesale at prices which vary from \$10 a hundred for specimens from four to six feet in height to \$60 a hundred for those which reach twelve to fourteen feet. Sold at retail in the large towns such sums are more than quadrupled, and particularly fine specimens, perfectly symmetrical, tapered to a single leader, full in foliage, and fresh in color, may bring any price within the means of the buyer.

The Petit Trianon at Versailles.

THE palace called the Petit Trianon in the park at Versailles was built for Louis XV. in 1766 (nearly a century later than the Grand Trianon which Louis XIV. built for Madame de Montespan), but is most intimately connected with the memory of Marie Antoinette, who created its famous “English garden” and Swiss chalets. These lie on one side of the building, while its main façade, shown in our picture on p. 619, has always looked out on a “French garden” connected with the grounds of the Grand Trianon. Although the details of this garden have been altered in recent times, it expresses as clearly as in its first estate typical French ideas with regard to the arrangement of grounds in the vicinity of a stately building.

There are avenues of clipped trees, straight paths and long rectangular flower-beds to harmonize with the lines of the architectural mass, to lead the eye directly toward it, and to show it, above the wide central lawn, as though set in a dignified and appropriate frame, while the curve of the great basin agreeably relieves the prevalence of right angles. It is evident that such an arrangement is far better in keeping with a building of this character than a “natural” landscape design would be. But it may be pointed out that its whole effect would be ruined had flower-beds or “ornamental” plants been allowed to intrude on the lawn. It is the simplicity of this that throws the bright-colored beds and the masses of foliage, as well as the building itself, into effective relief, and that gives breadth, repose and unity to the scene as a whole.

The Great Sequoia.

THE first white man who set eyes on the *Sequoia gigantea* was probably General John Bidwell, now one of the best known of the California pioneers. He has told me in a very simple and careful way the incident in his journey across the continent in 1841. He was a mere boy in years then, but a man in experience. The adventures of the party would fill

a volume. All that concerns the Sequoias is to this effect. The explorers were on the summit of the Sierras, worn out and anxious to descend into the valley. They were in an Indian country; the game was very scarce, and Bidwell went ahead to hunt and explore the region. Late in the afternoon, while in the midst of the deep cañons of Calaveras, and hastening to reach the river gorge to rejoin his companions, young Bidwell passed through the Calaveras grove of Sequoias. He was in such haste that he only noticed the immense size of the trees as he stood a moment beside one of the fallen giants. He said nothing of his discovery; but afterward, when in the employ of General Sutter at New Helvetia, he planned an exploring party to find the great trees he had seen at dusk that afternoon in 1841. Other business delayed the expedition. Then came the war, the conquest of California and the discovery of gold. Bidwell went first to the mines, and then was busy in securing his great Rancho Chico, and had no time to look for his big trees.

At last, in the spring of 1852, A. T. Dowd, a hunter of Murphy's Camp, Calaveras, while following a wounded grizzly, passed through the forests of *Pinus Lambertiana* and *Pinus ponderosa*, and came upon the Giant Sequoia-grove, since so famous. He was laughed at when he told his story; but the next Sunday he rushed wildly down the hill and called to “the boys” that he had “shot an enormous grizzly.” They went with him to the base of the largest tree in the grove: “There, boys,” he said, “is my grizzly!” When General Bidwell heard the story of the discovery he said at once: “Those are my big trees; I am very glad they have been found.”

The California Academy of Sciences received specimens of foliage, bark and cones of the Sequoia from the Calaveras grove before June, 1852. The late Dr. Kellogg forwarded specimens to Professor Asa Gray and to Dr. John Torrey, who at once recognized a second species of Sequoia. Veitch had some time before sent William Lobb, as a collector of plants, to the Pacific Coast. He was then at Monterey, I think, with Dr. C. C. Parry. Dr. Kellogg told him about the Sequoias, and he procured specimens for Dr. Lindley, who, failing to understand its true relationship, described the tree in the *Gardeners' Chronicle* of December 24th, 1853, as *Wellingtonia*—the name by which it is still almost universally known in English gardens.

When I was in Fresno, two years ago, I was told by the proprietor of the leading newspaper of the county that he had just returned from the Redwood-forests in the Sierras, and that there were thousands of acres of timber waiting to be taken up. “It is better timber than the Redwood of the Coast Range,” he said, “and constitutes one of the great resources of Fresno and Tulare Counties. There are several mills at work in the forests, and we shall have a narrow gauge railroad there in a few years.” I looked further into the matter, and discovered that the Redwood referred to was the largest and finest forest of *Sequoia gigantea* in California, and that it was rapidly passing into private ownership and was being cut into lumber and split into fence posts. During the past two years the destruction of these forests has gone on with accelerated speed, owing to the rapid settlement of the foot-hills by farmers, who are far removed from the railroad, and find it cheaper to get *Sequoia gigantea* Redwood from the mountains than *Sequoia sempervirens* Redwood from the coast.

There are ten groups of *Sequoia gigantea* in the Sierra Nevada Mountains, and the descriptions of most of them are found in the writings of Muir, Whitney and Clarence King. Beginning at the north, these groups are named as follows: The Calaveras grove, the South Calaveras grove, the Tuolumne grove, the Merced grove, the Mariposa grove, the Fresno grove, the Dinky grove, the King's River grove, the new King's River grove and the large Kaweah groves. The latter consists of a number of small Sequoia-forests extending over a belt of country five miles wide and fifty miles long. It is in this region that the Kaweah colony of Socialists have secured most of the timber lands,

and are now building large mills. It is not probable that in ten years any of these ten forest groups will remain except the Calaveras groves, and perhaps one or two other small groups, now used as summer resorts, unless immediate steps are taken to prevent the further filings of timber claims. The records at the Land Office show that in the past twenty-two months 131,680 acres of heavily timbered land have been bought from the Government, much of it obtained by a systematic evasion of the laws. Four-fifths of this land has been taken up along the western slope of the Sierra Nevada, and includes most of the *Sequoia gigantea* districts.

The Calaveras grove covers fifty acres, and contains ninety-three large trees. One tree in 1854 was stripped of its bark to a height of 116 feet, by a man who thought he could make a fortune exhibiting it. The speculation, fortunately, failed, or the grove would have been ruined by similar enterprises. This tree is estimated to contain 537,000 feet of marketable lumber, and stands 325 feet in height, girthing eighty-four feet without the bark. A fallen tree was about 400 feet in height, and the circumference of the trunk near the base is 110 feet. The south grove contains 380 Sequoias of good size—some very large. One of the largest of the standing trees in the Calaveras groves is the "Grizzly Giant," thirty-three feet in diameter near the ground. There is a tree in the Kaweah region that is thirty-six feet in diameter, and there may be even larger ones.

The Giant Sequoia yields seeds in such abundance (Mr. Bradley counting 324 seeds in a small cone) and the vitality of fresh seed is so uniform that millions of trees could be grown and planted on the mountain slopes of California. In the Sacramento, San Joaquin, Sonoma, Santa Clara and other large valleys the tree thrives without especial care. In most places it has grown faster than the *S. sempervirens*. If the state were to undertake to reforest the waste lands, the Giant Sequoia would offer one of the best trees for that purpose. The reason why it now grows only in such isolated and small groups, instead of in extensive forests, is because its small, light seeds cannot easily root themselves on the dry, leaf-covered soil of the region. The climate has changed; the tree is slowly disappearing. Wherever mountain fires, or cloud-bursts, have swept away the thick layer of coniferous leaves and scales from the ground, young Sequoias have sprung up. This tree, like the Monterey Cypress, has every element of vitality but one—its light, thin seeds are not adapted to survive under the present climatic conditions. The successful type of tree-seed is that of the *Pinus Sabiniana*, which holds its own so well on the hot foot-hills of California. The Great Sequoia lacks the capacity of *S. sempervirens* to reproduce itself from suckers from the roots, and if it is ever to become an important factor in the timber supply of California, its seeds must be planted under favoring conditions. None of the Pacific Coast conifers are more easily grown when the seeds are sown in moist soil.

Another illustration of the dangers to which some tree-seeds are subjected may be found in the case of *Eucalyptus globulus*. Groves of this tree were planted on the dry California hill-sides twenty years ago. They now perfect millions of seeds, but the seeds never grow; they never reach the surface of the dry, leaf-covered soil, or insects carry them off. But many pounds of this seed are gathered by the nurserymen, and sown with better results than with imported seeds. In the moist valleys the *Eucalyptus* grows from self-sown seeds, but never on the hill-sides. Yet, seedlings three months old are fit to plant anywhere. Without replanting, the *Eucalyptus* forests of California will mostly disappear in the course of time, just as the Sequoias are disappearing.

The guide books to the Calaveras and other groves still place the age of the Sequoia trees at between three and four thousand years. Professor Whitney's count, it may be remembered, gave a result of 1,255 years. Mr. Bradley made a careful study of the same tree, counting the

two ends of the lowest section of the trunk, eighteen feet apart. His results were 1,240 and 1,226. This is a mature tree, fifteen feet in diameter. A large specimen of *Sequoia sempervirens*, 1,200 years old, measured eleven feet in diameter.

Mr. Bradley takes the Pavilion Tree, which Whitney first measured, divides the cross-section into annular zones of one hundred rings, and computes the area of each zone. In this way he arrives at the wood growth for each century. He assumes that 300 years brought the tree to its full height. His ratio of volumes of growth for twelve centuries, the maximum being 1,000, then becomes as follows: 77, 308, 557, 963, 1,000, 794, 841, 908, 828, 817, 907 and 958. The fourth and fifth centuries may be supposed to mark the period of expansion of the head, after the tree had reached light and air above the surrounding forests.

San Francisco.

Charles Howard Shinn.

Notes upon Some North American Trees.—XV.

I. *MAGNOLIA GRANDIFLORA*.—Linnæus, in the first edition of his "Species Plantarum," grouped provisionally all the species of *Magnolia* known to him under one comprehensive name, *Magnolia Virginiana*, distinguishing the different forms under varietal names. That he was not sure that these trees all belonged to the same species, and that his name was a provisional one only, is made clear by his remark that "only eye-witnesses of these trees in their native country can determine whether these (α , β , γ , δ , ϵ) are distinct."* Now what becomes of the name *M. Virginiana*, the oldest Linnæan name for any of our *Magnolias*? If these varieties had turned out after further investigation to be merely forms of one polymorphous species, then the Linnæan collective name would have held of course; but being provisional only, it was to be dropped if the provisional species had to be broken up. That this was Linnæus' intention seems clearly enough shown by the fact that having discovered before the publication of the second edition of the "Species" that his varieties were really distinct species, he gave them specific names, using, in every case but one, the varietal names of the first edition.

The exception was the variety β . *fetida*, which, in the second edition, became *Magnolia grandiflora*. There was confusion, evidently, with regard to this tree at the time of the publication of the "Species," for Linnæus quotes under his variety β . *fetida* after Ehret's figure of *M. grandiflora* in Catesby's "Natural History of Carolina," t. 61, Clayton's description of the Umbrella-tree, "*Magnolia flore maximo albo foetidio, foliis deciduis amplis, florum ad ramulorum seriem sphaerice cingentibus, fructu majori*" (*Flora Virginica*, 61). This confusion may account for Linnæus' considering that the flowers of the evergreen *Magnolia* had a disagreeable odor, a mistake which he very likely discovered before the publication of his second edition, the discovery inducing him to select a more appropriate name in place of the varietal name of the first edition. But if the oldest specific or varietal name is to be adopted, *Magnolia grandiflora* must give way to *Magnolia fetida*. The change is a most unfortunate one in every way and I have hesitated a long time before making it. In nomenclature, however, one principle or the other must be strictly adhered to, and nothing can safely be left to the judgment or the taste of the individual author. If an author believes that the oldest specific or varietal name given to a plant on or after 1753 (the date of the publication of the first edition of the "Species Plantarum") is the right one to use, the rule must be applied absolutely, or it is better to make no changes at all, and to allow the names which have come into common use to stand, whether they are the oldest names or not. Ornithologists invariably adopt the oldest specific name. Botanists, however, are still divided in their opinion on this subject. Those who agree with me that under all circumstances the oldest specific name is the

*1.—"Utrum bre: α , β , γ , δ , ϵ , sint distinctæ, determinant antoptæ in folo naturali?" Linnæus, "Species Plantarum," 536.

proper one to use, will regret the change, but accept *Magnolia foetida* in spite of its inappropriateness and the common use in all countries of *M. grandiflora*, which, by the way, is not itself a very appropriate name, as many *Magnolias* have larger flowers.

Linnæus' *Magnolia γ grisea* is probably only a *Magnolia* in part. It was based on a description in Ray ("Hist. Pl." II, 1798, not 1718, as quoted by Linnæus), of a plant cultivated in Bishop Compton's garden in Fulham. Ray's description of the fruit, "fructus hujus non conus est ut præcedentium (referring to the Tulip-tree) sed bacca calyculata," might refer to Persea; but the "florem autem speciosum tulipæ æmulum" seems to indicate that two distinct plants were confused in this description.

X. *ANONA LAURIFOLIA*, Dunal.—Our Florida *Anona* was first made known by Catesby, who published in his "Natural History of Carolina" two admirable figures of the fruit and foliage with a flower in the second figure (II, t. 64-67). Upon the first of these figures Linnæus founded his *Anona glabra* ("Species Plantarum," I, 537), giving Carolina as the habitat. But Catesby does not say where he got his plant, which grows both in Florida and in the Bahamas, but not in Carolina, so that the habitat given by Linnæus was supposition. The fact of the wrong habitat and the absence of flowers from Catesby's first plate led Griesbach ("Fl. British West Indies," 5) to suppress the Linnæan name entirely and to refer this plant to the *A. laurifolia* of Dunal ("Mon. Anon.," 65). But *A. laurifolia*, to which Dunal refers Catesby's second figure (t. 67), is the same plant as the *A. glabra* of Linnæus, so there can be no question of the propriety of restoring the Linnæan name, and our Florida tree becomes *A. glabra*, Linnæus, to which it was long ago rightly referred in Chapman's "Flora of the S. States."

XV. *GORDONIA PUBESCENS*.—This name was published by L'Heritier in 1785 in the sixth Fasciculus of the "Stirpes Novæ." The "Arbustum Americanum," in which Marshall published this plant as *Franklinia Altamaha*, bears the same date, 1785; but as Marshall's name is quoted by L'Heritier as a synonym, it is clearly the older name and *Gordonia pubescens* must become *G. Altamaha*.

XXIV. *XANTHOXYLUM CARIBEUM*, Lamarck.—I had an opportunity a few months ago to examine in Paris the Lamarckian herbarium now preserved in the Muséum d'Histoire Naturelle, and to see the specimen upon which Lamarck founded his *X. Caribeum*. There are leaves only; but these have membranaceous, acuminate and sharply serrate leaflets, with occasional spines on the petiole, and are quite distinct from the leaves of our Florida tree, for which, therefore, another name must be found. *X. Floridanum* of Nuttall, published in his "Sylva" in 1841 and based on the Florida plant itself, would be the name if there was not an older one. I came across in the Kew herbarium this year a specimen, collected in 1886 in Porto Rico, identical with our Florida plant, which Dr. Urban had named *X. cribrorum*, Sprengel, whose short description of his species is fairly descriptive of the Florida plant.* Specimens of our Florida tree have been sent since to the Berlin herbarium, and are pronounced to be identical with the original specimens of *X. cribrorum*, which, as this name was published in 1825, takes precedence of Nuttall's *X. Floridana* published in 1841, and our species becomes *X. cribrorum*, Sprengel.

XXXVI. *ILEX DAHOON*.—There has long been confusion in the names of the two Hollies of the southern states vernacularly known as the "Dahoon" and the "Cassina." The confusion started with Linnæus in the first edition of the "Species Plantarum." These two plants were there joined under the name of *Ilex Cassine*, the second or real *Cassina* being considered a variety of the first, the Dahoon. That Linnæus intended the Dahoon as the type of the species is shown by his reference to it of Catesby's figure in the "Natural History of Carolina" (I, t. 31), where the

Dahoon is well represented and the vernacular name "Dahoon" is quoted; while to his variety he refers Catesby's figure of the true *Cassina* (II, t. 57). Walter ("Flora Caroliniana" 241, published in 1788) thought to set the matter straight by reversing the names so as to bring them into accord with the vernacular nomenclature, transferring the specific name *Cassine* to the Linnæan variety properly made a species, and making a new name, *Ilex Dahoon*, for the Dahoon Holly. The Linnæan name, *I. Cassine*, should be restored to the plant upon which Linnæus bestowed it, making *I. Dahoon I. Cassine*, and the two published varieties become *Ilex Cassine* var. *angustifolia*, and var. *myrtifolia*. It remains to find the oldest name for the *Cassina*. It was described by Marshall in the "Arbustum Americanum," published in 1785, as *Cassine Paraguay*; but *Cassine Paraguay* is the name ("Mantissa," II, 220) to which Linnæus refers the figure in Miller's "Icones" (t. 83, f. 1), which has opposite leaves, and is not clearly referable to a North American plant, so that Marshall's name cannot be used.* The next name is *Cassine Caroliniana* of Lamarck, but as *Ilex Caroliniana* is Miller's name ("Dict.," ed. 8) for the Dahoon, it cannot, being a synonym of another species, be taken up for the *Cassina*. The next name and the one which should be adopted is *Ilex vomitoria* of Aiton ("Hort. Kew," i., 170), a good name as descriptive of the peculiar properties of this species. *Ilex Dahoon* thus becomes *Ilex Cassine* and *Ilex Cassine* becomes *Ilex vomitoria*.

New or Little Known Plants.

Philadelphus Lemoinei ×.

M. LEMOINE favors us with the following note of this hybrid *Philadelphus*, of which a figure appears upon page 617 of this issue. "The new *Philadelphus* is the result of a cross made in 1884 between *Philadelphus microphyllus* and one of the garden varieties of *P. coronarius*, the latter being the pollen-parent. The seedling flowered in 1886, when it formed a compact, nearly spherical, mass of foliage as wide as it was high. The leaves, which are narrowly oval, are about one-quarter the size of those of *P. coronarius* and nearly five times as large as those of *P. microphyllus*. The flowers, which are ranged along the branches, are large, with spreading petals. These are oval, somewhat cut at their edges and pure white. When the plant is in flower it produces a wonderful effect by the profusion and elegance of its fragrant flowers, which exhale an odor as agreeable as that of Orange-blossoms, reminding one of the odor of wild Strawberries. This new shrub is absolutely hardy here, and resists, without any protection whatever, the cold of our most severe winters.

"The cross which has produced *P. Lemoinei* has yielded a number of other plants, differing in habit, in size and in the arrangement of the flowers. We have succeeded also in crossing *P. Lemoinei* with some of the large-flowered garden varieties."

Philadelphus Lemoinei has not flowered yet in the United States and our illustration is from a sketch made last summer in M. Lemoine's garden in Nancy.

Foreign Correspondence.

London Letter.

A WEEK'S steady freezing, the thermometer registering nightly from eight to eighteen degrees of frost, has put an end to almost all out-door planting, and killed down what few flowers still remained out-of-doors. At Kew, where the amount of transplanting and planting annually done is enormous, it is usual to begin about the end of September and continue all through the winter until the beginning of May, or even later. Frost does not often interfere with this work before Christmas, and it is many years since the ground was

*1. "*Zanthoxylum cribrorum*, foliolis 3-jugis, oblongis obtusis, coriaceis crenatis, pellucido-punctatis, petiolis asperis."—"Systema," I., 946.

*It is evident that the second figure on Miller's plate, the "*Cassine foliis lanceolatis alternis sempervirentibus floribus axillaribus*," refers to the *Cassina*, which is well described in the early editions of Miller's Dictionary. Linnæus, however, quotes figure 2, and his description was intended, apparently, to cover this, a very doubtful plant, and the *Cassina*.

rendered too hard for planting so early as the beginning of December. Already the enormous collection of *Berberis* here has been lifted and replanted so as to afford more space to each plant. Many of these plants are very impatient of disturbance at the root, so that unless lifted with a good ball of soil they are almost certain to suffer severely. What a number of garden names there are in the genus *Berberis*! And that it is not easy to reduce the names to botanical order is shown by the fact that those best qualified to do it fight shy of the work. Probably a considerable number of these garden forms are really hybrids or accidental crosses of some kind, and their parentage cannot be traced. In the autumn, when clothed with their bright scarlet, orange, yellow, purple or black berries, a collection of large plants of *Berberis*, such as these at Kew or in the Botanic Garden at Cambridge, presents a most beautiful picture. The birds, however, soon rob the plants of their charm, and at Kew, where the birds are protected, they clear the bushes of all fruits in an incredibly short time. A large group of bamboos, which has just been planted on the side of one of the lakes, promises to be a magnificent feature next year. For purposes of this kind no plants are better suited than the hardy kinds of Bamboo. In the gardens on the Riviera they form a feature at least as striking in beauty and elegance as the Palms, also largely used there.

PALMS for in-door decoration (see p. 559) are almost uni-

too rare in gardens, while seeds of them are not yet procurable. In the four hundred and odd species of Palms represented at Kew there are many which are greatly admired on account of their elegance and other attractions, but they are not in the trade. In tropical countries, as, for instance, in Ceylon, Calcutta, Brazil, Brisbane, etc., collections of Palms are being gathered and planted with a view to the supply of seeds for the European market, and the seeds of many Palms which are now rare will soon be plentiful. Evidently popular taste runs just now on Palms, many of the growers for the London market devoting themselves almost exclusively to these plants.

A PERFECT PLANT LABEL is still a desideratum, here, as well as in America. Mr. R. T. Jackson's paper on "Methods of Labeling Trees and Plants," read before the Massachusetts Horticultural Society last year, is interesting and suggestive. In it Mr. Jackson appears to have come near to what we have found the most useful label at Kew, both for in-door and out-door plants. For temporary labels, such as are used for annuals and small nursery stock, there is nothing better than wood; but for permanent labels intended for collection plants, something more durable than wood is required, and the best material appears to be zinc. Iron, tin, slate, porcelain and teak have been and are still in use at Kew, but on the whole they are not as satisfactory as zinc. As Mr. Jackson says,

Fig. 154.—*Philadelphus Lemoinei* X—See page 616.

versally preferred before everything else. In England there are scores of nurseries where these plants are grown by tens and even by hundreds of thousands and disposed of to market dealers. Mr. Taplin omitted to mention the several kinds of *Kentia* (so called), which, in England, are very largely grown; one nurseryman alone sells about ten thousand of them annually. *K. Fosteriana*, *K. Balmoreana* and *K. Canterburyana* are the three which are most used, the last named being less popular than the other two. These plants bear the exposure and hard treatment incidental to decorative uses better than any other Palm, not even excepting the *Livistona* (*Latania Borbonica*). They are raised from seeds imported from Australia, Java, Brazil, etc., and grown in tropical houses until large enough for use, when they are hardened by exposure to a lower temperature. Their elegant, bright green, pinnate foliage and their graceful habit are just what is most desired for the decoration of tables, side-boards, window recesses, etc. Other Palms grown largely here are *Cocos flexuosa* or *plumosa*, *Geonoma gracilis*, *Phoenix rupicola*, a most elegant Palm, *Seaforthia elegans*, *Thrinax graminifolia* and *Hyophorbe Verschaffeltii*. These are all popular and abundant. It would be easy to add the names of a great number of Palms which would prove quite as serviceable as these, which every one knows and grows, but unfortunately many of them are

zinc "is reasonably imperishable, cheap and very easily handled." The chemical ink recommended for writing upon polished zinc, namely, a solution of chloride of platinum, or chloride of copper, or other patent mixtures of a similar nature, have not, however, proved a success, no matter how applied. Varnish rubbed over the face of the label after the ink has dried, preserves it from oxidation for a year or so, but as a rule the names are almost unreadable after a year's exposure outside. An improvement on this ink is the use of enamel paint, applied as follows: The labels are cleaned with emery paper and then coated on the face with white enamel paint. This is allowed to get quite dry, and then over it is painted a coat of the black enamel paint. The writing must be done while the black paint is wet, using for the purpose a pointed stick, such as a bit of bamboo shaped like a pen. In writing, the black paint is simply removed by the point of the stick. With a little practice the letters are as easily and clearly formed as if with pencil on white paint. The label should be thoroughly dried before being exposed to moisture. For trees and shrubs such as the labels can hang upon, the form preferred is a piece of zinc from three to four inches square, half an inch at the top to be bent over at an acute angle to afford protection from the weather; one or two holes should be made near the top, for wire or nails. For pots and herbaceous plants

strips six or eight inches long, and shaped like the ordinary "tally," are best. These are easily cut out of a sheet of zinc with a pair of strong scissors. Labels thus prepared have been in use at Kew two years and they are as perfect now as when they were first written. In the tropical houses, where the atmosphere is saturated all the year round, these labels are quite as good as in a dry house or out-of-doors. The first experiment with them was made with the Filmy Ferns, for which durable and neat labels were much wanted. They have stood this test. In appearance these labels are all that need be desired. They are not too conspicuous and therefore do not offend the eye as white labels do; on the other hand, they are easily read. In public gardens, such as Kew, labels are of considerable importance, as also they are wherever valuable collections of plants are grown. So far as our experience goes, this zinc label, when prepared as here directed, comes nearest to what is wanted.

THE DISEASES OF PLANTS are many and mysterious. Every gardener has had experience of their ravages in some form or other, and probably, also, has been disheartened by his failure to check the enemy by any means known to him. Canker, club, mould, rust, scab, spot; these are familiar terms in horticulture, but few, if any, horticulturists have a clear knowledge of what these diseases spring from, much less how they can be cured. It is only recently that one of our most eminent amateur horticulturists expressed to me his conviction that "spot" in Orchids was due to the attacks of some parasitic fungus, and that he always took the precaution to remove any leaf which showed signs of the disease. Had he been right in attributing the disease to a fungus, this action would be commendable. But it has been decided by one of our most eminent physiological botanists that Orchid "spot" is certainly not fungoid in its nature. This case is noteworthy as showing how much we are in ignorance of the real nature of the numerous diseases to which plants under cultivation are subject. The publication, therefore, of a trustworthy book dealing with some of the diseases of plants, may be hailed with pleasure by gardeners. Professor Marshall Ward, who is one of the most eminent of the modern school of botanists, and who has paid special attention to vegetable pathology, has written a delightfully readable book on this very subject. It is published by the Society for Promoting Christian Knowledge, and is one of a series of publications called "Romance of Science." The diseases treated upon by Mr. Ward are the commonest and best known, such as potato disease, smut, rust, hop disease and lily disease. These are diagnosed and prescribed for in a manner easy to understand, and at the same time thoroughly. One is surprised to read in the introductory chapter that "between 1866 and 1889 the amount of research in this department has been enormous, and the literature of the subject has become overwhelming." I once had occasion to collect information on this very subject, but could find exceedingly little, in English at any rate. Mr. Ward has made a beginning, and we may hope that he will extend his investigations to other of the diseases of plants besides those treated upon in his book. A really comprehensive, reliable book on the whole subject of plant diseases, and written for horticulturists and farmers, would be of great service. Mr. Ward himself says: "The time is rapidly approaching when a farmer or a gardener will as little dare to neglect the study of the physiology and pathology of plants as a surgeon dare practice without a knowledge of anatomy, or a sailor hope to become a captain without studying navigation. Moreover, these are not studies which will bear trifling with, and he who hopes to understand them must take the necessary trouble to learn how to trace the connection between cause and effect, and scientifically reason from the simple to the complex. In this department the days of empiricism are indeed numbered." Mr. Ward's book is precisely what is wanted as a beginning. It is published in New York by Young & Co. The price here is two shillings and sixpence.

ANTHRACITE COAL.—The fitness of this as a substitute for coke has been the subject of discussion here for some time, as the result of a rise in the price of the latter. It is stated by some who have used anthracite for years that a considerable saving is effected as compared with the cost of coke. But it does not appear to be satisfactory in all cases. An eminent American nurseryman when at Kew a little while ago informed me that anthracite is universally preferred to coke in America. It would be interesting to English readers of GARDEN AND FOREST if some one acquainted with the peculiarities of coke and anthracite, when used for horticultural heating, would relate his experience. We find a difficulty in using the anthracite for furnaces originally intended for the consumption of coke.

Some Wild Flowers of California.

Phacelia Parryi is one of the loveliest of the annuals of southern California and a universal favorite among those who have made its acquaintance. Every one who sees it face to face feels an instant admiration for its beauty, and a kind of friendship for it such as we experience in our intercourse with the Pansy and other flowers which confront us with something akin to a human expression.

The plant delights in warm, sunny exposures, on the banks of cañons, among the foot-hills, in fertile valleys and on the hill-sides. It extends in San Diego County from the seashore to the confines of the Colorado Desert, southward to near San Quintin Bay, Lower California, and perhaps beyond. It has an open, rotate corolla of a rich and brilliant royal purple, well set off by the dark green foliage. Occasionally a flower may be found of a paler color, sometimes nearly white. With nearly all of our native flowers that are normally purple in color, I find albinism a common occurrence, though rarer in some species than in others. This rule, if such it may be called, is also true of purplish pink flowers, like *Erythraea*.

In the spring of 1884 there was an unusually abundant rainfall, which played havoc with our roads, but the botanist who was driven to little used thoroughfares found himself repaid by the wealth of luxuriant vegetation which followed. A new grade had been built the previous season from San Diego City, leading into the old mission valley, and along the freshly cut embankment I found this beautiful plant growing in the greatest abundance. Since then it has been almost totally absent from this locality, not more than a score of plants growing on this road during the spring-time of 1889. Why this sudden disappearance? is the question which naturally arises and remains unanswered. The existing conditions seem equally as favorable as in other localities where it still thrives—and often in close proximity to well traveled roads.

For cultivation I should call this one of the most desirable of the many pretty annuals which California affords to the horticulturist. It is capable of most effective display, and under favorable conditions will produce a profusion of flowers for months.

Dodecatheon Clevelandi shows itself, generally, in early spring over the hills, mesas and valleys of southern and Lower California, especially near the coast. The flowers pass from clear pearly white through lovely shades of pink and rose-red into a brilliant purple, and a large field thickly dotted with their nodding heads is a vision of loveliness familiar to Californians. For many years this and numerous other forms throughout the western states have been known to botanists as the *Dodecatheon Meadia* of Linnæus. Within recent years Mr. E. L. Greene has studied our Californian forms, describing several as new species, and naming this in honor of the earliest resident botanist in San Diego, Mr. Daniel Cleveland, whose early collections brought many new plants to light. It is scarcely worthy of specific rank, but for cultural purposes may be allowed that honor. Every child is sure to gather large handfuls of the fragrant flowers when spring comes, and each has some pretty name for them, such as Rabbit-ears, Shooting-stars, Johnny-jump-ups or Mad Violets.

This flower should become as general a favorite as the Cyclamen. The perennial roots are easily transplanted, and no difficulty should be experienced in making it thrive in eastern houses and gardens. In California they may be planted as borders to beds, or grouped in masses, or dotted thickly over a garden as if they were wild. The broad leaves form a pretty rosette before the one or more spikes of flowers appear. The flowers are admirably adapted for bouquets and the use of florists, and their good qualities are already recognized away from their native home.

Gilia dianthoides bears a flower which in size and beauty is out of all proportion to the plant itself, which consists only of a slender, wiry stalk, half an inch or so in height, with narrow, inconspicuous leaves; but from this stalk appears one or several rotate, rosy pink flowers, half an inch across. The flower is of such a delicate texture and is borne so near the ground that it is scarcely available for any decorative purpose; but a field carpeted with them as they shine in the morning sunlight, cannot fail to kindle admiration. Under favorable conditions the plant attains a larger size and forms a dense mat spreading out over the ground. In cultivated fields I have found a single plant spreading in this way more than a foot across—completely hidden by the numerous wide-awake flowers. It is not rare to find a plant with pure white flowers, especially among the foot-hills. A similar species (*Gilia Orcuttii*), with white

flowers slightly variegated with purplish red, was collected in 1883 on a mountain in Lower California, but has not since been seen. Another equally beautiful species (*Gilia bella*) was discovered on the high table lands of northern Lower California among the Pinyon Pines, and I have since seen it abundantly on the mountains bordering the Colorado Desert. It has the same characteristics as the last, but more brilliant and darker flowers of smaller size.

San Diego, Cal.

C. R. Orcutt.

Large Glass in Green-houses.

MY first green-house was a small one, twelve by thirty-three feet in dimensions, with benches against the sides and a path down the centre. It was covered with a span-roof made of hot-bed sash of three by six feet dimensions, which were set with six by eight inch glass; it had a ridge made of boards two feet wide, which cast a shadow always, and the

growth was most marked. In the new house the Lettuce grew steadily and rapidly in the almost unobstructed sunlight, and made good heads for market, much better than had been obtained from the old house. The plants were free from the green fly and were grown without fumigation or artificial heat from September to December, while that in the span-roof house—a few plants put in as an experiment to test the comparative merits of the two houses—was as poor as usual. Although the house has been occasionally fumigated and supplied with some artificial heat, the Lettuce is still too small for market and is also troubled with the green fly.

This is an object lesson that is very convincing to all who have seen the contrast in growth and vigor in the tree houses. The chances were all in favor of the Lettuce in the old house, if care and attention could avail, but when simply left alone to grow in the free sunlight, that in the new house was altogether superior.

The Petit-Trianon at Versailles.—See page 614.

wood of the sash-bars and heavy rafters caused more shade still. Standing north and south, the shade, as the sun passed across the sky, was shifted from west to east, and in dark days and cloudy weather, with the sun low in the sky, the house was still more in the shade than in the fuller sunlight of the spring months, when the sun was higher.

This house is now used for growing Geraniums, Fuchsias, Verbenas, Petunias, Pansies, Callas, and other vigorous flowering plants; also for Dandelion, Radish, Cress and the like, among vegetables. I knew the lack of sunlight affected the growth and vigor of the plants to a considerable extent, but did not realize how much till the past season.

Last September I completed a structure, thirteen by twenty-five feet in dimensions, the south front covered with glass, and the back kept dark for storing things that did not need light, like Celery, Endive, Spinach and Salsify.

The front, five by twenty-five feet on the south side, was covered with double thick glass, sixteen by twenty-four inches in size, on slender rafters six feet long. I never had success with Lettuce in the span-roof house, but the other things mentioned always did well. In September last I set Lettuce in the new house, directly under the glass, and the contrast in

Lettuce has always been considered to be specially difficult to grow under glass, from its tendency to damp off and rot. Slow growth and the green fly have also been great hindrances, but in the light of this experience, sunlight seems more essential than any special care.

Houses twenty-two by two hundred feet, covered with sixteen by twenty-four-inch glass, on rafters three by four inches, facing the south or south-west, ten feet high on the back and three on the front, with sunken paths, and arranged to be aired across the beds, make the best houses so far devised for Lettuce-growing; and the same principles applied to a smaller house should produce similar results.

West Springfield, Mass.

W. H. Bull.

Orchid Notes.

Vanda cœrulea.—Taking a survey of the hundreds of Orchids known, one cannot fail to be struck with the remarkable scarcity of blue flowers among them. Such colors as red, orange, scarlet, yellow and their intermediate shades are well represented; various hues of crimson and purple (which, artificially, cannot be obtained without the assistance of blue) are frequently met with; and white—although artists

say such a color does not exist—forms the ground color of many flowers, but is very rarely seen absolutely pure. But blue—real blue—is conspicuous by its absence. The number of Orchids whose flowers are of this tint would not take long to enumerate. It is chiefly noticeable among such South African plants as *Herschelia caelestis*, *Disa longicornis*, *D. maculata*, *D. venusta*, and perhaps a few others. Bright blue is the characteristic color of the Australian Caladenias, and light and dark shades of the same color are found in the small-flowered Burmese *Vanda carulescens* and the larger and more beautiful *V. carulea*, the latter forming the subject of the present note.

It was named by its discoverer, Griffiths, who first found it in 1837 near the River Borpane, where, at an elevation of 2,500 feet, it was growing in forests of Pine and Oak on trees of *Gordonia*, a Ternstroemiaceous genus. Hooker and Thomson, when traveling in that region several years ago, met with it in a wild state on the Khasya Hills at a height of 3,000 to 4,000 feet. It grew in such abundance that in a short time they obtained no fewer than 360 spikes, each bearing from six to twenty large flowers.

The introduction of *V. carulea* to cultivation is due to Messrs. Veitch & Sons, of Chelsea, who received plants of it from their famous collector, Thomas Lobb, about forty years ago. Owing to the unique color of its flowers, it caused at the time a great sensation, and even nowadays a well grown specimen calls out many expressions of admiration. With the exception, perhaps, of the magnificent *V. Hookeriana*, noted at page 392 of GARDEN AND FOREST, and the gorgeous *V. Sanderiana*, it is perhaps the finest *Vanda* yet known. Well grown specimens are from eighteen to thirty inches high, their stems being furnished with distichous, oblong, leathery leaves, about six inches long, and deeply bilobed at the apex. The flexuose peduncle springs from the axil of a leaf about midway on the stem, and bears a variable number of flowers, each from three to four inches across, and supported on pale violet, sharp-angled pedicels about three inches long. The sepals and petals are more or less oval in shape, and vary in color between light and dark blue, handsomely reticulated with white veins, giving to the flowers a mottled appearance. The small, narrow, projecting lip is of a deep violet blue, and is furnished behind with a short conical spur, at whose opening is a pure white auricle on each side, and at the base of the short, thick, white column are a pair of bright yellow crescent-shaped blotches.

Last September I saw two fine specimens of this *Vanda* in flower in the Royal Gardens, Kew. One plant had a spike of fourteen tolerably deep blue flowers nearly four inches across. At the same time a plant was blooming in this nursery with twelve flowers on the spike. Each flower measured four and a quarter inches across, and was of an intense blue, a shade which is seldom seen in this species.

When *V. carulea* was first introduced to cultivation, the fact of its being a native of India was sufficient reason in those days for it to be regarded as a stove plant. The altitude at which it grows in its native haunts not having been taken into consideration, the warm treatment which this species received naturally produced such disastrous results—most of the plants dying—that it remained a rare plant until it became more common by the importations of later years. A cool, airy house, with a temperature of sixty to sixty-five degrees Fahrenheit, suits this species best in summer, although no harm will result if the thermometer rises a few degrees more with the sun, from which the plants must be shaded when it becomes too warm. The plants make their growth during the spring and summer, and must then receive more or less liberal supplies of water, according to the vigor of their growth. When this is about to cease the flowers appear, usually in September and October, and if kept in a dry atmosphere they will retain their freshness for six weeks or more. During the winter months the plants should be rested, and only small quantities of water are occasionally required. Well drained pots, baskets or cylinders are suitable for the cultivation of this species, plants of which will thrive either simply in crocks and charcoal, top dressed with fresh sphagnum, when more attention must be given to watering, or in a compost of rough peat, sphagnum and charcoal, well mixed.

St. Albans, England.

John Weathers.

Odontoglossum Sanderianum.—This is a charming free-flowering Orchid, its value being greatly enhanced by a delightful Hawthorn fragrance. By many this plant is considered only a superior variety of *O. constrictum*, but it is more probably a hybrid between that species and *O. gloriosum*. This is evident more especially in its larger and more robust growth, and the erect character of the inflores-

cence. The fragrance must also come from *O. gloriosum*, but *O. Sanderianum* is an extremely variable plant, and the good varieties are by no means plentiful. Even the poor ones will be found very useful for cutting, and a batch of plants will ensure flowers almost every month in the year. They grow freely and strong spikes will produce nearly a hundred blooms.

Trichosma suavis.—This pretty little plant is now in flower, and greatly appreciated for its delicious fragrance. It is the only species of the genus, and, though introduced fifty years since from the Khasya Hills, has always been a very rare plant. Recent importations, however, have brought it within the reach of all. It thrives in the cool house potted in peat and moss, and watered as if it were a bog plant. The reed-like stems are clustered, about ten inches long, and terminated by two lanceolate fleshy leaves, from between which spring the short racemes of creamy white flowers, about an inch across. The side lobes of the lip are prettily striped with crimson, the wavy, recurved middle lobe bearing a yellow, crispy crest on the disk. The flowers last quite a long time on the plant, and, though not showy, they are very attractive and fragrant. Altogether, this Orchid is a genuine acquisition, especially since it may be grown in a cool house with greenhouse plants, its greatest requirement being abundance of water.

Kenwood.

F. Goldring.

Some Good Variegated Plants.—Prominent among variegated plants of comparatively recent introduction is *Ficus elastica variegata*, which will probably be largely used for decorative purposes as it becomes more plentiful. Its growth seems to be nearly as vigorous as that of the type, and the large leaves, well marbled with light green and creamy white, make it a pleasing contrast with the dark foliage of the species. Some difficulty has been experienced in rooting cuttings of this variegated *Ficus*, it being more shy in this respect than the green form; but this trouble has been overcome to a great extent by grafting it on the latter.

Dracena indivisa variegata is another interesting addition to this already numerous family. It is very similar in general appearance to the type, having the same gracefully arched foliage, with the additional charm of variegation in the form of stripes of creamy white. This plant probably originated as a chance seedling.

Another introduction of considerable merit is *Heliconia aureo-striata*, which in form somewhat resembles the *Hedychiums*, and has large, robust, Canna-like foliage from one to two feet long. As its name indicates, this *Heliconia* is variegated with fine stripes of yellow, the stripes to a greater or less extent following the plan of the venation of the leaves from midrib to margin. It has thus far been grown in stove temperature, but it is quite possible that it may prove useful outdoors in summer, and if so, its varied utility will give it greater value. It may be propagated by division, and grows well in light loam when given an abundance of water.

Holmesburg.

W. H. Taplin.

Kniphofias.—When noting these plants in a letter to you last year, I mentioned Mr. Gumbleton, of Cork, as being a careful collector and cultivator of *Kniphofias*. He has lately contributed to the *Gardeners' Chronicle* a series of notes and observations on the species and varieties which he cultivates, and which have flowered during the past summer and autumn. Mr. Gumbleton often falls foul of plants which many of us consider handsome enough to cultivate. To win his admiration a plant must have undoubted merit. It follows, therefore, that anything recommended by him may be taken as deserving a place in the garden. The number of *Kniphofias* noted by Mr. Gumbleton in the communication referred to is twenty-seven species and varieties, whilst he professes to cultivate no less than forty. In English gardens these plants, commonly known as "Red-hot Pokers," are used very effectively both as masses on lawns or by the side of water, or as border plants. Many of them flower late in the autumn, several massive beds at Kew having been quite ablaze with flowers until a few days ago. The hybrids are mostly of exceptional merit, being, as a rule, hardier and freer in flower than the species. Mr. Max Leichtlin, of Baden-Baden, has been a breeder of *Kniphofias* for some years, and he has this year several which differ both in form and color from anything hitherto seen. They are the result of crossing *K. comosa* and *K. Leichtlini*, both Abyssinian species, with those which are natives of the Cape. It is a remarkable fact that these plants, which mostly come from tropical or semi-tropical Africa, are hardy in the warmer parts of Great Britain, whilst many plants from cooler parts of the same continent will bear only a moderate amount of cold.

Kew.

W. Watson.

Coreopsis Drummondii.—Few flowering plants can compare with this for winter cutting, either in beauty or productiveness. It excels *Leptosyne maritima*, *Chrysanthemum segetum*, or the yellow variety of *C. frutescens*, and, at the same time, does not require half the care. A few seeds sown in September gave us plants which are blooming now and will continue to do so all winter. Florists could plant them about eighteen inches apart, in borders, giving about three feet of head room, but, for convenience, they can be grown in ten-inch pots. They will take almost any quantity of water and delight in liquid manure frequently.

The flowers coming from a packet of seed will vary in shade of color and in form and size of flower, but with careful selection, which we have adopted, a very fine and constant variety may be obtained.

Alpine Auriculas.—Like many other so-called hardy plants, these require some protection in winter in order to grow them well, but they are worth the trouble. We have made a specialty of them for the last two or three years, forcing them first sufficiently to have them in bloom two or three weeks before the natural time, which is in the early part of May. For this purpose we pot about twenty-five and leave the remainder in a cold-frame covered with a few Pine-needles. Auriculas are easily raised from seed sown in a cool frame, from which frost is barely excluded, about the first of February. They will make good plants the first year and bloom the following spring. The soil most suitable is a good loam with well decayed manure. Green manure should never be used with them.

Wellesley, Mass.

T. D. H.

Quercus dentata.—The Daimio Oak of Dr. Hall is said to be (p. 537) about twenty-two feet high and the finest the writer has seen. I did not know I had one so near the best. Mine is twenty-two feet seven inches, and measures twenty-five inches in girth one foot from the ground. Plants grafted from this tree have borne acorns, though smaller trees, of course, than the parent. It is one of the most rapid growing of all Oaks. Three feet for one season is not uncommon; and I have had branches five feet. My tree was from an acorn from Japan, kindly given to me by my friend Peter Henderson, not so many years ago, though I neglected to note the exact date.

Germantown, Pa.

Thomas Meehan.

Elæagnus angustifolia.—The note on page 600 in regard to the Indian variety of *Elæagnus* "known in gardens often as *E. angustifolia*," suggests a good word for the typical *E. angustifolia* of east Europe and central Asia as an ornamental tree, and a windbreak tree for the prairie states. As we have received it from Riga, Proskau, Voronesh and other points in east Europe, and as introduced extensively into Nebraska by the Russian Mennonites, it does not appear to vary in hardiness, habits of growth, size of tree, or beauty of foliage. It is a much larger and stronger grower than the form known as *E. hortensis* of south-west Europe, yet it is quite as handsome in expression and as fragrant when in bloom.

We now have trees in Iowa, chance introductions, fully thirty-five feet in height and with a diameter of trunk of nearly one foot. As to hardiness, I have seen it growing in perfect health on the Red River of the North at Fargo, and I have never known it injured in any part of north Iowa during our recent test winters. It is a dry-climate plant and I suspect it will thrive much better on the prairies than in the relatively moister and cooler summer air of the states east of the lakes.

In isolated positions, with the stem trimmed up, it stands much better than our native *Shepherdia* of the upper Missouri, which sun-scalds with us on the south side of the stem if trimmed into tree form.

The *E. argentea* of the upper Missouri is also perfectly hardy as a bush upon the prairies, as is the *E. macrophylla* of central Asia; but unlike the *E. angustifolia*, these handsome bushes are great sprouters, and will not, probably, become popular for ornamental planting.

Berberis Thunbergii.—Mr. Jack's words of praise of this Oriental Barberry are well merited and I am glad to state that it is a thing of beauty also in our trying climate. As Japanese plants are tender with us, I suspect the species is from north-west China or central Asia. We have a section of low spreading hedge of this plant beside one of our drives which attracts much attention during the growing season, and at this time (December 14th) the berries are as bright and handsome as in early fall. That it is a distinct species is shown by the fact that seedlings we have grown retain the peculiarities of habit, leaf and fruit of the original plants.

Ames, Iowa.

Correspondence.

In the Hickory Matter.

To the Editor of GARDEN AND FOREST:

Sir.—In the issue of GARDEN AND FOREST for September 25th (vol. ii., pp. 459, 460), under the heading "Notes Upon Some North American Trees, XI.," being an installment of the exceedingly valuable and interesting series of papers upon this subject from the pen of the editor-in-chief, there is a discussion of the questions raised by me last November (*Bull. Torrey Club*, xv., 277), as to the generic name and classification of the Hickories. As I believe, however, that neither Professor Sargent nor I have written all that might advantageously be written on this subject, I venture to send you the following additions.

And, in the first place, I am of the opinion that there are more valid species than either he or I have yet been able to define. The specimen with curiously pallid under-surfaces of the leaves from Lookout Mountain, Tennessee, alluded to by me at the place above cited, may well be taken as an indication of an addition to the lists, from a region as yet but partially explored. Then there is a specimen here, collected by Mr. Frank Tweedy in Tom Greene County, Texas, evidently of the Pacanier section of the genus, but differing from the Pecan in its markedly punctate leaves and some other characters. As there are two names published, viz., *Hickoria Texana*, Le Conte, and *Carya Texana*, C. DC., both based on specimens of Texan origin, neither of which have yet been satisfactorily referred by subsequent writers, and Mr. Tweedy's specimen is only in flower, we are not yet able to characterize the species which it represents. Most likely it is *H. Texana*, Le Conte, but that was described from fruiting specimens only, and no mention is made of punctate leaves. *H. myristicaformis* has punctate leaves, but belongs to the other section (*Euhicoria*) of the genus, unless, indeed, its separation into two sections, as indicated by me, should be annulled by this Texan tree, a point which complete collections only can determine.

Professor Sargent differs with me in the spelling of Rafinesque's generic name, replacing the feminine noun *Hicoria* by *Hicorius*, which is masculine in form. Some of the reasons which governed me in taking up *Hicoria* are given in considerable detail in my paper above cited. There are a good many others, however, which my learned critic appears to have overlooked, but which hardly seemed necessary to establish my position. I did not discuss the fact that the names of trees are feminine in the Latin language, and that the Latinization of the Indian name "Hicory" would naturally be *Hicoria*; nor did I allude to the fact that Rafinesque's two modes of spelling actually represent but one word, which even made of masculine form in *Hicorius* would yet be feminine, and the specific names must agree in gender, and become, at any rate, *H. alba*, *H. glabra*, *H. minima*, etc., rather than *H. albus*, *H. glaber* and *H. minimus*, as he has written them. Clearly the two modes of spelling do not represent two genera, for there could not be *Hicoria* and *Hicorius* any more than *Popula* and *Populus*. The eccentric Rafinesque recognized this, for he wrote in his "Flora Ludoviciana" not *Hicorius integrifolius*, but *H. integrifolia*, and elsewhere used the two spellings interchangeably. And so I do not think Professor Sargent's charge that I have made a lot of synonyms will be considered a just one by students of botany or dendrology.

But the point in which he appears to me most at fault is in the following statement; he says, in speaking of Rafinesque's separation of the Hickories from the Walnuts: "His first attempt was made in 1808, in the *Medical Repository* (v. 352), in which, in a single paragraph, he simply enumerated, after the word *Scoria*, the specific names, in parenthesis, of five Hickories." Now, I do not wish to accuse Professor Sargent of unfairness, but I must reproduce here, for the sake of argument, just what Rafinesque is made to say at this place:

"*Scoria* (tormentosa, mucronata, alba, pyriformis, globosa, etc.), *Fuglans alba*, L., tomentosa, mucronata, Mich., etc. The Hickory."

Now, it is just as plain as day that Rafinesque indicated here a generic name for the Hickory, by giving the equivalent names already published by Linnæus, Michaux and others under *Fuglans*. This method of publication, by citing equivalents, has been used more or less by all modern authors. Indeed, Professor Sargent has himself used it in the very article I am now discussing. Desvaux, in translating Rafinesque's paper into his *Journal de Botanique*, has it "*Scoria tomentosa, mucronata*, etc., ce sont les *Fuglans alba*, L., etc."

(vol. ii., 170, Paris, 1809), showing that this was well understood at the time.

But, as I have elsewhere contended, Rafinesque evidently wrote *Hicoria*. The whole of his article in the *Medical Repository* shows faulty proof-reading, or no proof-reading at all, and the word came out *Scoria*. Afterward, except in the Louisiana Flora (1817), Rafinesque wrote it *Hicoria*, and the proof that he so wrote it originally is to be found in the following statements:

In the "Good Book and Amenities of Nature," pp. 48, 49 (1840), he says: "In the continuation of these trees in the 'American Grove,' American novelties are still more numerous. . . . The monographs of new and revised sp. are *Calycanthus*, 5 sp.; *Myrica*, 12 . . . of Hickory trees or *Hicoria*, Raf., 1808, 4 subg. and 4 new sp. . . ."

In his "Alsographia Americana" he says: "*Hicoria*, Raf., 1808. *Carya*, Nuttall, 1818, etc. As early as 1804 I proposed to separate the Hickories from the Walnuts, to which Muhlenberg objected. I did so in 1808 in my remarks on Michaux's Flora, and again in 1817 in my 'Florula Ludoviciana,' giving the almost Grecian name of *Hicoria*; yet Nuttall changed it in 1818 into *Carya*, which means merely nut. . . ."

Dr. Torrey has it *Hickoria* in his Catalogue of Plants growing within thirty miles of New York (1819), citing it as a synonym of *Carya*. There is a letter of Rafinesque extant protesting against this, and especially against the *k*. The word has also been spelled with a *k* by Le Conte and others, but there appears to be no authority for it.

It is, therefore, apparent that there is no valid choice between *Hicoria* and *Hicorius*; the only issue that can be raised is between *Hicoria*, a strictly applicable Latinized aboriginal name, and its misprint, *Scoria*, which, from what I have shown, can hardly be seriously taken up by any botanist.

Columbia College.

N. L. Britton.

[Dr. Britton's point as to the date (1805) of the establishment of the Rafinesquian genus would seem to be well taken, as there is no doubt what the species were that Rafinesque meant to include in it, and, consequently, no ambiguity in regard to the limits of his proposed genus can exist. His view is enforced by a canon (XLII.) of the code of nomenclature of the American Ornithologists' Union, which affirms that "The basis of a generic or subgeneric name is either (1) a designated recognizably described species, or (2) a designated recognizable plate or figure, or (3) a published diagnosis," to which is added as remarks: "Some writers insist that a generic or subgeneric name, in order to be tenable, must be accompanied by a diagnosis. However proper such a requisition may seem theoretically, the principle is thoroughly impracticable, and if enforced would lead to hopeless confusion. The custom of naturalists has been quite otherwise, and the mere mention of a type has been found to be often a better index to an author's meaning than is frequently a diagnosis or even a long description. Either of the three alternatives given above may alone be accepted as a proper definition. In the case of a diagnosis it must, of course, give some character or characters by which the organism it is intended to designate may be unmistakably recognized."

The question is, therefore, properly between *Scoria*, as printed, and *Hicoria*. The evidence points to a misprint certainly; and as a misprint it may, according to the rigid rules in nomenclature, be corrected. ("A generic name should subsist just as it was made, although a purely typographical error may be corrected." A. De Candolle.)—Ed.]

The Destruction of Evergreens for Christmas Decorations.

To the Editor of GARDEN AND FOREST:

Sir.—That the recent Forestry Congress in Philadelphia, which evidently had the preservation and prosperity of our forests honestly at heart, made no protest against the wholesale destruction of shapely young evergreens every year as Christmas-trees, strikes an interested onlooker as, at least, demanding comment. If this German fashion of sacrificing a tree at the Christmas-tide were a harmless fad, like the sending of holiday cards, or one likely to wear itself out before much positive hurt is done, it might pass unrebuked. But it is a growing custom, and has already reached such proportions that the yearly December slaughter of the "innocents"

unquestionably amounts to 1,000,000 or over east of the Mississippi River. That such an enormous devastation cannot long continue without impoverishing the forest supply of the future must be apparent to every one. No true lover of trees or intelligent patriot can behold the slain evergreen beauties stacked in the market-place at Christmas-time and consider their ultimate fate without a pang of regret, and even of anger, at the thoughtless sentiment that is gratified through such wicked waste, to say nothing of the ruthless extermination of various evergreen growths, which, if left undisturbed, make our woods forever beautiful, but, when woven into wreaths, soon perish, and then feed the fire or the garbage gulch.

No one is necessarily any the happier for the Christmas-tree, and the children who have been reared to regard the sacrifice of a lovely young tree for a few hours' entertainment as wicked and cruel, are as happy—if not happier—than the youngsters who, through custom, think Christmas a poor thing without a tree.

It is a possible thing in many families to use Orange and Oleander trees, which are grown in tubs, for Christmas decorating. It is also possible in many localities for young evergreens to be lifted, especially from nurseries, out of the ground, and the roots so cared for that the tree may be used for planting after the Christmas use is over, to live and grow into a perennial joy, more beautiful when decorated by nature with frost and gleam than a poor, murdered tree ever was, hung with strings and tinsel.

Seriously, is it not high time for all good people to frown upon a Christmas-custom that is neither Christian nor common sense, and which is at once so unnecessary and so harmful?

Bryn Mawr, Pa.

Mary Wager-Fisher.

[The trees which are used in the eastern states at Christmas are usually the Black Spruce and the Balsam Fir. The Hemlock, the Arbor-vitæ and the White Pine are used less commonly. These trees, where they spring up naturally, grow so close together that they are subjected, almost from the beginning of their existence, to a fierce and continuous struggle for life, in which hundreds perish where a single individual reaches maturity. The young trees in these forests would grow more quickly and with less expenditure of vital force if man would come in and help nature to destroy the weak for the benefit of the strong. This is what thinning means in forest-management. The coniferous forests of the United States can supply Christmas-trees for the whole world ten times over every year and be improved by the operation, provided they are cut with this purpose in view. The danger in this, as in every operation in the American forests, is, that the future is sacrificed for the present, and when young trees are cut for the Christmas-markets they are cut without any reference to the effect their removal will have on the future growth of the forest. This business is only a little rivulet added to the great stream which for two centuries has been slowly draining the American forests, and which is going to exterminate them unless some change takes place in the attitude of the American people toward forest-property. Nature does not recognize the infallibility of republics; nor can Americans, any more than less fortunate people, tamper with the workings of her immutable laws without incurring the penalties which follow their violation.—Ed.]

Wanted, a Chart of Standard Colors.

To the Editor of GARDEN AND FOREST:

Sir.—Permit me to call attention to an urgent need, which I believe is felt almost universally by naturalists—a complete nomenclature of colors for field use. It is not strange, without a standard authority upon the subject, that the colors of flowers are so rarely given with anything approaching uniformity or correctness. There are many puzzling shades and tints in nature which even artists who have made a special study of colors cannot name or correctly reproduce at first trial. It is even more difficult in animal life to correctly describe color, and this is found especially true when attempting to define the life colors of certain marine forms of the lower vertebrates and invertebrates. Mr. Robert Ridgeway, of the United States National Museum, has attempted to supply this want among ornithologists in an expensive volume encumbered by a dictionary of ornithological terms and other

technical matter, of use only to ornithologists. Further, as it was primarily designed for ornithologists, only those colors which obtain in our native birds are shown, and many colors and shades of common occurrence among our flowers and in the lower ranks of life are wholly unrepresented in the colored plates. Will not some one prepare a pocket edition, adapted alike to field and study, that shall, as far as possible, show every color in nature, and state also what combinations are necessary to produce each?

San Diego, Cal.

C. R. Orcutt.

The Disappearance of Wild Flowers.

To the Editor of GARDEN AND FOREST:

Sir.—In addition to the causes of the disappearance of our wild flowers, as stated by Professor Beal on page 527 of GARDEN AND FOREST, I would cite another. For many years I had been in the habit of visiting a cosy nook on Long Island, New York, where the *Sanguinaria Canadensis* grew luxuriantly, the ground being completely covered with foliage and flowers, in their season. The past spring I again visited the wood, after an absence of three years, but scarcely a flower was to be seen, only here and there one in the thicket, away from the former mass. Neither were there any tree leaves on the ground, the owner of the wood having raked them all off for bedding purposes, the result of which was the loss of our favorite flowers. The removal of the leaves left the Blood Root without the winter protection it needs. I think this will account for the loss of a great many of our native plants; the clearing of our forests has removed the protection that nature afforded them.

Floral Park, N. Y.

C. L. Allen.

The National Flower.

To the Editor of GARDEN AND FOREST:

Sir.—The national flower should be as nearly universal in the states as possible. It should be a home flower, not imported. It should lend itself to art in form and color. It should be significant of a national sentiment and embody an American idea. Let me suggest another, yet unnamed, for the honor of representing our country, namely, the Starwort or Aster. It is more abundant in North America than elsewhere. One hundred and twenty-four species belong to our flora. It ranges from the Atlantic to the Pacific and from Canada to Central America. It is beautiful; it is hardy; it is perennial; and deserves the sentimental regard of all who see it yearly adorning our fields and woods in summer and autumn.

Let the wild Aster be our country's flower.

See how it gems with stars the glorious flag!

Onward it spreads, the symbol of our power,

"The Star of Empire," past each barrier crag;

And every blossom, many joined in one,

Presents the Union, peace and freedom won.

Cambridge, Mass.

E. S. D.

Recent Publications.

A Rambler's Lease, by Bradford Torrey. Houghton, Mifflin & Co., 1889.

This little book is a record of the impressions and observations of one who, in the phrase he quotes from Charles Lamb, delights to "walk about, not to and from." Such books, as we have had occasion to say more than once before, are growing to be a prominent and distinctive feature in American literature, and each new one deserves a welcome as a sign that the love for out-door life, as it means not sport, but a keen, intelligent pleasure in the beauty and significance of natural objects, is steadily on the increase among our countrymen. Perhaps certain recent volumes by other hands have been more poetical, more full of the personality of the writer than Mr. Torrey's. Nevertheless there is individuality and a touch of poetic feeling in his pages, too; and he has occasionally an epigrammatic way of putting a valuable truth which should impress it with peculiar distinctness upon the mind of the reader. When, for example, he says that he has almost written "highwayman" instead of "highway surveyor," we feel a sympathetic thrill inspired by the memory of such ravages among beautiful road-side growths as he himself is deploring.

Birds, even more than plants, have been the objects of Mr. Torrey's studies, and his chapters are pretty equally divided between the attractions of animate and of inanimate nature, thus giving his book more variety than is found in some others of its character. Few pages are pleasanter than those which, under the title of "Bashful Drummers," describe his long-thwarted efforts to see as well as hear the partridge drum-

ming—none, unless it be those which recount his "Woodland Intimacy" with a vireo. Another very charming and more definitely instructive essay was noticed in these columns when first printed some months ago in the *Atlantic Monthly*—the one which recites the surprising number of plants which may be found blooming in November on a New England sea coast. In "Esoteric Peripateticism" we have a delightful plea for those contemplative rambles, which are too often considered a mere waste of time in this busy land. As Mr. Torrey well says, every impulse toward such a manner of spending one's hours should be sedulously encouraged because "there is little danger that the lives of any of us will be too solitary or lived at too leisurely a rate. The world grows busier and busier. Those whose passion for Nature is strongest and most deep-seated are driven to withhold from her all but the odds and ends of the day. We rebel sometimes; the yoke grows unendurable; come what may, we will be quit of it; but the existing order of things proves too strong for us, and anon we settle back into the old bondage." Mr. Torrey's "ideal plan" would include two walks a day—"one in the morning for observation, with every sense alert; the other toward night, for a mood of 'wise passiveness' wherein Nature should be left free to have her own way with the heart and the imagination." He well emphasizes the fact that really and fully to enjoy hours out-of-doors some branch of science should be studied, that the senses may be alert to good purpose and the intellect as well as the faculty of mere passive enjoyment be gratified. Of course, as he admits, there is some danger in scientific study—the danger that the receptive, emotional, beauty-loving faculties may be blunted and the mind alone be used. "One may become so zealous a botanist as almost to cease to be a man. The shifting panorama of the heavens and the earth no longer appeals to him. He is now a specialist, and, go where he will, he sees nothing but specimens." But this danger can be avoided. It is possible to "give free play to fancy and imagination without permitting ourselves to degenerate into impotent dreamers. Every walker ought to be a faithful student of at least one branch of natural history, not omitting Latin names and the very latest discoveries and theories. But, withal, let him make sure that his acquaintance with out-door life is sympathetic and not merely curious or scientific." Only by a combination or alternation of the two moods—the two attitudes—can the truest enjoyment be extracted from the natural world. And how the two may exist and develop together Mr. Torrey displays so well in his various chapters that his example should profit as well as entertain all those who are moved to make the best of that "Rambler's Lease" in the real estate of others to which they as well as he have a right.

Recent Plant Portraits.

Botanical Magazine, December.

THRINAX EXCELSA, *t.* 7088; probably one of the so-called Thatch Palms of the West Indies, but described from a plant of uncertain origin long cultivated in the stove-house of the Royal Gardens.

TIGRIDIA PRINGLEI, *t.* 7089; first described and figured by Mr. Watson in GARDEN AND FOREST (*i.*, 388, *f.* 61).

CABOMBA AQUATICA, *t.* 7090; an interesting aquatic plant found in still waters from Mexico to southern Brazil; differing from the species (*C. Caroliniana*) of the southern United States by its much narrower leaves and yellow flowers (those of the North American species are white). The Cabombas are remarkable in the two forms of leaves produced on the same stem, the one form submerged and the other floating. The submerged leaves are round in outline, but are cut into narrow, thread-like divisions, while the floating leaves, with much longer petioles, are round and peltate. The small flowers are attractive, although they remain open during a single day only.

AMORPHOPHALLUS EICHLERI, *t.* 7091; a showy species from an island in the Congo River. The flowers, like those of the other species, emit a horrible odor.

CLINTONIA ANDREWSIANA, *t.* 7092; a native of the California coast-region, with showy, rose colored flowers in a dense terminal umbel.

MASDEVALIA CHIMERA, *Gartenflora*, December 1st.

SALVIA SPLENDENS, var. Bruanti, *Gardeners' Chronicle*, December 7th. A variety with tall spikes of bright scarlet flowers and good habit.

SALVIA BETHELLI, *Gardeners' Chronicle*, December 7th. A form of *S. involucreata*, with very large spikes of puce-colored flowers.

Notes.

In all our eastern cities Carnations are scarce and high, owing to the unusually wet summer.

The growers who have succeeded in obtaining a very late crop of Chrysanthemums have been reaping a rich harvest. The variety named Christmas Eve has been an especial favorite in Boston.

The demand for Violets for the holiday trade has been urgent, both in Boston and New York, in spite of the high prices, caused by a limited supply, while in Philadelphia single Violets have never been so abundant. There is little call for white Violets.

Philadelphia florists are growing *Cypripedium Lawrenceanum* quite extensively, as its bold flowers, on long stems, are always salable, and generally one-third higher than those of *C. insignis*. Of the latter kind some 2,500 flowers were ready for market in Philadelphia on Monday.

Mistletoe has become very popular, and has been sold in great quantities this year in northern cities. The supply comes from the south, where collectors have learned to pack it properly, so that it reaches our markets in excellent condition. A few years ago a considerable quantity was sent here from England, but it was packed so carelessly that it was almost useless for any decorative purpose.

For the Christmas trade in Boston, Roses of various shades of pink and red have been in greatest demand. In Philadelphia a rather deep pink Hybrid Perpetual Rose has proved something of a sensation. It was at first considered a sport, but experts have identified it as Mademoiselle Marie Cointet. It is a globular flower, though not of such good form as either Mrs. Laing or Madame Gabriel Luizet, and it is rather darker than either. Its chief value is its earliness, as it will bloom a week or ten days before either of the above popular varieties.

The December number of the *Botanical Magazine* completes the 115th annual volume. It is dedicated by the editor, Sir Joseph Hooker, to Isaac Bayley Balfour, Professor of Botany in the University of Edinburgh, "the greatest and most influential botanical chair in the Queen's dominions," and the author of important books on the botany of Rodriguez and of Socotra. Seventeen years ago the same editor dedicated the ninety-eighth volume to Professor Balfour's father, then the distinguished occupant of the Edinburgh professorship.

A new industry seems to have been started in the Bermudas, where the culture of *Lilium Harrisii* has been made such a success. Early this fall there came to this market the first supply of dry rhizomes of Calla Lilies in sizes fit for forcing. Some of these are now in flower, having been potted about sixty days, but they would probably have bloomed in less time had careful attention been given to them. As these rhizomes can probably be produced very cheaply, no doubt the industry will increase, for there will be a large market for roots ready to throw bloom promptly, at a moderate price.

The new vegetable, *Stachys affinis*, has become quite popular in France, and is found now in all the principal fruit shops in Paris, the price varying from twelve to twenty-five cents a pound. At Amiens, one of the principal centres of production, it has been sold for fifteen francs a hundred pounds. Some one in that city conceived the happy idea of making a preserve of the tubers. Prepared in this way they lose nothing of their quality, and the question of keeping them is settled—a question of considerable importance, as the tubers in their natural state cannot bear exposure to the air for many days without decaying.

The sudden death on Tuesday, December 3d, of Dr. W. R. McNab is announced. Dr. McNab, the son and grandson of the distinguished curators of the Royal Botanic Garden at Edinburgh, was at the time of his death Professor of Botany at the Royal College of Science, Dublin, and the director at the Botanic Garden at Glasnevin. He was distinguished by his investigations in physiological botany and the minute anatomy of plants, both recent and fossil. Dr. McNab is, perhaps, best known by his researches into the minute anatomy of the leaves of conifers. He has for many years been an active and successful teacher.

The last issue of *Forest Leaves*, that for December, contains an interesting portrait of a specimen of the Bald Cypress from a photograph by Professor Rothrock. This specimen, which is growing on the borders of the James River, is a fair representative of the tree as it is seen sometimes standing alone in the water. It retains its wide-spreading branches, which

spring from the trunk at nearly right angles and which give to the top the flat appearance which characterizes the species. The trunk in the particular specimen selected for this illustration is surrounded by an unusual number of the peculiar growths known as "knees," which are unusually well developed.

In a speech before the Forestry Commission of New Hampshire, at a meeting held at Manchester, Mr. Joseph B. Walker, chairman of the commission, stated that \$2,500,000 were annually expended in New Hampshire by summer boarders. People more and more are coming to want country homes—and the charm of these country homes, he thought, lay in the forests that covered mountains, purified the air and beautified the landscape. He urged upon the people that if they denuded the mountains of their forests no one would want to come to New Hampshire, and the large revenue already received, and which was increasing from year to year, would be cut off. The *Southern Lumberman*, in commenting on this reason for forest-protection, shrewdly asks whether the same arguments could not be used for preserving the forests which help to make attractive the winter resorts of the south.

In view of the depression of the Orange market, President Fairbanks, of the Florida Fruit Exchange, publishes a statement of what he considers the material facts of the case. He first observes that while West India oranges mature in September and October and the Mediterranean and California oranges are not sweet until March, the fruit growers of Florida should have control of the market from the first of December until the first of March. Very few Florida oranges, however, attain much sweetness before the middle of December, but this year half a million boxes, probably more than one-fourth of the entire crop, of partly green and altogether sour fruit were thrown on the market in November. As a result of this excessive supply of green and acid fruit, which was a libel on the good name of Florida oranges, buyers became few and suspicious. The lesson to be learned from this recital is not far to seek.

A carefully illustrated bulletin, just issued by the Experiment Station of the Kansas Agricultural College, is devoted to the smut in Oats caused by the minute parasitic plant, *Ustilago Segetum*. The parasite is carried with the seed oats, and perhaps never by manure from smutted straw. The disease is more destructive than is generally believed, causing a loss this year of more than eleven per cent. of the crop on the college farm and a probable financial loss of more than a million dollars to the farmers of the state of Kansas every year. Various fungicides were tried, which lessened the amount of smut, but at the same time affected injuriously the germinating power of the seed and reduced the vigor of the plants. The chief interest of the bulletin, however, lies in the fact that a trial of the hot water treatment, first published in the *Gardeners' Chronicle* by Professor Jansen, of Copenhagen, showed that the smut could be entirely prevented by soaking the seed for fifteen minutes in water heated to a temperature of 132 degrees. A chapter on the natural enemies, both vegetable and animal, of the smut, contains much that is interesting, although of little practical importance, since the disease can be so easily controlled.

The endeavor to establish a botanic garden in the City of Montreal, three years ago, though it met with great opposition at the time, is likely to be realized at no distant day, though the original plan has been greatly modified. For some time past efforts have been directed toward the establishment of a garden in connection with McGill University, and the end has been so far attained that a portion of the grounds, embracing somewhat more than three acres, has been set apart for that purpose, the intention being to occupy eventually about six acres. During the past season a pond for aquatic plants has been constructed, and walks and beds have so far been laid out that planting will begin with the opening of spring. There are already in the grounds upward of one hundred native and exotic trees and shrubs, besides a fair collection of herbaceous plants. These will be added to from the native flora. There are also on hand several hundred specimens raised from seed received from the Imperial Botanic Gardens of St. Petersburg, and the Royal Gardens, Kew, all of which have been raised and cared for in private grounds and conservatories. Active efforts are being made for the construction of a conservatory, which it is hoped may be erected soon. It is the intention to adapt the garden to the purposes of collegiate work and the representation of the native flora, together with such exotic species as may be hardy and prove otherwise desirable.
