INDEX TO VOLUME II.

The asterisk (*) denotes that the subject is illustrated.

- Abelia rupestris..... 532, 555
 Abies amabilis..... 288, 525
 Appolinis..... 472
 balsamea..... 2, 472
 bifolia..... 144
 bracteata..... 167, 472, 496, 507
 Cephalonica..... 252, 472
 Cilicica..... 148, 472, 538, 507
 concolor..... 144, 202, 417, 472, 496
 firma..... 321, 538, 590
 Fortunei..... 507
 Fraseri*..... 472
 grandis..... 39, 144, 472, 598
 lasiocarpa..... 144, 496
 laxa..... 507
 Menziesii..... 202
 nobilis..... 2, 288, 598
 Nordmanniana..... 203, 472, 507
 pectinata..... 472, 538, 507, 612
 Pinsapo..... 168, 252, 472, 612
 Sibirica..... 472
 subalpina..... 144, 496, 552
 Veitchii..... 589
 venusta..... 496
 Abutilon Sinense..... 123
 Thompsoni..... 429
 Acacia acutifera..... 95
 armata..... 40
 Berlandieri..... 400
 chorophylla..... 95
 dealbata..... 289
 decurrens..... 289
 Drummondii..... 40
 Farnesiana..... 95, 393, 400
 flexicaulis*..... 394, 400
 Greggii..... 394
 melanoxylon..... 273, 289
 pycnantha..... 289
 Acanthopanax diversifolium..... 303
 ricinifolia..... 538, 568, 509
 Acer barbatum..... 369
 circinatum..... 39
 dasycarpum..... 303
 glaucum..... 304
 laetum..... 276
 macrophyllum..... 38, 39, 154
 Negundo..... 436
 Pennsylvanicum..... 574
 pictum..... 276
 polymorphum..... 322, 543, 504
 pseudo-platanus..... 349, 374
 rubrum..... 543
 saccharinum..... 302, 303, 304
 saccharum..... 304
 spicatum..... 543
 Achillea Millefolium..... 122
 Achyranthus Lindenii..... 584
 Aconite..... 180
 Aconitum autumnale..... 585
 Fischeri..... 585
 Napellus..... 585
 Acorns, sowing..... 116
 Acorus Japonicus..... 270
 Actaea spicata..... 356
 Actinidia volubilis..... 321
 Actinomeris alba..... 16
 Actinotinus Sinensis..... 124
 Ada aurantiaca..... 54
 Adiantum Capillus-Veneris..... 270, 518
 cuneatum..... 270, 465, 582
 nigrum..... 11
 pedatum..... 331
 pubescens..... 270
 Wiegandii..... 405
 Adirondack forests, the, 109, 146, 181, 325
 reservation and railroads, the
 Adonis vernalis..... 224
 Arides crassifolium..... 282
 crispum..... 272
 expansum..... 39, 311
 Fieldingii..... 235
 Lobbii..... 381
 Aeschynanthus speciosus..... 546
 Aesculus Chinensis..... 267, 291, 335
 flava..... 304
 lutea..... 304
 macrostachya..... 555
 octandra..... 304
 Aesculus Pavia..... 364
 turbinata..... 267, 291, 538, 509
 Afghanistan, irrigation in..... 84
 Agapanthus umbellatus..... 474
 Agapetes buxifolia..... 244
 Agathaea celestis..... 113, 533
 Agathis australis*..... 579
 Agaves..... 112, 603
 Agricultural charts..... 456
 Agrostis canina..... 183
 vulgaris..... 183
 Albemarle pippin, the..... 371
 Albizzia Julibrissin..... 503, 518, 532
 Alder, Black..... 177, 363, 488, 555, 595
 Buckthorn..... 438
 common..... 484
 Sea-side..... 487
 Smooth..... 428
 Allamanda cathartica..... 489
 Hendersonii..... 391
 Schottii..... 391
 violacea..... 489
 Allium cernuum..... 369
 scaposum..... 416
 Allotment gardening..... 144
 Almond-trees..... 202, 237
 Alnus incana..... 484
 maritima..... 428, 487
 oblongifolia..... 484
 rhombifolia..... 484
 rubra..... 484
 serrulata..... 428, 484
 Alsophila crinita..... 135
 excelsa..... 120
 Alstromeria aurantiaca..... 294
 Peruviana..... 294
 Althaea, shrubby..... 374
 Amaranth..... 375
 Amaranthus tricolor..... 518
 Amaryllis Belladonna..... 428
 Fothergill's..... 76
 John Ruskin..... 172
 lutea..... 549
 Mexican..... 416
 Amelanchier oligocarpa..... 238
 Amherstia nobilis..... 506
 Amorphophallus campanulatus..... 342
 Eichleri..... 183, 623
 giganteus..... 183
 Rivieri..... 183
 Titanum..... 183, 335, 340
 virosus..... 342
 Ampelopsis acutifolia..... 332
 bipinnata..... 332
 diseases of..... 407
 dissecta..... 332
 heterophylla..... 332
 humulifolia..... 332
 indivisa..... 332
 napaeiformis..... 332
 quinquefolia..... 407, 544
 serjaniæfolia..... 332
 tricuspidata..... 408, 544
 tuberosa..... 332
 Veitchii..... 24, 123, 408, 544
 Ampelovitis Davidii..... 299
 Amyris sylvatica..... 352
 Anagallis arvensis..... 375
 Anantherix connivens..... 16
 Andromeda Catesbeii..... 56, 94
 floribunda..... 213, 224, 594
 Japonica..... 213, 224
 ligustrina..... 363
 Androsace coronopifolia..... 216
 Anemone Appenina..... 236
 blanda..... 196
 dichotoma..... 306
 fulgens..... 453
 Japonica..... 474, 490, 501, 585
 nemorosa..... 247, 269
 Pennsylvanica..... 200, 306
 Pulsatilla..... 182, 224
 ranunculoides..... 247
 Angelica-tree..... 476
 Angreum Chailluanum..... 78, 462
 citratum..... 39, 103
 cryptodon..... 164
 eburneum..... 55
 Germanicum..... 323
 modestum..... 282
 Sanderianum..... 164
 sesquipedale..... 55, 582
 Anguloa Clowesii..... 331
 Anoganthus breviflorus..... 323, 443
 Anonaglabra..... 616
 laurifolia..... 616
 Anopterus glandulosa..... 191
 Anthurium Andreanum..... 534
 Roeblii..... 534
 Veitchii..... 534
 Aphelandra aurantiaca..... 113, 585
 chrysops..... 113
 fascinator..... 585
 Liboniana..... 585
 nitens..... 585
 Roeblii..... 585
 variegata..... 585
 Apios tuberosa..... 491
 Aplectrum hyemale..... 280
 Aponogeton distachyon..... 477, 603
 Apple, Japanese..... 108
 of Sodom..... 375
 pest, a new..... 477
 trees..... 72
 twigs..... 288
 grit in..... 399
 Apples, American and English, com-
 pared..... 84
 leading American..... 608
 New England winter..... 17
 notes on..... 260, 439
 Apricot, Siberian..... 237
 stones..... 180
 Aquatics in small gardens..... 405
 Aquilegia Canadensis..... 258, 306
 chrysantha..... 72, 258
 flavesces..... 306
 formosa..... 306
 Arachnantes Cathcartii..... 560
 Aralia Maximowiczii..... 569
 nudicaulis..... 443
 papyrifera..... 246, 391
 quinquefolia..... 217
 racemosa..... 443
 Sieboldii..... 246, 391
 Sinensis..... 552
 spinosa..... 3, 435
 Veitchii..... 270
 Araucaria Bidwillii..... 12, 202
 Brasiliensis..... 202, 507
 excelsa..... 12, 120
 imbricata..... 12, 120, 202
 Arbor days..... 13, 37, 181, 262
 Arbor Vitæ..... 554
 Arbutus Anracne..... 47
 Texana..... 436
 trailing..... 374
 Unedo..... 374
 Xalapensis..... 436
 Architect, the, and the landscape-
 gardener..... 445
 Arctostaphylos pungens..... 39
 Uva-ursi..... 30, 596
 Ardisia crenulata..... 113
 mamillata..... 113
 Areca Baueri..... 120, 135
 lutescens..... 317, 318, 560
 monostachya..... 135
 sapida..... 135
 Arethusa bulbosa..... 280, 332
 Aristolochia Brasiliensis..... 489
 elegans..... 65, 489
 ornithocephala..... 509
 ridicula..... 489
 Siphon..... 489
 tricaudata..... 489
 trilobata..... 489
 Arizona, flora of..... 72
 Arnold Arboretum, notes from..... 177, 237, 247, 259, 272, 284, 295, 308, 319, 332
 Arrow-head, the..... 428
 wood..... 437
 Arsenic injurious to bees..... 468

— Caucasicus 608
— niger 374, 600, 607
— orientalis 608
Helonias bullata 88, 479, 504
Hemerocallis graminea 273
Hemibea Henryi 231
Hemlock, Carolina* 267
— common 374
— European 374
— Japanese 575
— Western 525
Hemsleya Chinesis 231
Henderson's nursery 310
Hepatica triloba 226
Herbaceous perennials, transplant-
— ing 390
Herbariums 601
Hercules' club, Asian 552
Heuchera sanguinea 243, 271, 312, 348
Hexasia bidentata 23
Hibiscus Carolinianus 16
— grandiflorus 452
— moscheutos 532
— Syriacus 374, 414, 518, 570
Hickoria integrifolia 569
— Pecan 621
— Texana 460
Hicorius albus 459
— amarus 460
— aquaticus 460
— glaber 460
— microcarpus 460
— minimus 460
— myristiciformis 460
— odoratus 460
— ovatus 460
— Pecan 460
— sulcatus 460
Hickory, common 460
— nutmeg 460
— shell-bark* 460
Hippeastrum reticulatum 209
Hippeastrums, exhibition of 183
Hippophae rhamnoides 605
Holly trees, peculiar 117
Hollyhock fungus 360
Hollyhocks, named 392, 452
Holwood House park 336
"Home Acre, the" 345
Honeysuckle, bush 268
— Tartarian 378
Hornbeam, hop 484
- Horse-chestnut, double flowered, 80, 154
Horticultural register, a 40
Horticulture in ancient Egypt 278
— in California 231
— in Japan 84
— national school of, at Ver-
— sailles 27
— problems in 409
— schools of 25
Hot-beds and forcing-houses 187
House of Florence Nightingale, the* 387
House-surroundings, design in 397
Huckleberries 284, 396
— black 320
— dwarf 320
— white 10, 50, 309, 420
Hyacinth, the Grape 180, 224
Hyacinths, history of 196
— in the Boston Public Garden 216
Hyacinthus candicans 490
Hybridization 188
Hybridizing orchids 367
Hydrangea calycina 437
— Hortensia 362
— laeucolata 363
— longipes 363
— paniculata 347, 408, 414, 437
— petiolaris 363
— quercifolia 510
— radicans 283
— scabra 362
— scandens 363
Hymenocallis Amancaes 428
— Andreana 428
— calathina 428
— deflexa 428
— Macleana 428
— nutans 428
— Quitoensis 428
Hypericum Androsæmum 450
— Ascyron 450
— aurum* 184, 347, 450, 451
— Buckleyi 451
— calycinum 94, 374, 450, 491, 552
— cistifolium 451
— densiflorum 451
— fasciculatum 451
— hircinum 450
— Kalmianum 347, 450, 451
— Moserianum 552
— multiflorum 450
— oblongifolium 437, 450
— patulum 450, 552
— perforatum 450, 451
— prolificum 347, 450, 451
— pyramidatum 451
— sphaerocarpon 451
Hypochaeris Thibetica 147, 278
Hypochoeris radicata 144
- I
Idesia polycarpa 509
Ilex amelanchier* 40
— Aquifolium 124
— Cassine 2, 616
— cornuta 124
— Caroliniana 616
— Dahoon 616
— var. angustifolia 616
— var. myrtilloides 616
— decidua 352
— laevigata 488
— macrocarpa 124
— monticola 352
— Peryi 124
— verticillata 177, 488, 555, 595
— vomitoria 616

The Influence of Mountain Forests.

THE following paragraph appears in a paper recently read by Mr. Henry Gannett, Geographer of the United States Geological Survey, before the Philosophical Society of Washington:

"Although forests have no influence upon precipitation, yet they do exert a certain economic influence. Without increasing rainfall, they, in common with other forms of vegetation, economize that which falls, retaining it somewhat as a reservoir, and preventing its rapid descent into streams. In this way, too, forests tend to reduce the magnitude of floods and to regulate the flow of rivers, thus preventing disaster and improving navigation. This retention of the rainfall is, however, accompanied by a rapid evaporation from the leaf surface of the forest, whereby a considerable proportion of the rainfall returns to the atmosphere without reaching the earth. On this account it is urged, and I think with reason, that in our arid region, which is dependent for irrigation upon its streams, it is advisable to cut away as rapidly as possible all the forests, especially upon the mountains, where most of the rain falls, in order that as much of the precipitation as possible may be collected in the streams. This will cause, not a decrease in the annual flow of the streams, as commonly supposed, but an increase, coupled with a greater concentration of the flow in the spring months, and result in rendering fertile a greater area of the arid region. It may be added that the forests in the arid region are thus disappearing with commendable rapidity."

There are two reasons why Mr. Gannett's sweeping denial of the value of mountain forests cannot be accepted. In the first place, the fact is still to be demonstrated that the evaporation from the leaves of trees exceeds in volume the evaporation from the unprotected surface of the ground stripped of the same trees, the evaporation, of course, increasing in proportion to the dryness of the atmosphere. The truth of Mr. Gannett's statement can only be proved by measuring the total annual flow of two streams with water-sheds of similar extent and contour, and influenced by precisely similar climatic conditions, one cleared and

the other forest-covered. Such a record, we believe, has never been kept. But until such a method is adopted to demonstrate the soundness of his views, it is prudent to hold to the well-established fact that the evaporation from the surface of cleared land largely exceeds that from ground covered with forests.

The increased flow of streams, during the early spring months, must be stored in artificial reservoirs, constructed at no great distance from their sources, if the clearing of the mountain sides is to result "in rendering more fertile a greater area of the arid region," or the flow of water, whether it is increased or diminished by the destruction of the forests, will have passed away before it is needed for purposes of irrigation. Artificial reservoirs for the storage, for subsequent use, of the spring flow of rivers in mountain regions, can be made, under some circumstances, valuable adjuncts to the natural reservoirs existing in forest-covered water-sheds. But there are two serious objections to them. Water stored in this way is subject to enormous evaporation, which increases in proportion as it is most needed—a fact which may be expected to seriously affect the value of any system of irrigation in our arid western territories, based solely upon the use of artificial reservoirs. The danger, too, that such reservoirs, however solidly they are constructed, may be carried away during periods of exceptional floods, is very great; and the danger increases with the spring flow of the river, which, as Mr. Gannett points out, is concentrated at that season in proportion as the water-shed is deprived of its natural covering. An artificial reservoir at the head of a stream is always a danger and a menace to the people living below it; and while such reservoirs will no doubt have to be built in several places if the arid west is ever to be redeemed by irrigation in any comprehensive way, it will be simply folly to throw away, by allowing the forests to be destroyed, the opportunity of reducing this danger to a minimum.

The Yosemite Valley.

THE press of California is at last thoroughly aroused to the importance of reorganizing the Board of Yosemite Commissioners, who, if all the stories told about them are true, are about as undesirable a body of officials as can be found in California or any other state.

The territory in which the valley is situated was conveyed several years ago by the National Government to the State of California to be held as a public park, that its natural features might be preserved for the use and enjoyment of the people of the United States. The character of the Yosemite scenery is bold and striking; and its value for those purposes for which the park was created may be increased or diminished in proportion as the minor natural features of this scenery are maintained or destroyed. It was clearly the duty of the Commissioners to preserve the natural scenery of the valley intrusted in their care; but instead of doing this, they have leased out all its level parts to a firm of contractors for a nominal price, and have allowed them to convert it into a hay farm, and to acquire a monopoly of all the forage sold in the valley. No visitor can now enter the valley on horseback or in a carriage without being compelled to pay an exorbitant tax to these contractors in the shape of the price demanded for the feed for his animals, while all visitors are subjected to unauthorized extortions imposed by the Commissioners or by their agents. The noble Black Oaks and Pines which once dotted the park-like valley or lined the banks of the Merced, where it flowed through charming natural meadows, have been cut down or trimmed up in order to increase the area of arable land; and the wild flowers, the natural grasses, the clumps of wild Roses and other native shrubs have all been grubbed up.

The valley is everywhere intersected by barbed-wire fences, closing the paths which lead across its undulated surface and shutting up many of the best points of view of

the surrounding mountains. All freedom of enjoyment is ended, and all sense of naturalness destroyed. The grandeur of the mountains and the beauty of the mountain torrents the Commissioners have not yet been able to destroy, but the value of these even is lessened when seen across fields bounded by barbed-wire fences and torn up by a patent gang-plow. If in all the length and breadth of this land there was one spot which should have been held sacred to the wild beauty of nature—one spot which should not have been marred for sordid ends—it was the Yosemite Valley. It belongs to the Nation, and there is no intelligent American who does not rejoice that such a marvel of nature exists within the limits of his country. The people of the Pacific States are not more interested in its preservation in all the integrity of its beauty than are the inhabitants on this side of the continent, and the cry of warning and of protest raised by the press of California will be echoed from one end of the land to the other.

We begin this week the publication of a series of elementary articles upon Vegetable Physiology with special reference to the plants of the garden and the forest, from the pen of Professor George L. Goodale, Fisher Professor of Natural History in Harvard College, and a distinguished teacher of botany. They are written with the view of bringing the important subject of plant life within reach of all persons of ordinary intelligence and cultivation—business men who take pride in their gardens, professional growers of plants, pupils in high schools, and all the great class of readers who are interested more or less directly in plants, and who want to know something more about them than can be found in ordinary horticultural publications. A most suggestive and interesting fact brought out at the meeting of the American florists, held in this city last summer, was the expression of a belief by some of the most intelligent and progressive members of the Association, that even from a practical point of view some knowledge of botany is necessary to plant growers who aim to get the most out of their business. It is only those men whose practice is based upon a sound knowledge of Vegetable Physiology who are uniformly successful as cultivators. It is for this reason that we have asked our associate to prepare a series of papers which will cover the whole subject, and will make, when finished, an indispensable manual for all cultivators.

The Gardens of the Petit-Trianon.

IT is strange that so few Americans go to the gardens about the Petit-Trianon when they visit Versailles. After having walked all over the main palace and the gardens the day is far spent, and they are weary of sight-seeing. But what a relief it is, after the great masterpiece of Le Nôtre—the formal, clipped trees, the straight alleys and the architectural gardens—to find in the Petit-Trianon a piece of natural-looking country, large, well-formed trees and quiet scenery—a garden laid out in what used to be called, and is still, in France, the “English” style. And it is especially interesting to Americans on account of the large number of our native trees there, some of which are the original specimens sent over by the elder Michaux, and planted there nearly one hundred years ago.

In 1774 Louis XVI. presented the Petit-Trianon to Marie Antoinette, and at once, under her direction, began the formation of the “English Garden.” Of the many plans which were offered that of the Comte de Caranman was finally adopted, but was afterwards slightly modified by an architect named Mique, who had the carrying out of the work. The general design is very simple. A brook, starting from the highest point, winds about through the lawn in rather a needless manner, and three principal groups of trees are so placed as to form agreeable vistas. Such is the appearance from the windows of the

château, but on going a little further into the grounds there is a very pretty piece of water, with several picturesque buildings on the opposite shore. (See illustration, page 7.) Near by are several fine deciduous Cypressess (*Taxodium distichum*) growing on the very edge of the water, and sending up their curious knees, not only in the water itself, but in the grass, and even in a neighboring walk. And not far away are to be seen two or three magnificent White Pines, one of which must be fully 100 feet high and measuring ten and a half feet in circumference at five feet from the ground. But the most remarkable American trees there, besides those already mentioned, are the Cedars (*Juniperus Virginiana*), some thirty feet high, and developed into picturesque forms, with the lower branches resting on the ground. A long list could be made of the different kinds of American trees there; but a few may be named to show the great variety in the plantations. Among the Pines of our country, besides the White Pines, already mentioned, are: *P. inops*, *P. Tæda*, *P. insignis*, *P. ponderosa*, *P. Lambertiana* and *P. Coulteri*; among the Spruces, *Picea nigra* and *P. alba*; among the Firs, *Abies balsamea* and *A. nobilis*, and to these must be added the Hemlock, both the Sequoias, the Douglas Fir and the Larch (*Larix Americana*). The Oaks are well represented by fine specimens of the Red, Willow, Scarlet, White and Burr Oaks, with Birches, Hornbeams, Beeches, Elms, Liquidambars, Sour Gums, Cottonwoods, Lindens, Maples, Hickories, Magnolias, Tulip Trees and Catalpas.

Many of these trees at the time of the formation of the gardens were extremely rare or quite unknown in France.

On the site of what used to be the botanic garden, where some of the earliest experiments in the naturalization of foreign plants were made in France, is now a pretty flower-garden, which contains a good collection of American plants—Rhododendrons, Azaleas, Andromedas, Kalmias and Magnolias. Two fine Gingko trees, one of which is about forty feet high, stand here, and are, I believe, the oldest in France, having been planted about 1789. A fine cut-leaved Beech, a curious but handsome Weeping Sophora and a splendid Pyramidal Oak make up the more remarkable specimens in this part of the grounds.

Paris.

H. S. Codman.

Notes from a South Carolina Naturalist.—I.

THE following wayside notes of Pines, and other trees and plants, were made in October upon my return home from a day's ride to the Savannah River:

Our Carolina “low country,” with its sandy lands, its forests of Pine and swamps of Cypress, may seem tame and uninteresting to strangers, but to those of us whose home it has always been, it possesses a certain charm, especially during this delightful autumn season.

The river bluff fronts southward, and one looks across the marshes to the various islands which stretch out at last to Dawfuskie and the ocean. The growth along the river is mostly of Live Oak and Hickory, and only a few Palmettoes, once so plentiful here, are to be seen; and it is to be feared that this beautiful Palm, which is still being cut along the whole of our sea-coast to build the wharves of Charleston, will eventually be destroyed, and our historic tree be thus lost to us.

Besides the Live Oak, there are handsome trees of Water Oak (*Q. laurifolia*), perhaps the most beautiful of all of our Oaks; also of *Q. aquatica*, *Q. falcata*, *Q. alba*, *Q. obtusiloba* and *Q. Catesbæi*. *Ilex Cassene* is, of course, everywhere, its berries now reddening under the influence of the fall weather. The autumn show is not as brilliant as in past seasons, owing to the long and terrible drought of the summer and the late downpouring of rain, which have partly destroyed the harvest of Rice and Cotton. Yet the Yellow Gerardia is to be seen in all its glory, even though we fail to find in the damp lands the purple-flowered species (*G. purpurea*), which usually covers whole acres in extent, and gives such a charm to the landscape.

Along the sandy bluff-side I find *Liatris elegans*, with its tall purple spikes, some of them most deeply colored. Seeing these beautiful plants reminded me of a sight which I have never forgotten. Many years ago, passing through an old sandy field along the river at Montpellier Place, I saw an acre or two of them in full bloom. It was late in the fall, the atmos-

phere crisp and bracing, but in spite of the light frost the plants were in all their perfection of height and color, and I wondered at the great number of large and brilliant butterflies hovering over and alighting on the purple spikes. The thickly crowded purple blooms, the hovering insects, the sparkling river fringed with Live Oak and Palmetto, and overhead the autumn sky—all these producing a sense of exhilaration and happiness, the recollection of which at this day even is most pleasant.

Of Golden-rod I see mostly *Solidago tortifolia* and *S. retrorsa*. We now turn from the river, the road carrying us through a damp, flat Pine-land of Saw Palmetto (*S. serrulata*), and the first Pine to strike the attention of the botanist would probably be *P. Cubensis*, the *P. Elliottii* of Engelm. But the turpentine-chippers and wood-cutters are in the land, and the Pines are either scarred and mutilated for the still, or cut down for timber, and thus it happens that few large and handsome trees are now to be seen. This tree is the earliest of all our Pines to bloom, the deep violet-purple buds showing themselves in December or January, and later discharging their pollen from two to four weeks before the others, according to season and latitude.

The deep violet or rose-purple aments are in color like those of the long-leaved Pine (*P. palustris*), and every year does their exquisite hue surprise and charm us afresh, as does the blue of the Gentian (*G. Elliottii*) in November, or the pale lilac of the Swamp Aster (*A. paludosus*) in October. The leaves of *P. Cubensis* are by twos and threes, and of a deep green color. The female aments are at first erect, but they soon commence to recurve, so that in April or May they are close to the stem. I know not if other Pines, either in our country or elsewhere, ever show this striking peculiarity, but I am sure it is not seen in *P. palustris*, *P. serotina*, *P. glabra*, *P. mitis* or *P. Teda*. The red-brown bark resembles that of *P. palustris*, but, as was remarked long ago by Elliott (*P. Teda*, var. *heterophylla*), it exfoliates in "longer scales." At this date of writing I observe that the cones of our other Pines are still green, save perhaps those of *P. serotina*, which are of a very pale yellow, whereas those of *P. Cubensis* are brown or cinnamon-colored, and are now expanding wide on the approach of cold weather. A little later they will discharge their abundant seeds. A few of the cones are already dropping, but this usually occurs later in the fall or winter, as is the case with *P. palustris*, while the cones of all the rest cling till they drop, in after years, from decay. It is also worthy of remark that these two Pines, which drop their cones earlier, are the only two which run turpentine and whose timber is in all respects excellent. This tree (*P. Cubensis*), so far as I know, is found growing only under the influence of salt water. I find it in damp and flat Pine-lands, or in wet "slashes," often associated with *P. serotina*, also in sandy, and largely, too, in clay lands, while I have seen the young saplings overrunning the driest and sandiest old Cotton-fields. It is, I think, the tallest of our Pines, and the largest which I ever saw was 110 feet in height, and grew not far from me in a Pine-land "slash."

Many years ago I remember seeing just back of the sand hills on Hilton Head beach a few of these trees. They were not remarkable for height, yet from their girth and twisted branches one could imagine that they had stood the storms of centuries, and, for aught we know, had been sighted by Jean Ribault upon his making the harbor, or even by Melendez, when the "dark helm" of the Spaniard "hovered" over the waters of Port Royal!

Even as early as the 28th of September I observed that the cones of a few trees were opening, though I saw no mast falling. But this had not escaped the keen eyes of the jack-daws, for a tree top was black with them, and later the woods will ring with their joyous notes when they are picking the Pine mast from the cones. I hear now the rush of the birds and see their almost friendly rivalry as, with expanded wings, they take every attitude upon the cones, up or down, while the seeds are falling and twirling round and round in the autumn sunshine. Looking at such a picture, listening to the noise and clatter and the sweet exhilarating note of the birds, one craves the hand of Audubon to paint it! Nor is color wanting in the brown cones, the glossy blue-black of the birds and the deep green fans of the Pine!

As we go on we glance at the Pond Pine—the Black Pine of the country folk, the *P. serotina* of Michaux. Dr. Engelm. considered this Pine a variety of the Pitch Pine, *P. rigida*, but I am not sure that this has been accepted by all botanists. I am informed that this latter Pine, *P. rigida*, is invariably found further north in dry and sandy lands. Elliott speaks of a tree which he refers to as *P. rigida* and its being found sparsely in the low country of South Carolina. But this

tree I have never yet met, nor have I ever seen any one who could tell me anything about it. I have often looked for it. Elliott's home was not over twenty-five miles from this place and he speaks of *P. rigida* as "a large tree from 70 to 100 feet in height and two to three in diameter." He says, also: "This tree is not very common in the low country of Carolina, where it generally grows intermingled with trees of other kinds, not forming forests exclusively of Pine." Evidently he had seen it in the low country and it seems strange that it has disappeared. We next meet with *P. palustris* as we get into more sandy land. Although we have sometimes seen this tree in damp or wet places, the old name of *P. palustris* seems inapplicable, for, certainly, its finest forests are in the sandiest land. We have passed the *Eupatorium scabridum* of Elliott, which, after all, seems to be but a variety of *E. rotundifolium*, but the bloom of both has long since been over. Some fine plants, however, of *E. album*, are in bloom now, and *E. aromaticum* only in bud. The road becomes more deep and sandy, and on the roadside hedges are *Aralia spinosa*, and the "French Mulberry," *Callicarpa*. The fruit of this last is beautiful, indeed, but it is esteemed too common for cultivation. Some years ago, near sunset, I was collecting its fruit, but a mocking bird was standing guard on the shrub and most vociferously disputed my taking the purple clusters, flying up and around me with extended wings, as he might do when his nest is assailed in the spring. As I left with my booty he seemed clamorously to pursue me, and even when I was well out of his reach, I still heard his scolding. As I pass along the sandy field of cotton I recall that it was here, on each side of the roadside hedge, that I found, I think, three separate plants of an *Asclepias*, which seemed but a freak of *A. tuberosa*, which last was very abundant in this spot. It has long since utterly disappeared, but good specimens were sent both to Drs. Gray and Engelm., and, I think, also to Mr. Canby.

I append a few notes of this plant, which, at the time, greatly excited my curiosity: Leaves of the calyx linear, curved upwards between the leaves of the corolla, which are linear-lanceolate, and, as usual, reflexed, but of a deep blood-red color. Leaves of the staminal crown of the same deep crimson, spreading and reflexed, deeply cleft and bearing no horn. The gynostegium, therefore (which is greenish yellow), naked. Flowers much smaller, and umbels, also, than in *A. tuberosa*, but extremely brilliant and ornamental. This plant, like *A. tuberosa*, exudes no milk; it is hirsute, and in all other respects, both as to stem and leaf, like *A. tuberosa*. Whether hybrid or monstrosity, I never learned accurately.

Bluffton, S. C.

J. H. Mellechamp.

Foreign Correspondence.

London Letter.

BOOKS.—Several works by eminent botanists and gardeners have been added this year to the literature of the garden. The one likely to prove the most generally useful to the horticulturist is Nicholson's "Dictionary of Gardening," a careful and comprehensive encyclopædia of plants and garden matters generally. It has taken four years to complete it, and already it is quoted by many as the standard authority on garden nomenclature, the editor's well-known carefulness and extensive knowledge being a guarantee of its reliability in this respect. Certainly this work fills a gap which horticulturists generally often had occasion to deplore. Mr. Baker, of Kew, whose sympathy with horticulturists and interest in their work is quite exceptional among botanists, has added another useful work to the many already prepared by him. I refer to his book on the order *Amaryllidaceæ*. It contains descriptions, in good plain English, of all the species and most marked varieties of the genera included in this order, and it is the result of twenty-three years' notes and observations. Here this book is of great value for reference. It ought to be in every gardener's library. Mr. Bolus, an eminent Cape botanist, and certainly the first authority on Cape Orchids, has just published a very valuable book on the Orchids of the Cape Peninsula. Mr. Bolus has studied most of these plants in a living state, and, as he discourses on the conditions under which they grow naturally, much useful information for the cultivator is contained in his book. For with only one or two exceptions the management of Cape Orchids here has not yet been mastered. Veitch's splendid Orchid Manual already comprises *Odontoglossum*, *Cattleya*, *Lælia*, *Dendrobium* and several small genera, and I learn that the number on *Cypripedium* will shortly appear.

GRAMMATOPHYLLUM SPECIOSUM (see GARDEN AND FOREST,

p. 468).—This wonderful Orchid cannot be cultivated with any success in England. It has flowered only once here, I believe, namely, in the collection of the late Mr. John Day, of Tottenham, and that was on a newly imported plant. Mr. Day, who had seen the plant in its native haunts, said it grew on stout branches of trees overhanging rivers, and the plants were always within a foot or so of the surface, so that its roots were in the water. It also requires great heat and bright sunshine. Plants are in cultivation at Kew, but they do not thrive. An Orchid with pseudo-bulbs as thick as a man's wrist, and eight feet or more long, the flower-scape six feet high and one inch in diameter, bearing numerous flowers nearly six inches across, and colored rich yellow with purple spots, is something worth striving for; but these flowers seem unattainable in England.

CATASETUM BUNGEROTHII.—This plant is certain to bring many of the species of this extraordinary genus into popular favor, as it has proved surprisingly beautiful and easy to cultivate. When it was first talked of most Orchid-growers doubted there being a *Catasetum* with such attractive characters as were ascribed to *C. Bungeothii*, but it is immensely popular here now. Mr. Sander has a great number of plants in bloom, showing considerable variety in form and coloring. At Kew this and several other species are in flower. One of these, *C. lanuginosum*, had two supposed distinct varieties of flowers springing from the same pseudo-bulb. Had there been only one of the spikes, this plant would certainly have been called a new species, but the second spike proved that this was only one of the extraordinary freaks to which *Catasetums* are addicted. Dr. Lindley described one of them which bore flowers of three supposed genera on the same spike.

SOPHRONITIS.—A quantity of plants in good condition, of the rose-colored variety of *S. grandiflora*, have lately been imported. It is almost as large-flowered as the best form of the type; the pseudo-bulbs and foliage are brownish, the latter very thick and fleshy; but the only marked difference is that of color, the type having flowers of a brilliant scarlet, whilst in the variety rosea they are bright rose-purple, almost clear red. This form first appeared in a London collection in 1884, when it was figured in *The Garden*. A good example is now flowering at Kew. *S. cernua* is also in bloom here. It is small-flowered, each peduncle bearing several flowers of a cinnamon-red color. Except to complete a collection, this species is not worth cultivating. *S. violacea* is a better plant. It blooms in winter and spring, and lasts a long while; and the flowers are an inch across and violet-purple in color. In the form of its pseudo-bulbs and leaves, too, this species is peculiar and interesting. Of course, all the kinds thrive best when grown in the coolest and moistest Orchid-house.

CALANTHES form the brightest and most graceful picture in our Orchid houses just now. They are everybody's plants. Here they are grown for the conservatory, the two oldest and best, *C. vestita* and *C. Veitchii*, being as easy to grow and as beautiful when in flower as the most popular of decorative plants. But there exist kinds in a few English collections which, when sufficiently multiplied, will be a great acquisition as winter-flowering plants. Such are *C. Burfordiensis*, with crimson and vermilion flowers; *C. Veitchii splendens*, almost as dark in color; *C. Sandhurstiana*, and one or two others. These are seedlings or crosses from *C. vestita* and *C. Veitchii*, which have been raised in the gardens of Sir T. Laurence. *C. veratrifolia*, *C. biloba* and *C. Natalensis* are also flowering here.

There are four particularly bright plants in the green-house just now. The first is *Reinwardtia tetragyna*, a relative of the old *Linum trigynum*, but a much superior plant. Its flowers are borne in large clusters on the ends of the short branches, well grown plants being simply irregular masses of the softest yellow bloom. This plant is not understood well in nurseries, and I have heard it spoken of disparagingly by growers whose plants were a proof of their ignorance of its requirements. These are simple enough. A warm green-house, shade from bright sunshine, plenty of water always and a fair amount of root room, are the conditions which have produced the plants admired now by every one at Kew. *Mesembryanthemum blandum* is practically unknown in horticulture, but it is a handsome and useful winter-flowering plant, nevertheless. It is compact, the branches erect, with bright green, almost terete leaves, two inches long, and flowers, as big as half-crowns, white, full and lasting. Most of the plants of this genus close their flowers, except when the sun shines upon them, but this species is an exception, as its flowers are expanded in all lights. *Sericographis Ghiesbreghtii* makes a delightful little picture in our green-house just now. It is

treated in the same way as the *Reinwardtia*. It grows here to a height of twelve and a half feet, is freely branched, and clothed with axillary and terminal panicles of graceful, tubular, scarlet flowers. A group of well-grown plants when in flower cannot be easily beaten. *Luculia gratissima* completes the quartette, a plant which most people delight to see, but few cultivate with success. Planted in a bed of rich peat in a sunny position in the warm green-house it forms a shrub ten feet high, and every branch is now bearing a huge head of handsome rosy-white flowers, which emit a delicious fragrance, and remain in beauty a month or more.

PRIMULA JAPONICA.—By a little management this fine Primrose may be induced to flower almost at any time. At Kew it is now in beautiful condition in a cool green-house, where it will continue to flower all winter. In the summer it is happy in a sunny border out-of-doors. Plants raised late and kept in pots commence to flower in autumn, and so on. There are many varieties of it, one of the most distinct being pure white, save the blotch of dull yellow on the mouth of the tube. Rose-colored, deep crimson and flaked varieties are also common. This species is hardy enough to take care of itself out-of-doors all winter in England. There are not at present any yellow-flowered varieties known, but in *P. imperialis*, now called *P. prolifera*, we have a species very similar to *P. Japonica* in foliage and inflorescence, differing only in having pure sulphur-yellow flowers. They are not quite as large as those of the Japanese plant, the width of the limb being only half an inch. Some examples now in flower at Kew have peduncles two feet high, bearing four whorls, each three inches apart, and each whorl containing a dozen flowers. Good cultivation, with selection, ought to evolve a first-rate flowering plant out of this Primrose. The form in cultivation is that found in the Himalayas. There is, however, another variety of it in Java, with foliage like dock leaves, and a flower spike five feet high; but so far as is known, this noble Primrose has not yet been introduced.

Several species of *Kniphofia* are flowering out-of-doors here, an unusual occurrence in December. *K. hybrida sarmentosa* is quite gorgeous, even now. It has spikes a yard high, and heads of flowers eight inches long; the color of the upper flowers is bright orange-scarlet, the lower flowers being sulphur yellow. *K. Saundersoni* is also flowering freely. The *Kniphofias* are receiving careful attention from several horticulturists in England, who aim at improving them both in respect to hardiness and flower-color, by means of hybridization and selection. A great number of species and varieties are cultivated at Kew.

W. Watson.

New or Little Known Plants.

Neillia Torreyi.*

IT is somewhat remarkable that the dwarf Ninebark of the Rocky Mountains, the *Neillia Torreyi*, has not become common and a favorite on lawns and in shrubberies. The larger species, *N. opulifolia*, more popularly known as *Spiraea opulifolia*, with its golden-leaved variety, is in frequent use for hedges and for ornament. The great objection to it is its rampant growth and need of free and frequent cutting in. The *N. Torreyi*, on the contrary, while resembling it very closely in many respects, is rather compact in its habit and is only two or three feet in height. It is a free bloomer and would be perfectly hardy in the coldest winters. The form of the leaves is the same as in the other, but they are smaller and usually more pubescent, sometimes white-tomentose on the lower side. The flowers are in smaller clusters and scarcely more than half as large, and the fruit, which is composed of only one or two tomentose seed vessels, never becomes so inflated and conspicuous, as is the case in the common Ninebark. It would certainly be an ornament to any lawn, and where only a low hedge is needed, it would probably prove very satisfactory. The shrub is not rare in the mountains of Colorado and westward through the Wahsatch, and in some of the ranges of Nevada.

S. W.

[Mr. Faxon's drawing is made from a plant which has flowered during several years in the Arnold Arboretum. It is perfectly hardy, and ripens seeds abundantly.—ED.]

**NEILLIA TORREYI*, Watson, Proc. Amer. Acad., ii, 136.—Our two species that are referred to *Neillia* have been separated from that Asiatic genus by Dr. Maximowicz, of St. Petersburg, and constitute his genus *Physocarpus*.

Cultural Department.

Forcing Fruits and Vegetables Under Glass.

THE gardens of the country home of Mr. Pierre Lorillard, at Jobstown, New Jersey, have long been famous for the fruits and vegetables forced in the green-houses there. These gardens contain an unbroken range of glass over 900 feet in length, which is divided into many compartments to suit the different crops grown in them. The houses of this range face south, but there are others besides running north and south from the main range. A year ago Mr. John G. Gardner, formerly the gardener to Mr. Lorillard, leased these premises for six years, and is now operating them as a market garden.

PEACHES.—In the compartments devoted to peach-growing the trees are planted inside the house, and their tops are spread out on trellises. While these trees are inactive in winter, the temperature is kept constantly low, but as Peas and Mushrooms are grown in them at this season, frost is excluded. In some compartments Peach-trees grown in pots and tubs are forced, and these trees are now (December 10th) out-of-doors with their pots and tubs buried in the ground. This treatment serves to ripen the wood and prepare it for early forcing, and it also preserves the roots from any injury by frost. While frost may not injuriously affect the roots of Peach-trees growing permanently in the open ground, freezing the roots of pot or tub-bound plants, whether of Peach, Plum or any other tree or plant, no matter how hardy, does them no good, and possibly much harm. The green-houses now emptied of these Peach-trees are used as forcing-houses for Tomatoes.

All Peach-trees grown under glass, no matter whether planted out or grown in tubs, are on Plum roots. The Plum stock checks the gross luxuriance of the Peach, promotes the production of short-jointed, firm, fruit-bearing wood, adds vastly to the longevity of the tree, and, in Mr. Gardner's opinion, gives much more highly flavored fruit. Early Alexander, Early Louise and Early Rivers are his favored varieties. When the Peach and

Nectarine trees are in bloom, in order to assist in the fertilization of the flowers and set a heavy crop of fruit, Mr. Gardner brings a colony of bees into the green-houses, and they do the work effectually. I know from personal experience that honey-bees are among the most useful agents we can employ in fertilizing early-blooming plants, whether trees or herbs. And I have often insisted that if our Pansy and other seed-growers would keep bees in their seed-grounds they could harvest much more seed than they do, and that if the bees seem to ignore the special flowers in favor of more distant fields, they may be shut in green-houses with the flowers.

NECTARINES.—These are largely grown, both as planted-out and pot plants, and Mr. Gardner favors them, as they are in good demand, and the market is not nearly as well supplied with them as it is with peaches. Lord Napier is his favorite variety. They are on Plum stocks. The routine of their cultivation is much the same as that of the Peach-trees.

STRAWBERRIES.—These are forced in large quantities. They are all in pots and still outside. Although he grows Elton Pine (a foreign variety) a good deal, he is partial to the Sharpless, as it has the constitution, the foliage and the pollen, and not only sets well itself, but when grown along with other varieties, has a capital fertilizing effect upon them, and there is no better variety to associate with pistillate kinds.

GRAPES.—All the permanent vines—and they occupy many houses—are planted in-doors, but quite a number are also grown in pots. Those grown in pots are for early forcing mostly, and are now thoroughly ripened, pruned and buried under ground out-of-doors, like ordinary Catawbas or Raspberries, the pots having first been plunged in a row in the ground. Here they remain at rest till a house is empty and convenience permits of their being brought in-doors for

forcing. The vines occupying permanent green-house quarters were unfastened from their trellises, and pruned or partly pruned, the end of October, and then laid together in a row just over where they are planted (inside the house), and here boxed up securely from light or the warmth of the green-house, and, at intervals of several yards, are ventilating, chimney-like shafts running from the boxes up through the glass roof. These vineries are now used during the winter months for forcing Tomatoes and Snap Beans.

TOMATOES.—These are forced in very large quantity; indeed all of the vineries are used as Tomato forcing houses in winter. Some of the Tomato plants are grown in large pots, but the great mass of them are grown in boxes set upon the stages and within about five to seven feet of the glass. The variety grown is the Lorillard, which is a selection of Mr. Gardner's. It is a smooth, even, medium sized variety with a bright red skin, and the ripe fruits are firm and solid and capital for shipping. The plants are raised from seed sown in flats, and in order to maintain a regular succession of young stock a fresh sowing is made every ten days. As soon as the seedlings are big enough, they are potted singly into small pots, and they are repotted into larger sizes till the six-inch pot is reached, from which they are planted out in the boxes. They are never planted out till after they have shown one or two clusters of flower-buds, and this for a reason seldom observed by cultivators—that the flower clusters on Tomato vines all grow on one side of the vine and not here and there around the vine, and it is to note the side on which the blossoms appear that the plants are kept in the pots so long; for in planting in the boxes the gardener is always

careful to have the flower-bearing side of the vine face the south.

The boxes are of rough hemlock boards, and are a foot deep, and about two feet long by some twenty-two inches wide, and as they are set upon the green-house stages the boxes themselves are bottomless. The earth used is common garden soil and well rotted manure, and after the plants have attained considerable size a mulching of rotted manure is also added. Four

plants are set in each box—a plan in each corner. As Tomato plants seldom show any flowers from the first half dozen joints of the vines, in order to shorten the stems and let the fruit begin from the ground, the naked part is laid down and the plants at the opposite corners of the box cross each other—for instance, the plant set out in the north-east corner of the box is layered on the ground and brought up in the south-east corner, and the one that had been planted in the south-east corner is brought up in the north-east corner. The plants grown singly in large pots are coiled around on the surface till the first flower joint is reached.

The vines are all kept to a single stem—that is, no branches or laterals are allowed to grow—and each vine is trained up to a string fastened at the corner of the box, and, running perpendicularly, to the roof of the house. The boxes are not placed close against each other on the benches, but at intervals of nearly two feet apart. This allows the plants to be about two feet distant from each other, and admits sunshine and a free circulation of air. The plants are allowed to climb on the cord as high as they will, so long as they retain short-jointed, lusty vigor. The more vine, the more fruit, as every third, or sometimes every fourth, joint, has a fruit cluster.

A night temperature of 57° is maintained. Tomato plants in winter are slow to set fruit without artificial assistance, but Mr. Gardner finds no difficulty in securing sets on every cluster. First he provides a sweet, dry atmosphere in the house; then in the forenoon he takes a padded stick, and goes through the plants, giving each one a sharp but gentle tap to scatter the pollen. The first fruits are ripe for market in about ninety days from the time the seed is sown.

Fig. 84.—Neillia Torreyi.—See page 4.

ASPARAGUS.—Mr. Gardner forces a good deal of Asparagus, but does not begin with it so early as November. He uses four-year-old plants. These plants are grown expressly for forcing, and on the surface plan—that is, they are not planted deep in the ground as if for permanent beds. As good Asparagus comes in from Florida long before the winter leaves us, whatever money is to be made with this vegetable must be made before February is over. Asparagus-roots that have been forced are of no further use; strong, healthy, young stock is too easily raised to make it worth while to keep over enervated roots or to try to recuperate them.

CUCUMBERS.—These are grown in the small span-roofed structures, a row being planted on either side and trained up on trellises under the glass. A temperature of about 60° is maintained, and there is full provision for bottom heat. The Telegraph and Blue Gown are grown as the main crop, but the White Spine is largely forced also. The first two are English, long-fruited varieties, extremely prolific and long-lived, and there is a good sale for them in the Boston and Philadelphia markets, but very little demand for them in New York. Taking everything into consideration, the Telegraph is yet looked upon as the most desirable and profitable of the English varieties, while in the New York market there is a marked preference for what are known as American, or short, thick Cucumbers, although the whitish color of the skin that often appears near the end of the fruit in these sometimes gives them the appearance of having been kept too long. An effort is being made to get a short Cucumber that shall have a deep green skin, without any pale tinge or marking near the end.

PEAS.—Large quantities of these are grown and all in boxes. American Wonder is the variety used. It is very dwarf, a fair cropper, and has good sized Peas of excellent flavor. The boxes in which they are grown are long, narrow and trough-like, four to five inches wide and six inches deep, and of lengths to suit the spaces in which they are grown, say four to six feet long. The earth used is common garden soil enriched with rotted manure. A single row of Peas is sown along the middle of each box. After sowing and until the Peas are well up, they are kept as cool as possible, without subjecting them to frost, but after a good growth is made, a little higher temperature is maintained. In the green-houses the boxes are set about six inches apart from each other, and laid across the benches—that is, the Pea boxes are placed north and south in houses running east and west. This is to admit of a free circulation of air under, between and over them.

SNAP BEANS.—These are forced in abundance and are grown mainly in boxes, but, in some cases, also in temporary troughs on the benches. The boxes are six inches wide, six deep, and twenty or twenty-four inches long, and the soil used is the same as that used for Peas. Sion House, an English variety, is the only one grown, and this selection has been made after testing all other leading varieties. The Beans are sown in three-inch pots, and when the plants are four or five inches high, they are transplanted into the boxes, eight or ten plants in each box. The boxes are then placed on the benches in the warm green-houses, usually in the Tomato houses, crosswise, and each box distant from the other about six inches.

Glen Cove, N. Y.

Wm. Falconer.

The Francoas.

The Garden, of London, calls attention to the value of the Francoas as ornamental flowering garden-plants. They are all natives of Chili, and are perennial herbs, with white, pink or red Saxifrage-like flowers, produced in slender, graceful racemes. *Francoa ramosa*, which is very delightfully figured in *The Garden*, has been in cultivation for more than half a century, but none of the species are very often seen in American gardens, where this genus is practically unknown. It was named in honor of a Valentin, Dr. F. Franco, who promoted botany in the sixteenth century, and it belongs to the Saxifrage family. The following directions for the cultivation of these plants are quoted from *The Garden*:

"As in the case of many Chilean plants, Francoas are impatient of wet, needing, if they are grown in the open, a dry, sheltered position and a light loamy soil. We can occasionally see them in old cottage windows, where they often flourish amazingly. The best way is to raise the plants from seed, which can be sown at any time between the month of February and midsummer, but it is better to commence as early as possible, so that the plants will have a long season of growth before the winter. Sow the seed in a well-drained pan, and use a peaty soil mixed with sufficient sand to make it fairly light, and before sowing give it a careful watering and place a

sheet of glass over the pan, so as to promote quick germination. When the seedlings appear, remove the glass at once, and give water if necessary, placing the pan in a light position so as to keep the seedlings strong and healthy. After a time the seedlings may be pricked off into other pans filled with the same soil as recommended above, and be taken to the greenhouse or a cold-frame. It is essential to give air freely to prevent the plants becoming drawn. When of sufficient strength transfer them to five-inch pots, still keeping them in the greenhouse or frame. By the end of the summer some of the plants will commence to bloom if the seed was sown early, but if first-class specimens are wanted, it is better to pinch out the first spikes, so as to obtain an abundant supply the second year, when the plants will be much stronger. When the plants require repotting, give them pots one inch or two inches larger, and in the second year when the flower spikes are commencing to appear a few applications of weak liquid manure will be helpful. The seed may also be sown when it is ripe, which it will be at this season, and the young plants potted off in the spring. We have given a somewhat detailed description of the culture, because it is not every one who has grown the Francoa, and many consider it difficult to bring to perfection. There are many poor specimens in gardens, which often have the bottom leaves absent, but this is due in a great many instances to an over-supply of water. If there is one thing that the Francoa detests, it is a soil that is kept too moist. *Francoa ramosa* is the best of the three, and has spikes of great length, and the flowers are pure white. The leaves are something like those of a turnip, and of a paler shade of green. *F. appendiculata* has the petals of a soft reddish color, enriched near the base by a deep blotch. This is well worth growing, but the blooms are not so pure as those of *F. ramosa*. *F. appendiculata* is sometimes confused with *F. souchifolia*, but this is different, its flowers being of a purple shade. Although to obtain the finest specimens it is necessary to grow the plants in pots, the Francoas may sometimes be seen in splendid condition on the rockery."

Plants for a Trying Climate.

EIGHT or nine years ago Professor Sargent kindly sent us seeds of *Berberis Amurensis* and of *Lonicera splendens*. The seedlings of the Amur Barberry were planted in a row from the seed-bed, and have made a compact hedge without pruning, which a prairie steer could not penetrate. They have proved far more rapid in growth than any of the Barberries in our large collection, and their foliage has not been troubled with the cluster-cup fungus. When loaded with the oblong, scarlet fruit this section of hedge is much admired. As it proves perfectly hardy in the far North-west, and grows well where the rainfall is very light, I believe it will prove very valuable for hedging and also for planting as a large shrub upon the lawn.

The seedlings of *Lonicera splendens* were also set about two feet apart in a hedge-row. The uniform expression of the row indicates that *L. splendens* is a good species, or, at least, a strain quite distinct from *L. Tatarica*. The flowers vary in size, and from white to dark pink, and the berries vary from red to yellow, but as propagated from cuttings they all have the graceful, rounded habit of growth, and delicate, light green foliage of the typical *L. splendens*. Without exception these seedlings are an improvement for lawn planting or for screens on the Tartarian Honeysuckle or its seedlings.

At the West, what is known as the Wisconsin Weeping Willow, is our only hardy form of the old list common to the nurseries. This led us to introduce *Salix Napoleonis*, of which we saw hundreds of fine specimens on the steppes of east Europe, top-worked on *Salix aurea*, one of the yellowest of the Yellow Willows, that seems to be indigenous to east Europe and central Asia. *S. Napoleonis* has long, thin twigs that move with the breeze, showing to good advantage its blue-tinged foliage, forming a fine contrast with the bright golden-barked stock, on which it is worked. The stock from *S. aurea* is a rapid, upright grower from cuttings, and *S. Napoleonis* works readily upon it by either budding or grafting. It will prove specially valuable in the West, and, I think, generally in the Northern States.

Eleagnus hortensis is not hardy with us, but it is less a matter of regret, as we consider *E. angustifolia* a handsomer tree—larger in growth, and with more fragrant flowers. When favored by the breeze, the fragrance of its flowers has been noticed at a distance of forty rods. It is perfectly hardy up to the forty-fourth parallel in Minnesota and Dakota on dry soils, and it thrives where the rainfall is too light for most of our indigenous trees. It was introduced into

western Nebraska by the Russian Mennonites, where it has become common as an ornamental tree and for hedges and wind-breaks. If some attention is given to pruning up and shaping when young it soon makes one of our best silvery foliaged trees for large or small lawns. The seeds should be mixed with sand and kept where they will freeze during winter.

Even where *Tamarix Africana* and *T. Gallica* are hardy and flower freely, I think the *Tamarix* of the Amur, with some cutting back to secure compact growth, is more desirable as a lawn shrub. Its foliage is somewhat darker, its expression more graceful, and it flowers more profusely and for a much longer period. But at the west and north it is the only hardy species of the family, and the number of really beautiful shrubs is restricted, hence it should receive the attention of propagators. We find that it propagates readily from cuttings set in the open ground in autumn, and the young wood roots readily in the cutting bench. *J. L. Budd.*

Agricultural College, Ames, Iowa.

Jersey, is an improvement on the French spraying machines, and is now recommended and used by the Department of Agriculture.

Experimenters with the Bordeaux Mixture will find that their success in preventing Grape rot will be in proportion to the earliness and thoroughness with which the mixture is ap-

Boudoir of Marie Antoinette.—Park of the Petit-Trianon.—See page 2.

Diseases of the Grape.

SEVERAL inquiries have come to me from readers of GARDEN AND FOREST since the fact was published that experiments here, under direction of the Department of Agriculture, have demonstrated that spraying the Grape vine with copper sulphate solutions will prevent black rot and prevent or cure Grape-leaf mildew.

The best preparation is that known as the Bordeaux Mixture. This is made by dissolving six pounds of powdered copper sulphate (blue vitriol) in several gallons of hot water. Four pounds of new lime are then slaked in sufficient quantity of water. When the two solutions cool they are mixed and diluted with water to make twenty-two gallons.

The vines should be sprayed with this solution before vegetation starts in spring, and every three or four weeks thereafter until the grapes begin to color. The need for more or less frequently repeated spraying will probably depend on the weather. If hot and wet, frequent spraying will be needed. The Eureka Sprayer, made by Adam Weaber, Vineland, New

The Dairy.—Park of the Petit-Trianon.—See page 2.

plied. It may be beneficial to spray the vines in winter or in very early spring. It will also be well to practice as complete disinfection as possible. Clean the vineyard; strip and scrape the old bark from the vines after pruning; remove last year's deposits of leaves, petioles and rotted fruit. Bury everything afterward with the plow, and do not disturb this refuse during the summer by deep tillage. A light smoothing harrow will give all the summer cultivation needed.

When the foliage is dense, care should be taken that the clusters are reached by the spray. The liquid must reach the surface of the berry to exclude the rot-germ. Of course it is not advisable to spray the grapes near the time of the vintage. If the fruit is kept safe until it begins to ripen it is as much as can be hoped for. But the fruit may be infected by the fungus even after it is gathered. I now have white grapes spread out in my wine-house which were kept sound in bags until late in October. They are now specked with black rot.

Sulphate of copper thus used on the fruit is not dangerous to the health of those who partake of the grapes. In the wine made from grapes thus treated no trace of the chemical can be found.

Vineland, N. J., November 29th, 1888.

A. W. Pearson.

European Chrysanthemums.—I observe that these flowers, and especially the French varieties, are spoken of disparagingly by many American writers, and it cannot be denied that many new plants of very little merit have been sold to confiding buyers. The years 1886 and 1887 gave us a few choice varieties, but very few compared with the number

sent out by the French raisers. This year, however, really good varieties seem the rule rather than the exception, and the majority prove very valuable, in that they are early bloomers, an important item with those who grow their Chrysanthemums in the open air. Among the most distinct and meritorious of the year are Benoit Rozain, rosy pink, of good size and texture and perfectly formed; Condor, pure white, with broad, pendulous flat petals; Cythère, rosy violet, of immense size; Gustave Nadaud, with long, creamy petals, as round as seine cord, and a flower nearly globular; Harman Payne, bright rose; Magicienne, a large spathe orange-brown; Pierre Destombes, probably the finest of the set, with very long, needle-shaped florets of silvery dove color, the flower measuring six inches in diameter; Sabine and Nelson, two unusually large anemone flowered kinds, the first sulphur yellow, the other ashes of roses. All these varieties are distinct in color, of wonderful form, and are equal to any varieties shown in this country, and yet we frankly confess that those of the Philadelphia prize set sent out by Craig last year are the very finest twelve varieties ever introduced at one time.

Richmond, Indiana.

E. G. Hill.

Principles of Physiological Botany as applied to Horticulture and Forestry.

I.—INTRODUCTORY: REDUCTION OF A PLANT TO ITS LOWEST TERMS, CELLS.—THE LIVING MATTER IN A PLANT.—DIVISION OF LABOR.

PHYIOLOGICAL botany endeavors to investigate every reasonable question regarding the structure and the life of plants. It depends for the appliances which it uses in research chiefly upon Physics and Chemistry, and therefore its progress has been largely governed by the progress made in those departments of investigation. Hence it has been only within a very few years that improvements in the construction of certain instruments, notably the compound microscope, have rendered it possible for the physiologist to examine satisfactorily some of the more obscure processes of growth and of nutrition. Improved methods of research in chemistry, especially what is known as micro-chemistry, have lately enabled physiologists to attack some questions which were formerly considered to be beyond the reach of investigation; consequently, many difficulties have been cleared up in recent years. Although far too many questions have not even yet been answered satisfactorily, the additions to our knowledge of the phenomena presented by plants have been important and are worthy of careful consideration.

It seems proper that these recent discoveries in regard to the structure and life of plants should find some place in a journal devoted to the advancement of two important interests which are based largely on physiological botany, namely, forestry and horticulture. But, at the same time, it is clear that accounts of these discoveries can be given in a journal of this character only under certain difficulties, inasmuch as they must be presented in connection with a general view of the subject, and in language as free as possible from technicalities. Moreover, many of the broad, general statements cannot, from the nature of the case, be very strictly qualified, since reference to the numerous minor exceptions must be omitted. The latter are to be looked for in comprehensive treatises.*

The present series of familiar papers will deal with flowering plants—that is, with plants which produce true flowers and seeds, and the examples will be drawn as much as possible from those which possess special interest from the point of view of forestry and horticulture. These plants will be examined with reference to the manner in which they procure their food and perform their work. It is, therefore, necessary to obtain, at the outset, a general idea of the structure of plants; this can be most conveniently done by examining the plant as if it were, what indeed it is, a *machine*.

THE PLANT AS A MACHINE.—When we have any piece of machinery to investigate, our first aim is to ascertain what its essential parts are—that is, by reducing it to its lowest terms, we try to find out what parts could be dispensed with, if we wanted to make a simpler machine to do the same kind of work. Now, in all cases, we find that we can reduce plants to what must appear, at first, very simple terms, namely, *cells*. These cells are bodies of exceedingly minute size, extremely

diverse in form and general character, but all possessing certain features in common. These microscopic bodies, or cells, are variously united together to make up the structure of the different organs of the plant; hence we must examine the features which these constituents of the plant have in common before we can examine to advantage the plant itself.

If we make a thin slice through any active, living part of a plant, as, for instance, the tip of the root or the very tip of the stem, we see, under the compound microscope, that it is composed of what look like irregular cavities in a confused mass, and this is the view which the earliest observers held in regard to them. But we now know that these cavities are the interiors of minute bodies which are more or less firmly connected together, and which, from their union, give the whole mass a honeycombed appearance. Each of these bodies or cells coheres, by means of its wall, with the cells next to it. In the youngest parts the walls are thin and delicate, but as the part grows older the walls undergo great changes in thickness, hardness, color and so on, but great as these changes are, they are not so marked as that which goes on at the same time in the interior of the cell.

Each young living cell is filled more or less completely with living matter, technically termed *protoplasm*. This living matter in the cells is the only living thing in the whole plant; upon its health, activity and life depend the health, activity and the life of the plant. As long as the living matter in a cell is in a state of health and activity, the different kinds of work can go on. But it often happens, for instance in the cells of a seed which is fully ripe, that the living matter may become for a time inactive, but still ready to resume its activity under favorable conditions. Or, as is more frequently the case in our woody plants, the living matter may, as it builds up new cells, leave the seat of its former activities, and abandon the thick-walled cavity for a new home in the living and younger parts. When the living matter thus removes bodily, so to speak, from the older cavities, the shells, or cases, or old cell-walls, which once held it, become dead.

This is precisely what happens in the formation of woody parts; the cavities no longer contain living matter; their walls are simply the empty cases or shells of what once were the walls of living cells, now dead. Hence, when we speak of a piece of heart-wood exhibiting, under the microscope, the shapes of the cells, we mean merely that we have here the now hardened walls of what were once active, living cells.

It is difficult to realize that the only living parts in the stout trunk of a tree are the cells which are just under the bark, and the cells which are situated here and there in the bark itself. The wood, which plays such an important part as a mechanical support, is lifeless; it is the record of what once had life; it was built up by the living matter which now has passed on to further work of construction.

Nor is it less difficult to realize the significance of a fact which has been discovered within the last few years, namely, that an intimate union exists between the living contents of neighboring cells. It has been shown that the living matter in one active cell is connected with living matter in contiguous cells by exceedingly delicate threads of the same substance.

It is only by the use of recent improvements in appliances for investigation that these threads of living matter can be shown to exist, and hence formerly it was taught that there was no continuity between the living matter in one cell and that in those next to it. The discovery that such a vital connection does exist has led to a generalization which is probably sound, that all the living matter throughout a plant is in reality continuous.

There are many plants of minute size in which the living matter can be studied easily. These microscopic plants inhabit fresh water and possess the power of taking from it all they need for nutrition and growth. They simply consist of single cells, and yet they are able to perform practically all the kinds of work done by plants of such complicated structure as our forest trees and garden shrubs.

But in these exceedingly simple plants, where the different kinds of work are performed by a single cell, there is no clear division of labor; at least we cannot see by what part of the cell the absorption of food-materials takes place, or by what parts respiration is carried on. When, however, we examine any one of the common plants about which this series is to treat, there is more or less distinct separation of the kinds of work, and the division of labor requires different organs. These organs, such as roots, stems and leaves, all co-operate as completely as did the indistinguishable parts in the plants composed of a single cell; all the living cells in all the organs co-operate; each assists the others and is

in turn assisted by all the rest. There is a true community of interests throughout characterized by such complete co-ordination that we are accustomed to speak of a shrub or a tree as if it were in fact an individual, whereas it is composed of myriads of independent and yet dependent parts. These parts are the cells, apparently simple to the last degree in their structure, and yet infinitely complex in their organization. As a drop of water under the rays of light which strike it has been said to mirror the universe around it, so these simple spheres may reveal to us something of the mystery of life.

The Forest.

Forest Tree Planting in Massachusetts.

THE first issue of this journal (vol. i., page 11) contained the report of a committee appointed to award the prize offered by the Trustees of the Massachusetts Society for Promoting Agriculture for the best plantation in Massachusetts of not less than five acres of European Larch. The following report upon another competition under conditions explained in the text has lately been made to the Society. The committee of award were C. S. Sargent, John Lowell and F. H. Appleton; and it may be added that the recommendations of the committee have been adopted and the premiums paid.

The Trustees of the Massachusetts Society for Promoting Agriculture offered in 1876 six competitive prizes for plantations of trees, to be made in Massachusetts during the following year. The conditions of this competition required that the plantations should cover not less than five acres. Two plantations only were made, and the trustees being desirous of increasing the knowledge of tree planting, especially among working farmers, offered the next year (1878) a series of prizes to be awarded during the present year for another competition, into which were admitted smaller and less expensive plantations, and plantations to be made by sowing the seeds where the trees were to stand. The following prizes, amounting to fourteen hundred dollars (\$1,400), were offered in this second competition:

Two prizes for 5,000 White Ash trees.

Two prizes for 1,000 White Ash trees.

Two prizes for five acres of White Pine, raised from seed.

Two prizes for one acre of White Pine, raised from seed.

Two prizes for one acre of Scotch Pine, raised from seed.

Two prizes for one acre of European Larch, containing not less than 2,000 trees.

Thirty-four entries were made in competition for these prizes, by twelve competitors, and your committee find that eight of the twelve competitors have for various reasons withdrawn entirely; some failed to make their trees grow at all, and others neglected to take care of them after they had become partially established. The sowing of seed produced small results. In two cases it did not germinate at all, and in another the percentage of plants raised was small. It must be remembered, however, that there was an early and prolonged drought during the summer of 1878, and that the season was unusually unfavorable for tree planting, and for the germination of tree seeds.

Your committee has visited the plantations of the four competitors who had not formally relinquished their claims to the prizes—Mr. J. D. W. French, of North Andover, Mr. E. Pierson Beebe, of Falmouth, Mr. Thomas H. Lawrence, of Falmouth, and the widow of the late H. R. Hayward, of Lunenburg.

Mr. French entered for the prize for the best 1,000 White Ash trees. He planted 1,500 trees one to two feet high, in two lots. They were set in the sod four feet apart, and have received no care since they were planted. The first lot was planted upon a slope facing the west, in strong, rich soil. A slight depression in the lower end helped to retain the moisture and increase the value of the situation for the trees for which it was chosen. This piece of ground seems to have been well selected for Ash, both as regards soil and exposure. It contains 250 trees. The largest is twenty-five feet high, with a trunk, measured three feet from the ground, one foot in circumference, and the average height of the trees is eighteen feet. The second lot was planted on dry, gravelly upland, in an angle formed by the meeting of two public roads. The situation seems to have been badly selected, and the soil was not suitable for the Ash, which requires cool, moist land for good development. This lot contains 570 trees. The largest has attained a height of

fourteen feet, with a trunk circumference of seven inches three feet from the ground, although the average height of the trees is only seven feet. Mr. French reports that the entire cost of the operation was \$14.96 for the trees and for planting, and \$30.20 for preparing the ground and for fencing, a total of \$45.16, without interest. The conditions of the competition require 1,000 trees, and, although Mr. French's Ash trees are superior to any examined by your committee, it is of the opinion that as only 850 of the 1,500 trees now remain, he is not entitled to a prize.

Mr. E. Pierson Beebe entered for the prizes for the best 1,000 White Ash trees, and for the best acre of European Larch containing not less than 2,000 trees. 1,500 Ash trees were planted, at an entire cost, without interest, of \$17.78. They were set in very light, gravelly soil, quite unsuited for this tree, and they have made little or no growth. They are not, in the opinion of your committee, deserving of a prize. The Larch were planted upon land of the same character, and have grown remarkably. The largest specimens are from twenty-five to thirty feet high, and in some places entirely cover the ground. 3,000 trees, were planted at a total cost, without interest, of \$60.90. This plantation, however, occupies less than one acre of ground, and there are only 732 trees now standing. Your committee is of the opinion, therefore, that Mr. Beebe has not complied with the conditions of the competition.

Mr. Thomas H. Lawrence entered for the prizes for the best acre of Scotch Pine raised from seed; for the best and for the second best 1,000 White Ash; for the best acre of European Larch, and for the best five acres of White Pine raised from seed. He reported in October, 1882, that the plantation of Scotch Pine had been a complete failure. Few of the seeds germinated, and the land was plowed up and laid down to grass. The Ash trees were set in soil entirely unsuited to this tree, and Mr. Lawrence does not now offer them for competition. The Larch were planted about a mile from the coast, in a slight depression on one of the low slopes which rise from the plain upon which the town of Falmouth is built. The situation is an exposed one, and the soil is light, very gravelly and almost devoid of humus. The trees, however, have made an admirable growth; many of them are more than twenty-five feet in height; they stand regularly and compactly and entirely shade the ground. The cost of this plantation is, without interest, \$33.90. Your committee recommend that the prize of \$100 for the best acre of European Larch be awarded to Mr. Lawrence.

The five acres upon which Mr. Lawrence sowed the seeds of the White Pine adjoin his Larch plantation, and is covered with the same quality of soil. The cost of the seed was ten dollars, and the cost of mowing the Blackberry vines, and bushes which partially occupied the ground, and planting the seed, was \$13.95, making the total cost of the plantation \$23.95. It was probably a mistake to mow the bushes, as they would have checked evaporation from the surface of the ground and would have served to protect the young seedlings. The seeds germinated badly, the dry season being unfavorable for them, and a considerable number of the plants which did come up perished from exposure and drought during the first season. Mr. Lawrence believes his partial failure is due to the poor quality of the seed, which he purchased at a Boston seed-store. As the seeds of American Pines usually sold in this country by regular dealers have been sent across the Atlantic twice, or are gathered from trees grown in Europe under unnatural conditions, it is not surprising that they fail sometimes to germinate or to produce vigorous plants.

There are, nevertheless, between two and three thousand healthy White Pines, averaging about four feet in height, growing upon the five acres. They do not stand regularly, however, and there are often large gaps between them; eventually, however, there will be trees enough to cover the ground. This plantation cannot be considered a success from the point of view of the number of trees raised, but it seems to be successful in demonstrating the possibility of growing White Pines cheaply, from seeds, upon land too sterile for agriculture or profitable pasturage.

These prizes were offered for the purpose of stimulating experiments which may be expected to increase the knowledge of arboriculture, and not for the purpose of increasing by a few acres, more or less, the number of trees in the state. Your committee is of the opinion that, considering the lesson that can be learned from Mr. Lawrence's experiment in sowing Pine seeds, it contains one of the most valuable of the results obtained by the competitions of 1877 and 1878, and they recommend that, in view of all the circumstances, the second prize in this class of \$100 be awarded to him.

Mr. H. B. Hayward entered for prizes for the best 5,000 White Ash trees. His trees were planted in very light, gravely soil, entirely unsuited to the Ash. They have made a very unsatisfactory growth, and are not, in the opinion of your committee, deserving of a prize.

Mr. French and Mr. Beebe would have received recommendations for prizes, except for their failure to present the full number of trees required by the conditions of the competition. They have done, however, everything in their power to further the ideas which led to this contest; their interest in tree-planting and the example which they have given by their plantations to the communities in which they live have been of service to the people of this state and its agricultural interests. Your committee is of the opinion that their efforts should receive some recognition from the Society, and they recommend that a suitable remembrance, not to cost in each case over \$50.00, be sent to them, with a letter expressing the appreciation of the Board for their assistance.

Correspondence.

White Huckleberries.

To the Editor of GARDEN AND FOREST:

Sir.—The White Huckleberry, or the variety locally known by that name, is found growing in New Jersey in small, compact, isolated patches, upon the ridge of land running parallel with the Delaware River, and extending from Carpenter's Point to Wall-pack Bend.

The existence of this variety has been known here ever since the earliest settlement of the country by the whites. My attention was called to this berry by other boys, playmates of mine, fifty years ago. They generally kept their knowledge of such patches a secret, and though without especial value, they looked upon them as a great rarity, and prized them accordingly.

Geologically, it may be said that the Jersey ridge described is capped by "Canda Galli grit," a formation partaking largely of the elements of both the slaty shale on the Pennsylvania side of the river and the limestone on the other, and upon exposure to the elements it disintegrates readily, forming a calcareous loam of great natural fertility.

Since this ridge has been subjected to cultivation, wild fruits and berries of every kind have necessarily been swept away, and now can only be found where they have been suffered to exist in the woodlands that remain attached to the farms of this section. Occasionally, too, they may still be seen growing in bunches against a rock or large stump in an old field devoted exclusively to pasturage, where a lack of zeal in the use of the bush scythe upon the part of the owner has suffered them thus unwittingly to remain.

It is hardly necessary to state that the original forest growth was exceptionally heavy, which circumstance, a uniformly dense shade, added to soil, may have had much to do with originating this particular variety. I presume the birds and inferior animals may have distributed them somewhat after its character had once become fixed.

In flavor the berries are sweeter than the common black or the blue Huckleberries. I once saw a small quantity of them after they had been dried, and observed adhering to them white crystals of sugar. They are only white when grown and ripened in the shade. If partially exposed to the sun they will have a pink cheek. When exposed to the full rays of the sun, as in a field, they will be either pink or of a bright scarlet color.

B. A. Westbrook.

Montague, N. J.

[Mr. Westbrook has kindly sent a plant of this white Huckleberry to the Arnold Arboretum. It is a variety of *Gaylussacia resinosa*.—ED.]

Barberries.

To the Editor of GARDEN AND FOREST:

Sir.—Will you be so good as to tell me what are the "Barberries" referred to by Hazlitt in the following quotation, which he had seen and tasted when he was in America, from 1783 to 1787:

"The taste of Barberries which have hung out in the snow, during the severity of a North American winter, I have in my mouth still, after an interval of thirty years, for I have met with no other taste in all that time at all like it. It remains by itself, almost like the impression of a sixth sense."

Is the fruit of the North American *Berberis* (*Mahonia*) *Aquifolium* intended, which is often abundantly produced in English gardens and very beautiful, but, as I opine, very rarely

eaten in Britain? Of course, I know that pleasing and lasting gustatory sensations are often the result of a traveler's or explorer's hunger and fatigue, or thirst, or other accidental circumstances, as was the case with the fruit of your *Rubus deliciosus*, which, eaten under ordinary circumstances, is generally considered a very poor sort of a Blackberry. I shall be glad, however, if any of your readers can corroborate Hazlitt as to the distinct flavor of frozen Barberries, whatever they may be. The bright red fruits of our native *B. vulgaris* are pickled and candied and used for garnishing venison, etc., but they do not seem to be much appreciated for their flavor.

Botanical Garden, Dublin, Ireland.

F. W. Burbidge.

[Hazlitt's Barberries were the fruit of the common European *Berberis vulgaris*, which had become so firmly established in the Massachusetts colonies in the first century after the arrival of the pilgrims at Plymouth, that we find that the Province of Massachusetts passed on the 10th of June, 1764, "An act to prevent damage to English grain arising from Barberry bushes." It is a remarkable and interesting fact that the European Barberry, which even now is naturalized only near the coast of New England, mainly in Massachusetts, has failed to spread or gain a permanent foothold anywhere in the interior of this country, although it had almost at once established itself so firmly in one limited locality, that legislation seemed necessary in order to prevent it from injuring the farmers' grain. It has been suggested that the Barberry never did injure the Massachusetts grain crops to any appreciable extent, and that the law was passed on the strength of a popular belief brought from England that it was injurious to grain. "But if this is so," as Professor Gray once remarked, "we have a curious illustration of the precarious nature of testimony. For in Europe this colonial legislation has passed into history as independent evidence that the Barberry did damage grain in New England."

The Mahonia grows in a region several thousand miles from any part of America visited by Hazlitt, and was not known until the beginning of the present century, when Lewis and Clark crossed the continent to the north-west coast and discovered it on the banks of the Columbia River, in what is now the State of Oregon.—ED.]

Recent Publications.

Notes on the Art of House-planning, by C. Francis Osborne, Architect. New York, Wm. T. Comstock, 1888.

The author of this little handbook is professor of architecture at Cornell University, and its pages, reprinted from *The Builder*, embody the substance of a portion of the notes he has used in instructing his classes. Much that he says is adapted to be of great service to young architects, and may profitably be studied by their clients as well, in order that they may have a more accurate idea than is usually manifested with regard to the exact nature of the result which they wish to see achieved by the architect whom they may employ. But as an elementary treatise on the art of house-planning in America the book has certain grave deficiencies. We are warned in the preface not to judge it for sins of omission, as it is to be followed by a second volume on the same subject. Nevertheless, we may complain if in the first volume of a work which deals with a subject that may be divided into separate topics for special discussion any of those topics are omitted with which a designer must concern himself, if at all, at the very outset of his task. To omit any of these is to give a false idea with regard to the spirit in which the task, as a whole, should be approached, as well as seriously to impair the value of a first volume while it is awaiting its successor. To illustrate our meaning, it may be said that while the consideration which should be given to "aspect" in planning a country house is by no means wholly neglected, a fuller treatment of the question is relegated to the volume still unborn, together with all discussion of the equally important and fundamental question of "prospect." But until the claims of aspect and prospect are thoroughly considered, no feature of a plan can be properly decided upon, and it would have been better to finish with this matter before beginning to discuss the relative claims of separate apartments. A still more serious blemish, however, is the omission to recognize the piazza as a feature of equal importance with any of the interior rooms. The author rightly remarks that the history of house-building is the history of civilization, and one might therefore

expect that he would perceive that the peculiarities of American civilization, as expressed in the tastes, habits, and physical and mental needs of our people, are nowhere so clearly revealed as in the importance which the covered piazza has assumed in our country homes of every size and class. The subject has been so recently discussed in these pages, that no further explanation of it is necessary here. We would merely state that although the veranda is once or twice incidentally mentioned in Mr. Osborne's pages, it is nowhere dwelt upon as an important feature, and still less is it recognized as a feature which should be considered in the very beginning with the greatest care as one upon the right arrangement of which the comfort of a country home is always very largely dependent, and one which, in many cases, may well have a controlling influence upon the arrangement of the whole interior. To plan the inside of a country house without distinct reference in every part to the position and extent of its piazzas, and then to add these as chance may allow—this is one of the grossest mistakes into which an American architect can fall; and it is one, therefore, which should have been guarded against in the very first chapter of a book like Mr. Osborne's. We should have been glad, again, had he said something of the need for considering the approaches to a house, and for consulting a landscape-architect—or, at least, consulting the principles of landscape-architecture—before even the station of the house and of its entrance are decided upon. Perhaps this very vital point will come up for discussion in his second volume; but it is one, we must say again, which might better have been explained at the beginning, since it must be understood and settled at the beginning, if at all, whenever the student commences actual construction.

Periodical Literature.

THE flower trade of London is estimated at £5,000 a day, and, as well as the trade in fresh fruits, is rapidly increasing, a fact which is held by Mr. Sampson Morgan, whose interesting paper upon "Imported Flowers" has recently been issued by the Cobden Club as one of their 'Leaflets' to show "that there is improvement in a nation whose taste is changing in such a remarkable manner from drink to fruit, and from gaudy gildings to fragrant flowers."

From the same paper it appears that "between Nice and Cannes to London, especially during the winter and spring, there is a special railway and postal service by which the flower cultivators of France are enabled to pour into the English markets such things as White Lilac, Violets, Snowdrops, Lilies-of-the-Valley, Daffodils, Roses, Hyacinths and Fern by the thousand dozen bunches at the time; in fact, these consignments are at times prodigious. The growers of the Riviera and elsewhere in the south of France are now paying special attention to the culture of cut flowers for the English markets; and when we consider the tasty manner in which their consignments are got up, one can hardly be surprised that these goods have become so deservedly popular with English buyers. Many men might be mentioned whose names in our markets have almost become household words; but I would simply refer to M. Solignac, of Cannes, whose *champs-fleurs* (field-flowers) have for years past been so much sought after and bought up, especially by the London florist, and who, it is believed, disposes of various kinds of flowers, such as Roses, Carnations, Violets, Anemones and "Marguerites," annually, to the extent of £12,000, and in the face of this fact we can easily see that it must be a very profitable branch of trade. Of course his goods are well grown, and for some years during the "great run" on the "Yellow Marguerite," his consignments secured very high prices indeed. Further, Mr. Potter points out a fact that is totally ignored, even by men in the horticultural world, for although these flowers are called in France *Champs-fleurs*, yet they are always protected mostly with glass, and the ranges of these glass erections at Cannes, and especially on the hill-sides, is a sight worth seeing.

"The principal kinds of flowers imported to our markets, especially Covent Garden, from the Continent, etc., consist of Lilac and Syringa, Violets, both Parma and the Czar, and Mignonette and Lent Lilies, in enormous quantities, Mimosa or Acacia in two or three kinds, Narcissus in several varieties, including Paper White, Double Roman, Grand Monarque, Soleil d'Or, and the White Roman Hyacinth. All the above, if English grown, realize a better price in the market, but they are not grown in sufficient quantity in this country, and the Anglo-French salesmen in Covent Garden are now—during the winter, I might state, without hesitation—the most important venders in the market, and they are fully aware of

their importance. Safrano Roses, too, are sent us in abundance, and Fern, the black Spleenwort, *Asplenium* and *Adiantum nigrum*, known as French Fern, are disposed of to the tune of some thousands of pounds. Orange blossom, too, is another imported article that fetches a large sum.

The following extracts taken from this instructive paper are of general interest:

"It is said that attar of Roses, manufactured in the Valley of Kesanlik, Roumelia, is exported to the value of £44,000; and some one has made a calculation to show that ten billions one hundred and four millions of blossoms are used each year at this one place alone. In connection with flower culture on the Continent, and now in the United States of America, the manufacture of perfumes from flowers forms a very profitable industry, and one which certainly might be adopted by the English grower. The town of Grasse, near Cannes, the capital of the department of the Alpes Maritimes, is the centre of a flower-growing district, and the principal seat of the manufacture of perfumes in France.

"It is stated that the famous attar of Roses is made from the *Rosa Damascena*, which grows like a weed in Smyrna, and in some parts of Turkey and France, though the growth is comparatively small in the latter country. The natives of these places collect this oil in a simple manner. The Roses are placed in water, and after decomposition sets in, the oil floats on the surface, and is absorbed by cotton balls deftly dipped into the liquid. The cotton under pressure gives up this oil, which is bottled and sealed. A bushel of flowers will produce only a few drops of oil. The genuine is the most expensive oil in the market and worth over £6 an ounce. It is adulterated with oil of rhodium, wax and other substances, and the price is arranged to suit the purchaser. The strength of this oil makes it sickening in its natural state. The adulteration has reached such a high state of perfection that even the most expert judges of perfumes are deceived by it.

"Patchouli is made from a natural plant growing in great abundance in the Malay Islands, and is a great favorite as a perfume. There is a growing demand now for lavender water. It is made by mixing Rose and Orange waters with the oil of lavender, and has a refined and pleasant as well as refreshing odor. The English oil of lavender is the best that is on the market, and besides being used as a perfume, is a favorite article in bakeries as a flavor for cakes and fancy products. It is a high stimulant and an efficient aid to digestion until the system becomes used to it, and then it is liable to breed one of the worst forms of dyspepsia. The Lavender shrub and the Jessamine plant are cultivated to a large extent in England and France for this industry. The genuine Heliotrope is not as fine an odor as the imitation. The latter is known as the White Heliotrope, and is made from a combination of violet and vanilla, and has a soporific tendency if breathed any length of time. Bergamot, with musk, forms the staple perfume of the colored."

It was not until the year 1652 that Coffee was introduced into London as an article of commerce and that the first Coffee house was opened by a Greek named Pasqua Rossie. For many years Arabia, where the Coffee plant had been introduced from Abyssinia, was the only country which produced it, but in 1696 the Governor-General of the Dutch East Indies procured a few of the seed and planted them in a garden at Batavia. The plants flourished and some were sent to Java, whence one went to the Botanic Garden in Amsterdam. From this plant seedlings were raised and sent to Suinam, where the cultivation of Coffee was established in 1718. Ten years later plants from the same source were sent to the West Indies, so that the offspring of the single plant which grew in the Amsterdam garden now produces, it is said, more Coffee than all the other plants in the world. These statements are taken from the fifth bulletin issued by the Botanical Department of Trinidad, which is devoted to "A Short Treatise on Coffee Cultivation," filled with practical instruction upon the cultivation of Coffee in the Island of Trinidad, including directions for selecting sites for plantations, clearing land, the formation of nurseries, planting, weeding, pruning, manuring, harvesting and curing the crop, with descriptions of the most improved machinery now used in preparing the berries for market. Half a dozen varieties of different origin of the Abyssinian plant (*Coffea Arabica*) are cultivated in the Trinidad Botanic Garden, as well as the species discovered a few years ago on the west coast of Africa and known as the Liberian Coffee (*C. Liberica*) and now widely disseminated in Coffee-growing countries. This plant flourishes in Trinidad and has already attained a height of thirty feet, producing large crops

of berries. Its great height, however, makes the collection of the fruit slow and expensive, and it is perhaps doubtful if it will ever really supplant the dwarf Abyssinian plant. This instructive and interesting report upon one of the most valuable industries of the West Indies is from the pen of Mr. J. H. Hart, F.L.S., long connected with the Botanical Department of Jamaica and now the energetic and successful head of that of Trinidad.

Notes.

The Colorado State Horticultural and Forestry Association will meet at Denver on the 10th instant.

December was so exceptionally mild in England that Snowdrops and Marechal Neil Roses, Hepaticas and Christmas Roses were blooming together in gardens.

Mr. Henslow, at a recent meeting of the scientific committee of the Royal Horticultural Society, of London, called attention to the fact that the Dahlia was first introduced into England 100 years ago by the Marchioness of Bute.

The pretty little *Draba verna*, one of the earliest of spring flowers, was blooming holiday week in abundance in Germantown. The constant rains of late summer advanced the plants much more than usual, and it takes but a few warm days to bring them into bloom. It has been many a year since this flower could be gathered at Christmas.

In the Colorado State Agricultural College, theoretical and practical arboriculture form part of the regular course of study. Preparation has been made for the establishment of four experimental stations in as many different sections of the state, to be conducted in connection with the college, and special attention will be given to trees and tree-planting.

The Phylloxera has made its appearance at the very gates of Paris, having been detected recently in the grounds of the School of Agriculture at Grignon. The discovery naturally causes great excitement and alarm among the Grape-growers of Argenteuil, who derive an annual revenue of a million francs from their vineyards. They have petitioned the Minister of Agriculture to order the destruction of all the vines at the school.

It is stated upon good authority that in Germany the small holdings in land of two and a half acres and less exceed 1,000,000; of two and a half acres to twenty-five, 2,000,000; and while, in the whole kingdom, 14,000,000 acres are devoted to grass, 47,000,000 to vegetables and corn, over 64,000,000 are utilized for fruit and the productions of market gardens worked by the spade, in England there are to every five acres devoted to fruit over 1,000 devoted to root crops and corn.

The American Philosophical Society is printing the manuscript diary kept by the French botanist Michaux during his travels in America during the last century. It was presented to the Society more than sixty years ago, by his son, the younger Michaux, the author of the standard work upon American forest trees. This curious document, which covers the whole period of Michaux's residence in America, with the exception of the two first years, contains much information of interest to students of the habits and customs of the people of this country, especially of the inhabitants of the frontier settlements during the last century, as well as to botanists. The Journal is edited by Professor Sargent.

In the report made by Professor Beal upon his examination of the Jack Pine Plains of Michigan, he says: "In watching the rapid flow of the Au Sable and the Manistee passing by the plains which were thirsting for water, it often occurred to me, 'Why not turn the waters on the fields and make them fertile, instead of using them to float logs to the lakes?' A thing so easily done, I believe one day will be done—and done with great profit—not likely by those owning small farms, but by those owning land by townships and sections. If we could control the water on these plains, so they should not lack for it, we could grow good crops, and with good crops the soil would rapidly improve in fertility."

The following description of a singular freak of nature was recently printed in *The Garden*: A few days ago a friend was exploring a room in a dwelling house which appeared to have been unused for a long time, when he found a curiosity in the shape of a Potato plant which had sprung from a large Kidney Potato that was lying at the bottom of a damp cupboard. It had made no roots, but had thrown up several leafless stems which were perfectly white and had filled the lower compartment of the cupboard. From every

joint of these stems, long white filaments were sent out, each of which bore several small tubers. In all, the Potatoes must number some hundreds, all grown from the same parent tuber.

An English correspondent of *The Garden* writes as follows with regard to the effect that the wet summer of 1888, followed by a very warm autumn, has had upon the foliage of Oaks: "Last year, growth was made early and became well ripened, and the leaves fell at the usual time. But this year the first growth of the Oaks was stripped of leaves by a plague of caterpillars. After the plague subsided a second growth, in some cases as much as nine inches in length, was made. This wood was quite soft when early frosts came in October and the leaves were perfectly green; but gradually the shoots have hardened, the leaves have colored, although they refuse to drop, and resist the force of strong November gales which have been recently sweeping over the country."

According to the Cairo correspondent of the London *Times* the arable area of Egypt has been almost quadrupled since the days of Mohammed Ali, half a century ago. An immense impulse was given during the reign of Ismail, when the War of the Rebellion in this country stimulated the cultivation of cotton in other lands; the cultivable area of Egypt then increased at the rate of 22,000 acres a year. During the last five years, when the English have administered the departments of Finance and Public Works, an almost equally rapid increase has taken place, and it is said that during 1888 no less than 75,000 acres will have been reclaimed. Irrigation is, of course, the expedient employed. When one stands on an elevated point in any part of the Nile Valley, a straight, clear line is described which separates the rich growing crops from stretches of white sand, as barren and hopeless-looking as the beaches of the sea. But this line merely marks the extent to which the waters of the river have been admitted at the time of their annual overflow; and it only needs that they shall be admitted further and stored by a simple system of little dams and canals, for the sand to become a soil of marvelous fertility. A certain verse in the Bible speaks of the laborer as "watering the ground with his foot"; and the persistence of Eastern customs is revealed by the fact that to-day this process may be seen in execution. The fields in many districts are cut into rectangular squares, between which run little canals, their banks formed by low ridges of earth. At due intervals the cultivator goes from one to another, pressing down a bit of the ridge with his foot, letting the water overflow the square, and then closing the aperture in the same manner. The arable area of Egypt is now 4,885,968 acres, as against 1,856,000 estimated for the year 1833.

A correspondent of the *Gartenflora*, writing from Caracas, in South America, tells of the recent development of horticulture in that country. Twenty-five years ago, he says, the art was almost unknown; no public parks or gardens existed, and private cultivators made but a sorry showing with a few species of common garden flowers and native plants grown, very often, in broken pots and boxes. The first impulse toward improvement was given by a German botanist, Moritz, who laid out a charming garden for a German colony at Tovar and introduced many unfamiliar plants, among them the *Gladiolus*. His efforts were followed by those of a fellow-countryman, Herr Hahn, who formed a beautiful Rose garden near Caracas, and then by those of General Guzman Blanco, who established the first public park, and turned the squares of Caracas—formerly mere stone-covered or weed-grown spaces—into charming gardens. A French gardener was imported, who, in addition to his other enterprises, succeeded in the difficult task of making beautiful lawns in this hot, dry climate. The principal park is now called "Paseo Guzman Blanco," and adorns a hillside near the city which was formerly a sterile expanse of red-brown earth. Now it is terraced and planted with fine groups of trees, shrubs and flowers—various species of *Ficus* and *Cassia* being conspicuous—and among them large clumps of a tree-like Grass (*Guadua*) and of broad-leaved *Aroideæ*. Among the native shrubs, the writer notes as most beautiful, *Duranta Plumieri*, which has a compact growth and evergreen foliage, and bears its violet-blue flowers and profuse yellow-red fruit together. *Araucarias* have been largely planted, and while *A. imbricata* does not do well, *A. Bidwelli* flourishes and *A. excelsa* seems likely to succeed. Fortunately, adds our author, only a single formal bed can be seen in this park. Private citizens have had their ambition excited by the success of the park, and many of them can now show delightful gardens for which they import plants from Belgium and England.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, JANUARY 9, 1889.

The Needs of American Forestry.

EXCEPTION was taken in our last issue to Mr. Gannett's sweeping statement that cutting off the forest from the watershed of a mountain stream increases its irrigating capacities, a statement which we believe has not been confirmed by a record of the exact flow of any stream before and after the forests had been cut from about its sources. We quote, however, the closing sentences of the same address, which contain the whole gist of the forestry question of the United States at the present time, as we understand it:

"It seems to me that, apart from the uselessness of it, Nature is planting trees at an infinitely more rapid rate than man. For every tree planted under the Timber-culture Act, or on Arbor Day, a thousand spring up of their own accord. Every deserted farm east of the plains grows up to a forest. Half of southern New England to-day is wooded, and the proportion is increasing every year, and yet in Massachusetts they have every year an Arbor Day, when the farmers turn out and solemnly plant a tree apiece."

What we need, indeed, in this country is not so much to plant trees for forests, as to take care of those which are planted without the assistance of man. The climate of eastern North America is surprisingly favorable for the growth of trees. They spring up in every part of the country, from the Atlantic Coast to the Missouri River, wherever a piece of ground is left undisturbed; and it is only in the arid parts of the country, where the rainfall is too small or too unevenly distributed to develop forest-growth, that trees are not as common as weeds in a neglected field. But in all that has been said and done in this country under the general and rather ambiguous term of "forestry," attention has been paid mainly to the subject of planting trees, while little has been said in regard to the necessity of taking care of and improving the natural woods. This, perhaps, is not surprising. There has been no question in the Eastern States until recent years of any scarcity of naturally-grown timber, or any practical necessity of husbanding the abundant stores which were encountered on every side as the tide of

immigration pushed westward. It reached in time, however, the treeless prairies and plains which distinguish the interior of this continent; and the efforts of the settler were turned to securing shelter and a supply of fuel by planting trees. The treelessness of the interior of the continent directed popular attention, naturally, to tree-planting, which has gradually come to mean forestry in the minds of most Americans, as nearly all American writers and speakers upon this subject confine their remarks to this comparatively unimportant branch of forestry, and overlook the broader question of forest-protection.

What is really needed in this country, now that the most valuable products of the forests are growing scarce, is an appreciation of the value of our native forests, and a comprehension of the natural laws upon which the development of forests depends. We have yet to learn as a people that fires are destructive not only to trees, but to the productive capacity of the ground which bears trees; that animals browsing in the forest will, in time, destroy it entirely; that some trees are more valuable than others, and that the development of the valuable ones can be hastened and increased by the assistance of man. The real work for those persons who are interested in the forest as a source of material prosperity for this nation is in inculcating sound principles for the management of the forests that spring up spontaneously on all sides, and not in urging tree-planting exclusively as the only branch of forestry worthy of consideration.

Arbor Days have their uses, and they are not unimportant ones, perhaps, but the mistake is often made of considering that Arbor Day has anything to do with forestry, or can have any direct influence upon the forest-question. The educational influence of Arbor Day is already considerable, and this purely American institution is capable, no doubt, of being turned to better account even than it has been up to the present time. But we are among those who believe that the care and development of a single acre of self-sown White Pine seedlings will do more for American forestry than has ever been accomplished under the working of the Timber-culture Act or of all the Arbor Days that have ever been celebrated.

When to Employ the Landscape-Gardener.

IT has been said more than once in these pages that small gardening problems, as well as great ones, demand the artist's aid. Parks and city squares, cemeteries and large country-places must be laid out and planted by one who has studied design, and the effects and needs of trees, shrubs and flowers. This has long been acknowledged, and if we sometimes fail to act upon our knowledge, we do it with full consciousness of error. But small country-places and even villa-plots, if they are to be made the most of, must be entrusted, too, to competent hands. Whenever building, road-making and planting mean arrangement, they mean varied combinations of lines, masses and colors; this means the opportunity for a work of art. We certainly do not make the most of our surroundings if we miss this opportunity when it offers; and we are almost sure to miss it unless an artist tells us how to seize it. This fact also we are gradually, but surely, learning in America. Every prominent American landscape-gardener would affirm, if asked, that he has more work to do now than he had ten or fifteen years ago, and that the increase has come largely in the shape of problems which, ten or fifteen years ago, would have been thought too small and simple for professional treatment.

There is much that is encouraging in this evidence of increasing wisdom and good taste on the part of the public. But it is important that another necessity should be clearly understood, and that the client who feels the need for a landscape-gardener's services should understand just when they ought to be secured.

This time is at the very outset of his undertaking. As

soon as he thinks of building—as soon as he consults his architect, or even sooner—he should consult his landscape-gardener. Each artist is equally needed, whether the scheme be great or small, and the chief need is that they should work together from the very outset. The landscape-gardener should be the first to speak, though the architect may be the first to act, and within certain limits should throughout be allowed the controlling voice. It is for the advantage of both, and therefore doubly for the interest of the client, that such should be the case. When a landscape-gardener is called in after the house is finished, he too often finds that it is impossible to do the best that might have been done for the grounds. But he often finds, as well, that the best has not been done for the house itself. A building that is conspicuously placed is not of necessity well placed, although it often looks as though its designer had thought so. Only the trained landscape-gardener can tell what may be done to a spot to improve it as a building site. If he understands architecture as he should, he is at least as competent as an architect to say where, under existing conditions, a building will look best; and if he understands his own art, he is far better able to decide where it should be placed in order that the outside world will look well from windows—the most important of all considerations to its owners. Moreover, he alone can understand the suggestions of the site with regard to the laying out of approaches and the placing of minor buildings. His advice may be very helpful to the architect in deciding the question, What sort of an architectural design will best suit this locality? And when the locality has a very distinct expression, or when he desires to give it such an expression, then the architect is bound at least to consider his intentions. An architect ought to be willing to make great personal sacrifices if it can be proved that great benefit to beauty or convenience in the general result of his work and his fellow-artist's will result; but rarely will such sacrifices be required. Very often such slight modifications of the architect's wishes as even the stubbornest spirit would not object to making, may result in all the difference between a well laid out place, with convenient approaches and dependencies and beautiful views, and a botched place, the owners of which, if they have eyes to see, will be perpetually tormented by the thought of what might have been. Even a different arrangement of two or three windows, a different allotment of two or three rooms to their special purposes, may vastly increase the pleasure which the owner will take in his home; and when an architect is an artist, he will be quick to see the fact if another artist points it out, and quick to feel how his design can be adapted to a necessity which, unassisted, he might never have divined. Moreover, with regard to certain things of a purely architectural sort, the landscape-gardener should be allowed to speak in a very emphatic voice—if, we repeat, he understands architecture as he is bound by the canons of his own art to understand it. All architectural features which come in close contact with natural features—piazzas, terraces, external stairs, steps and seats, summer-houses, boat-houses, bridges, balustrades and boundary walls—should, whenever possible, be built with his assistance.

This, then, is the way a landscape-gardener's services should be sought. Send for him first of all, even though it is but a villa on an acre of ground that you mean to build; ask him where your house had better stand, where is the best place for the main entrance, the piazzas, the stable, the gates, the dog-house, even; if the grounds are larger, ask what architectural style seems to him most fitting, where on the plan the chief rooms should stand, what views their windows should command; then send for your architect, let them devise and decide together and work together till the work is done. If they are both of the right sort—and there are many of the right sort in our country to-day—they will not greatly disagree; or if they do at first, they will find a scheme of mutual compromise and eventual harmony; and you will run a far better chance of getting a

good house and a good place than if they had worked separately—the architect building his house without knowing where it might best be placed or how best surrounded, and the landscape-gardener coming in afterwards to find, perhaps, that no chance was left him to assist the house or to do his own work well.

The possession of a remarkable tree even in communities from which better things might be expected, has little influence upon its owner when a few dollars are placed in the balance against it. The *Salem Gazette* and other papers of Essex County, Massachusetts, have recently made an appeal for the life of a remarkable Walnut-tree which grew near the house of the late Ben Perley Poor, Indian Orchard Farm, near Newburyport. The tree, which was a very large one, with a trunk circumference of some twelve feet, was considered by Mr. Poor to be an English Walnut, but while the general habit and foliage were those of that species, the nuts were almost identical in appearance with those of the common Butternut, and suggested that it was a hybrid between the English Walnut and one of the American species. Such hybrids are not unknown, and there are two or three well-established instances of their existence in Europe. This tree was large, broad-branched and stately. For years it had been the pride of its owner, while its botanical peculiarities made it one of the most interesting trees in New England. The man who had nurtured it all his life was dead. It contained a few hundred feet of valuable lumber, and so, in spite of a general protest, it has been sent to the saw-mill.

Bamboos.

A VIEW of the entrance of the Botanic Garden at Peradenia, in the Island of Ceylon, appeared in one of the early numbers of the first volume of *GARDEN AND FOREST*. Among the most striking features of this garden are the clumps of giant Grasses which serve to illustrate the present issue. The one in which the base only of the stems appear is the great Bamboo of Penang (*Dendrocalamus giganteus*), of which the shoots, eight or nine inches through at the base, attain a height of a hundred feet. The second illustration represents a clump of the Java *Gigantochloa atter*, a plant hardly less stately than the last. Ernst Hackel, in his "Visit to Ceylon," thus describes the striking appearance of these plants: "If on entering the garden we turn to the left towards the river (the Mahavili) and follow its beautiful banks, we see from afar enormous green thickets of Bamboo, more than a hundred feet high, and as many wide, bending their mighty crowns like huge waving plumes of some giant's helmet over the river and the path, bestowing shade and coolness on both. As we go nearer we see that each of these bushes consists of several—often sixty to eighty—tall, cylindrical stems, each from one to two feet thick. They grow closely crowded together, like the creeping stems of a Rush." The rapidity of the growth of the stems is astonishing. They appear during the rainy season—that is, during the months of June and July—and are said to grow sometimes at the rate of a foot in every twenty-four hours.

The Bamboos, of which some 180 species, divided among eighteen genera, are now known, are widely and generally distributed through the tropics of both hemispheres. A single species (*Bambusa vulgaris*) is cosmopolitan, being found in both the old and new worlds, although General Munro, the author of the classical monograph of these plants, was uncertain if it was known anywhere in a truly wild state. Some genera are strictly American and others are found in the East only. *Arundinaria*, which furnishes the only Bamboo which grows spontaneously within the limits of the United States, is represented in both hemispheres, reaching to great elevations in the Himalayas, while a representative of an allied genus, *Chusquea*, first makes its appearance at an elevation of 13,000 feet in the Andes, and 2,000 feet higher

completely covers the surface with thickets impenetrable to man or beast.

The berry-bearing Bamboos, of which there are eight genera, are all found in the East; three of the species are found in Madagascar, one (*Schizostachyum parvifolium*) is described by Ellis in his account of that island, as "an elegant, slender creeper, with a stem scarcely as thick as a quill, growing nine to ten feet long, and hanging in most elegant festoons from tree to tree alongside of the roads."

No native Bamboo occurs in Europe, while from the whole of the vast continent of Africa only one native species is known. Bamboos are found widely distributed through southern China, in Japan, the Philippine and Fiji Islands, and one species occurs in the Sandwich Island group. The largest of the whole tribe, *Bambusa Brandisi*, a native of the hill districts of India, attains a height of 120 feet, with stems nine inches in diameter.

No group of plants, not even the Palms, is more useful to man than the Bamboos. They supply food and raiment and shelter to millions of people. The young shoots and the seeds furnish food to man, and the leaves fodder for domestic animals. The stems are used for building purposes and the leaves for mats and cordage; paper is made from the leaves, and furniture and almost everything else, where wood can be used, from the stems. The whole industrial fabric of the East is dependent upon these great Grasses, and it is impossible to think of a Chinaman or a Malay, without associating with him, in some form or another, the Bamboo.

The arborescent species have long been familiar ornaments in all tropical gardens; and, as our illustrations show, no plants of the north possess their stately grace and beauty. A good deal of attention has been paid in late years to the cultivation of some of the smaller species, of which several have proved hardy in the more temperate parts of Europe. Some of these are highly valued as ornamental plants, and their general introduction and cultivation in the gardens of southern Europe is one of the interesting events of modern horticultural progress. These dwarf Bamboos are not yet very well known in this country, although the climate of the Southern States is admirably suited to them, and there are several species which can be grown in California, with the aid of irrigation. There is at least one species, although unfortunately of dwarf and not very attractive habit, which is hardy in New England, *Arundinaria Japonica* (the *Bambusa Metake* of most gardens), and there are probably six or eight more, natives of Japan, China and the Himalayas, which can be grown in the more temperate parts of this country. None of them have stems which exceed, under the most favorable conditions, a height of twenty feet, so that while they may serve to add grace and charm to any garden, and to recall the vegetation of the tropics, they can give but a very faint idea of the veritable giants of the race, which can be seen in all the splendor of their beauty in the tropics themselves only.

Notes from a South Carolina Naturalist.—II.

AT Sandy Run I find *Euonymus Americanus*, the bursting capsules gladdening the heart, and here, also, I see a few of the prickly follicles of *Gonolobus hirsutus*. Formerly there were many vines here, all growing together, but bearing flowers of different colors, yet they were all *G. hirsutus*. Some of the flowers were palish yellow or straw color, others brownish purple and some almost black. One vine had paler flowers, somewhat approaching lilac. The petals in all were veined, the straw color showing it best. *G. suberosus*, Gray (*G. macrophyllus*, Chap.), with its smooth and angled fruit, is found some miles off. The road runs through deep sand, still following the river westward, with Corn and Cotton on each side. We pass Linden, see the large Magnolia, so prized by the ancient owner, and think of the days that are no more! Next, Gascoigne's Bluff on the one side and Middleton swamp on the other, on whose knolls of Beech and Magnolia and Hickory the wood-cutter is

now cutting down the finest trees of Walter's Pine (*Pinus glabra*), so long ignored, till rediscovered by Dr. Ravenel—now, alas! lost to us; lost to the science he loved! In the surrounding Pine-land I have seen only one or two trees of this Pine, but deep in the recesses of the swamp it is abundant enough to be cut and floated to the mill, which, like a devouring monster, is taking the choicest treasures of our woods. Certainly a beautiful Pine, with its peculiar bark, its smooth limbs, its soft looking foliage. The wood-cutter told me that he had cut trees there thirty inches in diameter. I have often wondered that this tree had been so long ignored, or that it was not cultivated as an ornamental shade tree. So far as I know, it makes no forests of its own, but is found only sparsely among other trees, yet very lately it is said to have been found in great abundance in Wassamassaw Swamp, not far from Charlestown, the trees there being of great size and beauty, tall, stately, columnar. As to its locality, it is never found, I believe, very far from salt water. I find it on the banks of the Edisto, in the swamps near Jacksonboro' station on the railroad, in the swamps bordering the Savannah River rice fields, in the driest soil not far from the Colleton River, and on Hilton Head, along the bluffs of Calebogue Sound, between "Spanish Wells" and the ocean. It will grow, therefore, in most soils, both dry and wet, in the low country, save some Pine-lands. It is doubtful whether it would grow at the north, but it is worth the trial.

In many trees I have observed that the small branches grow out horizontally from the larger limbs, making the foliage appear dense and flattened, even though the smaller branchlets be really erect. The spray, therefore, often looks flattened, and it has always seemed to me a striking peculiarity. On James Island, near Charlestown, there were formerly many large trees, but the finest, which, it is said, were ninety or even a hundred feet high, were killed by the great cyclone of 1885. At "Burch's," on the same island, there are others left (so a friend writes me) which are about eighty feet high, tall and straight, having no branches for sixty feet from the ground.

As we continue, a few trees of the Swamp Chestnut Oak (*Quercus Michauxii*) are seen with Beech, and Magnolia and Maple, but the only Pine is Loblolly (*P. Teda*), which indeed is everywhere. At a roadside bridge, as we approach "Rose Dhue," vines of *Forsteronia difformis* are growing, the bloom, of course, long over, but I look in vain—as I had looked for years—for the long follicles. The road is now overarched with a dense growth of Cedar (*Juniperus Virginiana*) on one side and Live Oak on the other, making a dark and shady avenue, which carries us at last to the salt-water bridge, where, in the hottest days of summer, a sweet, cool draught comes to us across the marshes from "Rephaim." As we cross the next bridge a sad sight meets us in the utter destruction of a field of sea-island cotton by the caterpillar. Close to the marsh a few acres of brackish myrtle land had been cleared by the industry of negroes, and when last I saw it there was the promise of a most abundant crop, but what a scene of blackness and desolation met us! The tall stalks were all stripped bare of leaves, with only the black and shriveled pods remaining. Only a few of these were bursting here and there with the "snow of Southern summers." We were glad to pass on till we reach the deep swamp at the foot of a white and sandy hill, as we of the low country call so slight an elevation. Here is the usual swamp growth of Nyssa, Maple, one or two small Cypresses, and a single high-climbing vine of *Decumaria*; but the tree which will most attract our attention will be the (to us) rare *Pinckneya pubens*. We see the greenish and pale yellow capsules in thick clusters among the mellowing leaves, but they will soon be ruddy-tinged when the later frosts come. This spot is, so far as I know, its farthest northern limit, and I have seen it in only one other place not far off, and a single small shrub near the Savannah River. It is a shrub-like tree, but it reaches a height of twenty-five feet, and a section of one such I sent, some years ago, to Professor Sargent for the Jesup collection. The flowers in June, with their beautiful peach or rose-bloom floral envelope, are very showy. The young trees sometimes have the floral envelope almost white, with but a tinge of pale pink, but those of the old trees are usually most deeply colored, and are very beautiful.

The edges of this swamp in June, all ablaze with the rose-pink bloom, is a sight worth seeing, and at such a time I wonder the more that it has never been cultivated. As it seems most likely that this was the tree which Bartram found growing with his now long-lost *Gordonia pubescens* (*Franklinia Altamaha*), I thought it barely possible that I

might stumble upon it here. My explorations have never rewarded me with its rediscovery, but it may doubtless yet be found in the Fort Barrington region, where Bartram first saw it in 1773. We take our last draught of water from the cool spring, mount the sandy hill, and for some distance see only trees of *Pinus palustris*, and of Oaks—*Q. cinerea* and *Q. Catesbaei*—fit soil for them all! Passing through a wet "gall," I look for Elliott's *Solidago elliptica*? which I met with at this spot a few years ago, but I failed to see it; yet I have since found it not far from the Okeetee, where, also (but in clay land near the bridge), I was fortunate enough to collect, for Dr. Gray, fine specimens of the equally rare *Actinomeris alba*. We toil on laboriously through Scrub Oaks and Pines, and, before we leave the sand, look for *Asimina parviflora* (which grows abundantly in an old field near by), but no plants were to be seen on the roadside.

At last we reach the cane-brakes of the "Great Swamp," and, by the new growth of Pine met with, know that clay soil has been reached. It is the rough "Spruce Pine," to distinguish it from Walter's smooth Spruce (*P. glabra*). I refer to *P. mitis*. I have but rarely met with the three leaves in a sheath. *P. Tæda* is here, also—for it is everywhere. *Collinsonia punctata* was once most abundant in the woodlands about, but it seems to be disappearing, and a little further on I see but a single specimen of *C. scabriuscula*. The last seems very rare. We pass the old Garvey gate, with its few Cypressess, and are cheered by the autumn colors of Golden-rod—seemingly *Solidago tortifolia*—covering whole fields. The faint glow of coming winter is already in the trees about the river, chiefly Nyssa and Maple, and now the distant rice-fields are seen. We cross the bridge at New River, and see the signs of the late disastrous freshet which had burst over the railroad, overleaping dams and submerging the harvest-fields of rice, and had carried destruction with it, thus mingling the red waters of the Savannah with the purer tide of New River! The marks were on every side in the bending and prostrate plants and sheaves of golden grain, still lodged high and dry on the shrubs and tall grasses.

It was the highest, and, I believe, the most destructive freshet ever known in the rice-field country hereabouts, and will never be forgotten either by planters or negroes. On the middle bridge of the Causeway I looked for the remains of *Eryngium præaltum*, where I collected specimens in the summer, but I saw none, and but one tall specimen some six or seven feet high (of what I took to be *Eupatorium serotinum*), was left green and flowering, of the many formerly seen.

Turning, now, sharply to the right, I look down the Screven's Ferry road to the left, and recall, with the same glow of pleasure, my great "find" last summer of the (to me) most rare *Anantherix connivens*. This was but the third plant I had ever seen—the second having been collected many years ago, some fifteen miles away in a damp Pine-land, and sent to Dr. Gray. That plant was about eighteen inches high, if I remember aright—this four feet three inches. We wade through long slashes of water on the edges of swamps with *Quercus Phellos* abounding. Emerging from these glooms, we come to red clay, which soon runs off into a drier and more gravelly soil, and here I was glad to see several acres of the young saplings of *Pinus palustris*, to the exclusion of all other Pines. As we go on through damper soil we see the long, slender plumes of *Liatris graminifolia*, with here and there the *L. gracilis* of Elliott. *Liatris odoratissima* is also here, but its bloom is long since over. *L. paniculata* we left behind long ago, with also *L. scariosa* in the dry woodlands, but the show of the fall is poor in comparison with former years. Visiting the house of a negro patient, and seeing a splendid Hibiscus in full bloom, I hoped that by a mere chance it was the long-lost *H. Carolinianus* of Elliott, but a closer examination proved it to be only the *H. grandiflorus* of Michaux. It was brought from Georgia, but it grows also in South Carolina, for I once saw several acres of it in black and brackish soil just back of the sand hills on Hilton Head. Few sights more beautiful could be imagined. Again we meet with *Pinus Cubensis* abundantly, and at last reach the railroad, where my journey ends and my work begins.

Bluffton, S. C.

J. H. Mellichamp.

"Meantime, there is one duty obvious to us all: it is that we should set ourselves each one of us to doing our best to guard the natural beauty of the earth: we ought to look upon it as a crime, an injury to our fellows, only excusable because of ignorance, to mar that natural beauty which is the property of all men."

—Morris' Lectures on Art.

Cultural Department.

Selaginellas.

ACCORDING to the latest monograph of these plants, there are no less than 334 species now known. For horticultural purposes many of them are either wanting in beauty and interest, or are too much like other species to be worth growing. The collection of species and varieties of Selaginella cultivated at Kew is the largest I have seen, comprising, as it does, ninety-two species and varieties. Most of these are grown in a portion of the large house devoted to tropical Ferns, the Selaginellas occupying a side stage on the north-west side. Each kind is represented by several large panfuls, the pans being from one and a half to two feet square and about six inches deep. The effect of these plants, when grouped as at Kew, is exceptionally handsome, and they are looked upon as one of the most interesting and attractive features of the house collections. They are easily managed—in fact, no plants more easily; they grow quickly into perfect specimens, and they may be propagated to almost any extent in a short time. Many of them are of dimensions large enough to be grown as big specimen plants, others make pretty basket plants, while the smaller creeping kinds may be employed for many purposes, such as forming a carpet under large plants either when grown in pots or planted out. But to enjoy these plants to the full they should have a house or portion of a house to themselves. There is variety enough among them to please any one. Next to the filmy Ferns, I consider the Selaginellas the most delicately beautiful of all the Vascular Cryptogams.

The following list of twelve good kinds, for the stove or warm green-house, comprises representatives of all the most attractive types or groups. They are the pick of the Kew collection, and they have the merit of keeping well through the winter. Probably, however, delicate plants such as these do not suffer so much in America in winter as they do here.

The soil used is a mixture of loam and leaf-mould, with a good sprinkling of silver sand. It should not be pressed hard into the pans or pots, but about as firm as for Verbenas, etc. The drainage should be carefully prepared, so that the water daily required by these plants all through the summer will not have any difficulty in passing away. The temperature of the house where they are grown at Kew does not fall below 60° Fahrenheit in winter, and 70° Fahrenheit in summer. About the end of February cuttings of all the kinds should be put into pans or boxes, so that any specimens which are too shabby to be worth keeping another year may be replaced. Such species as *S. Mertensii*, *S. denticulata*, etc., are omitted from the list, as they are already universally grown, the object here being to call attention to the many beautiful kinds of Selaginellas which are in cultivation in a few gardens, such as Kew, but which are almost unknown in general horticulture.

S. affinis, a recent introduction from British Guiana. It has stems nearly a foot high, with the habit of a dense variety of *S. Mertensii*, and scale-like leaves, crisp, imbricated, rather firm and bright green. The branches are tasseled and curved back. This is a beautiful plant, as delicate and soft-looking as a *Todea pellucida*.

S. atroviridis, a fairly well-known plant, a native of India, China, etc. It is remarkable for the shining dark olive-green of its broad fronds. In tropical countries its leaves are almost black. The stems are about nine inches high, freely branched, the leaves being very broad and flat in their arrangement. This is as easy to grow as *S. Mertensii*.

S. caulescens, var. *argentea*. The lower part of the stem of this kind is unbranched, while the upper half is bent horizontally and covered with lance-shaped, overlapping branches, so that the whole stem has the appearance of a large deltoid frond with a long stalk. The branched portion is a foot long by about eight inches broad, beautifully clothed with small bright green leaves arranged almost flat; the tips of the upper branches are whitish. This grows freely, and is the handsomest of all the varieties of *S. caulescens*. It is a native of the Malay Peninsula.

S. Emeliana, a semi-erect kind, nine inches high, the fronds like those of *S. Mertensii*, but much more delicately divided and triangular in outline, while the leaves are smaller and inclined to curl. The color is a soft, deep green. It was introduced by B. S. Williams, of Holloway, in 1886.

S. grandis, the handsomest of all cultivated Selaginellas. It grows to a height of two feet, the stems erect and unbranched, except on the upper six inches, where the branches are numerous, arranged side by side so as to form a flat, shell-like frond, of the brightest and clearest blue-green. Each

branch is terminated by a square, tassel-like spike one and a half inches long. It was introduced in 1882 from Borneo.

S. hamatodes, a large-fronded, beautiful plant, which will grow into very fine exhibition specimens. Nothing could be more delicate and pleasing than the arrangement of the branches and leaves of this species. The stems are from one to two feet long, bright crimson, unbranched in the lower half, the upper half horizontal, and branching freely, so as to form a large frond a foot across, and as delicate in its details as a *Todea superba*. There are several varieties, all of them beautiful. It is a native of Peru.

S. inequalifolia, an erect grower, two feet high, with the main branches arranged alternately at regular intervals from the base to the top of the stem, the branchlets forming flat, deep-green fronds five inches long and four inches across the base. It forms a very distinct and handsome specimen when grown in a mass. It is a native of India.

S. stenophylla, var. *albospica*, a graceful plant of medium size, with erect stems, freely branched, somewhat like *S. Mertensii*, but much more delicately divided. It is one of the prettiest for growing in masses in large pans. The branches are sometimes tipped with yellow. It is a native of Mexico.

S. suberosa, similar to the last, but deeper green, and the stems are brown, those of *S. stenophylla* being pale straw-colored.

S. uncinata (*S. casia*), a pretty little trailer, with alternate branches, somewhat triangular in shape, about three inches long, and covered with tiny leaves of a steel-blue color. This color varies in intensity at different times of the day, sometimes being almost pure green, at others an intense shining steel-blue. It is a useful plant for growing amongst Orchid-pots, and like situations. It comes from China, and is often met with in cultivation in England.

S. Wallichii, an arboreal kind, attaining a height of three feet or more. The stems are upright, clothed with horizontal branches, each of which is a triangular frond nine inches long by three inches at the base, plumose, and bearing small, rigid spikes from the tip of every branchlet. This is a very handsome species, which may soon be grown into a large specimen, if properly staked and trained. It is a native of India and neighboring countries.

S. Willdenovii (*casia arborea*), a remarkable plant, the stems climbing to a length of twenty feet or more, as thick as a goose-quill, and bearing at intervals of about six inches frond-like branches, each two feet long, triangular in outline, and covered with the small scab-like leaves, which are shining blue-green. There is a mass of this species in the Fernery at Kew eight feet through and ten feet high, forming a most beautiful specimen. It is a native of India.

Many more species, quite as handsome as those described, might be added, but these dozen kinds will give a very good idea of what the rest are like.

Kew, December, 1883.

W. Watson.

Winter Apples of New England.

UNQUESTIONABLY the Baldwin is the leading market apple grown in southern New England, and westward, along the same parallel, to western New York and Michigan. The Rhode Island Greening makes a close second; while, as a long keeper, the Roxbury Russet has no rival among the commercial sorts. In the business sense these are favorite apples, and a well-grown, yellow-fleshed Rhode Island Greening is worthy to rank with our really best apples in quality, for dessert, as well as for the kitchen. And here it may be well to say, that it is a mistake to speak slightly, as some do, of cooking apples. Much the larger part of our great apple-crop comes at last to pies, dumplings and apple sauce. Equally is it wrong to suppose that an apple poor in quality is good enough for cooking. We often hear the Esopus Spitzenburg referred to as the *ne plus ultra*, in quality, of American apples. It is all that, as a cooking apple—preserving its high, aromatic flavor through the trial of fire; but I never could consider it as a dessert apple. Its flesh is too solid for that.

The Baldwin, well grown and well ripened, is a fair dessert apple. We could get along with it, if we had no better. But we have. Among the big red apples, Northern Spy is much its superior. The Red Russet is an apple superior to the Baldwin in quality, keeping and vigor of tree, and its equal in size and productiveness. It is supposed (by Cole) to be a cross between the Baldwin and the Roxbury Russet, but no reason is given for the supposition. It had its origin on the Sanborn farm at Hampton Falls, New Hampshire. In Maine it thrives so well, that in all but a few localities it seems to be supplanting the Baldwin. Though not an "iron-clad," its northward

range is beyond the Baldwin's, perhaps coincident with Jewett's Red, or Northern Spy. It is worthy of much more attention than it has yet had from commercial growers.

Another very valuable winter apple of Massachusetts origin is Sutton Beauty. It is not so good a keeper as the Baldwin, and though often called a large apple, it requires good soil and treatment to do justice to itself in this particular. As usually seen, it is not so large as the Baldwin. Its color is crimson red on a waxen yellow ground. It is a crisp, juicy apple, with a sprightly, pleasant, acid flavor. Though highly prized in Massachusetts, the fame of the Baldwin overshadows it and keeps it in the background.

Yellow Bellflower is an apple hard to surpass when in perfection, and prime fruit of this variety always fetches a high price in Boston. But it is very particular in its choice of locality. I have never seen first-class Bellflowers grown anywhere except upon the banks of, or near to, some large river, like the Connecticut, or the Kennebec. When suited in location, no Apple yields better or finer fruit. Maine-grown Bellflowers keep as well as Baldwins, though it is reckoned an early winter sort. Although called a yellow apple, choice river-bank fruit always has a fine pink cheek, which is not only an additional beauty, but a seal of excellence.

It is a curious fact that so great an apple-growing state as Maine should not yet have produced a first rate market apple, that is also a long keeper. Black Oxford, perhaps the best keeper among the well known Maine apples, is but a third rate fruit in quality. New Hampshire has her Red Russet; Connecticut her Westfield and her McLellan; Rhode Island her Greening; and Vermont her Landon; but Maine is yet in arrears to the country on this point.

The Westfield Seek-no-Further of Connecticut is a market and dessert apple of a high grade, successful over a broad extent of country. It is grown westward to Michigan, and the finest specimens of the variety that I have seen on exhibition have been from that state. It is an apple very even in size, a thing important in barrel-fruit. The peculiar Pearmain flavor, noted by Downing, makes the Westfield very popular with old-fashioned people. The McLellan, somewhat less in size than the Westfield, is not inferior in quality. A yellow apple, marbled and splashed with clear red, its white under flesh juicy, and with a saccharo-vinous flavor, rare to find, makes it a choice apple indeed. The tree is vigorous, productive, and hardy nearly up to 45°, though, unfortunately, not "iron-clad." Peck's Pleasant must not be forgotten among Connecticut's choice apples; indeed there are many who would name it first. Large, round, fair, greenish yellow, with a sunny blush, as rich in flavor as Newtown Pippin, with a softer flesh, it must long remain among New England's best apples. It is a fair, but not very long, keeper.

Vermont's Landon has not received the notice among pomologists which its merit deserves, possibly because it is not a large apple—merely medium. Round, slightly conical, yellow, mottled and shaded with rich crimson, with a little russet around the stem, it is handsome enough, as it is good enough, to be better known. Flesh yellowish, firm, crisp, juicy and aromatic, and but slightly acid, this is a choice apple indeed. Origin, the Landon farm, on Grand Isle, Lake Champlain. Season, February to May. The one apple, which space now allows me to notice, and which should not be omitted, is Hunt's Russet, sometimes called "The Golden Russet of Massachusetts." If there is a best apple, surely we have it here. (Downing has it under both names, seemingly unaware of the fact.) It originated in Concord, the home of patriotism, poetry and philosophy. Not a large fruit, rather small indeed, it illustrates the saying that the best things are put up in smallest packages. It is thinly russeted on a yellow ground, with a bright, rich red cheek; with a fine-grained, yellowish flesh; with a tender, juicy, very rich, aromatic, and briskly (but not excessively) acid taste, and altogether, Hunt's Russet is an apple to offer to our most highly valued friends, in our most friendly mood.

About Sea Kale.

WHERE the plants are obtained from seed this is sown in early spring, either in the open ground, in hot-beds, or green-houses. If the seed is sown in the open ground in drills, these should be two feet apart, and the seed should be dropped thinly, so that the plants stand twelve inches apart in the row. Under good cultivation the plants may become strong enough to force the first year, but it often happens that they do not get sufficiently large until the second year, when the seed is sown in the open ground.

When the seed is sown in the green-house or hot-bed during

February or early in March, and well cared for, nine-tenths of the plants will be strong enough to force the same season.

My treatment of the crop the past year was this: As soon as the seed was received, about the tenth of February, a boy was set to crack the capsules which contain it. The seed was sowed in drills between rows of Smilax, in a temperature of about fifty-five degrees. The plants appeared quickly, and as

They were stripped of their leaves and buried in sand out-of-doors, so that they could be reached from time to time during the winter.

The first lot for forcing was brought in the last day of November, and planted in rows eight inches apart, each way, in ordinary soil. The temperature was kept at fifty-five to sixty degrees. The house was kept as dark as tight boards all around and over head could make it. Water was given twice a week,

Fig. 85.—Giant Bamboo (*Dendrocalamus giganteus*) in the Botanic Garden, Ceylon.—See page 14.

soon as the two seed leaves were developed and the third leaf could be seen, they were potted into two-inch pots and placed close to the glass, in about the same temperature. They were kept well watered, and often moved to prevent their rooting in the soil beneath the pots, until the end of May, when they were planted in the open ground, fifteen inches apart in the rows, which were three feet apart. After this they received exactly the same attention as did other members of the Cabbage family.

On the 7th of November the roots were dug and stored, many of the largest ones being two inches in diameter, and the smallest three-fourths of an inch in diameter, although there were few of the last size.

and the crop was ready to cut on Christmas. In appearance it was like very fair, perfectly blanched celery. A succession of crops is now following, and as the season advances, two weeks, instead of three, will be long enough for forcing a crop.

It is surprising that Sea Kale is so rarely grown in this country, since it is a delightful dish when properly cooked and served. It should never be used when in the least wilted or flabby. When not perfectly crisp it should be immersed entirely in water for six or seven hours before it is plunged in the boiling water. This water should contain enough salt to give it a distinct flavor, and a lump of soda as large as a hickory nut will improve the appearance and flavor of the vegetable.

Pearl River, N. Y.

John Thorpe.

Orchid Notes.

Zygopetalum Mackayii.—Several plants of this old and well-known Orchid are now in full beauty here, and the bold spikes of bloom form quite a prominent feature of the collection at this season. The value of the flowers is enhanced by their lasting quality, both on the plant and after having been

which, if strong, will produce two, each bearing from eight to twelve of its large, handsome flowers. The sepals and petals are yellowish-green blotched with purplish-brown. The large, spreading lip is pure white striped with blue. There are several varieties, differing chiefly in color. It is a native of Brazil.

Odontoglossum Dormanianum.—This rare and pretty little

Fig. 86.—Giant Bamboo (*Gigantochloa atter*) in the Botanic Garden, Ceylon.—See page 14.

cut. This species will be found exceedingly useful to florists for cutting. It can be grown easily and will accommodate itself to almost any house, thriving well among foliage plants, Roses, or in the coolest plant-house. The flowers appear at different periods, according to the temperature given them. A strong compost of fibrous loam, kept open with nodules of charcoal, seems to suit the thick, fleshy roots, and during active growth it needs a plentiful supply of water, and if in good condition is benefited by frequent waterings of weak, liquid manure. The spikes appear from the young growths,

Orchid is now in flower. In habit it bears some resemblance to *O. blandum*, and is probably only a geographical form of it. The flowers, borne on drooping racemes, are about two inches across, and are pure white densely spotted with mauve-purple, excepting the tips of the segments. It is a robust grower, and requires the treatment usually given to the genus.

Odontoglossum ramosissimum is a rare species producing branching scapes with numerous, wavy, speckled flowers which, in a mass, are particularly attractive. The bulbs are

large, compressed and ovate, surmounted by a linear-lanceolate leathery leaf about a foot long. The flowers are about two inches across, wavy in outline, white speckled with rose-purple. This plant is found in dense forests on the central Corderillas at elevations of 6,500 to 1,300 feet; consequently it will stand very cool treatment, but does best with an average temperature of 55°.

Odontoglossum Shuttleworthæ.—This is a superb species, and the specimen in flower here is unique. It is presumed to be a natural hybrid between *O. triumphans* and *O. Pescatorei*. The habit and inflorescence resemble the latter, but the bulbs attain an immense size. The flowers are about three inches across, the sepals and petals of a straw-color margined with deep yellow, the sepals being spotted and blotched with cinnamon red. The large pandurate lip is yellow, with a large, broken blotch of reddish-brown on the crest. The plant was imported among a consignment of *O. Pescatorei*.

Oncidium excavatum is a very strong, free-growing kind, with large, ovate bulbs, and broad, deep-green leaves about twelve inches long. The strong, branching scapes are three to four feet long, and bear numerous showy flowers about two inches across. The sepals and petals are bright yellow blotched with brown. The lip is large, flat and of a deep golden color. The crest, which is very prominent, is yellow marbled with brown. This is a particularly showy species, producing its flower-spikes freely, and it would also be extremely useful to florists for cut-flower purposes. It is a native of Peru, and grows freely in a cool, damp atmosphere with the *Odontoglossums*, but should be accorded a good rest as soon as growth is finished, or new growths will appear instead of flowers.

Principles of Physiological Botany as applied to Horticulture and Forestry.

II.—THE CONTENTS OF VEGETABLE CELLS; PROTOPLASM, OR LIVING MATTER; THE VARIOUS LIVING GRANULES, OR PLASTIDS; RELATIONS OF THESE TO THEIR SURROUNDINGS.

STARTING from the point reached in the first paper of this series, we recognize these facts (1), that all plants are composed of minute bodies, termed cells, and of the products formed by them; (2), that these cells, while living, contain active living matter, or protoplasm, in which and by which all the proper work of the plant is carried on, and (3) that this living matter, or protoplasm, in one cell, is practically continuous with that in adjoining cells, and so on throughout the whole plant.

The properties of protoplasm must now engage our attention, since we cannot understand in what way all these cells work harmoniously together and accomplish certain results, unless we first ascertain the teachings of modern science regarding their active contents.

It should be stated frankly at the outset, that it is a hard matter for one who is not engaged directly in the study of plants to get a clear notion of this part of the subject. A tree appears so strong in its framework, and we have seen it resist so many gales of summer and storms of winter, that, as we have said before, we can hardly realize that the stout framework is not alive, but is merely the mechanical support of a film, or succession of films, of extremely delicate cells which lie just under the protecting coats of the inner bark. And it is still more difficult to realize that it is the living matter of these cells that we must look for every sound explanation of the phenomena of plant life. Our present course of thought must lie, therefore, for a time among the things which are unseen except by aid of high powers of the best microscopes. In fact, one or two of the more recent acquisitions in this field have been possible only because of important advances made of late years in the construction of microscope lenses.

PROTOPLASM, OR THE LIVING MATTER OF THE CELL.—This is essentially the same in animals that it is in plants, and presents about the same phenomena. Under the microscope it appears as a colorless, somewhat granular, half-liquid mass, which in certain thin-walled cells, which it does not quite fill, can be observed to change its shape more or less rapidly. These movements of protoplasm can be readily made out in such thin-walled cells as the hairs of the Squash-vine and Nettle, and in innumerable other instances may serve as a good criterion of its activity. For the examination of such phenomena it is not necessary to use a very high power of the microscope, two or three hundred diameters being sufficient. These movements are hastened by increasing the warmth of the cell up to a certain temperature, say about

one hundred Fahrenheit; but when we reach a temperature forty or fifty degrees higher than this, all motion stops and does not begin again. If, on the other hand, we cool the cell down, the motion can be retarded until, a little above the freezing point of water, it is arrested, but on warming the cell again, very cautiously, the movement is resumed.

There are many ways in which the movement can be arrested—as, for instance, by strong electrical shock, or by crushing, and so on; but the only ones which need to be particularly noticed now are the following: (1) by shutting off all water and food from the cell, as in starvation, and (2) by shutting off all oxygen, as in preventing free access of air. It is proved beyond question that when protoplasm is active there is a consumption of food, which, under the influence of the oxygen absorbed, is converted sooner or later into the gas known as carbon-dioxide* and water. The latter process is nothing more or less than respiration, so that we have here in the microscopic cell, two processes which are essential to all activity in the animal as well as in the vegetable world, namely (1), the appropriation and utilization of food, and (2) respiration or breathing. No growth can take place and no work can be done by the plant or by the animal if either of these processes is suspended.

But just here appears a world-wide difference between the plant and the animal. The plant, by virtue of certain granules which its protoplasm contains, can, under certain circumstances to be described later, construct its own food out of inorganic matters obtainable from the air and from water in the soil, whereas no animal can do this. (We are leaving out of account, as was explained in the introduction, some interesting exceptions, which will be found explained in all large works on the subject, for our purpose is merely to show what are the general cases and comprehensive rules.)

We must now look at the granules by which plants can effect this extraordinary change of inorganic into organic matter.

The cells in the green parts of plants contain, imbedded in their protoplasm, minute greenish granules of various shapes, generally roundish. These are known as the chlorophyll-granules, or, what means the same thing, leaf-green granules. When these are provided with a supply of carbon-dioxide in proper amount, and are exposed to sunlight, they can, if all the other conditions as to warmth and so on are favorable, manufacture a sort of sugar, or something very much like it, giving off at the same time a certain proportion of the oxygen which was in the carbon-dioxide. This sugar, or its equivalent, is the primary food of the plant. This process, which appears to be so simple, is in reality very complex, and can be only partially understood even after we have examined the structure of the parts where most of the green granules are found in our plants, that is, in the leaves. It is enough for the present to state that this wonderful laboratory of a green cell constructs all the food for animals, as well as for plants, since it is the excess of what plants make and do not themselves consume that animals employ as their food.

One more thing should be noticed at this point, namely, that part of this food made by plants is stored up in the form of starch or oil for future use by them, while a large part is turned to account in building up, in the form of cellulose, or cell-wall substance, the fabric of the plant.

We must next combine a few of the foregoing statements, in order that the relations of the cells to each other may become plain. The cells which contain the leaf-green granules require for the manufacture of sugar (1) water, which comes in by absorption from the immediate surroundings; (2) carbonic acid, procurable from the air; (3) light of a certain quality and intensity; (4) a certain temperature. Now, the green cells of our trees are mainly in the leaves. The position of the foliage exposes them sufficiently to light and air, while communication with the soil is effected through the stem and roots. In other words, millions of cells in the roots and elsewhere in the plant are tributary to these green cells of the transient foliage.

Our task is now fairly before us. We are to see in what way this co-operation between the cells in the roots and leaves is accomplished, and to what extent the roots, stem and leaves share in all the varied work of the plant. Reserving the examination of these organs to later papers, we may give a passing glance at certain curious relations which have been recently discovered by Professor Schimper, between the leaf-green granules and other granules within the cells of plants. In the cells at the growing points of plants

*Carbon-dioxide is often termed carbonic acid, and these terms may be used interchangeably.

there are discernible, under high powers of the microscope, minute granules which, without special chemical treatment, easily elude observation.

When the cells at the growing points develop into the leaves and into parts of the flower, changes take place in these granules, or plastids, as they are called. Some remain with hardly any change in the cells where starch and other substances are to be stored, and here they take on the work of gathering up the provision for future use. Others become the leaf-green granules, and have for their office the manufacture of food, while still others and their products are made to play the chief part in coloring our fruits and flowers. As we have seen that from modifications of the simple cell all the different parts of the plant are derived, so from modifications of the simplest plastids at the points where the cells arise, are formed the other plastids, or granules, in which the myriad activities of the plant are manifested.

There is still one other body to be referred to as existing in the protoplasm of the cell, namely, the nucleus, a somewhat denser part, which passes through a succession of remarkable changes when new cells are produced. The consideration of these changes must be deferred until, after having examined the roots, stems and leaves of the plant, we can properly approach the subject of growth. Our first work is to apply these general statements regarding the cell to an examination of the organs which the cells compose.

Cambridge, Mass.

George Lincoln Goodale.

The Forest.

The *Catalpa speciosa* for Timber Planting.

I READ with interest the address of Mr. Burnet Landreth, in GARDEN AND FOREST (December 12th, vol. i., p. 500), on "Forest Planting in Virginia," although to one about to start a young forest Mr. Landreth's experience would not be very encouraging. Forest planting, however, can be made a success if the right trees are planted and proper care given for only a few years. An improper selection of trees is the cause of most failures. Why should so many trees be recommended, when a very few would answer every purpose? For a timber tree in the central part of the United States (including the great corn-producing States, Ohio, Indiana, Illinois, Iowa, Missouri, Kansas and Nebraska), no other tree is equal to *Catalpa speciosa*. It is very easy to grow from seed, transplants from nursery to field better than any other, and, after a plantation is once set, it is as easily cared for as so much corn. In three years from planting the trees will almost completely shade the ground, keep out weeds and retain moisture, and then cultivating can be dispensed with.

These trees should always be planted four feet by four, and at from nine to fifteen years the trees can be thinned so as to stand eight feet apart each way. If planted closely they will trim themselves, and, in time, grow into tall, straight trees. But while close planting helps the young trees, thinning should not be delayed too long or the entire grove will suffer. The value of the tree for posts alone makes it the very best kind to plant for profit, as it only takes a few years to grow one large enough for fence posts, while many other forest trees—notably Black Walnut, Red Cedar and White Pine—are worth very little while young. In the prairie region of Kansas and Nebraska the demand for posts is very great, the prices are good and likely to improve. What the forest tree planter wants is a tree that will grow into usefulness in a dozen years. To plant trees that will take forty or fifty years to have a market value, requires too much trust in the future. White Ash would be the best tree in many places, for it can be used even earlier than the *Catalpa*.

Desiring to ascertain, for my own information, what tree would best endure dry, hot weather, I examined many groves during the dry period of July, 1886. I visited the Farlington forests, located in Crawford County, Kansas, and composed mostly of *Catalpa speciosa*. They are from five to eight years planted. Small bodies of *Ailanthus*, *Osage Orange*, *White Ash* and *Black Walnut* were scattered among them. These forests cover a section of prairie (640 acres) located in an exposed and treeless region, having, at the time, no protection from the prevailing strong winds.

This immense body of trees having passed through a long period of intense heat, without rain, was healthy and vigorous, and had made an annual wood growth that was surprising. Among the trees the ground was in fine condition, with plenty of moisture, and that, too, when the thermometer stood at 104° in the shade.

They had not been cultivated for some years, but their

foliage had formed a complete shade to the land, stopping the growth of weeds and grass and restraining evaporation from the soil.

The *Ailanthus* showed no signs of dry weather. *Black Walnut* and *Osage Orange* looked very well, but were making a very slow growth. *White Ash* was making feeble growth, and showed the injurious effects of the intense heat.

The *Catalpa*-trees at Fort Scott, Topeka, and in a grove in Morris County, Kansas, were also examined, and in each case were found doing better than any other tree.

Observations during the last two years have confirmed the belief that under our trying prairie climate this tree has no rival for forest planting. The wood is beautiful, and takes a fine polish; for durability in posts and fencing material it is only equaled by the *Red Cedar* and *Black Locust*.

So far as I can see, there is little danger of failure with the *Catalpa* here. Close planting seems to be the one thing needed, so that the ground may receive as soon as possible that shading which is always afforded by natural forest-growth.

Topeka, Kansas.

G. W. Fincher.

[As our correspondent insists, the first and most essential step in tree-planting is the selection of trees suited to the climate and the soil of the locality in which the plantations are to be made. The importance of knowledge of the requirements of trees, and the unsatisfactory results which must follow the planting of trees where their nature and wants are not understood, are made apparent by the result of the tree-planting experiments recently described in this journal.

A little knowledge, the result of the most casual observation, would have shown the men who competed in Massachusetts for the prizes offered by the Trustees of the Agricultural Society of that state, that they could not hope to induce the *White Ash* to grow to any size or value upon thin, gravelly, worn-out drift, upon which they would not have found an *Ash-tree* of any size growing naturally.

Mr. Landreth's experiments in tree-planting in eastern Virginia (see vol. 1, p. 500) show too, that observation of natural conditions may save useless expenditures of time, energy and money. The soil with which he had to deal was never very strong, and it had been practically exhausted by long years of cultivation upon the wasteful principles which have ruined much of the soil of the south Atlantic sea-board States. Upon this soil, when fire is kept away, the *Loblolly*, or *Old Field Pine* (*Pinus Tæda*), springs up in the greatest profusion, and, during many years, grows with great rapidity. But the presence of this tree shows that the land is of poor quality, and that it has been so impoverished that other trees cannot grow vigorously in these old fields with the *Pines*. A knowledge of the *Loblolly Pine* and its habits might have saved all the cost and trouble of these plantations, which lead only to the inevitable conclusion, that the best tree for any particular climate or soil or location is the one which is growing naturally and flourishing in that climate and location and upon that soil; and that in eastern North America the planting of trees in forests is not so much needed as the care of the trees which spring up freely in all situations and upon all soils.

The absence of trees, due to causes not entirely climatic, from the region extending along the eastern border of the dry and treeless central plateau of the continent, made experiments in tree-planting in this part of the country necessary in order to establish the fact that trees could be grown there successfully on a large scale, and to determine the varieties of trees best suited to flourish under conditions in which the controlling features were dry and hot summers, cold winters, fierce winds at all seasons of the year, and deep and very rich soil.

The large plantations at Farlington, in eastern Kansas, described by our correspondent, were made for the special object of determining what trees would thrive under these peculiar conditions; and while sufficient time has not yet passed since the trees were planted to make the result conclusive in any way, it is evident that the *Western Catalpa* is the most promising tree which has yet been tried to any extent on the western prairies. It is not wise,

however, to decide hastily in regard to the value of any tree for planting under conditions quite dissimilar to those in which it grows naturally.

The Western Catalpa is confined to a comparatively small area, of which the junction of the Ohio and Mississippi Rivers may be taken as the centre; it grows only in deep, river-bottom lands, which are often submerged for weeks together; and while it flourishes while young, growing with remarkable rapidity when planted under conditions entirely dissimilar to those under which this species has been produced, it has not been tested yet long enough in cultivation to enable any one to speak with entire positiveness of its adaptability to prairie-planting. The fact that it becomes valuable for many purposes in comparatively few years, is a great point in its favor, as many trees, placed in the midst of abnormal surroundings, thrive for many years and do not display their inability to adapt themselves to new conditions until they begin to approach maturity.—Ed.]

Correspondence.

To the Editor of GARDEN AND FOREST:

Sir.—In one of your recent numbers you spoke of experiments in the use of elastic cement for filling decayed places in the trunks and limbs of trees, resulting from neglected amputations. Can you refer me to any parties for particulars and for the purchase of the proper article? I have heard of introducing cotton-batting, steeped in turpentine, and then closing over tight.

It seems as if this subject of tree-doctoring is of sufficient importance to justify a hope of some attention in your columns, for general use.

New York.

G. M. Weld.

[We have had no experience in the use of elastic cement for filling the cavities in the trunks and branches of trees. The method recommended for the treatment of trees in this condition is as follows: The edge of the cavity should be cut away smooth and even, and all decomposed matter or growth of new bark formed in the interior should be removed. A coating of coal-tar should then be applied to the surface of the cavity, and the mouth protected with a piece of well-seasoned oak securely driven into it. The end of this plug should be cut even with the surface of the trunk or limb, made perfectly smooth, and then coated with coal-tar. If the cavity is too large to be closed in this manner, a piece of seasoned oak-board should be fitted and securely nailed into it, and then covered with coal-tar. A new growth of bark will gradually extend over the board and so effectually cover the cavity.—Ed.]

About Kniphofias.

To the Editor of GARDEN AND FOREST:

Sir.—In the article by Mr. T. D. Hatfield concerning these plants I observe a few slight errors, arising, probably, from want of true material, which I hope he will kindly permit me to amend.

The name of *K. carnosa* has been given by erroneous distinction and bad handwriting; the plant certainly is but *K. Leichtlinii*. *K. media*, of Gawler, identical with *K. sarmentosa*, Kunth, is a very distinct plant, and differs in many points from *K. aloides*, Moench. The former has broader and shorter leaves, which are glaucous. It has a longer flower-stem, and the flower-spike has a different form from that of *K. aloides*; while the flowers of *K. aloides* are fiery red to yellow, those of *K. media* are somewhat rainbow-colored, at first greenish-brown, then changing to blood-red, and finally turning to a sulphury yellow, the whole spike shaded off by a thick glaucous bloom, which causes the colors to appear very dull. *K. nobilis* and *K. Saundersi* are very distinct plants, and far superior to *K. grandis* or *K. grandiflora*. *K. nobilis*, which may be considered a giant variety of *K. aloides*, was discovered by Mr. Parker in a small garden near London, and *K. Saundersi* I found in the garden of Mr. W. Wilson Saunders, at Worthing, probably a remnant of Mr. Cooper's introductions from Caffraria. I am inclined to take *K. Saundersi* as a species. The two plants look very much alike, except in the flowers; the foliage looks coarse and ro-

bust, that of *K. Saundersi* being a little narrower and deeper green; the stems reach up to five feet; the spikes of *K. nobilis* are of an ovoid shape, being thickest in the middle; its color is a fiery scarlet turning to deep bright yellow, and its size is eight inches long by more than four inches wide. The spikes of *K. Saundersi* are cylindrical, scarlet, with a brick-red shade turning yellowish. The spike is thirteen inches long and three and a half inches in diameter. This is by far the noblest of the whole genus. I have of late raised some most beautiful hybrids and varieties; a blood red and a golden yellow variety of *K. Leichtlinii*, and among the hybrids some bright canary-yellow ones, and others with anthers far protruding, looking just like a brush. The small-flowered *K. albi-flora*, introduced by myself from Madagascar, is pretty, but of botanical interest mainly. *K. Natalensis*, which flowered here for the first time in Europe, is not very showy, yet highly interesting; the spikes being over two feet long, loosely beset with narrow flowers of a foxy brown color.

Baden-Baden, December, 1888.

Max Leichtlin.

Periodical Literature.

The December number of the *Bulletin of Miscellaneous Information*, issued by the Royal Gardens at Kew, completes the second volume of this useful publication, from which we have more than once had occasion to make copious extracts. The present number contains articles on *Inhambane Copal* (*Copaifera Gorskiana*), a new tropical-African product, from which it appears that "the term copal is commercially applied to various hard gum-resins yielded by certain tropical and sub-tropical trees. In the majority of cases copal is obtained in a semi-fossil state on land where no trees at present are found, but where at one time large forests existed. In other cases, what may be termed recent copal is a gum-resin in a comparatively fresh state, collected from living trees or from trees in a state of decay.

There is also an exhaustive report upon the cultivation of Rice in Bengal, which should be reprinted for the benefit of the rice-planters of the Southern States.

The Silkworm Thorn of China (*Cadrania triloba*), which has been successfully introduced into the Royal Gardens, is described. There are notes upon a new rubber-producing plant of Jamaica (*Forsteronia floribunda*), and upon some supposed seedlings of the Sugar-cane which have been detected at Barbadoes, and which are of special interest, as the following extracts will show:

"The Sugar-cane is one of the most valuable economic plants we possess. It has been cultivated for so long a period that the primitive habitat of the species, according to De Candolle, is unknown. Bentham, in the "Flora of Hong Kong," page 420, states that 'We have no authentic record of any really wild station of the common Sugar-cane.' Further than this, in common with many plants that have been for a long time under cultivation, and reproduced solely by means of buds and suckers, the Sugar-cane so rarely produces mature fruits that no one, as far as we are aware, has ever seen them. Certainly in the rich Herbarium at Kew there are no seed-bearing specimens. In botanical works the subject is often referred to, but apparently only to restate the fact that botanists like McFadyen, in the West Indies, and Roxburgh, in India, 'have never seen the seeds of the Sugar-cane.'

"Schacht is one of the few persons who has given a good analysis of the flower of the Sugar-cane, including the pistil; he also had not seen the ripe seed.

"In discussing the problem how far the saccharine qualities of Sugar-cane could be improved on the same lines as those so successfully adopted with regard to the Beet, it was lately pointed out in a letter addressed to the Colonial Office that, owing to the power of producing fertile seeds having apparently been lost in the Sugar-cane, it was impracticable to deal with it by means of cross-fertilization or by the ordinary course of seminal selection. It was further pointed out that new and improved varieties amongst Sugar-canes were to be looked for amongst bud variations, and planters were advised to mark any canes that showed a departure from the type and cultivate them separately for experimental purposes, with a view to test their yield in sugar.

"Recently, however, a statement has reached Kew from a trustworthy source that seedling Sugar-canes have been found at Barbadoes, and that the plants were in course of being raised at the Botanical Station in that island, under the care of Mr. Harrison and Mr. Bovell.

"The statement sent by Professor Harrison appears to prove, in a perfectly natural and circumstantial manner, that a few mature seeds may occasionally be produced by the

Sugar-cane under certain circumstances. It is stated by Rumphius that the Sugar-cane 'never produces flowers or fruit unless it has remained several years in a stony place.' He does not, however, say whether he ever saw the fruit, nor does he cite any proof of the fact in the shape of seedlings, self-sown or otherwise. The canes that would be likely to produce fruit would be those varieties nearest the original wild cane, and probably on that account they would be less rich in sugar than the canes improved by a long course of cultivation.

"Without expressing a decided opinion on the subject, and in the absence of the specimens themselves, the information supplied by Professor Harrison is, so far, the most tangible of any yet received to show that the cultivated Sugar-cane may occasionally produce mature fruits."

The December number of the *English Illustrated Magazine* contains a charming article by Mr. Grant Allen on "Surrey Farmhouses." Many Americans know the beautiful village of Dorking, not far from London, and those who are familiar with that delightful book, Cobbett's "Rural Rides," have some idea of the surrounding country. But even among Londoners there are few who have realized its loveliness for themselves or seen its richness in examples of domestic architecture. It is one of the most primitive districts in all England, despite its proximity to the capital; for its heavy clay soil has prevented agricultural advance. But in the sixteenth century it had what Mr. Allen calls a temporary "boom" from the discovery of iron-ore in its hillsides, and the consequent enrichment of many families has left its trace in beautiful manor houses, while nowhere have so many old farmhouses escaped the hand of modern progress. The "Weald of Surrey," as it is called, once formed part of the famous "Andreaswald"—the impenetrable forest which withstood the feet of the advancing Saxons and furnished a refuge for the Britons whom they displaced; and in the aspect of its present population Mr. Allen thinks he can read patent signs of Celtic descent. "The great characteristics of the Surrey village," he writes, "are green and common. No county in England, perhaps, except Yorkshire, Devonshire and the Cumbrian shires, has so large a proportion of its area still unclosed. As late as Queen Anne's day Holmwood was a deer-forest, and . . . for miles even now one may traverse the open heather and bracken along the sandstone hills; while on the plain itself the amount of open common always surprises the stranger in a Surrey district. The fact is, till very recently, land in Surrey had but a ridiculously small value. The county remained very sparsely inhabited, and the area for the most part was unfit for tillage. Hence every hamlet had its corner of green, and it is the existence of these universal cricket-fields at their very doors, with the consequent practice from early childhood, that has made the Surrey men the champions of England." But, interesting as is Mr. Allen's text, we desire especially to call our readers' attention to the numerous pictures which accompany it. Perhaps they do not deserve, from the point of view of artistic execution, the very enthusiastic praise which the author gives them; but they show, at all events, an exceptional feeling for the most picturesque points of view and much skill in the rendering of tree forms; and the subjects themselves are so charming, that we should be glad to see them even though the pictures had much less artistic merit than they possess. Most of the houses are of half-timbered construction, with beautiful tall polygonal chimneys and many gables; and helpful lessons for our own practice may be gained from them, as they show how a diversified ground-plan need not give a disjointed, heterogeneous look to a house, and how broken roofs and conspicuous gables of different sizes may be brought into a result of the greatest harmony and charm. Only, in studying such houses as these, it must not be forgotten that time has added vastly to their picturesqueness. If one of these gabled houses were to be copied exactly, it would by no means have exactly the same effect—great softness and grace having often been given by such practically unfortunate facts as a sagging of the roof-ridge and a slight inclination in the walls. Nor could one immediately imitate the charming effects produced by the trees and shrubs that grow so harmoniously up to the very base-course, and by the mellowing mosses, grasses and flowers that, in the damp English climate, have seized upon every smallest foothold in brick or stone. Nevertheless there is much to be learned from these pictures, as well as much to be enjoyed by the mere casual observer.

Mr. Arthur Hollick contributes to the December number of the *Bulletin of the Torrey Botanical Club* an interesting account

of a group of remarkable Oaks recently detected near Tottenville, on Staten Island, and containing plants of a supposed hybrid between *Quercus Phellos* and *Q. nigra*, which has been described by Dr. Britton as *Quercus Rudkini*, and of *Quercus heterophylla*, the Bartram Oak, the range of which is now extended considerably further north than it has been known before. This is the plant which has, for a century almost, been the subject of active discussion on the part of various botanists who have studied our Oaks. It has been considered a species by some, and by others a hybrid between *Q. Phellos* and one of the other Black Oaks—*Q. aquatica*, *Q. imbricaria*, *Q. falcata*, *Q. coccinea*, *Q. tinctoria* and *Q. palustris*, all being made to serve in turn as the other parent. Mr. Hollick agrees with those botanists who believe that *Q. heterophylla* is a hybrid derived from *Q. Phellos*, but he discards all the species which have been named as the other parent, and suggests that it is *Q. rubra*, arguing that the shallow cup of the supposed hybrid attaches it to that species, which, moreover, he believes is the only Black Oak constantly found growing in the neighborhood of *Q. Phellos* in the region occupied by *Q. heterophylla*.

Every additional station of *Q. heterophylla* which is found—and it is now known in many places between Staten Island and Newcastle County, in Delaware, besides having been collected in North Carolina by Curtis (*vide* Herb. Canby), and by Hall in Texas—would seem to confirm the ideas of those botanists who have considered it a species of recent hybrid origin, perhaps, but now fixed in its characters to the degree of being able to reproduce itself exactly from seed. The important thing, however, is that the tree exists, and that there is no confusion in regard to its name, which is not obscured under a mass of useless and annoying synonyms. Its origin and parentage cannot be accurately determined, and must always, of necessity, remain a matter of personal opinion.

Recent Plant Portraits.

PITTOSPORUM PHILLYROIDES, *Bulletino de la R. Soc. Toscana de Orticultura*, November.

Botanical Magazine, December:

BEGONIA SCHARFFEL, *t.* 7028; a native of the Peninsula of Desierto, in southern Brazil; and described by Sir Joseph Hooker as "one of the most magnificent species of the whole genus."

IRIS SUWAROWI, *t.* 7029; another distinct Iris recently discovered in central Asia by Dr. Albert Regel.

PENTAPERA SICULA, *t.* 7030; a low, much-branched, Heath-like shrub; a native of Sicily, Cyprus and Barca, and the only representative of a genus distinguished from the true Heaths by its pentamerous flowers (which Sir Joseph Hooker points out is not a constant character), by its large sepals and pubescent ovary. The flowers are larger than those of the other European Heaths, and are pure white.

HEXISIA BIDENTATA, *t.* 7031; a small Central American Orchid, with scarlet flowers, which possess a botanical rather than a horticultural interest.

PRIMULA RUSBYI, *t.* 7032; a native of the mountains of southern New Mexico and Arizona, already described in the columns of GARDEN AND FOREST, p. 320.

ARUNDINA BAMBUSÆFOLIA, *Gardeners' Chronicle*, December 1st.

DISA LACERA, var. MULTIFIDA, *Gardeners' Chronicle*, December 8th.

DISA GRANDIFLORA, *Gardeners' Chronicle*, December 8th.

NEPENTHES RUFESCENS, *Gardeners' Chronicle*, December 8th; "this is stated to be a cross between *N. Courtii* × and *N. Zeylanica rubra*. *N. Courtii* is itself a cross between an unnamed Bornean species and *N. Dominiana* ×, this latter being a cross between *N. Rafflesiana* and the same undetermined Bornean species."

PHILLYREA DECORA, *Gardeners' Chronicle*, December; this is the *Phillyrea Vilmoriniana* of many gardens; a native of the shores of the Black Sea, and a member of the Olive family. It is a strikingly handsome shrub, with bright green, coriaceous leaves and axillary clusters of white flowers, which are followed in the autumn by olive-shaped, reddish-purple fruit. It is specially recommended for planting in cities, as smoke and dust does not affect it seriously. Its hardiness in this country, however, has not been established yet.

KALMIA LATIFOLIA PAVARTI, *Revue Horticole*, December 1st; a handsome variety of the common American Laurel, with high-colored, almost red, flowers, obtained in the garden of the Trianon by Monsieur Pavart.

QUERCUS RUBRA, *Bulletin Torrey Botanical Club*, *t.* 83, December.

QUERCUS PHELLOS, *Bulletin Torrey Botanical Club*, *t.* 83, December.

Notes.

Dr. Regel, in a private note, calls attention to the interesting fact that *Picea pungens*, the so-called Colorado or Blue Spruce of the Central Rocky Mountains, is by far the hardiest and most desirable of all the Spruces in the very severe and trying climate of St. Petersburg.

Among flowers forced for the holiday trade in this city were both white and red varieties of the Japan Quince. The white was especially admired, making a satisfactory substitute for Orange blossoms. These plants flower under glass as readily as Lilacs. They are grown in pots for a year before being forced, to encourage an abundant growth of roots.

Professor B. D. Halsted, of the Agricultural College of Iowa, will remove next month to New Brunswick, New Jersey, to accept the Chair of Botany in Rutgers College, and to assume charge of the Horticultural Department of the Agricultural Experiment Station. Professor Halsted will continue his special study of American weeds, and will be glad to receive reports in regard to plant pests from any part of the continent.

The value of the so-called Japanese Ivy (*Ampelopsis Veitchii*) for use along railroads is rapidly being recognized. Its compact, clinging habit serves to bind together loose stones and shaly surfaces, thus protecting the sides of embankments and cuttings, and in consequence the track itself, while delighting, in summer, the eyes of the weary traveler. Thousands of plants are already sold each year to railroad companies.

During the past season Mr. A. A. Crozier cross-fertilized a large number of the blossoms of different kinds of Apples, Pears, Plums, Grapes and Squashes, with a view to ascertain whether any effect from the cross appears in the fruit of the first year. An account of the results of these tests is given in full in the December number of *Agricultural Science*, and in no case could the influence of the variety furnishing the pollen be detected in the fruit.

The cultivation of flowers for the manufacture of perfumes has been begun in this country with seemingly good results. A company already exists in Florida which has planted for this purpose 200 acres in Tuberose, while a correspondent of *The American Garden* writes from South Carolina that the preparation of pomades is easily practiced by individuals, and that she is herself engaged in it, having planted this fall 150,000 Tuberose (which require three acres of ground) and about double the quantity of Jonquils, and having engaged 10,000 roots of Violets for spring planting.

The teak baskets which are commonly used in England for growing epiphytal Orchids are made of wood obtained from broken-up ships in the London docks. The wood is supplied in square rods about as long as ordinary builders' laths, though, of course, a good deal thicker. The edges of the rods are rounded off, and then they are cut into the required lengths and pierced at each end with holes, through which copper wires are inserted to bind them together. Such baskets are said to last from ten to twelve years if thoroughly cleansed whenever a plant is removed from them. They are furnished in every size from three inches to a yard square.

Among the newer and more promising varieties of Grapes is a very early, greenish-white one, first brought to notice by Mr. James M. Paul, of North Adams, Massachusetts, who found it growing wild in the Green Mountains, after which it has been named. Mr. E. S. Goff, who has fruited this Grape for the past two seasons, writes in *Popular Gardening* that it ripens about with Champion, while in quality it ranks with the best. The vine is vigorous and quite productive, bearing medium-sized, not very compact bunches, with berries a little larger than those of the Delaware. The flesh is quite free from hard pulp, and entirely without harshness or foxiness, and its flavor is very sweet, with a slight inclination toward the vinous. The Green Mountain is the only Grape so far tested at the New York Experiment Station which is at once very early and of the best quality.

The meeting of the Illinois State Agricultural Society held last week proved unusually profitable and pleasant. The managers made a special effort to secure a fine display of fruit, and especially of new varieties from all parts of the state, and so many liberal premiums were offered, that all exhibitors of fine specimens were sure of gaining something to help pay expenses. These facts were well advertised through the press and by private letters, and as a result, the attendance was very large, even the remote parts of the state being well represented. One session of the meeting was conducted entirely by the young people, who read carefully prepared papers and discussed the subjects presented with such intelli-

gence, that the session was pronounced the most interesting of the entire series. It is probable that other states will follow the example of Illinois in this particular, as it promises to encourage the study and practice of certain branches of horticulture among the boys and girls from the farms, as well as those in towns and cities.

We have already referred to Dr. Ernst's first article, published in the *Gartenflora*, on "Horticulture in Caracas." It has been followed by a second chapter that contains much interesting information with regard to the plants which flourish in the Venezuelan climate, and those which, upon trial, have been found ill suited to it. The cultivation of useful plants, he tells us, has lagged so far behind that of flowering and ornamental plants, that it is no exaggeration to say, not a single new fruit or vegetable has been introduced into the country during the last fifty years. On the other hand, the prices paid for flowers are enormous, running so high in the case of native Orchids, that their re-importation from England may prove profitable. A specimen of *Cattleya Wagneriana*, with twelve leaves and eight blossoms, had recently been offered to the author for \$45, and he attributes such demands to the fact, that collectors for English firms have given such enormous sums for white-flowering Cattleyas, that the natives in consequence have "lost their heads" to a degree which can only be cured by a persistent abstinence from purchase on the part of local customers. That they have by no means lost their cunning, is shown by the statement that they treat the common *Cattleya Mossiae* with sulphur fumes so as to make it look like *C. Reineckiana*, bring the plants bearing these blanched blossoms to unsuspecting amateurs in twilight hours, and often receive large prices for them.

Professor L. H. Bailey recently contributed to *The American Garden* some "Rural Notes from Scandinavia," from which we extract the following passages: "In ornamental gardening the traveler finds much to admire, particularly in Sweden. There is not that richness of finish and variety of plants which one sees in England, but there is usually a most excellent and tasteful use of materials. The Slots Park, at Christiania, is an admirable example of the adaptation of common plants to ornamental gardening of a high character. The greater part of the plantings are Birches and Elms, trees which everywhere clothe the adjacent hill-sides. Perhaps the very contrast of this simple park with the ornate and burdened ones of England and other parts of Europe may heighten its charms in the mind of the traveler. Yet one must feel that the absence of effort and artifice and the repose which comes from the very simplicity of its design and details gives this park an intrinsic merit. Parks are usually burdened with accessories, mere display, a feature of gardening—if gardening it can be called—which is supported and often demanded by the popular desire for show and curiosities. One extreme in this direction now holds rule in America—the craze for carpet-bedding, which is so generally and so unfortunately denominated landscape-gardening! It is said that American carpet-bedding 'beats the world,' and my own observation thus far sustains the boast, much to the credit of other countries."

At the International Exposition held at Barcelona during the past season, the Department of Forestry was a conspicuous feature. It embraced general forest maps of Spain and more detailed maps of the different provinces; maps showing the distribution of the most important trees, such as the Aleppo Pine, the Beech, Cork Oak, etc.; a herbarium of the plants of the forest; relief plans of the Mountain of Covadonga, and of the Dunes of Cadiz, with their artificial plantations, plans for forest cottages for workmen and forest guardians. One of the most interesting things in the exhibition was a scheme for the establishment of a telegraph system to announce fires in the forest. A detailed forest map of the Philippine Islands was contributed from the Bureau of the Minister of Foreign Affairs. The second section of the exhibition contained a large collection of forest products, such as woods, resins, barks, various textile products, specimens of charcoal and seeds of trees. In this collection there is also a very large collection of woods and other industrial and economic products of the Philippines. All the instruments used in the Spanish Forest Department were displayed, while upon a lawn near the exhibition building, a miniature mountain was created, upon which were shown, of the size of life, the different methods used for transporting wood from mountain forests, such as slides, narrow gauge railroads, and the like. A collection of insects, wild animals and fish collected in the Spanish forests, made another group of this exhibition, which was probably the most complete and interesting seen in Europe for many years.

Schools of Horticulture.

A CORRESPONDENT describes upon another page the organization of the National School of Horticulture of France, one of the most successful in Europe for the purpose for which it was established—the training of practical, working gardeners. The theory of the school is, that instruction in horticulture, if it is to be of any value, must be both practical and scientific. The courses of instruction, therefore, extend over a period sufficiently long to permit the students to acquire, by actual practice, under experienced cultivators, the skill which will enable them to perform all the operations of the garden in its various departments, and to learn, from lectures and by study, something of the sciences upon which the art of horticulture rests. All the operations of the establishment, which is a large one and admirably kept, are performed by the students; and, although it is not self-supporting, the sales of produce of various kinds are sufficient to pay a considerable part of the expenses, including the salaries of several instructors. The institution is an excellent example, certainly, of what a large School of Horticulture can be made.

A number of Schools of Horticulture were established in this country several years ago, and some of them are still in operation. They have all been connected, more or less intimately, with agricultural colleges; for, with the exception of a school for women which existed for a short time in Newton, Massachusetts, a few years ago, there has been no institution in this country devoted solely to horticultural instruction. These schools have, in some instances, done admirable work as horticultural experiment-stations, and the country is indebted to them, in their capacity as such, for much valuable information. Many of them now provide an excellent course of botanical study and offer instruction in some branches of practical horticulture. It will not, however, be maintained by the best friends of these schools, that a well equipped gardener was ever graduated from any one of them.

The causes of the failure of these schools are deep seated. They spring, in part, from the want of appreciation of the requirement of a sound horticultural education

on the part of their founders, and in part from the prevailing tendency of the American people to be satisfied with a hasty and insufficient training for any vocation in life. A young man who devotes an hour or two a week during the thirty or forty weeks of a school course, even if his studies are carried into the second year, may find a certain amount of satisfaction in thus playing at horticulture, but he will gain little that will be of any practical value to him in earning his living as a gardener. And yet, to create gardeners of broader intelligence and greater skill than can be gained from the rule-of-thumb system of the old apprentice days, is the only legitimate purpose for which such schools can be established merely as schools.

But the directors of our Schools of Horticulture are not altogether responsible for the existing state of affairs. Americans are in too great a hurry to learn anything thoroughly. The lad who has passed a few months in some successful florist's green-house, or in the garden of some private establishment of good reputation, is generally pretty sure, in this country, to obtain a responsible situation in which he is practically his own master, and where he gets as high wages as if he had devoted a number of years to learning his profession. It is not surprising, therefore, that Schools of Horticulture are not supported in this country, and that the number of ignorant and half-trained gardeners is far in excess of those who really understand their business. The best gardeners in America, with a few exceptions, are foreign born, and got their early training before they came to this country. Really good gardeners are rare, of course, in every country, for the combination of knowledge with the qualities that make a great gardener is seldom found. They are more rare here, however, than they are in Europe, because absence of competition permits very inferior men to aspire to important positions; and we must continue to depend, as a rule, upon foreign nations for gardeners, until the struggle for existence here is so sharp that only men thoroughly trained in their profession can hope to live by it, or until a more general knowledge of gardening and its possibilities among the class who employ labor makes it impossible for ignorant men to obtain positions requiring such a high order of intelligence, industry and zeal. Such a change will come to pass, perhaps, in the United States, sooner or later; but in the meantime our Schools of Horticulture can wisely give up trying to teach young men who do not want to be taught, and devote their energies to those wider fields of usefulness which, fortunately, are open to them, and by experiments, and in many other ways, at least help to create the demand for skilled gardeners which they were founded to supply.

There is no better season of the year than winter to study trees with reference to their surroundings, or to determine the amount of the damage inflicted by one tree upon another when they are brought together too closely in ornamental plantations. If there is any one in this city interested in trees in their ornamental aspects, he cannot devote a few hours of one of these days of early winter, before the snow makes walking uncomfortable, to a better purpose than a stroll through Central Park. The overcrowding and the poor condition of many of the trees there is more apparent now than at any other season of the year, and tree-lovers will be able to see for themselves that many trees should be removed at once if there are to be any fine ones left in the Park at the end of another quarter of a century. Large and healthy trees are crowded in all parts of the Park by smaller and less valuable ones. There can be but one ending to the struggle between a strong and a weak tree; but the process of destruction is slow, and the victorious giant too often carries through life the marks of the contest. Man can aid nature wonderfully by the judicious use of the axe, and there is hardly an acre of the Park plantations which has not suffered, and is not now suffering, from ill-judged caution in cutting. The sickly and often half dead Norway

Spruces and foreign Pines look even more wretched and unhappy in winter than they do when the leaves cover the branches of neighboring trees. Still they are allowed to disfigure the Park year after year—while they are dying slowly—and what is a great deal more serious, they are allowed to inflict great and ever-increasing injury upon valuable trees which are unfortunate enough to stand near them. The interesting and unique Japanese Elm, near the Seventy-second Street entrance to the Park from Fifth Avenue, to which we have more than once called the attention of the lovers of rare and handsome trees, is still crowded and injured by neighbors of no value or beauty—a piece of neglect on the part of the Park authorities which is inexcusable, and should cause the indignation of all persons who can appreciate the beauty and value of this remarkable tree.

A Japanese Stable.

A FEW weeks ago we illustrated the approach to the famous memorial temples at Nikko, in Japan. On page 31 we now reproduce a photograph of one of the minor buildings within the wide temple enclosure. It is neither a temple nor a dwelling, but a stable, yet—as we might divine from its ornamentation, which is much richer than that of the habitations of Japanese humanity—not a stable destined for an ordinary steed. It houses one of the sacred ponies—albino animals with pink eyes—which are frequently found within the precincts of large temples. These ponies live on the charity of visitors to the temple, who are in the habit of piously investing a few coppers in peas or grain for their sustenance.

Despite the peculiar service to which it is put, this building is not only charming to look at, but suggestive of schemes which might serve an American architect for work of another kind. The strong yet graceful sweeping roof is, of course, its chief claim to admiration; and although such a roof is used in Japan upon sacred or semi-sacred edifices only, this canon need not bind foreigners who find it beautiful. Modified to suit our methods of construction, yet not deprived of its essential character, it might well be used to cover some minor building in the neighborhood of an American country home—a lodge or tool-house, a summer-house or well. Nor is the construction and ornamentation of the walls devoid of interest for a people like ourselves, who are often at one with the Japanese in using wood without an admixture of more monumental materials, but who have much to learn in the way of using it in fashions at once simple and strong. Rich color, of course, adds much to the effect of such Japanese buildings—so much, that their beauty, displayed, as it is, against a background of deep green foliage, cannot be at all appreciated from a black-and-white print. The flagged path in front of the stable is a good example of Japanese workmanship in another and likewise interesting direction.

Boundary Walls and Entrances for Prospect Park.

IT was decided some time ago by the Brooklyn Park Commissioners to surround a great part of Prospect Park with a substantial stone wall in place of the rough wooden paling which has stood there so long, and to furnish the chief approaches with entrances of corresponding dignity. Some of the designs for this work have now been prepared and approved, and their execution will soon be begun. An inspection of these designs shows that the park and the city will be vastly improved by the constructions which they portray.

The wall is to be low but massive, carefully profiled, and constructed of Milford granite, the soft pinkish tone of which, mottled with black, is well adapted for association with masses of verdure. At the approach facing Coney Island Avenue the wall ends at points considerably removed from one another and the entrance for carriages is set somewhat far back from its line. Each side of this entrance—which is to have no gates—is flanked by a large but not lofty rectangular pier bearing a sculptured group. From these piers long stone seats with low but massive backs curve outward toward the ends of the wall;

and at the points of junction stand large rectangular pavilions, open except for a colonnade formed by square angle-piers with two intermediate columns on each side and covered with red-tiled roofs. Each long curved bench is broken midway of its length to admit of the passage of persons on foot, and behind each (within the park) stand two graceful, tall columns, bearing the national eagle. The design is classic in character, simple in its elements, but scholarly and beautiful, and exquisitely treated as regards matters of detail. The combination of the massive central piers with their groups of sculpture, the long, curving benches, the colonnaded shelters, and the tall, isolated shafts, forms a composition of the most dignified simplicity and harmonious variety. It is a great pity that in accepting this design the Commissioners should have thought best to mutilate it by the omission of the four isolated shafts. Not only are they beautiful in themselves, but their slender, aspiring lines are needed to relieve and dignify the low horizontal lines that elsewhere prevail. Without them the park will still have a good and tasteful entrance, but with them it would have an architectural adornment of the highest monumental beauty.

The design for the Willink entrance shows again no gate, but two massive round low piers, with conical roofs covered with the scale-like stone tiling familiar to all students of classic art. From the apex of these roofs rise rich finials of wrought-iron, and between them springs a lofty elaborate arch of the same material, from which depends a lantern. Long stone seats flank this entrance also, divided as before for the passage of pedestrians; but in place of the colonnaded shelters, we have here two small circular entry-boxes, with conical red-tiled roofs. This design, it will be seen, is less ambitious than the other, but it is as good in its own way; and again one must count it a great misfortune that it must be executed in a mutilated shape—the iron-work is to be entirely omitted, though it adds immensely to the effectiveness of the composition, which without it seems almost too simple and severe. In both cases, however, these mutilations can easily be rectified at a later day, and meanwhile Brooklyn may congratulate itself upon having secured the services of genuine artists for this part of its park improvements. No competition was opened for the walls, or for these two gates, or for the still simpler one which will face Third Street and Ninth Avenue. The task was given directly to Messrs. McKim, Mead and White, of this city, and the excellence of the result secured by this simple process of selecting architects of recognized ability, may well encourage other commissioners and committees to a similar course.

It remains, however, to speak of the most important item in the scheme for improving the circuit of Prospect Park. This is the gateway for the main entrance on the Plaza, which it is proposed to make a memorial to those citizens of Brooklyn who fell in the War for the Union.

Several years ago it was proposed to build such a monument on the Plaza, and a design was selected which would have cost \$250,000, and represented a huge drum surmounted by emblematical figures. But the Legislature voted only \$100,000 for the work, the design was fortunately abandoned, and the matter was turned over to the Board of Aldermen. This Board had almost decided to erect an isolated commemorative shaft, when it was suggested that the memorial should take the shape of a triumphal arch (such as has often been used for a similar purpose abroad and in our own country at Hartford, Connecticut), and should stand, not on the Plaza, but beyond it, forming the entrance to the park. This new idea was adopted, and the control of the scheme was placed in the hands of Mayor Chapin, the City Works Commissioner, and the President of the Grand Army of the Republic. Competitive designs were solicited by them for a monument which should cost \$250,000, and these designs have recently been on view in the Brooklyn Art Rooms, on Montague Street. An inspection of them has given no such grounds for satisfaction as were felt when the drawings for the wall and the smaller entrances were studied.

Just how the competition was organized we are unable to say, but, apparently, not in the only right and proper way—as one in which all the contestants were to be paid for preparing their studies, and in which their names were to be concealed until after the committee's decision had been made. All the sets of drawings, with one exception, were signed in full; and so few of the names thus revealed were well and favorably known, that the observer was forced to believe either that no intelligent choice among American architects had been made when the circulars were sent out, or that no payment had been promised which could induce self-respecting and busy practitioners to compete. The result was what might have been

expected. A more unscholarly and inartistic collection of designs it would be impossible to imagine, or one which should be further from representing the real status of American architecture in its best developments at the present day. It is impossible here even to hint at all the vagaries, trivialities, monstrosities and veritable nightmares in the shape of triumphal arches which the collection revealed, or the manner in which Romanesque art, especially, had been maltreated and caricatured in an attempt after magnificence of general effect and symbolic significance in detail. Suffice it to say that, in the large collection there was but one really good design, and two others to which a qualified word of praise might be given. The rectangular Romanesque castle-like building which the Messrs. Parfitt Brothers, of Brooklyn, showed as their second or alternate design, had a certain dignity and grandeur, and, by contrast with its fellows, much simplicity and good sense; and with certain alterations in matters of treatment—notably as regards the four angle turrets which surmount the roof—it might be made into a fine structure. But its form is hardly appropriate for a gateway—it is a building, rather than a triumphal arch—and its style alone would render it inappropriate for the place now in view. Mr. Page Brown's classic design, on the other hand, though sensible and scholarly, lacks beauty of outline, and is too heavy and utilitarian of air.

The one design which is really excellent in itself, and really appropriate, is the single one which was sent in without a signature. It shows a deep and lofty semi-circular arch, with figures of victories in the spandrels, above which runs in large letters the simple but sufficient legend: "To the Defenders of the Union, 1861-1865." This arch is recessed between two large and solid rectangular wings, from the front of each of which projects a colonnaded portico, bearing groups of sculpture. At the level of the springing of the arch these wings are encircled by a simple but effective cornice-string, and, together with the curtain of wall above the arch, they are crowned by a true cornice, simple again, but massive, and amply sufficient to cast an effective shadow. Above this cornice is an attic, with groups of pilaster-piers and circular openings between them, crowned itself by a lighter cornice; and the whole is surmounted by a group, finely suggested in the drawing, of Victory in a chariot with plunging horses. This group is exhibited on a separate sheet, so that the effect of the arch without it may be appreciated. Even without it the effect is fine; but of course a really good sculptured group would vastly increase beauty and dignity of air. The style is classic, with Composite capitals to the portico columns. The monument, as will be seen, is very simple, yet it is not too plain, for the porticoes and the three works of sculpture would give sufficient lightness and grace, and the cornices and strings and water-tables which alone relieve the massive side walls, are charmingly profiled and adorned. On the whole, it is an excellent, scholarly and appropriate design, and the judges would commit no sin in selecting it, although their fault would be great, towards Art and towards their fellow citizens, did they even think of selecting any other among those as yet submitted. It seems strange that the necessity should not at once have been recognized of limiting the contestants to classic designs. Such designs having been chosen for the other gateways, common sense, not to speak of good taste, dictates that no Romanesque or other alien style should be chosen for the main gateway. It has not yet been announced that a decision with regard to these designs has been arrived at by the committee, so it is, perhaps, not too late to say that three courses are open to it—either to select the unsigned design just described; to put the work directly into the hands of the able architects who have undertaken the rest of the park inclosure; or to open a fresh competition, inviting a number of competent artists to take part, paying them fairly for their labor, and prescribing that only designs in a classic style shall be submitted.

The National School of Horticulture at Versailles.

THIS admirable institution for the education of practical gardeners dates from the year 1874, and is probably the best of similar schools in Europe. Its present situation is historically an interesting one and is well suited for the purpose, though perhaps the soil is rather too heavy and cold. As early as the year 1679, this piece of ground was laid out as a *potager* or kitchen-garden for Louis XIV., and for years, centuries even, it supplied the royal and imperial tables of France with vegetables, fruits and flowers.

It is entirely a free school, and the only requirements of admission necessary are, that the student on entering should be between seventeen and twenty-seven years of age, and that he should pass an easy examination in reading, writing, spell-

ing and simple arithmetic. The regular course is for three years and at the end of each year an examination is held covering the work gone over. Those students who fail to pass this examination cease to be members of the school. Those who pass a satisfactory final examination at the end of the course receive a certificate from the Minister of Agriculture.

The work of the school is divided into eleven departments: 1. The cultivation of fruit trees in the open air and under glass; 2. The cultivation of ornamental and forest trees; 3. The cultivation of vegetables in the open air and by forcing; 4. The cultivation of flowering-plants in the open air and by forcing; 5. Elementary and descriptive Botany; 6. Principles of Landscape Gardening and Garden Architecture; 7. Elements of Physics, Meteorology, Chemistry, Geology and Mineralogy as applied to Horticulture; 8. Elements of Zoology and Entomology as applied to Horticulture and Arboriculture; 9. Geometry and Arithmetic necessary for gardening purposes; 10. Linear design and the sketching of plants and implements; 11. French Language and Book-keeping.

Instruction is given by means of lectures and recitations. In addition every student is expected to actually do his share in the necessary manual labor required for the maintenance of the gardens. The time is so divided between the theoretical and practical branches of instruction, that all the students take a part in the work of the garden every day, and divided into squads of ten or more under the guidance of well-trained master gardeners, they spend at least a fortnight in each department of the garden, thus acquiring the manual dexterity which is so indispensable. In addition to the instruction given in the school, the students are taken from time to time to visit the large horticultural establishments in France in order to make them familiar with the methods employed in them.

Good permanent collections are all the time being formed, and already there is one of seeds and cones, one of wood-specimens, a large herbarium, a quantity of models of fruits, etc., a collection of animals, birds and insects harmful to vegetation, and an excellent library. There is also a living collection of trees and shrubs, but this is in rather bad condition at present owing to overcrowding on account of lack of space and consequent heavy pruning. It serves, however, to make the students familiar with the more common varieties usually found in gardens and furnishes a constant supply of herbarium specimens.

Much attention is paid here to the espalier system of growing fruit trees, now so popular in France, and this school has, without doubt, done much towards diffusing information as to this method of growing fruit in the open air.

Paris, 1888.

Foreign Correspondence.

London Letter.

AFTER a week of heavy fog the unusually mild and sunny weather has returned, which, at the beginning of December, had such an extraordinary effect on vegetation. The poisonous gases of a London fog destroy most white flowers, a foggy day leaving such flowers as those of *Phlox*, *Calanthe*, many *Begonias* and white *Chrysanthemums* withered or limp, as if they had been dipped in boiling water. The recent fog has done a great deal of mischief here, very few choice flowers of any kind remaining in London gardens.

In the markets the principal plants are the same as those we had at least five years ago:—*Epiphyllums*, *Erica hyemalis*, *E. caffra*, *E. gracilis*, Roman Hyacinths, Lily-of-the-Valley, Tulips, Marguerites, Primulas and Poinsettias. It takes a long time for a new and useful winter-flowering plant to gain favor with market-growers, so that, notwithstanding the numerous good plants of recent introduction, the market-favorites here are almost identical with those grown a generation ago. No one suspected that *Epiphyllum* would prove a good market plant, till one of the shrewdest and most enterprising of London market-growers tested it and found out its worth. The cut flowers of the season are the same as of old. We have *Gardenias*, *Eucharis*, *Tuberose*, *Stephanotis*, forced *Lilac* and a few other things of less importance. All these are abundant, and they are always in great demand. I am told that flower-growing in winter is done better in the neighborhood of New York than in England. Probably the advantage you have in drier, brighter winter-weather will account for this. Cut flowers are very abundant here this Christmas.

FREESIAS.—These beautiful cape-bulbs are amongst the very best of the newer additions to winter-flowering green-house

plants. It is only about five years since they were brought into notice, and now they are in almost every garden. But their cultivation is not yet properly understood, save by a few. They are as easily managed as Roman Hyacinths; but one point of special importance must be observed. This is, the plants ought to be kept growing all the year round, not rested, as is the usual practice. The best plants in flower now have spikes two feet high, with from four to seven branches and many large, pure white, deliciously fragrant flowers. These have not been rested since they flowered last year, but kept watered and shifted into a size larger pot in May. Bulbs which were dried off and rested dry have not produced nearly such fine spikes. It is true that at the Cape, where Freesias are native, they undergo a long period of drought and enforced rest, but nature is not always the best guide in regard to the cultivation of other plants besides Freesias. There is only one really first-rate kind, and that is the one known as *F. refracta-alba*. All the known kinds are varieties of one, or at most two, species.

LACHENALIAS.—The first species to flower here is *L. pendula*, and, taken altogether, this is the best of all. It blooms early, lasts a long time, the flowers are the largest, most numerous on the spike, and their colors are attractive. The species varies somewhat, the best form having erect spikes, fifteen inches long, with from thirty to forty flowers on a spike, each flower one and a half inches long, of good width and substance, and colored vermilion, marked and tinted with sea-green and purple. *L. quadricolor* (syn. *L. tigrina-Warei* and *L. superba*) is also in bloom. It is a variety of the old and common *L. tricolor*, which every one grows, or should grow, and of which we have several other distinct and pretty varieties. This has erect spikes nearly a foot long, with from ten to fifteen nodding flowers, each one inch long; the sepals, yellow tipped with emerald green, half as long as the petals, which are greenish-yellow, banded at the apex with brown-purple. Well grown plants of these two Lachenalias make a fresh and pretty display in December and January. The genus is limited to the Cape, where there are about thirty species. They are commonly known as Cape Hyacinths. If not already well known in American gardens, they deserve to become so. We grow large quantities of most of those above named for the conservatory in winter and early spring.

SKIMMIA FOREMANNI.—A group of small, bushy plants, grown in pots and covered with berries, was exhibited at the last meeting of the Royal Horticultural Society under this name. The berries were in large clusters, as in the Holly, about the size of small peas and shining coral-red in color. The plants were very ornamental, and exactly of that character which is certain to prove valuable for Christmas decorations. Mr. Foremann, nurseryman, of Eskbank, Dalkeith, professes to have obtained them by crossing *S. fragrans* and *S. oblata*, but they look rather like a seedling sport from the well-known *S. Japonica*, though they promise to be much more useful in the garden than even that good old plant. Mr. Foremann states that the berries remain on the plants eighteen months or two years.

CYDONIA MOERLOOSEI is a new variety of *C. Japonica* recently obtained by Messrs. Veitch, and till lately flowering in their nursery at Coombe Wood. In a mild winter it is usual for *C. Japonica* to develop a few straggling flowers; it has done so somewhat freely this month. But *C. Moerloosei* was covered with bloom and buds in mid-December, so that if the mild weather continues it will be in full bloom at Christmas. This free-flowering plant would probably be worth growing in pots for the supply of cut bloom in mid-winter. The flowers are scarlet, and larger than in the type. Apparently there is another variety, with white and carmine flowers, under the name of *C. Moerloosei*, in continental gardens.

BOUVARDIAS.—I am told that these plants are grown a great deal better in America than we can hope to grow them here, owing, no doubt, to your bright winter sun. In England no one grows them better than the Messrs. Low, of Clapton, where I saw half a dozen enormous houses full of them, all either in full bloom or in bud. The single-flowered varieties are beautiful, President Cleveland being perhaps best of all. But the doubled-flowered kinds are ugly, stiff, ungainly, bearing the stamp of monster on every petal. I believe they all originated in America. Would it be asking too much if one requested your Bouvardia raisers to burn all the double sports they get and limit their efforts to singled-flowered varieties? Many double flowers are ugly; double Bouvardias are especially so.

CHRISTMAS ROSES are in glorious perfection in sheltered borders out-of-doors here. Some of the clumps bear each fifty or more flowers, all expanded, pure white or rose-tinted, and

promising to remain in beauty for weeks if the fog will only permit them.

PLATYCLINIS.—These plants are better known by the garden name of *Dendrochilum*. Several species are flowering at Kew, the two best being *P. Cobbiana* and *P. uncatata*. I suppose these plants are well known in America, and I only notice them here for the purpose of stating a fact which may not be known to all growers, in regard to the temperature they like best. Until about three years ago we grew them in our East India house, treating them as distinctly tropical Orchids. They thrive under such treatment for a time, and then weakened, becoming spotted and sickly. On removing them to the Cattleya house they improved, and have continued to do well and flower freely every winter since.

MAXILLARIA GRANDIFLORA is the best of those species which thrive in a cool house. It is much superior to *M. venusta*, its nearest affinity, the leaves being less apt to spot and the flowers better in shape and more upright. Each flower is elevated on a peduncle six inches long and is nearly four inches across, pure white, save the soft yellow of the front lobe of the labelum and the tinge of rose on its two side lobes. The flowers are fragrant and remain fresh at least a month.

BROMELIADS.—There is a very large collection of these plants at Kew, some of which are always in bloom. The order is not popular in England, a few only, such as *Tillandsia Lindenii*, being recognized by horticulturists here. In Continental gardens these plants are as popular as Orchids are here. The late Professor Morren had a large range of houses filled with all kinds of Bromeliads, which made a glorious display of a very interesting and exceptional kind at all seasons. Such fine genera as Billbergia, Vriesia, Æchmea and Pitcairnea are now represented by flowering examples at Kew, where, singularly enough, they are as much admired by visitors as the best of Orchids.

December 21st, 1888.

W. Watson.

New or Little Known Plants.

An Addition to the Trees of Florida.

IT is only after a good deal of hesitation and a careful examination of the material which illustrates the American species in the herbaria at Kew, Paris and Berlin, that I venture to propose a new species in the large and very difficult tropical genus *Eugenia* for a Florida tree which none of the described species with axillary inflorescence at all resembles.

Eugenia Garberi, nov. spec.,* which is figured upon page 29 of the present issue, is, in Florida, a tree fifty to sixty feet high, with a straight trunk, eighteen to twenty inches in diameter, covered with thin, bright red bark, separating freely into thin, flaky scales; the branches are rather stout, upright and covered with reddish bark; the branchlets are round, very slender and ashy gray. The leaves are an inch and a half to two inches long, and a half to nearly three-quarters of an inch wide; they are ovate-oblong, acute, or more rarely somewhat rounded at the base, and gradually contracted at the other end into a long, obtuse point; the margins are revolute and thickened. The leaves are very coriaceous, dark green and glandular-punctate on the lower surface; the mid-rib is prominent, and the primary veins are connected near the margins, and form a conspicuous line nearly parallel with them. They are borne on stout petioles one-third to nearly one-half an inch long. The flowers, which appear in September, are small, hardly more than an eighth of an inch across when fully expanded, with short, rounded, obtuse sepals and nearly round white petals. They are produced in several-flowered axillary umbels upon glabrous, slender pedicels, which about equal the peduncles in length, and have two minute, acuminate, deciduous bracts just below the flowers. The ovary is two-celled, with numerous ovules. The fruit, which matures in March and April, is

* *EUGENIA GARBERI*, nov. spec.; arbor mediocris; ramulis novellis teretiusculis, glabris; foliis petiolatis, ovato-oblongis, obtuse longiuscule acuminatis, basi acutis, vel sub-rotundatis, glabris, rigide coriaceis, margine revolutis, subtus minute punctato-glandulosus, nervis mediis supra vix impressis, subtus prominentibus, venis tenuibus, arcuatis limbinervis, utrinque reticulatis; pedicellis glabris, umbellatis, axillaribus, 4-floris, sub. flore bibracteatis, folio 4-5-plo brevioribus; sepalis 4, ovatis, membranaceis; petalis subrotundatis; ovaris, bicoloris, loculis multiovulis; baccis calyce coronatis, sub-globosis vel obovatis, longe-pedunculatis, x-spermis, coccineis.

Habitat in silvis Floridae australis, et in insulis New Providence et Antigua. E. PROCERA, Sargent, Reports Tenth Census United States, ix., 89, in parte.

round or obovate, a quarter to a third of an inch in diameter, crowned with the calyx-lobes, one-seeded, and bright scarlet when fully ripe. The wood is very heavy, exceedingly hard, very strong, close-grained and compact; bright orange-brown, with somewhat darker sap-wood. This tree grows very slowly, the specimen in the Jesup collection in the American Museum of Natural History (now labeled *E. procera*) is but twelve and a half inches in diameter, and shows 155 rings of annual growth, with fifty-one rings of sap-wood.

Eugenia Garberi occupies a rich hummock or low island, raised somewhat above the level, sandy, Pine-covered plain which separates Bay Biscayne, in the extreme southeastern part of Florida, from the Atlantic Ocean, and situated about three-quarters of a mile east of the mouth

noviana) here replacing the more northern Sassafras; while the margin of the bay, a few hundred feet away, is lined with the Red Mangrove (*Rhizophora*), the familiar inhabitant of tropical shores, and here attaining in the United States its greatest size.

Eugenia Garberi has been detected also by Curtiss upon Old Rhodes and Elliott's Keys, two of the Florida reef-keys west of Bay Biscayne. It was collected by Brace upon the Island of New Providence in 1878 (Herb. Kew., without flowers and fruit), and by Dr. Nicholson, in Antigua (Herb. Kew., without flowers and fruit and without date).

It is by far the largest, as well as the most beautiful, of the species which occur in Florida, and may commemorate fitly the botanical services of the late Dr. A. P.

Fig. 87.—*Eugenia Garberi*.—The flower and fruit much enlarged.—See page 28.

of the Miami River, and close to the shores of the bay (*Garber* (1877) in flower; *Curtiss, Sargent*). It is the most common, and, with its bright red bark and lustrous foliage, by far the most conspicuous object in this particular spot, which is one of the most interesting in the United States for the student of trees; for here, and in no other place with which I am acquainted, are seen trees of the typical North American flora mingling freely with tropical West Indian species. Here, in an area of a few acres, besides this *Eugenia*, are found the Live Oak of very large size, the Red Mulberry, the Palmetto, the Pine (*Pinus Cubensis*), the Mastic (*Sideroxylon Masticodendron*), the Gumbo Limbo (*Bursera gummifera*), the Iron-wood (*Condalia ferrea*), the Marlberry (*Ardisia Pickeringia*), the Busic (*Dipholis salicifolia*), the Calabash (*Crescentia cucurbitina*), the Pigeon Plum (*Coccoloba Floridana*), the Lance-wood (*Nectandra Willde-*

Garber, of Pennsylvania, who, so far as I have been able to learn, was the first botanist who visited Bay Biscayne, and who was the discoverer of this species, which has heretofore been confounded in herbaria with *E. procera* of Poiret, a very different and much smaller plant, with smooth, gray bark, and thinner and less coriaceous leaves, larger flowers on longer pedicels, appearing in May, and large, black fruit, which ripens in November.

Six species of *Eugenia* are known in Florida. They are all trees, with the exception of *E. longipes*, Berg., a Cuban species, discovered upon No Name Key by Mr. A. H. Curtiss a few years ago, and not seen elsewhere within the territory of the United States. It is a low branching shrub, growing in an open forest of *Pinus Cubensis* and *Thrinax argentea*. The other Florida species (*E. buxifolia*, *E. dichotoma*, *E. monticola* and *E. procera*) are,

with the exception of the second, all common upon Key West, where they form, especially *E. buxifolia*, a large part of the forest scrub, and have been known as North American plants for half a century, or since their discovery on the Florida Keys by Dr. J. L. Blodget, who first made the botany of this region known.

The *Eugenias* are members of the Myrtle family. No less than 750 species have been described by botanists, of which nearly two-thirds are found in tropical and sub-tropical America. The genus, however, is widely and quite generally distributed through the warmer parts of the two hemispheres. Several of the species produce valuable fruit. The most important is *E. Pimenta*, which produces the allspice of commerce, and is largely cultivated in some of the West Indian Islands, especially in Jamaica. The well-known Jabuticaba fruit of Brazil is produced by *E. cauliflora*, and the Rose Apples of the East are the fruit of *E. Malacensis* and *E. Jambos*. Several species are grown in tropical gardens for their handsome evergreen foliage and fragrant flowers. C. S. S.

Cultural Department.

Lachenalias.

THE Lachenalias are bulbous plants, natives of south Africa. Their flowers are all pretty and interesting; some are very beautiful and a few are fragrant. They deserve to be better known and more widely cultivated than they are.

Their needs are few and easily provided for. Briefly stated, their requirements are: (1) A season of complete rest in the summer, when the bulbs may be left in the pot where they grew, or, better, may be taken out of the earth and put away in boxes or bags; (2) a good supply of water and a moderate heat in their growing season; and (3) an open soil. Their culture being so easy and their habit of growth very neat and compact, and their spike of flowers so sure to appear, they are excellent for window-gardening as well as for more extensive planting in green-houses or frames.

I propose in this paper to name all the species of the genus, giving notes and descriptions of the kinds I have grown, with some account of a few of the varieties which occur in a natural state. Of hybrids there are as yet very few. Neither *L. Nelsoni* nor *L. Cami* is an improvement upon the best forms of *L. tricolor*, from which both are descended. I have not yet flowered the series of hybrids offered by Dammann & Co., nor do I expect to be very much pleased with them, for the pendulous-flowered species are not the most promising.

Lachenalia pendula is an exceedingly beautiful species. Its flowers are of a bright coral color; the three inner segments—which, as in all the species, form a tube inside of the three shorter outside ones—are tipped with deep purple and green. This species is the earliest of all to blossom. If its bulbs are potted, as they should be, about September 10th, they will be in blossom by the end of November. Although so showy, *L. pendula* does not depend upon insect-fertilization, but forms fertile seed abundantly, being the only species, so far as I know, which does this. Bulbs purchased under the name of *L. pendula* very often prove to be *L. tricolor*.

The last named species, though very pretty, is inferior to *L. pendula*. It is of weaker growth, and its flowers are much smaller, being usually not over seven-eighths of an inch long. The colors are deep yellow as a ground, with green on the tips of all six segments and deep red at the base of the flower. As the flower grows older the red and green fade, and the yellow alone remains.

L. tricolor has two varieties, which are almost, if not quite, equal in beauty to *L. pendula*. These are var. *luteola*, which is twice as large in flower as the type, and much superior in color, which is a full, deep golden yellow, and var. *quadricolor*, a magnificent kind, whose colors are crimson, deep yellow, emerald green and violet in about equal proportions. Both of these varieties are larger than the type in all their parts, and increase by offsets much more rapidly; they have the same beautifully spotted leaves. The variety *quadricolor* is often sold under the names of *superba* and *versicolor*.

L. rubida is rarely found under its true name in catalogues, but is usually offered as *L. contaminata*, a widely different plant. A few years ago I bought as *L. rubida* and *L. stolonifera* two bulbs which I found would not blossom under ordinary conditions, though they multiplied rapidly. Tired of the vain attempt, I planted them out-of-doors and let them take their chance. The next spring they came up, much to my

surprise, and grew vigorously, but did not flower. I spoke of the hardness of these Cape bulbs to several persons, who were as much surprised as I had been. A few weeks ago a note appeared in an English paper to the effect that the writer had persuaded both of these to blossom, and found that they were identical, and not Lachenalias at all, but Scillas. Since then I have had the true *L. rubida* (there is no *L. stolonifera*). It is a very pretty kind, with broad leaves, faintly marked with dark green. Its flowers are eight to ten in number, an inch and a quarter long, deep pink, spotted and freckled with other shapes of the same color. It is Jacquin's *L. tigrina*.

L. contaminata has four or five long, narrow leaves, and a flower-stalk thickly set with greenish-white flowers, with brownish-purple-tipped segments and conspicuous green seed-vessel. The position of the flowers is as nearly erect as their crowded condition will allow. The flowers are not showy, but they have the merit of fragrance. It is sometimes sold as *L. orchoides*, but the true *L. orchoides* is very different.

L. orthopetala has from twenty to thirty white flowers, somewhat tinged outside with purple, and not very showy.

L. orchoides is very variable, and not easy to get in any form. The one I have shows numerous yellow, red-tipped flowers, purple in the bud, and very fragrant. Plate 854 of the *Botanical Magazine* represents a far less showy variety, having the outer segments green and the inner dark purple.

L. glauca is exceedingly variable, and highly ornamental in all of its forms. Andrews (*Botanical Repository*, t. 460) gives, under the name of *L. sessiliflora*, a bright rose-pink variety of this species, and the *Botanical Magazine* (t. 3552) gives one almost white, tinged with purple and spotted with blue. The form I have is, I think, the most beautiful of all Lachenalias. Its leaves and flower-stems are strongly and thickly mottled with chocolate-purple. The flowers are about twenty-five in number, violet and indigo in bud, becoming, when open, the color of a robin's-egg, with white or flesh-colored tips, and shading off in sea-green. They are about an inch in length, and incline upward. This is sometimes sold as *L. reflexa*; sometimes as *Calanthus complicatus*.

L. pallida, sold sometimes as *L. carulescens*, is exceedingly beautiful, being, in its best form, light blue, with one inner segment much expanded like a lip and marked with lemon-yellow. Another inferior form has outer segments dark blue and inner ones light green. There are one or two other forms which I have not seen.

L. unifolia has a single rolled-up leaf, expanding, however, as it rises, the lower part of which is mottled and lined with crimson and gray, like a water-snake. The flowers are short and broad, much like the Lily-of-the-Valley. The outer segments are blue, running to red; the inner, white and green.

L. isopetala is very handsome in its best form, having bright rosy flowers an inch long. Another variety is so inferior as not to be worth describing. I see no reason for its name.

L. pustulata has erect flowers of small size, light green and very fragrant. The leaves are curiously blistered.

L. anguinea has most singular leaves, so strongly blotched with light green on a dark-green ground, as to resemble a snake. The flowers are whitish and not attractive.

L. lucida has nothing of horticultural interest except the perfume of its flowers, and even that has a somewhat disagreeable sweetness. I have grown it for many years as *L. fragrans*, under which name it is sometimes sold.

L. racemosa has postulate leaves, and flowers which are placed horizontally on the stem, whose three inner segments are white, tipped with purple, and whose outer are much shorter, white, tipped with olive. About thirty are borne on a stem, and are somewhat fragrant.

L. purpureo-carulea has blue and dull red flowers and blistered leaves. It is not very attractive.

L. reflexa (syn. *Calanthus complicatus*) is the least showy of all I have seen. The flowers are very small and few, greenish-yellow, marked with dull red.

The following species constitute the remainder of the genus. I have some of them, but they have not yet blossomed, and I cannot describe them: *L. patula*, *liliflora*, *carnosa*, *Zeyheri*, *convallarioides*, *hirta*, *Cooperi*, *juncifolia*, *versicolor*, *violacea*, *nervosa*, *Bowieana*, *bifolia*.

Canton, Massachusetts.

W. E. Endicott.

The *Arctostaphylos Uva-ursi* seems a much neglected evergreen. I passed a clump of it to-day that covered a space of six square feet. Planted in light, sandy soil, it is exactly suited, and soon spreads so that the ground is completely covered. At this season of the year its shining leaves are of a dark chocolate color above and redder beneath. There are many positions which it would fill well.

New Chrysanthemums.

DR. WALCOTT'S article in the issue of December 29th must have interested all Chrysanthemum growers. As he has stated, new offerings have been so numerous lately (S. Delaux alone putting out 100 in 1887), that no one grower has been able to test them all. As I have had strong slips of the most promising foreign varieties, I can add a few names to those given. Of recent French varieties, Madame Baco is distinct—a rose colored Mrs. Bullock. Of Delaux's list for 1887, William Cobbett (salmon, with a violet cast) is a first-rate addition to the October flowering varieties. Royal Aquarium (white, with violet tips) is good for the same season. With the numerous early varieties

remarkably fine; Ralph Brockelbank (yellow sport of Meg Merrilies), identical with the original in form and size; William Stevens (orange, shaded red).

Ed. Audiguier has distinct flowers, but bluish-red. To the list of American importations may be added The Bride—a first-rate white. (Is this Avalanche?) Has any one found any prizes among the American seedlings of 1888? Many of the prize kinds failed to give me any results from the forced slips sent out, while of numerous kinds under trial, E. Oakley (Spaulding) is the only one to be saved—it is a medium-sized flower of the clearest, brightest light chrome. J. Thorpe (Spaulding) is marked for a discard, its blue-red not being counterbalanced by enough good qualities. Judging from

A Japanese Stable.—See page 26.

one can now have, if desired, a show of large flowers from early September onward. Of the general list, Mr. Garnar (canary and bronze), Arthur Payne (deep red), Charles Waggstaff (fine white) and Mina (white, striped with pink) have proved best with me. Duke of Berwick has met with most success, but with me its beauty is doubtful. Among others of the same list, perhaps Samuel Morley (red, early), Hogarth, Priscilla and Madame Payne may develop better on a second trial. Lord Mayor I shall try again on Dr. Walcott's recommendation. Le Reveil is a very large quilled ball, of no great beauty. Of Cannell's Japanese collection, Mr. H. Cannell seems to me only fit for exhibition boards. Lady Lawrence is R. Bottomley repeated. There seems some confusion as to Mrs. Cannell, several different plants having been sent here so named. Edward Molyneux is easily first of this list. Of English kinds, mostly sports, I can recommend Mr. Charles Gibson (bronze, sport of Mrs. N. Davis); Miss Annie Lowe (primrose, sport of Lady Margaret), a very fine and lovely flower; Carew Underwood (bronze, sport of Baron Prailly), a very large and light flower,

appearances, we shall have the best lot of American seedlings in 1889 ever sent out. The plant of Mrs. A. Carnegie, shown in New York, scarcely allows a doubt that this is a very valuable variety for general culture; for exhibition its merits were well shown in a few specimens. It seems to be a decided step toward a dark, wide-petaled, self-colored flower.

The market value of novel Chrysanthemums has evidently not yet reached its limit, since M. Delaux holds a small stock of a new variety at 10,000 francs. The interest in Chrysanthemums, too, is extending, and a national society, with a committee to which new flowers could be referred for endorsement, would be a help to amateurs and the trade as well. Too many new varieties are now offered at high prices with the simple endorsement of the raiser, no doubt in most cases given in perfect honesty, for every one who has raised seedlings will understand how difficult it is to take an unbiased view of one's own productions.

Elizabeth, N. J.

J. N. Gerard.

Orchid Notes.

Cattleya Triana.—This magnificent winter flowering Cattleya has now commenced to enrich our Orchid houses with its large and very handsome blossoms. A great treat is in store for those who may visit the collections of Messrs. Kimball, Corning, Ames and others, where these plants are to be seen rapidly developing their enormous flowers, which are remarkable for great variation and brilliancy of color. At a recent visit to Mr. De Forest's Orchid houses at Summit, New Jersey, this Cattleya was seen by the thousand, abundantly furnished with foliage and literally covered with flower sheaths. Some flowers were already expanded, having label-lums of a fine magenta purple, and exquisitely fringed. Besides this variety, there were hundreds of *C. Mossiae*, *C. Bowringiana*, *C. Percivaliana*, *C. Gaskelliana* and many other free flowering varieties. It is safe to assert that the possessor of this vast number of plants is the largest Cattleya-grower in the country. As a florist's flower, *C. Triana* is fast becoming popular, as it blooms at a season when flowers are in great demand, and its easy culture, with the abundance and lasting quality of its flowers, make it a specially desirable Orchid. During the months of March and April importations of this species generally arrive. They are then in a dormant condition, and this will also be found a very convenient season to commence establishing them, as the spring and summer months enable the plants to make strong and satisfactory growth. They enjoy a mixture of rough fibrous peat, clean sphagnum in small quantities, with charcoal added, which last is a sure preventive of stagnant compost. When making their growth full sunlight should be kept from them carefully, as the foliage is not so robust as that of *C. El-Dorado*, *C. speciosissima*, *C. Walkeriana*, and such varieties. All thin-leaved Cattleyas, such as *C. Mendelii*, *C. Chocensis*, *C. Gaskelliana*, *C. Percivaliana*, would grow as well if not fully exposed to direct sunlight, as good, sturdy growths and bold, substantial blossoms are easily obtained by giving the plants a thorough rest after flowering, and an abundant supply of pure air and moisture during their growing period. A. D.

Principles of Physiological Botany as Applied to Horticulture and Forestry.

III.—THE ABSORPTION OF LIQUIDS BY PLANTS—THE TRANSFER OF WATER FROM THE SOIL TO THE ROOTS.

THAT plants have in their composition a large proportion of water is a very familiar fact. The amount of water differs in different kinds of plants, in different parts of the same plant, and, as has been repeatedly shown by experiment, in the same part at different seasons. Illustrations of these differences will occur to every one upon reflection, and do not require to be further examined at this time. But, back of these differences lies a fact that a certain percentage of water in plants is essential to their activity. When this amount is diminished below a certain point the activity of the plant is diminished, and, if the lack is long-continued, the life of the plant is imperiled. The first case is well illustrated by the slow ripening of seeds, the latter is too often illustrated in times of drought.

Part of the water in the plant exists as liquid water in the sap of the active cells. In what are popularly called the pores of wood—namely, the microscopic tubular bodies known as ducts—produced by a peculiar development of coherent cells—it is rather uncommon to find any liquid water, although this does occur at times. The sides of the ducts are moist, and the whole wall seems to be saturated with water, but the cavities themselves do not generally contain any water at all. In these and similar cases it is believed that the water exists in a combined state so thoroughly incorporated with the substance of the walls of the long cells and ducts that it cannot be discerned as water. But it can be proved to exist there by the simple experiment of drying the whole. It is not, however, very clear in what way the water is combined with the cell-wall substance in plants. One theory, which has met with general recognition as capable of explaining a large number of facts, is that the water surrounds each structural molecule as a delicate film which is practically continuous with the films nearest to it, and thus all the water throughout the plant is a connected whole which, under normal conditions, is in a state of equilibrium very easily disturbed. Thus it can be disturbed by the evaporation of the films of water around the structural molecules in foliage, which makes a demand upon the supply of water below the point of loss, and so on down the whole stem, until the roots are reached, and here, of course, all further supply must come from the soil. This

transfer can be easily examined in the case of our forest trees and shrubs after we have ascertained the manner in which the loss from evaporation can be made good by means of the roots. Under ordinary circumstances no water even in the state of vapor is absorbed by leaves.

MICROSCOPIC STRUCTURE OF ROOTS.—The structure of roots can be most readily understood by confining our attention at first to the parts of the root which are near the end of the delicate root-branches. These parts may be considered in the order of their succession, beginning at the very tip. The extreme tip has, in the case of our common plants now under consideration, a well-marked cap of a protective nature, made up of somewhat flattened cells constituting a hollow cone, in the inner angle of which is a group of cells. Each of these cells is completely filled with protoplasm, and is actively engaged in the work of producing new cells; hence the group is conveniently known as the "growing point." New cells are formed in front and around this growing point, and these new cells, through changes in their size and shape, serve to extend the rootlet by terminal growth. Thus the minute rootlets are ever reaching forth into new soil, into the crevices of which they can, owing to their minute size, make their way. After they have crept into the interstices of the soil, they thicken up sooner or later, while far ahead of the thickening parts is the still advancing point of growth protected by its root-cap.

The tip of the root is not, however, a passive thing, merely pushed forward by something behind it; it possesses sensitiveness and the power of spontaneous motion. It is constantly revolving within a very narrow orbit. When it is in the soil, this motion is wholly obscured by the crowding of the particles of earth, nevertheless by this restricted motion in a cramped space, the tip can work along almost as if in search of a pathway. Moreover, the tip by its dull sensitiveness can distinguish between particles of soil which have different physical properties, and thus, one might say, choose its course. The description of the marvelous faculties possessed by the tip of the rootlet, as given in the "Power of Movement in Plants," is among the most interesting of the writings of the late Charles Darwin.

ROOT-HAIRS AND OTHER ABSORBING CELLS.*—It was formerly thought that the tip of the root, having, as appears under the microscope, a sort of spongy structure, is the efficient agent in soaking up moisture from the soil. But it is now well known that it is the cells which lie just behind the tip of the young rootlets which perform the work of absorption. These thin-walled cells on the surface of the rootlet, just behind its tip, are in most cases associated with peculiar cells which have slender outgrowths or prolongations like hairs, and these are sometimes so thickly crowded together that they give to the narrow zone the appearance of white or almost colorless velvet. The root-hairs are transient, working actively for a time, and then falling off, but the newer parts of the extending rootlets are continuously provided with fresh ones, and thus the supply of absorbing organs is constantly increasing just in proportion to the branching of roots and the formation of new rootlets, each of which is, of course, furnished with its zone of plant-hairs. And, furthermore, from the manner of growth, the new root-hairs are formed just where they can find fresh soil for their work of absorption, ever foraging through new fields.

The root-hairs come into most intimate contact with particles of soil, and undergo, in many if not most cases, a modification of their walls which may be said to glue them to the contiguous particles. It is probable, but not yet positively proved, that they exert a slight solvent action even upon some sorts of soil which appear to be otherwise practically insoluble in any aqueous solutions. As we shall later see, when we examine the action of the tip during the process of growth, there is always a slight excretion of an acid at the tip itself. Soil-water, as well as the water of our rivers and ponds, contains in solution small amounts of various mineral and other matters, and these in certain proportions are absorbed by the rootlets through the mechanism before described. The mineral substances are, for the most part, compounds of the following elements (chiefly with phosphoric and sulphuric acids, together with chlorine): Calcium, magnesium, potassium, iron, and others in smaller amount. Besides these, certain compounds of nitrogen are absorbed. The origin and destination of all these substances will be discussed when we take up the subject of nutrition.

OSMOSE.—Absorption of liquids takes place through the activity of the superficial portion of the thin layer of proto-

* Another possible manner in which roots may absorb will be taken up for consideration in a subsequent paper of this series.

plasm which lines the newer cells just back of the tip of the rootlets. When two liquids which can diffuse through one another are separated by a membrane which the two liquids can moisten, diffusion goes on rather more rapidly than if no membrane were interposed. The process is termed osmose. But in the case of such a membrane as parchment and those formerly used in experiments, it was found that there was always an outgoing current to replace the incoming one, and that these currents, if one can call them such, had certain relations of equivalence to each other. Now, as there is no true compensatory outward current in the case of absorption by root-hairs, it was beginning to be felt that the theory of osmose, as formerly understood, was inadequate to explain the taking up of matters from the soil. Professor Pfeffer has shown within a few years that in some artificial membranes, which are very nearly like those of the root-hairs, there is for a time a process of repair going on, by which the activity of the artificial membranes is constantly renewed, and in such cases, just as in that of the root-hairs, there is no compensatory outward current to be observed. Thus strengthened by Pfeffer's contributions, the theory of osmose has again taken its place as sufficient to explain the process of root-absorption, or, rather, speaking more generally, the absorption of liquids by any active cells. It is as yet impossible to understand clearly the ultimate nature of the force at work in osmose. We know that it is correlated with certain molecular activities, such as electricity, and that its principal seat in plants is in the surface of the film of protoplasm which lines living vegetable cells. We know also that it is related to imbibition and to capillarity, as these are manifested in non-living matter. Furthermore, we know that the capacity of the protoplasmic matter in cells, for the repair by which osmose can alone be continued, is limited in some cells sooner than in others; but why the chemical changes underlying repair should cease in root-hairs sooner than in some other cells of the plant, is, thus far, beyond the reach of experiment. We know, however, that when the power of osmose fails in the root-hairs or in the cells near these, the work of absorption is taken up by others which are freshly formed, and these new ones are, in their turn, soon replaced by others. In every case the new ones are produced in new soil, where fresh materials can be obtained.

The Forest.

The Forests and Woodlands of New Jersey.—I.

THE following is the first part of a report on the forests and woodlands of New Jersey which has been prepared for the final Report of the Geological Survey of that State by J. B. Harrison, Secretary of the American Forestry Congress. Advance sheets have been kindly furnished to GARDEN AND FOREST by Professor George H. Cook, Director of the Survey.

The area of the woodlands in New Jersey is about 41.5 per cent. of the surface of the state. This area is slowly diminishing, but the diminution has been but slight during recent years. In the mountain regions of the northern part of the state, some small fields that were once cleared and cultivated are relapsing into forest. Seedling trees are encroaching upon them from all sides, and the woods are re-establishing themselves in their ancient dominion. There are instances of the same thing in southern New Jersey; but they are few and unimportant, and in the whole state the area of land once cultivated which is being again surrendered to forest growth is very small.

Wherever the soil is worth cultivating, on the plains and in the river-valleys, and even on the hills in the limestone lands of the northern part of the state, a little more of the remaining woodland is cut off and cleared up each year. In the Pine country of southern New Jersey some considerable tracts have been cleared for farming purposes within a few years.

Considering that the state has been settled so long, the proportion of forest land is very large. The soil varies greatly in quality. In the limestone regions and in the river-valleys in the northern part of the state, much of it is very fertile, and the growth of the trees is rapid, while on the granite and slate lands the soil is thin and poor, and the trees grow much more slowly. On a few small tracts there is so little soil, that when the forest is once cut off it does not reproduce itself. That is, the new growth is so scant and scrubby that it has no value as timber. But over the whole state, with this very slight exception, the forest grows again after it has

been cut off, the deciduous or hardwood trees sprouting up from the stumps and the evergreens coming again from the seed.

The time required to reproduce the forest after it is cut off varies according to the differences of soil and the habit or character of different kinds of trees. In the fertile lands of Salem County, and in other parts of the state, trees will continue growing, and the value of a tract of woodland will go on increasing for a hundred years or more. But in some parts of the forest about Ringwood, and in other portions of the mountain region of northern New Jersey, the trees reach their culmination, or condition of greatest value, within twenty-five years after the former growth has been cut off, and it is then best to cut them again. Some tracts which have been standing for thirty-five years are no better now, the owners say, than they were ten years ago.

When the perpetuation of the forest is desired, it is best to cut it off a little before the trees reach maturity, as the succeeding coppice growth after young trees have been cut off is much more vigorous and rapid than the process of reproduction after an old or mature forest has been removed. Each new growth of timber is apt to be somewhat different from the one which it succeeds. Some kinds of trees sprout from the stump more vigorously than others. Chestnut, for instance, usually sends up a greater number of sprouts than any other kind of timber which grows in the region under consideration, and cutting off a forest composed of Chestnut, Hickory, Ash, Oak and other kinds of trees will often increase the relative number of Chestnut trees.

FOREST PRODUCTS.—The chief products of the forests or woodlands of New Jersey are lumber, shingles and other building materials, timber for bridges and ships, wagons and carriages, telegraph poles, railroad ties, posts and fencing materials, staves and heads for barrels, tubs and pails, hoop-poles, and handles for axes, agricultural implements and umbrella-sticks. Baskets, wooden ladles and spoons and spools are sometimes manufactured in the state, and wood-pulp to be used in the manufacture of paper is made in small quantities. The use of wood for fuel is general though not universal in the state, and charcoal is made in some places.

As is well known, large quantities of White Cedar timber were formerly "mined," or taken from underground, in swamps in the southern part of the state, but in most of these the available supply is nearly exhausted, what remains being mostly too far underground to admit of its being raised and manufactured with profit, though logs are still sometimes taken out. The same industry was formerly carried on in some of the northern swamps, though less extensively than in the south, and logs are even now occasionally raised in the north for materials for tubs and pails. Dense swamps of Tamarack (*Larix Americana*) were formerly a prominent feature of the forests in some parts of northern New Jersey, but they have nearly all been cut off, and the Larch does not appear to have reproduced itself to any great extent.

In some parts of the state many Christmas trees are cut for the markets of the towns and cities, and the boughs of the Holly, with its bright green and unfading leaves and its beautiful red berries, are gathered in large quantities in the month of December and sold in Philadelphia and perhaps in other places. In the spring and summer there is a very considerable traffic in wild flowers and plants of various kinds from the woodlands of the state. Great quantities of Water Lilies and Azaleas are sold, with the Trailing Arbutus, Iris, Wild Violets, *Xerophyllum asphodeloides*, *Helonias bullata*, *Pyxidanthra barbulata*, *Arethusa bulbosa*, the Pogonias and Calopogons, Clethra, Swamp Magnolia and other flowers.

The oil of sassafras is sometimes distilled in places in the southern part of the state, where also quercitron, a preparation of Black Oak bark, for dyeing purposes, was formerly made in considerable quantities. This latter industry appears to have been relinquished several years ago.

ORIGINAL FOREST.—There is not much really original or primeval forest left standing in New Jersey. That is, there are few, if any, large tracts of forest that have not been cut off at some time since the settlement of the state by white men. There is a small piece of White Oak woods on the farm of Mr. Thomas Lawrence, near Hamburg, in Sussex County, which has never been cut. These trees cover a remarkable hill, or long, narrow ridge, which rises eighty or a hundred feet above the fertile valley of the Walkill River, and one would have to travel far to find a more interesting or attractive grove. Though they stand very near to the busy haunts of men, the great trees are populous with gray squirrels, who appear to have learned to feel entirely comfortable and secure among them.

Correspondence.

Rare Trees of Rhode Island.

To the Editor of GARDEN AND FOREST:

Sir.—There are very few acres of undisturbed forest land in Rhode Island. Most of the land now devoted to wood-growing has been subjected to one, two, or more choppings, either by culling the best trees or by clean cutting. Yet, while this general deforestation has been going on, many single trees and groups have been spared, some of which have attained a large growth and a fine development of shape. Such trees are now not only objects of beauty in themselves, but add greatly to the pleasing scenic effects of the grounds where they grow. The location of the state with reference to ocean currents, and its greatly varied surface and soil, afford favorable conditions for a larger number of tree species than are usually found in such a small territory. Certain localities show a mingling of two quite distinct floras, and this is seen in the tree growth as well as in smaller plant life. Among trees, I will refer to a few species which, although rare and local in the state, flourish well when found.

The Swamp Spanish Oak or Pin Oak (*Quercus palustris*) is found along streams and in low grounds in the southern part of the state. I have been unable to find any record of the natural growth of this Oak anywhere else so far east. Of the eleven or twelve species of Oak indigenous to this state, this is the most free and graceful in its habit of growth, and one of the most ornamental in its general appearance. In open ground it has a symmetrical, rounded head, without the stiffness of most of the Oaks. Its limbs, slender for an Oak, divide into spray-like branchlets, bearing deep-cut, wide-spreading, shining leaves, giving the tree a cheerful aspect. Overhanging a stream or pool, it assumes a somewhat one-sided, drooping habit, the branches often touching the water. This tree is found, here and there, on the borders of the Great Kingstown Swamp and on the margins of the Pawcatuck River.

Another species decidedly local in the state is the Post Oak or Box White Oak (*Quercus obtusiloba*). The only specimens of this Oak, so far reported in this state, are growing near the shore of the most northern arm of Wickford Harbor, North Kingstown. There are trees there of this kind, in the edge of a wood-lot, which are fifty or sixty feet high; but in the open ground they form low, wide-spreading heads, the limbs bending downwards, with the lower ones actually resting upon the ground. The obtuse-lobed, glossy leaves, overlapping each other from branch to branch, form a living thatch of notable beauty.

The Tulip-tree (*Liriodendron tulipifera*), although only local in the state, is found in groups in several of the towns in the central and south-western parts. It grows to fine proportions, and is occasionally planted as an ornamental tree.

The Black Walnut (*Juglans nigra*) has been reported as indigenous to the state, but this is doubtful. But trees of this species have grown to stately proportions around some of the old homesteads, and young trees are now in thrifty condition where they may have been self-planted.

The Persimmon (*Diospyros Virginiana*) has been growing in a locality where it is highly improbable that any white man planted it. It may have been introduced by the Indians and have become naturalized. A Persimmon, which was standing some years since, measured three feet eleven inches girth at base, and three feet at seven feet up, and tapered gradually to a height of more than forty feet. This tree is now dead.

I will close by reference to some noteworthy Sassafras trees. A tree of this species of remarkable size stands upon the Spring Brook Farm, in Cranston, two or three miles from Providence. It is in a field of several acres, which has been cultivated for more than a century. It was probably saved on account of its size and beauty. A careful measurement, six years ago, gave the following results: Girth, near the ground, fourteen feet three inches; two feet up, eleven feet ten and one-half inches, with little diminution in its size to the limbs, eleven feet up. The height, computed by ratio from its shadow, was forty-nine and one-half feet. The tree has lost some limbs and shows other signs of great age; but its massive trunk, with its deeply furrowed bark, is still unbroken. It is a grand old sentinel, that has put forth its jaunty blossoms at more than a hundred seed times, and dropped its beautiful leaves at more than a hundred harvests, in the ground over which it has watched.

A group—or, rather, an irregular row—of trees of this kind, numbering over sixty, stands by the side of a stone wall near by, probably the progeny of the patriarch tree in the field. The estimated average diameter of three trees, two feet from the

ground, is eight inches, and their height thirty feet. There is another notable group of these trees upon the peninsula known as Bullock's Point, a few miles below Providence, on Narragansett Bay. They grow among Cedars and Pitch Pines, but, from their spread and height, are evidently older than these. These trees number a dozen or more, and several of them are eight to ten feet in girth three feet from the ground and forty to fifty feet high.

The Sassafras tree is quite plentifully distributed throughout the state and many fine specimens may be seen by stone walls and in out-of-the-way places.

L. W. Russell.

Providence, R. I.

[Mr. Russell's communication is of special interest, as it records, for the first time, the presence in Rhode Island of the Post Oak (*Quercus obtusiloba*), the Pin Oak (*Quercus palustris*) and the Tulip tree. The Post Oak had not been detected before in New England, except on the Islands of Martha's Vineyard and Naushon, in Massachusetts; and the Pin Oak was not known east of the valley of the Connecticut River, although a common tree along the Sound-coast in eastern Connecticut, and occurring sparingly near Amherst, Massachusetts. The Tulip tree has not been reported before east of western New England. The Persimmon has been supposed generally to have been introduced into Rhode Island in recent years, but, as it is found growing spontaneously in Connecticut, near the Sound, it is, perhaps, not improbable that it extends also into that state.—Ed.]

The American Mistletoe.

To the Editor of GARDEN AND FOREST:

Sir.—Referring to what is said of the Mistletoe in your article entitled "Christmas Green," in the issue of GARDEN AND FOREST for December 19th, permit me to say that this plant is found only in a few scattered localities in southern New Jersey, though within the memory of some persons it was occasionally found on the yellow-drift formation in the north-eastern part of the state. It is not now abundant in any true sense of the word in any part of southern New Jersey, with the possible exception of the region which may be called the head waters of the Great Egg-Harbor River, where within a radius of say ten or twelve miles I have counted over forty trees, large and small, with from one to twenty-five bunches of Mistletoe upon each of them. There is not enough of it, even here, to permit of its being gathered, except to supply herbariums with specimens from New Jersey. The localities are usually too far separated, and too much concealed in the swamps, to tempt even the cupidity of those who make the gathering of Christmas greens a business; and where it is known to exist it is usually too highly prized as a curiosity by people in the locality to permit of its being wantonly destroyed.

It is not likely that its extermination will be caused by its reputed medicinal virtues, but it is to be feared that if the Black Gum should become marketable, the Mistletoe would quickly disappear from this part of New Jersey; for in this region it grows only upon one kind of tree, the Black or Sour Gum (*Nyssa sylvatica*). C. F. Parker, however, found it growing at Jackson, Camden County, New Jersey, on the Red Maple, which fact establishes the possibility of its being found on other deciduous-leaved trees. But though I have carefully searched Apple trees and Swamp or Red Maples for it, I have never found it on them in this locality; and I do not think there is any record of its being detected upon any of the dozen or more varieties of Oaks found on the yellow drift in New Jersey.

Mays Landing, N. J.

John E. Peters.

Shortia galacifolia.

To the Editor of GARDEN AND FOREST:

Sir.—In your interesting sketch of Shortia, published December 19th, you say that Mr. Hyams discovered, "with the aid of a correspondent, what a treasure he had."

As this whole discovery was under my eyes, I would like to say that to Mr. Joseph W. Congdon, then of Providence, now of Mariposa, California, the credit of the identification belongs. He came to my room and told me what he had found in Hyams' package, and had sent to Dr. Gray. An answer came from the latter, "If you think you have Shortia, send it on," or words to that effect. It was sent. Then came from Dr. Gray the characteristic postal, "It is so. Now let me sing my *nunc dimittis*!" I think this is worth preserving.

Providence, Rhode Island.

W. W. Bailey.

Periodical Literature.

A pleasing article on "Shakespeare's Trees," by Mr. Arthur Gaye, may be read in the *Gentleman's Magazine* for December. Knowing how rich are the great poet's plays in allusions to flowers, it is somewhat of a surprise to find that he paid much scantier attention to trees. But, in the author's words, "though it would not be right to say that his 'tongues in trees' are among the most important, or even the most discriminating of his utterances, yet, regarded as a *parergon*, as so much extra matter 'thrown in' where there was already an infinity of subjects treated, they are deserving of notice and often of admiration." As we naturally expect, the Oak stands first on the list of native trees which Shakespeare celebrated, and is often referred to in a way which showed that he had a keen sense for its distinctive peculiarities of form, as well as a knowledge of the exceptional strength and toughness of its wood. But to the Elm, almost as conspicuous a tree in Britain as the Oak, "Shakespeare has not done justice." He mentions it only twice, and in both cases, oddly enough, in figures of speech which contrast its sturdiness with the clinging habits of the Ivy. And "for the Beeches, which share with the Oaks the chief forest honors of the land, he has no word of admiration or even of recognition. They are utterly ignored"; and this although "the tree lends itself with such facility to poetical language and from the days of *sub tegmine fagi* has always been in request," and although Shakespeare "must often have traversed Buckinghamshire, with its far-stretching beechen groves." The Ash is perhaps the fourth tree in importance on English soil; yet the Ash, too, is ignored by the poet, who makes use of the word but once, and then to denote a spear. So, also, with the Birch. Its name also comes only once, and then to figure a switch!

On the other hand, we find, with perhaps as much surprise, the Cedar of Lebanon, no living specimen of which existed in England in Shakespeare's day, is frequently referred to in his plays, not merely as a symbol of pride and beauty, but in descriptions which would lead us to imagine that it was a familiar object to his eyes. The Pine he often mentions, and the Yew, the Cypress and the Willow, while the Sycamore (by which we must understand the Sycamore Maple) comes in for an almost undue share of his attention. The same is the case with the Elder, which he mentions seven or eight times. The Olive, Laurel and Bay appear of course—how could a poet do without them?—and the Hawthorne, the Crab-tree, the Box-tree, the Holly and the Hazle, while the Alder is not mentioned and the Lime or Linden only once. The most charming part of Mr. Gaye's little essay is perhaps the first page, where he pays a graceful tribute to the Autocrat of the Breakfast Table, recalls his "rapturous love of trees," and regrets that we have never had from his hand a chapter on Shakespearean dendrology.

In the *Nineteenth Century* for December we find a sensible and interesting chapter on "The Fruit-growing Revival" in England, by Mr. Frank A. Morgan, editor of the *Horticultural Times*. Mr. Morgan does not give way to the exuberant prophecies which some writers, taking up Mr. Gladstone's now famous piece of advice, have voiced with regard to fruit growing as a panacea for all the agricultural woes of England; but neither does he take the pessimistic, discouraging tone which others have adopted in consequence of the many failures which have followed upon first attempts in a new direction. Having studied the matter carefully and intelligently, he decides that the industry is rapidly developing, that probably the next five years will see an enormous increase in the present area of orchard land; and that so long as £8,000,000 sterling are annually paid to foreigners for fruit and garden produce, there is no real ground for any apprehension of overproduction. But, he adds, while "it will pay to grow good produce, it will not pay to raise common goods. . . . The causes of failure in fruit growing may be summed up in two words—ignorance and indolence. It is practically impossible to find an experienced and energetic fruit grower assert that he cannot make a living." Taking up the various kinds of fruit in turn, he gives sensible advice with regard to them, insisting, especially, that only a very few varieties—and those the very best—of each kind should be grown. But the most interesting part of his article to American readers is where he insists that the best English fruit is better than the best imported kinds, and that tradesmen, as well as the public, are well aware of the fact. "Who," he asks, "would buy a pound of Newtown Pippins (the best imported apple), when he can obtain the luscious Cox's Orange Pippin, or who would eat a Baldwin when a Blenheim Orange apple is available? The English fruit-

erers—not a class given to sentiment—are so conscious of this fact, that in London, at the present moment, nearly every American apple sold is labeled 'Choice English Fruit.' So with grapes, pears, plums, tomatoes, and even with walnuts and other kinds of nuts. . . . The buyers for the foreign restaurants . . . are as eager as other purchasers to obtain English fruit, and pay for it a much higher price than for foreign produce. The reason for this superiority of home grown produce I attribute to the fact that, though our climate is proverbially fickle, it is, on the whole, more equable, and the season is more prolonged, than that of foreign countries. Though, to use an old English proverb, 'We get our sun by installments,' old Sol lingers with us long enough to slowly, but surely, ripen our fruit; and it is this prolongation of sun heat that seems to render our English out-door fruit so full of rich juices—the very point in which the imported fruit is lacking." Those who have eaten American fruit in America and English fruit in England may not agree with Mr. Morgan in his conclusions. But the facts he gives are undoubtedly trustworthy, and if his anticipations with regard to the prospects of fruit culture in England are equally so, American producers may well fear some diminution in their export trade. The chief obstacle to the industry he finds in a fact which has no parallel with us and which may prove very difficult to overcome. Few English horticulturists are able to own their own land; few landlords are willing to cut up their large existing farms into the smaller holdings more suitable for fruit culture, or to rent them on long leases, with satisfactory guarantee against ultimate loss to the tenant on the orchards he may plant; and, meanwhile, men are naturally averse to putting their money permanently into ground which they hold on year-to-year leases, without any pledge securing its return to them in case of dispossession.

Notes.

M. Paillet, in *Revue Horticole*, finds saddle-grafting the most desirable with Rhododendrons.

Fifty-five distinct varieties of Pansies were shown not long ago at a meeting of the Wisconsin Horticultural Society by a single exhibitor—Mr. William Toole.

No less than 2,000 species of flowering plants have been collected at Mount Bair, Tonkin, by M. Balansa, a French explorer. Numerous species of Oak abound in the forests.

Near Philadelphia, on the 8th of January, fully-expanded blossoms were quite abundant on a *Fasminium nudiflorum*, which stands fully exposed towards the north and west, and buds were opening on a Japan Quince in a sheltered position near by.

M. André, commenting in the *Revue Horticole* upon the reprint of a catalogue published in 1790 by a French nursery-gardener, finds the fact interesting, that among the thirty varieties of Peach and sixty-one of Pear are found all the best and most popular varieties cultivated to-day, with the exception of those of American origin.

The *Revue Horticole* records the fact that a Nectarine tree at Montrouge, near Paris, bore the past season a crop of Peaches, but no Nectarines. This is not the first time that this has been observed, and it is not unusual to find an occasional Peach among Nectarines, a fact which seems to point pretty clearly to the varietal origin of this fruit.

Mr. T. S. Brandegee left San Francisco on the 3d instant for Magdalena Bay for the purpose of exploring the botany of Lower California. The plants of this whole region are as little known as those of any part of the North American Continent, and large collections and important results may be expected from Mr. Brandegee's investigation.

The Messrs. Veitch have imported from a French nurseryman specimens of a red-fruited Ivy, to which the name *Hedera aurentiaca* has been given! No fruit has yet been perfected on English soil, but, as a local journal says, if the variety fruits prolifically and is good in other respects, it should prove a welcome addition to the list of ornamental evergreen plants.

The cultivation of Pampas grass seems to be spreading in California. Formerly the only place where it was grown was Santa Barbara, but now large plantations may be found in many other neighborhoods. As the grass needs no treatment after cutting, but to be dried in the sun for a few days, the cost of harvesting is small and the profits proportionately large. A California journal declares that an acre of land will yield \$250 worth of plumes.

Few persons know that the fruit of the Horse-Chestnut has any economic value. But a recent report of the Agricultural Department in Washington states that a flour is prepared from it with which a paste is made for the use of bookbinders—the bitter taste preventing the attacks of insects which are often so destructive when a more palatable kind of paste is employed.

The fourth number of *Lindenia* contains portraits and descriptions of the following Orchids: *Liptotes bicolor*, introduced from Brazil in 1831, a species with white flowers, with a red lip tinged with violet; *Odontoglossum Halli*, a Peruvian species, which bears the name of its discoverer; it has yellow flowers spotted with brown; *Cypripedium Mastersianum* and *Vanda cœrulea*.

M. Ed. André publishes, in a recent issue of the *Revue Horticole*, a preliminary list, with characters, of the new species and varieties of Bromeliads—no less than eighty-three in number—discovered by him during his journey in South America in 1875 and 1876. An important work upon these plants, with figures and more detailed descriptions, is announced and may soon be expected.

The leaves of *Galax Aphylla* at this season are remarkably beautiful, and they are now gathered in considerable quantities on the mountains of western North Carolina and sent north to be used in winter decoration. Florists might make good use of them in certain arrangements. The leaves range in color from a bright, glossy green to deep crimson, maroon and dark bronze, and often richly variegated.

The State Horticultural Association of Oregon has prepared a bill for the creation of a State Board of Agriculture, which will be introduced in the coming session of the Legislature. It looks to the protection of the fruit industries of the state—directing that the Board shall have power to enforce certain restrictions, appoint an inspector of fruit-pests, etc.—and also to the advancement of horticulture in other ways.

A florist of this city recently exhibited in his window some flourishing plants of the common Red Clover (*Trifolium pratense*), almost every leaf of which had four, five or six leaflets. The leaves are much smaller than those usually seen when the plant has grown out-of-doors, but were proportionately more delicate and graceful on their long stalks; and, set in large silver bowls, the plants were ornamental enough to be prized at this season even apart from their significance as harbingers of good luck.

Mr. G. P. Rexford, of San Francisco, is preparing, under the direction of the Department of Agriculture, an exhibit of California-grown Figs, for the coming Paris Exposition. It is proposed to make the fact more generally known that the Smyrna Fig of commerce, as well as another choice variety, the White Adriatic, is successfully grown in California, and in order that the whole industry may be represented, not only dried fruit, but Figs crystallized, pickled and preserved by all methods, are to be included in the exhibit.

It has been established by ample proof that injury to plums can be prevented by spraying the trees early in the season with one of the arsenites, but no explanation has been made as to whether the adult beetles are destroyed, or whether the poison reaches the young larvæ. From a late bulletin issued by the Cornell College Experiment Station it would seem to be established that the adult beetles gnaw the surface of fruits for food as well as for oviposition. Besides this they eat freely of the leaves of the tree, so that the curculio is freely exposed to destruction, without reference to its habit of oviposition or to the fruit food of the larvæ.

On the 5th of January the Museum of Natural History in this city, which contains the Jesup Collection of American Woods, was for the first time opened in the evening, and hereafter it will not be closed on Saturdays until ten o'clock, and on Wednesdays will be closed at the usual hour, but re-opened between eight and ten o'clock. Of course it would have been better for the public, and especially for that portion of it which can derive the most practical good from such collections, had the authorities consented to open the Museum on Sundays; but while awaiting the time when this change must surely be made, its opening on two evenings each week is a distinct benefit.

An interesting little article in *Popular Gardening* tells us that the first green-house known to have been constructed in America was built in this city in 1764, on the grounds of Mr. James Beekman, a property which lay where Fifty-second Street now runs. It was a small rectangular building with no sky-lights, but a solid hipped roof, and walls formed by a suc-

cession of simple piers and large windows. The next form adopted for green-houses had a hood-like roof with slanting windows. This was followed by the lean-to—a house with a back wall about twelve feet in height and a front wall about four feet in height, with a slanting roof of glass. Two of these structures joined together give, of course, the form now commonly employed.

The most popular ornamental baskets for florists' use seem just now to be rather large and shallow ones, with tall handles, bent to a rectangular shape, which are covered, body and handle both, with folds of ribbon. It is a question whether it is as tasteful to use such an extent of color in connection with flowers as to use the simple, harmonious tone of uncolored straw. Nevertheless, the public always fancies new and "effective" arrangements, and when the color of the ribbon contrasts properly with that of the flowers, and too many bows and streamers are not employed, these baskets are distinctly better than many we have seen in recent years. The fashion seems to have come from France, where baskets of this kind are often used to contain two or three pots with growing plants, the pots themselves being covered from sight with trimmings of green. Something may be learned from Parisian florists as regards the number of blossoms which should be used. Too often in this country we see more blossoms and less foliage than is desirable, while in Paris, even when cut flowers are used, four or six fine specimens, relieved against a great mass of green, are preferred to a more compact display in which the beauty of individual flowers cannot be so well revealed.

The Garden (London) recently offered a series of prizes for collections of photographs of rural and horticultural subjects taken by amateurs. The result has just been announced, and a very large number of pictures seems to have been submitted, showing much diversity of subject matter. The first prize fell to the Earl of Annesley for a collection of "interesting garden subjects"; the second to Mr. Good, for "pretty garden plants and country houses," and the third to Mr. Murray, for "fine old Devonshire gardens and country houses, Cork-trees at Mount Edgcombe," and other similar subjects. A long list of minor prizes is also printed, and many of the photographs in question will be reproduced in the columns of *The Garden*. Some remarks appended by the editors to their list of prizes may well be quoted for the benefit of American photographers. Among the causes of failure they noted were: "The want of simple, natural ways of arranging cut flowers. The complex bundles generally seen look worse in a photograph than they actually are. The backgrounds, too, are not always considered in relation to the color of the flowers; a crowd of so-called 'artistic' objects around is fatal, as is the flower-jar all set over with a pattern. . . . Very common subjects now and then result in failure, as *Lilium auratum*, which has been so often well done. On the other hand, some beautiful common things are never done well—as the Apple, Pear or Thorn-tree in bloom, and many wild flowers."

"In Sweden," writes a correspondent of *The American Garden*, "railroad gardening has reached a considerable advancement far greater than it has in England. The state roads in particular have done much to adorn all their stations. The station buildings themselves, though unpretentious, are neat and tasteful in construction. The out-houses are always partially or wholly concealed, and are never unsightly even when most conspicuous. . . . An area of from two to four rods in width and from twice to ten times as long is devoted to the railroad gardens. The general plan of this ornamentation consists in planting so as to hide the outer boundary and in laying walks to various objects in such a manner as to represent a pleasure ground. The planting is always well done, mostly of native trees and bushes, and, better than all, the plants are cared for. At the larger stations these gardens are of considerable extent and form important openings in the city. The one about the central station at Stockholm is worthy the denomination of park. Between stations there are at short and regular intervals the residences of section overseers—the *banwakt*—about which are small and tidy kitchen gardens and beds of flowers and clumps of bushes. These houses are usually all of a pattern, small and attractive, and are furnished by the railroad company, along with a parcel of land for private use. The *banwakt* receives in addition a salary of 80 kroner (something over \$20 per month), and has free transportation on the road to and from market and is given his uniform. A certain portion of the road is allotted to his care, and in addition to duties connected with the track itself, he keeps the roadside tidy. American railways have too much land lying idle along their lines to allow of tidy roadsides."

Arbor Day Tree-Planting.

TREE planting is, of course, not forestry, nor is there any close or necessary relation between them, but tree planting is itself a good thing if it is done intelligently. We need more trees, of the best and most suitable kinds, nearly everywhere in the settled portions of this country. If there is a fixed day for the work, at the proper season of the year, with ceremonies, social observances, and opportunity for "a few remarks," many persons are likely to plant a few trees who would not otherwise think of it. If good trees are selected, and they are handled with care and intelligence, both in the process of transplanting and afterward, we shall probably have, in the course of time, more good trees than now, and this is to be desired. A beautiful, graceful or majestic tree is a valuable possession for any community.

But the tree is not an end in itself. It does not exist for its own sake. It is valuable solely for its effect upon human health and human psychology, for its relations to the welfare of the men, women and children who see it. Whatever tends to implant or nourish right feeling about trees, or more intelligent regard for them than now prevails in this country, helps along a little the long, slow process of human development and elevation, which, with many fluctuations, goes on from age to age among the best races of mankind. The development of ideas connected with the subjects of forestry and landscape-art, and their continued discussion and illustration, are of value simply because they constitute a real and vital contribution to the sum of the forces by which human life is refined and strengthened, made more vital and interesting. This is an object in itself, and all means to this end are to be valued in proportion to their comparative efficiency.

The new interest in forestry and related subjects in this country is a natural development. It is time for it. It is an important next step in our national progress. The production among our people generally of a vital and intelligent appreciation of the true place of forestry and landscape-art among the forces which improve man-

kind would constitute a real advance in civilization. Whatever tends to increase popular interest in these subjects is to be encouraged, utilized and made more efficient. It is greatly to be desired that the people of this country should know more about trees, should think more intelligently of their varied relations to human life and welfare, and should become capable of deeper and keener delight in their exhaustless charm, and especially in their capabilities for the expression of ideas of beauty and of peace.

It is good to have people think and talk of these subjects until they shall be "in the air" everywhere. How to bring this about is a psychological problem, and most of our problems in this country are largely psychological. That is, they are questions of means and methods for the propagation of ideas—of the best way to go to work to produce the conditions of public intelligence, thought and feeling which we esteem desirable, and which will lead to more efficient action for right and noble ends. Arbor Day observances may be so managed that they shall be distinctly helpful. But all fine writing and long essays are a hindrance when we wish to accomplish anything. Tree-planting is a good object-lesson for the boys and girls of our country, if they learn to plant the trees properly, and with their own hands.

A general interest in trees, and in forestry and in landscape-art, would supply favorable conditions, soil and atmosphere for the development of just and rational taste regarding them, and of ability to deal with their problems successfully. Such results are impossible under conditions of national indifference and ignorance. A great musician could not be produced by a race which cared nothing for music. If all the men and women in this country who are working for any good object will help to make it the fashion to care about the subjects we have here discussed, they will find the material upon which they work, the minds of the American people, more tractable and responsive than they now are to all good and elevating influences.

Professor F. L. Harvey, in an address delivered in Bangor last month, gave the people of Maine some sound advice about the forest interests of the state which is of general application. The statement that "it is of the utmost concern to owners of timber lands, or those in any way connected with the lumber industry, that they inform themselves upon all matters relating to forest management and the care of lumber after it is cut, so that the greatest returns be realized from the money invested," may well be applied to lumbermen everywhere; and "the question for our lumbermen to solve, is whether they adopt the selfish policy of devastating forests for present gain, or whether, by proper care and management, and being satisfied with the annual growth, they will bequeath them to future generations with their original productiveness," is one which affects the whole country; or, at least, all that part of it east of the Rocky Mountains, where the control of the forests has now passed from the ownership of the government into that of private holders. The future, therefore, of all our eastern forests, is now in the hands of individuals, who are at liberty, of course, unless a very radical change in the control of private property in this country can be effected, to decide, each man for himself, whether he will turn his forest into money at once, or manage it in such a way that it will continue to be productive permanently to an amount equal to the annual increase of timber. That is, whether he shall manage his forest as a prudent farmer manages his land, and maintain and increase its productiveness. It must be remembered in this connection that the owner of a forest who allows it to be destroyed sacrifices one of the most permanently productive and stable of all properties; and sacrifices, moreover, the prospect for much larger returns in the future, when increased population and smaller forest areas in all parts of the world must inevitably increase the value of forest products.

Hints About Lawns.

TO one accustomed to the studious contemplation of natural scenery, there is apt to come, sometimes, the desire to possess some particular scene which has been found to affect the emotions—to own it as a pleasure and a means of refreshment to the mind through the eyes, as one might own a beautiful painting. The many practical conditions of life rarely permit the indulgence in such a luxury; but with the recurrence of the desire with each new experience, there comes to be an impulse that leads to the attempt to imitate certain elements of natural scenery in places in which it will be convenient to enjoy the result. There are many more who, while they are by no means students of Nature, yet have an instinctive appreciation of the beautiful and the picturesque in Nature; which manifests itself in the selection of their house sites, and in the general style at which they aim in their planting and other out-of-door work, rather than in the planning and carrying out of any consistent, complete ideal, or than in the imitation or perfecting of an existing natural scene.

There is, however, one type of natural scene, the beauty of which is so generally recognized, that every one who has the slightest opportunity desires to imitate it. It is that which is called a lawn.

Strictly speaking, the term lawn is applied to a natural opening, of limited extent, clothed with low verdure (grass or small bushes) and surrounded by woods dense enough to confine the eye. Its essential qualities are openness, breadth, seclusion and repose, together with a subtle combination of contrast (between its openness and the shady mystery of the wood) with harmony (the sense of seclusion being common to both).

In creating a lawn, considerable variation from the natural type is permissible, provided its essential qualities are preserved. For instance, the element of contrast with the wooded borders is heightened if the lawn is covered with an unbroken sweep of finely clipped turf, even though the lawn loses something of its charm of naturalness thereby. Likewise, it is not essential that the inclosing wood should be composed solely of large, tall trees, showing their trunks and with dark shadows under and behind them, nor that it should present a simple mass of foliage faced out or bottomed out with smaller trees and bushes, so that the interior of the wood is invisible; both of these conditions are common in Nature. Other minor features of woodland scenery may partially border a lawn, such as herbaceous plants, rocks, steep banks, or even water, but all such features should appear natural and subordinate. A lawn should have a moderately undulating surface, because a dead flat would be suggestive of artificiality. If a lawn is to be smoother than is natural, the turf must be kept short, preferably by the most natural means, as by the grazing of sheep. The difficulty of adjusting the planting of the borders of a lawn so that it will not be injured by the browsing of sheep or cattle has, however, led to the general use of the scythe and the lawn-mower, but the more natural way should be kept in mind and reverted to when practicable.

A lawn is often used, in connection with a house, as the foreground of a more extended, park-like opening or distant view. The extreme neatness usually desirable immediately about a house, suggests that that part of the lawn should be clipped, leaving those parts further away to be grazed. Such an arrangement is, in fact, common abroad, the pastured ground being cleverly separated from the clipped ground by a sunken wall (called a ha! ha!), or by a ditch with turfed slopes, deep enough to conceal a fence placed in the bottom, or by a river or elongated pool simulating a river. Even though the means of separation be visible, the disadvantage of the division in breaking the apparent continuity of the view may be, in a great measure, compensated for by the economy of pasturing over clipping and by the greater naturalness of the pastured lawn.

However intricate and irregular in shape a lawn may be, it should, as a general rule, have a predominating, central, unbroken area, in order to give it its characteristic qualities of breadth and repose.

The element of openness is essential. It is not uncommon to leave many existing trees scattered over a lawn or a single tree in the midst of it, or to plant trees promiscuously over it. This is usually done either from a love of trees as beautiful objects, or from the dread of a bare, unfurnished look. No greater mistake could be made.

It is with a lawn as with a picture. The subject of a picture should be at or near the centre, the composition should be such as to direct attention toward the subject, other objects shown should be subordinated to the subject, and there should be a border or frame to assist in confining the eye to

the picture itself. So in a lawn, the eye should rest at or near the centre instinctively and easily, and since the turf is the characteristic and valuable thing, no other object should be allowed so near the centre or be so conspicuous as to distract the mind from receiving the impression which the lawn is calculated to produce. It would be as reasonable to put a large yellow star in the middle of a picture as to have a fountain or bed of flowers or a specimen tree in the midst of a lawn.

While there certainly is, in the long run, a more refined and lasting enjoyment to be obtained from a lawn the borders of which are so planted as to appear absolutely natural, and which makes a complete scene in itself, yet a good deal of the value of a lawn—its suggestion of simple breadth and repose—may be retained, while a certain amount of gaiety of foliage and of flowers, of interest in specimen plants, and of beauty of constructive art, is associated with it in the same view as a foreground, but not as a part of the lawn. There would be a contrast which might enhance the effect of gaiety, but at the expense of the lawn, because the sensation of gaiety and the interest in the artificial objects would overwhelm the milder, shyer feelings properly to be derived from the contemplation of the lawn. The one tires, while the other refreshes, the mind.

A lawn is at its best when there is no evidence of the handiwork of man—no formality in the grading, none in the planting, no exotic plants, no fountain-jet or basin, no vase or statue, no nicely trimmed path, no fence or formal terrace. Such a lawn conveys the purest impression and gives the most lasting satisfaction. One who cultivates a taste for formality and things evidencing the skillfulness of man is apt to tire of any one object or composition of that kind. It is true that there is a certain kind of refreshment to be obtained from variety in such things, but it is a stimulating, nerve-consuming kind of refreshment, the opposite of that which is encouraged by repose. But to one who cultivates a taste for the beautiful and picturesque in Nature, a single, purely natural scene is never tiresome if seen again and again. The infinite variety in the details and in their disposition, the differences of aspect caused by changes of weather and by the seasons, by the growth of plants, by birds and other animal life—all are harmonious with the natural scene, are not conspicuous enough to injure any artistic impression which the scene may give, and yet make the scene endlessly interesting.

Too often a lawn is spoiled for the gratification of tastes and pleasures that have nothing to do with the true source of the enjoyment to be derived from looking at it. And it is usually done, too, under the mistaken idea of decorating or improving the appearance of the lawn. That is the pity of it. For instance, it is not an uncommon thing to see a formal bed of scarlet Geraniums in the midst of a lawn that would otherwise have had much suggestion of a natural breadth and repose. The bed of flowers may be a good thing in itself. It is bright and gay, enlivening and stimulating, and it is well set off by the surrounding turf, but the lawn is sacrificed to it—that which has a permanent worth is made to give way to that which has but a passing value, a source of endless satisfaction to a pretty toy of which every one soon tires. Again, consider the case of a lawn “decorated” with statuary. A beautiful nymph splashing in a fountain, were it not a very hackneyed idea, and where it is the work of a true artist, would be a most enjoyable and valuable possession; but a poor, cheap, painted, cast-iron imitation of such a piece of sculpture, placed so as to dominate a fine lawn, is a barbarism which it is hardly conceivable that any intelligent person could be guilty of. The same thing might be said of almost all the usual so-called “decorations” of lawns. To decorate the face of a beautiful woman with painted ornaments would not be one whit more savage. Our civilization is spotted all over with the relics of barbarism; good taste is always striving to get rid of them, and they should be particularly avoided when we set about making a natural lawn.

Brookline, Massachusetts.

J. C. Olmsted.

Autumn in Oregon.

A LARGE-LEAVED Maple (*Acer macrophyllum*) in the gulch above my house (the hills slope to the west) kept its leaves green this fall some six weeks longer than trees of the same species growing on lower land along the main creeks or in the gullies on the more open and exposed hillsides, and one to two weeks later than others growing in its own immediate vicinity. These leaves were green until the middle of November, while those of other Maples had begun to turn yellow by the first of October, were in a blaze of color by the 28th, and had mostly fallen from the trees by the 6th of November. Visiting this gulch November 18th, I found my Maple displaying a wealth of soft golden color that I have rarely seen equaled.

About its base, tall, straggling bushes of the Oregon Grape (*Berberis Aquifolium*) held their clear green, leathery, spinulose-toothed leaves, for these, too, like those of the bright and handsome Madroña, are persistent; but the Mock Orange (*Philadelphus Lewisii* (?)) and the little Snowberry (*Symphoricarpos*) had only a few pale, yellowish leaves remaining. The Ninebarks, too, were bare, excepting a few leaves on shoots of the present season. Some of the Hazels were still in full leaf, and, indeed, one bush was still fresh and green. Of course the Manzanitas (*Arctostaphylos pungens*, var. *platyphylla* (?)), near relatives of the Madroña, held their leaves—for these, too, are persistent. The little Tea brush, as we sometimes call *Ceanothus integerrimus*, still held many of its leaves; and the Rose bushes growing along the gulch were yet green, though in more exposed places the leaves of many of them were beautifully colored.

In southern Oregon—a region embracing that part of the state west of the Cascade Range and south of the Calapooya Mountains—we have many shrubs and trees, interesting by reason of their autumnal foliage, besides the large-leaved Maple and the shrubs already mentioned. Conspicuous among these is the large-flowering Dogwood (*Cornus Nuttallii*), which is very abundant here in the woods. The arrangement of the coloring on the leaves of this tree during the transition from its summer's green to its autumnal red is very fine, and is displayed in a great variety of forms. Later the color becomes more uniformly red, at which time the leaves are not nearly so pretty as they were before; but the tree—or shrub, it may be—then becomes a conspicuous feature in the landscape.

Even our two deciduous Oaks, *Quercus Kelloggii* and *Q. Garryana* (the Black Oak and the White Oak), often present great beauty in their autumnal foliage. This, it is true, does not occur on all the trees nor in every locality; it is observed most frequently on the more shrubby forms and on the hill-sides, where the leaves are well exposed to the sun. Our common Poison Oak (*Rhus diversiloba*) often ornaments whole hillsides in the fall with the rich coloring of its foliage. In moist and shady woods the Low Oregon Grape (*Berberis nervosa*), a much handsomer shrub, I think, than even the larger *B. Aquifolium*, often shows great beauty of coloring, though, to be sure, its leaves are evergreen. Sometimes a single leaflet, or part of a leaflet even, will be colored a deep shining red, while all the others are of their usual bright green. Again the coloring will be varied by a dash of bright yellow, or of orange, with a sprinkling of the red. Our common wild Blackberry (*Rubus ursinus*), growing in similar localities, often displays great beauty in the coloring of some of its leaves, though this plant usually keeps its leaves green throughout the year.

The Wild Grape (*Vitis Californica*) is very abundant here. In default of any support this plant will form clumps upon the ground; but, wherever it has the opportunity, will climb lofty trees; smaller trees it will frequently completely cover with a mass of foliage. In the fall these leaves become usually of a deep crimson color, but with an almost infinite variety of marking and mottlings, shades and tints.

But by far the richest, most varied, most beautiful and most profuse display of coloring in this region is seen in the dying leaves of the Vine-Maple (*Acer circinatum*). I should despair, however, of giving anything like an adequate description of these, and can only say that the leaves—delicate of texture and beautiful in form, borne on the branches of long, straggling stems, and thrust out, therefore, to long distances in every direction, often intersecting the foliage of other shrubs and trees, contrasting finely with these and with the much lighter and more uniformly colored foliage of its large-leaved relative, *Acer macrophyllum*—display the most beautiful and varied arrangement of the different tones of crimson and scarlet, of yellow and green, it is possible to conceive.

When these shrubs and trees are decked with their October coloring and scattered among huge Douglas Spruces, Yellow Pines (*Pinus ponderosa*) and White Firs (*Abies grandis*)—the most beautiful, to my thinking, of our Conifers—the effect is most pleasing, and it is often heightened by vines and trailing plants that carpet the ground on every side. Among these last are *Whipplea modesta*, *Linnæa borealis* and the Yerba Buena (*Micromeria Douglasii*).

We have here in the spring and in the summer a wealth of wild flowers, the ground in many places being literally covered with different species in succession. But as the season proceeds they disappear, and now one or two late-blooming Polygonums are about the only things left, except a few scattered individuals of a little Blepharipappus (*B. scaber*) and an occasional Monardella (*M. odoratissima* (?)), called Pennyroyal here, from the odor of its leaves.

But the vegetation has started finely again since the rains have come, and many species of plants that will not bloom until spring are now clothing the ground with a carpet of green.

During our mildest winters the wild strawberry blooms sparingly all winter; the same is true of a little Ranunculus, and the pretty little *Dentaria tenella* may nearly always be found blooming in January. In most places in the timber *Synthyris rotundifolia* always begins to bloom by the holidays, or a little later.

Foreign Correspondence.

London Letter.

THE nurseries of Messrs. Hugh Low & Co., of Clapton and Enfield, are amongst the most famous plant factories in the world. In England they have for many years held a position almost unique. Their trade is almost exclusively with other nurserymen, the hundreds of thousands of plants of all kinds annually grown there being dispatched every autumn to nurseries all over the British Isles, and even to America. The two nurseries contain glass structures, chiefly houses, which cover an area of upwards of 300,000 superficial feet. These are filled with enormous numbers of all kinds of ornamental plants, everything likely to sell, from fifty-guinea Orchids to sixpenny Genistas, being represented by hundreds, thousands or tens of thousands. Specialists the Messrs. Low & Co. certainly are, but they make a specialty of almost every good garden plant. The extent and work of this establishment are almost unknown outside what is termed the trade. I lately had an opportunity of inspecting the contents of both nurseries, and as these appear to me to be a sure index to the horticultural tastes in England at the present time, it seems proper to devote a letter to an account of some of the most noteworthy of the plants there.

The nurseries at Clapton are about five miles from the city. They were founded in 1820 by Francis Henschman. At that time New Holland plants were in high favor, and Henschman sent a collector to Australia to obtain plants and seeds. The Clapton Nurseries soon became famed for choice and new Australian plants. This expedition, alone, cost Henschman over £1,000. Mr. Hugh Low was at that time manager. He afterwards became sole owner, and continued to collect and cultivate Australian plants, Cape Heaths, and hard-wooded plants generally, until his death. His son, Stuart Henry Low, is the head of the present firm. He has made his nursery as famous for Orchids as his father did for New Holland plants. He was one of the first to send collectors for Orchids, and he has continued to employ a number of them, from whom enormous quantities of all kinds of Orchids are being constantly received, and not always alive, Mr. Low significantly remarked. The greater portion of the glass structures at Clapton are devoted exclusively to Orchids. Some idea of the magnitude of the collection may be obtained from the fact that five houses, each eighty feet long, and each containing nine feet width of staging, are filled with the following species of Cypripedium: *C. niveum*, *C. bellatulum*, *C. lævigatum*, *C. Haynaldianum*, *C. hirsutissimum*, *C. Sanderianum* and *C. Lawrencianum*. These are each represented by thousands of plants, all in perfect health, and mostly in five-inch pots. Of *C. Lawrencianum* there were probably 20,000 plants, and the richly variegated foliage of these fields of leaves was a glorious sight. *Cattleya Mossiæ* entirely filled a gigantic house 150 feet long, with fifteen feet width of staging. The display of bloom in this house when the plants are in full flower must be a grand picture. Another house, equally large, is filled to the door with healthy plants in all sizes of *Cattleya Gaskelliana*. Bushels of flowers were cut from these plants this autumn. There can be no question of the superior qualities of this species as a garden Orchid. The three kinds of *Cattleya* which I should be disposed to name as the best of all *Cattleyas* for the million are *C. Trianae*, *C. Mossiæ* and *C. Gaskelliana*. Thousands of plants of *Phalaenopsis amabilis*, *P. Schilleriana* (now a comparatively rare species in a wild state, I am told) and *P. grandiflora*; hundreds of the variety of the latter known as *aurea*, also of *P. denticulata* and *P. gloriosa*, all in good health, many of them recently imported. *Aërides expansum*, *Saccolabium guttatum*, *Cymbidium Lowianum*, *Dendrobium Brymerianum*, *D. suavisimum*, *D. Cambridgeanum*, *D. nobile* in variety, and many other species of *Dendrobium*; *Vanda Amesiana*, *Angraecum citratum*, *Lælia purpurata*, *Cattleya Mendelli*, *C. Gigas*; these were all represented by hundreds or thousands, mostly the latter. I have mentioned only those species which

are grown in these nurseries in surprisingly large quantities. The numbers given must not be taken as exaggerations; they are astonishingly large, but they represent the facts. The *Odontoglossums* at Clapton are almost as sand on the seashore. In their long houses they suggest huge beds of Leeks. A large house is filled with plants of *Cælogyne cristata*, some of them being very large specimens. They are planted out in beds, and apparently this treatment agrees with them. In addition to the above popular Orchids, Messrs. Low & Co. have a great number of varieties, *Cypripediums* being conspicuous amongst them. But units in such an immense collection do not get even passing notice from a visitor. The question one naturally asks on seeing these hundreds of thousands of plants, the bulk of which have closely followed after others which have been sold, is, What becomes of them all? It is almost distressing to have to admit that most of them must perish through improper treatment. If it were not so Messrs. Low & Co. would soon choke the horticultural world with Orchids.

But Orchids are only one of the specialties of this firm. Hard-wooded plants are grown in thousands, both at Clapton and Enfield. At the latter nursery there are about eleven acres covered with glass. The form, size, internal arrangement and general plan of this extent of plant houses are of the most perfect kind. The nursery is only young, but neither pains nor expense have been spared to make it capable of performing the work intended in the best and cheapest way. The houses are of great length and grouped in dozens. Each group has walls only on the outside, so that practically it may be called a large, low house, with ridge and furrow roof. Necessarily all the houses in the group are of the same temperature. It is only when looking below the stage that the absence of partition walls is seen; above the stage each division appears to be a house by itself.

Enfield is famous for its market gardens. It stands high and is practically in what we call the country. The growth made by the plants there is astonishing—in England, at any rate. Thus, Tea Roses only ten months old have shoots six to eight feet long, many of the plants having half a dozen such shoots. The plants are grafted in December and ready for sale by the following September. Clematis, the same age, were equally large. Amongst the plants grown for their flowers in winter I noted: *Acacia armata*, many thousands; *A. Drummondii*, hundreds; *Erica hyemalis*, *E. gracilis*, *E. persoluta alba*, Genistas, many thousands; *Polygala acuminata*, *Choisya ternata*, beautiful little pot-shrubs, well branched and full of flower buds; *Tremandras*, *Thibautia acuminata*, *Fabiana imbricata*, a first-rate pot plant, with white, tubular flowers, not unlike some *Ericas*; *Abutilons*, many fine varieties—Lemoine's, I believe—all in full flower at Christmas time; Ivy-leaved *Pelargoniums*, *Epiphyllums*, *Tecoma capensis*, with large heads of brilliant scarlet flowers, on plants about two feet high; *Gardenias*, *Callas* and *Daphne Indica*. These are all grown in very large quantities, few, if any, being in a larger pot than a six-inch. Of Palms, such as *Kentias*, *Latanias* and *Phoenix rupicola*, there are hundreds of thousands, from seedlings up to handsome table plants. *Lomaria gibba* is grown in thousands, and is one of the most popular of all Ferns for decorative work. *Cyperus distans* of gardens, which is *C. Meyenianus* of Kunth, the handsomest of all "grasses," as a pot plant fills an enormous house. *Celosia pyramidalis*, an improved strain, is here grown for the sake of its flowers in winter. The seeds are sown in July and by the middle of December the plants are in full flower. There were white, yellow, rose and crimson flowers amongst them. For cutting, I imagine, these plants must have great value in winter. *Bouvardias* are very largely grown, several large houses being filled with shapely, well flowered plants when I saw them. The best kinds were *Humboldtii corymbiflora*, *Jasminoides*, *President Cleveland*, *Dazzler* and *Maiden's Blush*. A house full of *Asparagus plumosus* was pointed out as "all we have left." For cutting, as well as a pot plant for table decoration, this graceful plant has very few equals. It is easily grown, easily multiplied, and stands much longer than any Fern. A large piece of naked land had just been cleared of dwarf Roses, most of which had gone to America. *Rhododendrons*, the Javanese kinds, are grown in large quantities, and many of them flower in midwinter. There can be no question as to the large place these plants are destined to soon fill in winter floral decorations.

I have only mentioned those plants which are grown in exceptionally large quantities, or which are comparatively unknown as useful winter-flowering plants. In America most things are done on a big scale, but I doubt if you have anything in the nature of a plant factory to compare with that of Messrs. Hugh Low & Co.

W. Watson.

New or Little Known Plants.

Ilex Amelanchier.

THIS shrub, of which our figure upon page 41 is the first which has been published, is one of the rarest and least known plants of eastern North America.

It is the *Ilex Amelanchier** of M. A. Curtis, who described it from specimens gathered by himself nearly thirty years ago in a swamp near Society Hill, in South Carolina, the only station in which this plant has been seen in recent times. A specimen of what is evidently the same plant is preserved in the Gray herbarium, labeled "*Prinos corymbosus*, Ph. Herb. Barton (from Bartram's Garden, from Machorin Rives)." No such name, however, was published by Pursh, and the source whence Bartram obtained his plant is, to say the least, vague. Another specimen of this plant in fruit is preserved in the Gray herbarium, labeled "Drummond in Herb. Hooker, Alabama or Covington." It is probable, therefore, that it will be found in other parts of the country besides the Society Hill swamp. This plant seems to be cultivated in England, as I possess a specimen made by Mr. Nicholson (No. 2,074 of the Kew Arboretum herbarium) without flowers or fruit, which clearly belongs here, although labeled *Prinos lanceolatus*, Pursh. *P. lanceolatus* is a very doubtful plant, entirely unknown to American botanists, and probably founded upon the figure in Hill's "Vegetable System," published in London in the middle of the last century. Pursh, however, who claims to have seen a specimen of this plant, describes it in his Flora, ascribing it to the low country of Carolina and Georgia, and his characters are copied by Chapman in the "Flora of the Southern States."

Our figure is prepared from one of Dr. Curtis' specimens, who described his plant as a shrub three to six feet high. It is to be hoped that its publication may draw the attention of botanists in the South Atlantic and Gulf States to this plant, and to the other southern species of the *Prinos* section of *Ilex*, which are still insufficiently represented in herbaria, and very imperfectly known. Cultural Department.

Sub-irrigated Gardens.

IN the advertising of Florida as it has been carried on for a score of years, the practice has been to hold up the orange as the leading attraction, while market-gardening is made to figure as a secondary industry, a degree less genteel than orange growing, but a very convenient resource for meeting current expenses "while the grove is coming into bearing." However the other industrial resources of Florida may stand the test of experience, candor compels me to say that market-gardening in this state, as a rule, is as precarious an industry as can be engaged in. In the neighborhood of the leading winter resorts, where there is a good local demand, vegetable-growing may prove profitable, especially if no severe frosts occur in winter. Strawberries pay well where they are grown systematically, as at Lawtey, and good shipping facilities are at hand; but as a rule, market-gardeners hardly recover expenses.

With natural waste, stealage and high freight-rates, the net returns from market-gardening seldom exceed the expenses of packing and production. Other obstacles which are encountered alike by those who grow vegetables for marketing or home consumption, are found in the chances of severe frosts in winter and drought in early spring, the latter amounting almost to a certainty. In the southern half of the peninsula danger from frost need hardly be taken into account, but in the northern half, winter gardens, which are the only ones planted for profit, are constantly in peril.

Droughts in Florida are particularly trying on cultivated plants whose feeding roots are within a foot or two of the surface. The soil in nearly all parts of the state is sandy, and lacks the capillarity by which soils of firm texture are enabled to withstand droughts. This evil is increased by tillage, which sepa-

*"*Ilex Amelanchier*. M. A. Curtis. Leaves oblong, barely acute at each end, serrulate, pubescent, and finely reticulate beneath; fruiting pedicels solitary, as long as the petioles; drupe large, red; nutlets strongly three-ribbed on the back; calyx-teeth acute. Leaves about two inches long, one inch wide. Drupe three to four lines in diameter."

rates the coarse particles still more from each other, and it is lessened by admixture of such substances as lime and muck. On wild vegetation, growing on undisturbed land, drought seems to inflict less damage than it does in other states. Without pausing to consider these seemingly contradictory phenomena, it suffices to say that the spring drought in Florida is an obstacle that cannot be overcome or counteracted except by some system of irrigation.

may be termed intensive gardening, and in localities where there is good demand for garden produce. It is a modification of Mr. A. N. Cole's system—an adaptation of it to sandy land, the principle involved being the retention of water supply just beneath the roots, so that by capillary action it may readily be supplied to them as needed. The first essential is an abundant supply of water, as from an artesian well, and the second is a subterranean reservoir or trench which will retain

Fig. 88.—*Ilex Amelanchier*.—See page 40.

In a soil so porous as that of Florida surface irrigation is impracticable. Windmills and other mechanical means of raising water are too expensive, except in peculiarly favorable locations. Artesian wells are most satisfactory, but they are not for poor men; and after a flow of water is obtained there arises the problem of distributing it to best advantage.

On the eastern coast of Florida, at Daytona and a few other places, there has come into use within two or three years a system of sub-irrigation, which answers admirably for what

a small quantity of water, and allow an excess, as from heavy rainfall, to escape.

The productiveness of the first gardens thus irrigated was so surprising that last winter a stock company was formed, with a capital of \$50,000, for the establishment of an extensive garden at Ormond. In their construction parallel trenches are dug two hundred feet long by four feet wide and twenty-two inches deep, they being sixteen feet apart between sides and ends. A thin mortar is then prepared, composed of one part

Portland cement and seven parts sand, which is poured over the bottom within a rough curbing of loose boards. After being smoothed to a level by drawing a short piece of timber over it, this bed is allowed three days to harden. Then a border is made all around by pouring the same kind of mortar between two courses of boards four inches wide, set on edge one inch apart, the space within the border measuring two hundred feet long by three feet wide. After the sides have been left three days longer to harden, the inner boards are removed and the whole inner surface receives a thin coat of pure cement in order that it may be water-tight.

At either end of the cemented bottom are set wooden boxes six inches square, rising six inches above the surface of the ground. Through these the gardener may see how much water is in the trench, and regulate the supply accordingly. Next to these are laid lengthwise of the cemented bottom five courses of narrow inch boards. Crosswise of these a second layer of boards is put on closer together than the first. Then Palmetto leaves are laid over the boards and the trench is filled in with earth. The water from the well is led through the garden in two-inch pipes and distributed to the beds in half-inch pipes, which open through faucets in one of the boxes that lead to the bottom of each bed.

It is found that by keeping up the supply of water in the trenches the ground over and between them is kept sufficiently moist in the driest weather, and that a most luxuriant growth of vegetables can be obtained. In order to economize space, different kinds of vegetables are planted in alternate rows—for example, several rows of Beets, Radishes and Lettuce between two rows of Cabbages. A close succession is kept up also, the intention being to have the ground constantly and fully occupied with the most profitable varieties. The cost of such beds is considerable, but it is found that one measuring four by fifty feet can be prepared for \$15 or \$20, and this affords a garden spot sixteen by sixty-six feet in area, on which may be grown a very large quantity of vegetables of quality and size not obtainable in any ordinary garden. An acre of ground thus prepared costs \$1,000, but it is believed that it will produce to the value of \$3,000 in a year. The length of the growing season in Florida is greatly in favor of this system, and it is not improbable that it will come into general use in localities where there is large demand for fresh vegetables in winter and spring. It is, of course, equally well adapted for flower-gardens.

Jacksonville, Fla.

A. H. Curtiss.

The Relation Between Blossoming and the Tubers in the Potato.

THE following abstract from *Annales Agronomiques* of a paper by Dr. E. Wollny has, perhaps, a practical as well as a botanical interest. Whatever may be the case in Germany, the flowering of the Potato is usually abundant here, but in a large portion of our best varieties no fruit is produced. It is not probable that the removal of the flowers or such varieties would in any way increase the development of tubers. If, however, the removal of the young tubers as they appear would increase the vigor of the growth of the flowers, this fact might be of advantage to those who are trying to produce new varieties from seed. It is now almost impossible to secure seedlings from some of our choice varieties, although they blossom freely. Some investigations by Dr. B. D. Halsted seem to indicate that failure to set fruit is due to defective or imperfectly developed pollen. It might be worth while to remove the young tubers from some of these varieties as they appear, in order to ascertain whether this treatment would encourage greater vigor in the development of the pollen, and the consequent production of seed.

In the climate of Germany the blooming of different varieties of Potatoes is very much restricted. Most of the varieties do not flower, excepting here and there in the course of years; a small number only flower regularly and bear fruit. It is not so in Chili, the habitat of the Potato. There it flowers abundantly, but the tubers remain small, while in the temperate zone the formation of the tubers is favored at the expense of fertilization.

This fact seems to indicate a sort of balance between the two modes of reproduction by the tubers, and by the seeds: the energy of the one seems to bring about the decadence of the other. In fact, Knight and Langenthal have found that they may increase the blooming by detaching the young

tubers as they appear. Inversely, they found that suppressing the flowers favored the development of the tubers of many varieties. An anonymous English author has obtained by this method an increase in harvest of 2,670 pounds per acre.

Wollny recognizes that, from his experiments, the development of the flower is prejudicial to that of the tubers. Experiments were conducted in 1886 on many varieties that produce flowers. Four plots were planted with each variety, one acting as a duplicate or control, being left to itself; the inflorescence on the other three was cut at three different periods. The inflorescence oftenest cut off produced the crop of greatest weight; it also exercised an influence on the number as well as size of the tubers. However, the early varieties, and the plants which had not been topped till late, gave a contrary result, one crop being poor, probably because there remained some little time between the operation and the maturity of the tubers, and the season had been especially dry from July 14th to August 25th.

These experiments enable us to understand why the Potato does not thrive alike in Chili and Germany. It is probable that dryness and sunlight induce bloom, and humidity, and a sky more or less cloudy, the formation of tubers. In fact, in dry years a great number of varieties flower, while the same varieties do not bloom when the weather is moist and the sky is obscure.

The influence of light upon the production of flowers is a fact that has been long known, and very recently Sachs has shown that it is the chemical rays which provoke flowering. Plants of *Nasturtium*, a flowering plant of the first class, produced no flowers behind a screen of a solution of sulphate of quinine. But it seems to us that it is necessary to divide the problem into two, and to distinguish one immediate influence and another indirect influence, the effect of which is itself accumulated by heredity, in order to become a race characteristic. These two features necessarily combine, and act in the same way in our country. We do not think, however, that these things are brought about by purely physical influence.

There are, in fact, many examples of plants being reproduced artificially or naturally by budding, root-grafting, tubers, etc., and which in flowering do not produce fruit, or which, producing fruits, are none the less sterile, as seeds are not formed in them. *Lysimachia nummularia*, a creeping plant; the Tarragon, which flowers but does not set seed; *Garlic rocambole*, which produces bulbs in place of flowers; a variety of *Ficaria ranunculoides*, which produces tubercles in the axils of the leaves; and Sugar-cane and Bananas, which are nearly always sterile.

Rose Notes.

JANUARY is one of the most critical months of the year to the Rose-grower, not only because the flowers are in greater demand at that season than at any other during the winter, but also on account of the weather, which in this latitude is usually severe and frequently dull. It therefore becomes necessary to exercise greater care in watering, as excessive moisture, either at the root or in the air, proves injurious, the diminished sunshine rendering the evaporation much slower than during the autumn months.

As to ventilation, it may be repeated that fresh air, carefully admitted, is one of the most valuable aids to the Rose-grower, but no hard-and-fast rule can be laid down for this operation, as it depends entirely on the condition of the weather. Similar advice may be offered in regard to firing, as this part of the work also needs careful handling to keep an even temperature of from 55° to 58° at night, this being found most satisfactory for an assortment of varieties. More Roses are injured by too high a temperature than by allowing the heat to fall a few degrees below the standard mentioned. It should be remembered that the original species, from which our fine varieties have been derived, were found in temperate climates, and it is only reasonable to suppose that their offspring will flourish under somewhat similar conditions as to temperature, although some allowance should be made for the extra stimulation required for the production of a succession of flowers at this season.

The effect, also, of any previous error in management, will be more noticeable at this time. Such mistakes, for instance, as the dangerous plan of running the houses at a specially high temperature just before the holiday season, to open an extra quantity of flowers, is a practice almost invariably followed by so great a falling off in the succeeding crop as to more than counterbalance the advantage gained.

Where a stock of young plants has been secured from early cuttings, some of them may now be ready for repotting, and

this operation should be attended to as soon as the roots are in a condition to require it, for when the plants are allowed to become stunted much valuable time is lost while they are recovering their vigor, and in some cases permanent injury follows.

Unless already provided for, no time should now be lost before putting in Rose-cuttings for the stock of next season, so that the plants may be in readiness for timely planting. It has been often proved that while a good crop of Roses may sometimes be secured from late planting, it is far preferable to have a strong and healthy growth and well-established plants before the dark days of early winter set in.

ately light loam on shallow benches, on which the depth of soil is from four to five inches.

Philadelphia, Pa.

Polyantha Rose, Mme. Georges Pernet.—The Polyantha Rose is year by year claiming more attention from American Rose-growers, and, as many of us think, quite justly; we doubt, though, if any considerable number of the Rose-loving public appreciate as they should its sterling merits. The dwarf Polyanthas are perfectly hardy, and will endure many degrees below zero with but slight protection. For the edging of beds or for running lines, they have no superior. Several introductions of late years in this class have evidently the blood of the Tea Rose in their veins. A question may be raised as to the

Fig. 89.—The Banyan Tree in the Botanic Garden, Calcutta.—See page 44.

The Hybrid Tea Rose, Puritan.—This Rose, like many other new varieties, was presented to the American trade with the highest testimonials, but the result, as is well known, has been a disappointment in a majority of cases, even in the hands of growers successful with other kinds. It would be both unwise and unfair to condemn a new Rose before a careful and thorough test had been made of its capabilities, but in the case of the Puritan a test of three seasons' duration has not proved it to be a commercial success, and though it may be an exceptionally fine variety in Europe, it does not seem to be adapted to our climate, at least as a forcing Rose. One great objection to it is its tendency to produce a large percentage of unformed flowers during the winter months, though this trouble has been partially removed by grafting it on Manetti, by which means a more vigorous growth and better flowers have been secured than when the Rose is grown on its own roots. But even under the most favorable circumstances, the large proportion of knotty, greenish-colored flowers has been a noticeable feature in a house planted with the Puritan.

Another objection to this Rose urged by some lovers of the beautiful, is that the growth and flower stems are so erect and coarse as to give a very stiff effect unless most carefully arranged, though it must be admitted even by these critics that a large bunch of long-stemmed Puritans loosely arranged in a vase is very beautiful indeed.

One point in favor of the Puritan is that it is an excellent keeper, retaining its freshness after cutting for as long a time as any variety with which we are familiar. In regard to treatment, it may be said that in the establishment of its introducer (where probably as good a result has been obtained with the Puritan as anywhere in this country) it is planted in moder-

ately light loam on shallow benches, on which the depth of soil is from four to five inches. W. Philadelphia, Pa. **Polyantha Rose, Mme. Georges Pernet.**—The Polyantha Rose is year by year claiming more attention from American Rose-growers, and, as many of us think, quite justly; we doubt, though, if any considerable number of the Rose-loving public appreciate as they should its sterling merits. The dwarf Polyanthas are perfectly hardy, and will endure many degrees below zero with but slight protection. For the edging of beds or for running lines, they have no superior. Several introductions of late years in this class have evidently the blood of the Tea Rose in their veins. A question may be raised as to the advisability of infusing the blood of *Rosa Indica* into these plants, for it at once lessens the hardness of varieties thus produced, and also, in great measure, destroys the simple charm of their flowers by producing varieties that are types of neither class; too large for Polyanthas and very insignificant as Teas. One of the most distinct and beautiful sorts introduced so far is Madame Georges Pernet, an exquisite shell-pink in color, often deepening to a rich crimson at the centre; larger than others of the dwarf section, but retaining the original flat, open form of the family. It is wonderfully profuse in the production of its clustered flowers, and all who see it are captivated by its simplicity and the richness of its coloring.

Orchid Notes.

Lælia anceps Dawsoni.—Ever since this, the gem of all the white varieties of this species, made its appearance in European gardens, it has been the admiration of Orchid lovers. Some twenty years have now elapsed since its introduction, and during that period importers have failed in their many efforts to obtain a supply, consequently it still remains a very rare plant. They have, however, been successful in discovering several white forms which are very beautiful, but the variety under note has not yet been equaled for form and loveliness. The whole flower is large and round, its sepals and petals being of the purest white, the latter being remarkable for their extraordinary breadth, having a lip blotched with rich purple, and the throat handsomely veined with the same color. A specimen with a dozen flowers is now adorning the Cattleya house of Mr. F. L. Ames, at North Easton, Massachusetts.

Summit, N. J.

A. D.

Phalænopsis gloriosa.—This is one of the latest additions to this beautiful genus. It is presumed to be a natural hybrid between *P. amabilis* and *P. grandiflora*, its habit and inflorescence assuming a character intermediate between these two species. It appears to be a very robust grower, and excepting in this respect it is by no means an improvement on either of its supposed parents. But not so with the hybrids of *P. Schilleriana* and *P. amabilis*, namely, *P. casta* and *P. leucorrhoda*. These are among the most beautiful of the whole genus, the former having bronzy green leaves, while the latter has the marbled leaves of *P. Schilleriana*. They vary little in the inflorescence, the flowers resembling those of *P. amabilis* in form, being pure white, with the base of the segments tinged with rosy lilac, and the lip beautifully speckled and marbled with purple. Some fine examples of these are now in full beauty here, bearing many flowered branching spikes. A rare variety of *P. leucorrhoda* (var. *alba*) is also in flower. This plant varies from the type in the color of its flowers, which are almost white. Another beautiful hybrid *Phalænopsis* is *P. intermedia Brymeriana*. This is a rare kind, differing from the type in its long, narrow leaves, which are pale green and speckled. The flower spike is deep green and more in the way of *P. rosea*; the flowers are white, suffused near the centre with rose, while the lip is a rich amethyst color. The handsomest and most interesting hybrid at present in flower here is *P. Harriettia*, a hybrid between *P. amabilis* and *P. violacea*, and previously noted in these columns. This plant improves greatly in size and color each year as it gets stronger.

Kenwood, N. Y.

F. Goldring.

Zygopetalum Mackayi.—This is by no means a new or expensive plant, having been introduced from Brazil in 1825. I consider it one of the very best amongst the autumn and winter flowering Orchids. It grows and flowers profusely under green-house treatment, not requiring as much heat as some of the other species of this genus. If grown in too warm a temperature the leaves are very liable to become spotted, which detracts very much from the beauty of the plant. For florists' purposes, like filling a large centre piece for table decoration, three or four spikes of this plant in the centre with other Orchids surrounding them would make a fine show. The flower-stalk or raceme grows from one to two feet in height, with large, purplish blue and white flowers, which emit a very delicate fragrance. The cultivation of this Orchid is very simple, for it will grow equally well in either rough loam or peat-soil if it only has good drainage. The pot should be about half full of crocks to secure that result. It should have plenty of water when in active growth, and even when dormant should be kept moderately moist.

Plant Notes.

The Banyan Tree.

A REPRESENTATION of one of the most remarkable trees now known appears in our illustration upon page 43. It is the great Banyan tree in the Botanic Gardens upon the banks of the Hoogly, below Calcutta, and the only survivor of many hurricanes among the large trees which long made this garden famous. It is believed to be only a few years more than a century since the seed from which this tree sprang was dropped by a passing bird into the crown of a wild Date Palm. The main trunk is now, however, according to the latest statistics which have been published in regard to this tree, forty-two feet in circumference; there are two hundred and thirty-two additional trunks, many of them eight or ten feet in circumference, and the branches extend over an area eight hundred and fifty feet in circumference, and form a dense canopy of perpetual verdure, through which the sun never penetrates.

The Banyan (*Ficus Indica*), like many species of the genus, springs from seed dropped upon the bark or in the crown of some other tree. The young plant as it grows sends down its roots, which finally reach the earth, and, increasing in vigor, finish by strangling their host. These roots grow together and form the nucleus of the main stem of the future giant. The branches send down to the ground in turn roots which, in time, become trunks, and so the tree goes on, spreading farther and farther, until it may, in time, cover acres of ground with its branches and afford shelter to thousands of men. The famous Banyan upon the banks of the Nerbaddo, beneath which Alexander the Great is said to have camped, once sheltered—if the story is a true one—7,000 men; and in the present century, although much reduced by the washing away of some of its trunks by floods, this tree has measured nearly 2,000 feet in circumference and has had more than 3,000 stems.

The tree in the Calcutta garden has been well cared for, and every effort has been made to induce it to develop new trunks to support the gigantic limbs which spread out horizontally about ten feet from the ground, as appears from the following extract from Hooker's "Himalayan Journals," published in 1855, in which a most interesting account of this tree may be found: "The props are induced to sprout by wet clay and moss tied to the branches, beneath which a little pot of water is hung, and after they have made some progress they are inclosed in bamboo tubes, and so coaxed down to the ground. They are mere slender whip-cords before reaching the earth, where they root, remaining very lax for several months, but gradually, as they grow and swell to the size of cables, they tighten, and eventually become very tense. This is a curious phenomenon, and so rapid that it appears to be due to the rooting part dragging down the aerial. The branch, meanwhile, continues to grow outwards, and, being supplied by the new support, thickens beyond it, whence the props always start outwards from the ground towards the circumference of the tree."

The Banyan, as this particular species of the Fig is called, although several others (including the Florida species figured upon page 128 of our first volume) spread by supports developed from aerial roots, has large coriaceous, dark green leaves, five to six inches long by three or four inches broad, and somewhat pubescent on both surfaces. The figs are the size of cherries.

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

IV.—THE DESTINATION OF THE LIQUIDS ABSORBED BY ROOTS.—EVAPORATION OF WATER FROM LEAVES.—INTERRUPTION OF THE WATER CURRENT.—EXTENT OF ROOT SYSTEM.

SOME very interesting facts appear when we compare the amount of roots in any given plant with the spread of foliage. One of the earliest recorded comparisons is that of Hales, in 1731, who gives the following figures in regard to Sunflower, three and one-half feet high. There were "eight main roots reaching fifteen inches deep, and sideways from the stem; it had, besides, a very thick bush of lateral roots, which extended every way in a hemisphere about nine inches from the stem and main roots." Adding together all the different measurements, he found the roots were no less than 1,448 feet in length, and the entire surface to be 2,286 square inches, or about sixteen square feet. The leaves of the same plant measured 5,616 square inches, or about thirty-nine square feet.

Recent estimates give the following ratios of the parts below ground to those above ground:

Silver Fir,	169:100
Norway Spruce,	267:100
Scotch Pine,	477:100
Hales' ratio would be for the Sunflower,	41:100

But from what was shown in the last paper, these figures are very misleading, since they do not take into account the surface of the root-hairs in the case of the Sunflower. In *Abies pectinata* and some other Gymnosperms, no perfect root-hairs are discoverable; the work of absorption is here* carried on by the delicate cells just behind the tip, which are sometimes branched, but do not take on the regular forms of ordinary root-hairs. When root-hairs are present in abundance, as in the Sunflower and by far the greater number of all our plants, the absorbing surface is surprisingly increased. Estimates of the amount of increase can be only approximate, but the following are given by authors: In some instances the surface is five times, and, in others, fifteen times greater than without them. It should be borne in mind that roots of some plants, especially trees, run through the ground to very great distances, such as those commonly planted for shade.

The absorbing rootlets, with their zones of absorbing cells, lie far away from the base of the trunk, and extend even beyond the eaves of the canopy of foliage, where it would seem as if the supply of water during a rain might be shed rather more abundantly. In any event, the absurdity of watering a shade tree near the trunk in time of drought is apparent. The strong root-branches near the trunk are for mechanical support, and take no part in the process of absorption from the soil, except to transfer what the rootlets far remote from them take in.

THE PATH OF TRANSFER.—The dilute aqueous solutions from the soil absorbed by the rootlets are carried to the leaves.

* There is possibly another mode in which these rootlets absorb nutriment from the soil. This will be considered later.

This transfer in our woody plants is effected wholly through the younger woody part of the stem, as will presently be seen, but in our herbaceous plants the transfer is through the cells of soft tissues, especially those which are unhardened elements, answering to what is true wood in our woody plants.

When a girdle of bark is removed from the trunk of a forest tree the leaves remain for a time, frequently for a season, or even more, about as fresh as ever; but as the wood begins to yield to the invasion of decay, the transfer of liquids from the roots to the leaves is more or less completely checked, and the tree dies. On the other hand, if, after having built up a staging around a tree to give it enough support to keep it in place, we should cut out all the wood of the trunk, leaving the bark, the transfer of liquids from the roots would be checked at once and the withering of the leaves would follow in a single day. Thus, by these two experiments, it is easy to prove that the path of readiest transfer of liquids from the roots is in the woody part of a tree trunk. This transfer is, in no sense, a circulation.

STOMATA, OR BREATHING-PORES OF LEAVES.—The leaves are practically continuous in their tissues with the fabric of the twigs, and, therefore, with the branches and main stem, just as the main stem is continuous with the main trunk and larger divisions of the roots and these latter with the rootlets. There is an unbroken connection between the rootlets, with their absorbing cells in the ground, and the thin tissues of the leaves exposed to the air. Now, from the thin tissues of the leaves water evaporates.

The external surfaces of the leaf are waterproofed by a substance known as cutin, which covers every part of the exterior, except at certain openings, chiefly on the under side, known as breathing-pores or stomata. These are so numerous in a single leaf as to be counted by hundreds of thousands.

They are, in fact, delicately-balanced valves of very minute size, which are so perfectly governed in their working that they can control the amount of water which is lost by evaporation through the otherwise impermeable covering of the leaf surface. The relations which these bear in point of number and method of construction to the peculiar surroundings of swamp and desert plants, are among the most interesting in the whole range of exquisite adaptations among plants. It is enough to say, at present, that the amount of water lost by evaporation, under ordinary conditions, is not larger than the roots can readily supply. When a greater demand is made on the roots than they can meet, the deficiency is revealed promptly by the wilting of the lower leaves and afterwards by those higher up on the stem. By this wilting the amount of evaporation is temporarily lessened, and thus a chance is afforded for the loss to be made good.

Recalling what was pointed out in the third paper of this series, namely, that the water throughout the plant is practically continuous, surrounding, as it does, in the form of films, each structural molecule of the whole plant, the current of water to meet that which is lost by evaporation through the stomata is uninterrupted as long as the supply from the roots holds good. But when the soil is relatively cold, the current is checked and the leaves wilt, as can be easily shown by a simple experiment. But the most common interruption is, of course, caused by too great dryness of the soil. Soil may and frequently does appear dry, and yet may have plenty of water clinging to its particles, affording an adequate supply for the plant, but when a certain limit of dryness beyond this is passed, the plant feels it and shows it. By the wilting of the lower and afterwards of the upper leaves, the evaporation is checked, and unless the interruption is too long continued, the current can be resumed when more water is supplied to the soil.

When a branch is cut off the current is arrested at once, and is not resumed completely, even if the cut end is plunged instantly in water. But it is an interesting fact that the leaves keep fresh longer if the branch is *cut off under water*; in this case, interruption of the current, even for an instant, is avoided; the continuity of the water system in the plant is unbroken. It is possible, in this way, to keep some branches fresh until decay of the cut surface begins.

It is said by Mr. K. Miyabe to be a common practice in Japan to cut with care flowering branches of ornamental shrubs and trees for decorative purposes, and to char the cut ends quickly and thoroughly before placing them in the water of the vase. By this simple plan, which prevents the attacks of fungi, causing decay, the branches remain fresh for a longer time than in any other way. Repetitions of this practice in Cambridge, last summer, showed great differences in this respect between different plants.

A modification of the practice of cutting off branches under water, to make them keep longer unwilted, is easily managed, namely, by making a second cut after the piece is put in water. The amount of water lost by evaporation differs according to various circumstances, such as the temperature of the air, the amount of moisture in the air, and so on, but the following figures may be of interest, although they are, at best, only rough estimates. Professor Prestwich, quoted by Rolleston, states that a tree of average size gives off two and one-half gallons of water per diem.

Hartig gives, as his estimate, about three pounds to an average tree of twenty years' standing.

Hales found that the Sunflower previously referred to in this paper, gave off about a pound and a third every day.

Evaporation of water from the leaves concentrates the dilute solutions of mineral matters brought up from the soil, (2) it drains the soil to a certain extent, and lastly (3), it adds a certain amount of moisture to the air. But these effects on the plant, the soil and the air have so many practical bearings, that they must be deferred for special consideration.

George Lincoln Goodale.

The Forest.

The Forests and Woodlands of New Jersey.*—II.

A PURE FOREST.—There is a pure forest of Pitch Pine (*Pinus rigida*) near Lakewood, in Ocean County.† The trees are fifty or sixty feet high, and they average about ten inches through. No underbrush grows among them, nor anything but moss. The ground on which they stand was cultivated a half a century ago, and this piece of forest shows that under favorable conditions trees grow much faster than most persons believe. The land here would have very little value for any other use, and this is true of a great deal of land in southern New Jersey. It cannot be made so valuable in any other way as by perpetuating forest growth upon it. Few things would be of greater benefit to this region than the recognition by its land-owners of the fact that Pitch Pine is a good crop.

CHANGES IN THE WOODLANDS.—There has not been much change in the condition of the woodlands of New Jersey during recent years, except what has been produced by the fluctuation which is always going on in the local industries in different parts of the state. As a consequence of this fluctuation there is some variation in the market for fuel and other products of the forest. In some districts of northern New Jersey lime-burning has been actively carried on for the last few years, and wherever this is the case it creates a demand for wood, which gives employment to many men as wood-cutters and teamsters, and considerable tracts of timber are cut off which would otherwise be allowed to stand longer. The profitability of forest-lands thus depends so largely upon local conditions that no general statement can be made regarding it. The establishment of a lime-kiln or other wood-consuming industry may render investments in forest-lands in its immediate vicinity profitable when they would not have been so without it. Considerable movements of the population of some portions of the mountain region in the northern part of the state have sometimes resulted from such changes in local industries which depend more or less directly on the supply of fuel and other forest-products. Between Deckertown and Brick House, and in other parts of this hill-country, there are hundreds of places still plainly marked by old Apple and Cherry trees, or by the mounds where the chimneys have crumbled down, where once stood the cabins of woodsmen. A new forest growth crowds and chokes the fruit-trees planted by these transient settlers, and vigorous Oaks and Chestnuts are growing in the very places where once the fire burned bright on the family hearth. An old resident of that part of the state told me he remembered when those woods were full of people, and mentioned having once been present at a Democratic mass-meeting at a remote point which he named, when there were hundreds in attendance; and he added, by way of emphasis, "Where are those Democrats now?"

BEAUTIFUL SCENERY.—There is a great deal of beautiful scenery in northern New Jersey, and more and more of the people of New York City will doubtless go to this region to live. Many thousands of them have already established their homes for the summer, or for the whole year, in the highlands of this state which lie nearest the great town; but the movement will go on increasing, and the beautiful hill-country, which is still further away, is certain to attract multitudes of

*From advance sheets of the Report of the Geological Survey of New Jersey.

†An illustration of the Lakewood forest appeared in this journal, on page 164 of Volume I.

men and women who value the healthful conditions of life in a region of hills and forests. All such persons have, whether they think about it or not, a vital interest in the treatment of forest-lands and trees, and in the diffusion of knowledge and the development of intelligent sentiment regarding these subjects. Unless thought and intelligence are applied to these matters, the beauty which now attracts people to these regions will be in a great measure destroyed by the advent and operations of a considerable population.

THE SOUTHERN PINE BARRENS.—The southern part of the state is rather monotonous in appearance, and in winter it is desolate looking and uninviting. But the winter is short here, and during the remainder of the year the Pine country is to the botanist one of the most attractive and interesting regions of the United States. There are many beautiful and interesting plants here, some of them extremely local, and others very rare. The queer little Fern, the *Schizæa pusilla*, is found nowhere else in the world, I believe, and many southern plants are found here which go no further north, while, on the other hand, many plants come down from the north as far as this, but are not found farther south, so that the flora of the region is remarkably rich, copious and interesting.

It is probable that the next few years will bring increasing changes in the woodlands of this part of the state. The chief value of the region depends upon its climate and upon the sanitary influences of its Pine forests. There is probably no part of the world which is healthful for everybody. I have known people who received decided benefit by removal from southern New Jersey to northern New England. But there are many thousands of persons in New England who are oppressed and depressed by the rigor of the northern winter who would be greatly benefited by removal to southern New Jersey, and some of them would live many years longer in this salubrious region than they are likely to do if they remain in their northern homes. Many such persons have already come here from Maine, Massachusetts, New Hampshire, New York and other states, most of them going into the towns to live. But the true place for such health-seekers is in the Pine woods.

The poorest people cannot well come, for there would be no way for them to make a living. The land in southern New Jersey is not rich, and some capital is required for successful farming here. It is never wise to go to a new or unknown region to live without some direct personal examination of the country and its resources. It is not judicious to make a change by which so much is placed at risk on the strength of any report whatever—not even on the one which I am now writing. I wish merely to point out the fact that during the next few years there is likely to be a gradual and considerable increase in the demand for forest lands in southern New Jersey and a consequent advance in prices. The people who should come here from the states farther north are those who have sufficient means to live without any very profitable industry; whose investments yield an income which will support them, or nearly support them, and whose health would be improved by living here. For such persons fruit-raising, gardening or farming in this region would be a most healthful and pleasant recreation—if they like that kind of work. But the real reason for their coming here is to be found in the comparative mildness of the winters, in the soft yet bracing atmosphere, and especially in the great number of days in the year when any man or woman who can be out of bed can live out-of-doors.

The woods of southern New Jersey should not be cut off. The land now in forest ought never to be cultivated—not much of it. The whole Pine region ought to be gradually filled up by a population able to live without much general agriculture. The country is naturally fitted to be a great sanitarium, and there will soon be an imperative need that the people who are to live here shall learn what are the true uses of the forests, and how they can be permanently preserved and made most valuable to their owners.

Franklin Falls, N. H.

J. B. Harrison.

Correspondence.

A Horticultural Register.

To the Editor of GARDEN AND FOREST:

Sir,—I read with interest the remarks on nomenclature by Mr. R. J. Halliday at the Florists' Convention in New York, and the editorial remarks on the subject in your paper. This is a movement in the right direction, and I hope the committee appointed to determine names by which flowers shall be known will be successful.

While approving everything done in this direction at the convention, I wish to submit a supplemental suggestion.

When the names have been definitely fixed they should be registered, with Number, Name, Description and History, in a book, or series of volumes, to be called the *American Horticultural Register*.

In this register should be recorded, first, the names of all varieties of flowers, fruits and plants which are now cultivated, to be followed with new varieties as they are originated and found to be worthy of propagation. This register should be authorized by the association, and kept by, or at the office of, GARDEN AND FOREST, and new varieties could be submitted and recorded, and a certificate be furnished the originator. A separate series of numbers should be devoted to each flower; fruit or plant—for instance, make a separate list of Roses, Chrysanthemums, Pansies, Apples, Pears, Grapes, Ferns, and then number each list separately, commencing each with number one, and continuing the lists and numbers as new varieties are offered for registration.

Every one can see the advantages of a system of this kind, without enlarging upon them.

The system of registering fine live stock is well known, different registers being opened for the various kinds, such as trotting-horses and thoroughbreds, short horns and Jerseys, and so on. Flowers, fruit and plants can all be as well included in one register.

Some of the numbers of such numerous families of flowers and fruits as Roses, Chrysanthemums, Grapes, might become so familiar as to be used in some cases in place of names. Any one knowing anything about trotting horses knows that Hambletonian 10 is Rysdyk's Hambletonian.

The American Trotting Register is kept by John H. Wallace, of New York, editor of *Wallace's Monthly*, under the supervision of the National Association of Trotting Horse Breeders, and a fee is charged for registration, which, I suppose, pays all expenses of keeping the register.

Walnut Creek, California.

A. L. Bancroft.

[Our correspondent hardly needs to be reminded that herd-books and stud-books are prepared for purposes quite distinct from those which it is proposed to secure by this system of plant-registration. Individual animals are registered in order that they may be identified, that their pedigree may be established, and that purity of blood may be maintained in a given breed or strain of live stock. In the case of plants, however, where a single registration is made for all the individuals of a given variety, and where the parentage of a plant is often unknown and always of secondary importance, it is difficult to see how a register would prevent the evils complained of. The concerted action of florists and nurserymen to prevent "substitutions," and to insist upon the abolition of duplicate names in the trade, is one step in the right direction, and the organization of some authoritative body, who shall issue certificates for plants and fruits of merit, and to whom appeal can be made in cases of doubtful identity, is another.—Ed.]

Fruits for Cold Climates.

To the Editor of GARDEN AND FOREST:

Sir.—Under this title some late articles from Vermont have been extremely interesting to western people, as showing how the question of adapting Russian fruits to American conditions looks to one in the far north-east. But some of the views must be profoundly modified to suit the longitude of Iowa.

The writer truly says, "In the prairie states intense summer heat and drought and the fatal sap blight must be encountered." Then he adds: "The fruits of the Russian and Asiatic Steppes furnish the best material to meet these contingencies." In this last statement the writer has certainly been misled by incautious statements. The best and most conservative horticulturists of the prairie states are not satisfied with the past performance of Russian fruits, nor hopeful of their future success here.

The Russian apples, from which most has been hoped, have developed in the prairie states three serious (and with most varieties fatal) defects, (1) winter-killing, (2) sap blight and (3) unfruitfulness, to say nothing of the poor quality and early decay of most of the fruit produced.

During the season just past the sap blight has ruined some varieties upon which the highest hopes had hitherto been built. This disease has made our nurseries and orchards of Russian Apples look like a typical case of measles after the

disease has "come out." I have lately attended a meeting of the Horticultural Society of eastern Iowa and the meeting of the society of western Iowa, and failed to hear even one variety of Russian Apples—or any other Russian fruit—commended as reliable for general cultivation in Iowa.

Regarding Russian Pears and stone fruits, no man can say that any one variety has yet shown reasonable ground to expect of it permanent usefulness in any single region of the west. The truth is that experience on the prairies has thus far failed to justify the expectations raised by the over-hopeful introducers of Russian fruits. The failures have not all been proclaimed. We are awaiting further trials, but without enthusiasm.

It would be interesting to know upon what authority Dr. Hoskins bases his belief that "The Russian tree fruits are undoubtedly of hybrid origin; . . . in the valley of the Volga and the Steppe region the influence of north Asia stock preponderates." De Candolle, who had been supposed very high authority, takes a diametrically opposite view, saying of the Apple: "The lack of communication with Asia before the Aryan invasion, makes it probable that the tree was indigenous in Europe, as in Anatolia, the south of the Caucasus and northern Russia, and that its cultivation began early everywhere."

The names of a large portion of the Russian fruits received in the west indicate a German origin.

Des Moines, Iowa, December 24th, 1888.

C. L. Watrous.

Periodical Literature.

A supplement published with the Christmas number of the *American Florist* gives one a good chance to see the average level attained by our florists in the preparation of "set pieces" and floral decorations for public and domestic buildings on festal occasions. It contains more than seventy pictures of such designs, ranging from small baskets and bouquets to altar decorations, including a number of arrangements for funerals and weddings. In many cases great ingenuity is shown in the application of flowers to would-be decorative purposes; but, unfortunately, in many instances it is ingenuity misapplied. In one picture we see an upright piano swathed with roses in a way that could hardly be improved upon, if it is assumed that so to enwrap a piece of furniture is a task that good taste can sanction. And the artist who constructed the "Funeral Design of Jacob's Ladder, or the Golden Stairs," or the "Floral Table," or huge "Floral Butterfly," must have possessed a degree of skill which might profitably have been devoted to a better purpose. Among the worst things in the collection are those which show the manner in which certain public monuments had been treated on Decoration Day—notably the Farragut statue on Madison Square, where "the old Salamander" is made to look ridiculous with a huge wreath encircling his body, while the sculptured base is entirely concealed by ugly constructions representing ladders, swords, cannon and a steamship at sea. Some of the chancel and staircase arrangements of foliage plants, on the other hand, are very good; and nothing in the shape of a set piece could be better than the "Trinity Cross," composed chiefly of Lilies and very graceful in shape. A simple and appropriate funeral wreath is one formed of four Palm branches held together by two bunches of Lilies-of-the-Valley, and some of the little baskets filled with only one or two kinds of flowers are also pretty. But too many of the baskets shown are far too elaborate for their purpose, and we find that even the perverted taste for baskets in the form of shoes, hats and other objects wholly inappropriate for association with flowers, still persists. On the whole, the collection of pictures proves that good taste is by no means absent in this community, which uses cut flowers more profusely than any other in the world, but that there is still great room for improvement, and much need for the cultivation of greater simplicity and a truer appreciation of what the beauty of flowers really is.

It appears from an interesting article published in the December number of the *Druggist's Bulletin* that the annual crop of the American Ginseng-root, which for the last twenty years has amounted, on an average, to 400,000 pounds, is all exported to China. The first shipments are said to have been made in the year 1718 through the agency of the French missionaries in China. The American Ginseng (*Aralia quinquefolia*) grows in the dense forests from Canada to the high mountains of Carolina and Tennessee, and from Maine to the Mississippi. It has a stout root, three to six inches in length, divided into two lobes at the base, which is usually harvested before

the ripening of the seed, a practice which is gradually exterminating the plant. The demand, however, is steadily increasing, while the production in late years is falling off, so that the price at the present time has risen to two dollars and a half a pound. The maximum export of 600,000 pounds was reached in 1860, since which time it has gradually diminished, and is now lower than the average of the last forty years; and it seems to be only a question of time when the Ginseng will be exterminated, unless the time of gathering the roots can be regulated so that the seeds may ripen and fall before the roots are dug.

Various attempts have been made to cultivate the Ginseng, especially in New York, Pennsylvania and Wisconsin, but no satisfactory results have yet been reached. Large roots, which are the only ones that find a ready sale at remunerative prices, have only been produced from plants grown naturally in the shade of dense forests. As is well known, the roots of the Ginseng have no medical value whatever, and their use by the Chinese from time immemorial seems based upon some popular superstition in regard to this plant. But whether it is valuable or not, it is an important article of export, for which there is, and probably always will be, an active demand; and it seems for the interest of the communities in which this plant grows to prevent its extermination by legislation, for the same reason and in the same manner that game is protected during a certain part of each year.

In a late number of *Nature* it is stated that at the meeting of the Scientific Committee of the Royal Horticultural Society on November 13th, Mr. Henslow showed specimens of several species of plants which are propagated by cleistogamous flower-buds. By that means, while retaining a dwarf habit, they are able to multiply very rapidly, and to extend over considerable areas in a tennis-lawn. Although none of them are perennials, they remain so reduced in size that they are not exterminated by the mowing-machine periodically cutting them down. The result is that each species has more or less covered certain patches of ground, to the almost entire exclusion of everything else. The plants in question are *Cerastium glomeratum*, *Montia fontana*, *Trifolium procumbens*, *Sagina procumbens*, *Alchemilla arvensis*, *Veronica arvensis* and *Poa annua*. Mr. Henslow added that he had observed, many years ago, *Trifolium subterraneum* flourishing in the same way in the close-cut grass in Kew Gardens, on the site of the present rockery.

Recent Plant Portraits.

PINUS LARICIO, *Gardeners' Chronicle*, December 15th; a portrait of the specimen growing in Kew Gardens near the principal entrance, and planted by R. A. Salisbury in 1814.

SATYRIUM CARNIUM, *Gardeners' Chronicle*, December 15th.

FICUS ROXBURGHII, *Gardeners' Chronicle*, December 15th; an admirable reproduction of the frontispiece to Dr. King's monograph of the south Asia Figs, showing the curious way in which the abundant fruit of this species is produced. "*Ficus Roxburghii*," to quote from the columns of our contemporary, "is a native of the lower and outer Himalayas from Nepal to Bhotan, being found at elevations of from 1,000 to 3,000 feet. It is a tree from fifteen to twenty-five feet in height, and with a wide, spreading head. The leaves are large, measuring from one to one and a half feet in length, and from twelve to fifteen inches in breadth. The most striking feature in the tree is, however, the great abundance of its handsome, russet-red figs. These figs, in shape and size, much resemble Dutch turnips. They are carried in enormous bunches on the stem, especially near its base, and smaller bunches on the main branches. The mass of figs borne at the collar of the stem on this singular tree at the time when it was photographed, as Dr. King informs us, was about a hundred weight. The fruit, however, although eaten by the unfastidious Indian laborer, is quite unpalatable to a European, being insipid and sloppy."

ARBUTUS ANRACHNE, *Gardeners' Chronicle*, December 22d; a view of a fine specimen tree in Kew Gardens.

STAPELIA GIGANTEA, *Gardeners' Chronicle*, December 22d.

LODOICEA SEYCHELLARUM, *Gardeners' Chronicle*, December 22d; a figure showing the method of germination of this plant—the so-called "Double Cocoanut."

PASSION FLOWER, WOODHATCH HYBRID, *Gardeners' Chronicle*, December 22d; a hybrid raised in an English garden between *P. racemosa* and *P. quadrangularis*.

CRATÆGUS MEXICANA, var. CARRIERI, *Gardeners' Chronicle*, December 22d; from a specimen in Mr. Gumbleton's garden, near Cork, in Ireland.

Notes.

More than twenty million pounds of raisins were packed in California last year.

Tomatoes growing in the open air were picked fresh from gardens in Santa Rosa, California, on Christmas day.

Small Holly-trees three or four feet high were imported from England for holiday decorations, and are still seen in many windows in this city. They were, in most cases, symmetrical and well formed, superior both in berry and foliage to the loose Holly imported in crates. In addition to the ordinary form were shapely little trees with variegated foliage and golden berries.

The range of the Post Oak (*Quercus obtusiloba*) may be extended eastward to Brewster, on the border of Chatham and Harwich, in Massachusetts, where Professor Farlow informs us that he has detected this tree in what is the only station reported for it on the mainland of Massachusetts. This, Professor Farlow tells us, is also the most eastern station of *Lachnanthes tinctoria* known.

Professor Church has recently given an account of his analysis of the tubers of *Stachys tubifera*, the new Japanese vegetable, from which it appears that they contain 78 per cent. of water, 1.5 per cent. of albuminoids, 1.7 per cent. of non-albuminoids, 16.6 per cent. of sugar, .7 per cent. of fibre, .1 per cent. of ash, .2 per cent. of fat, with a trace only of starch. A comparison of this analysis with that of the Potato shows a much larger amount of water, and rather more flesh-forming albuminoids than are found in the Potato, and that the sugar replaces the starch, which the analysis of the Potato shows to be 15 per cent.

A correspondent calls our attention to an error in the account of the "Washington Oak at Fishkill," published in our issue of December 19th, 1888. William Denning was described as Washington's Adjutant-General, upon authority which seemed adequate, and without reference to the rolls of the Colonial Army. It appears, however, upon further investigation, that Mr. Denning held no commission in the army, although as a patriotic citizen of Orange County in this state, eager to aid in supplying the army, his relations with the headquarters during Washington's residence in Newburgh were, his grand-daughter informs us, intimate and cordial.

Herr Max Leichtlin writes to *The Garden* that the fungus disease which has caused such serious damage to Christmas Roses in Europe is probably induced by a disregard of the natural conditions under which these plants have been produced. In their wild haunts they thrive in shady nooks in loamy soil, with no other added nourishment than the decaying leaves supply. In cultivation they are often kept in sandy soil that has been highly manured, and planted in the open sun. The remedy is to wash off the roots, replant in a border which has been filled in for a foot with fresh loam, and which is shaded for a portion of the time at least, in mid-day; then mulch with half-decayed leaves and let the plants alone.

A tersely written Bulletin from the California Board of Forestry calls the attention of the citizens of that state, and especially of the farmers and irrigators, to the dangers that threaten their interests from the destruction of mountain-forests. The wasteful and ruinous methods of cutting timber, the increasing damage by fire, land-laws that invite fraud, the neglect of the school forest-lands, all combine to rob the people of their rights. The Board asks the people to urge upon Congress to withdraw all Government timber-lands in the state of California from sale or entry, and to insist that certain lands be maintained permanently in forest to guarantee verdure on the water-sheds and preserve the springs and streams.

Of tomatoes there were packed last season 3,319,437 cases of two dozen tins each, or a total of 79,666,488 cans, costing at points of production about \$6,000,000, and reaching consumers at a total expense of \$8,000,000. The total pack in 1887 was 2,817,048 cases. The canning industry has grown rapidly in the Western and Southern States, largely reducing the demand upon Baltimore, Philadelphia and New York for such goods. In a few years each section of the country bids fair to supply its wants from home canneries. The leading points of production are Maryland and Virginia, credited with 1,118,733 cases; New Jersey, 788,363; Delaware, 227,030; New York, 197,432; Western States, 796,599; Eastern States, 43,360; Canada, 73,990.

Baron Eggers, well known for his botanical explorations in Saint Thomas, San Domingo, and more recently in the Bahama Islands, is about to engage in an examination of the flora of the high mountain ranges of the eastern part of the Island of Cuba, first made known by Charles Wright twenty-five years ago. Some of the highest summits of Cuba reach an elevation of about 9,000 feet, and as these mountains have only been partially explored, Baron Eggers may be expected to add a considerable number of species to the Cuba flora. Baron Eggers, who may be addressed to the care of Messrs. Brooks Brothers & Co., Santiago de Cuba, will be prepared to furnish sets of Cuban plants for ten dollars the 100 specimens, delivered in this city.

A correspondent in Germantown sends us a box of the deliciously fragrant flowers of *Chimonanthus*, the east Asian representative of our *Calycanthus*, or Sweet Shrub. The flowers of *Chimonanthus* are rarely seen in this climate in good condition, as they appear in January, and are destroyed by cold as soon as they open, in ordinary seasons. The flowers are pale yellow or nearly white, and purple on the inner face of the petals. They appear before the leaves. If this shrub, which is quite hardy here, is planted at the north, a very sheltered spot near a building should be selected for it, in order to secure as much protection as possible for the flowers. *Chimonanthus* in the extreme Southern States is one of the most delightful winter-blooming shrubs which can be planted in a garden.

A correspondent of the *Independent*, writing from Orleans, Illinois, makes a strong plea for the Barberry as a hedge-plant. "Planted in hedges," he truthfully explains, "the Barberry is a bower of beauty from the time its pendulous racemes of yellow bells swing in the spring sunshine throughout the winter, when the scarlet berries blush under veils of snow and sleet." Moreover, the Barberry has practical value as well as beauty to recommend it. It "makes a sauce which rivals the Cranberry in excellence, . . . and has sufficient juice to make most delicious jelly, especially if mixed with apple juice, which relieves the tartness and enhances the beauty of the color." The bark, too, we are told, is useful for tanning purposes, the roots for dyeing yellow, and the berries as a source whence malic acid may be extracted.

"The fundamental difference," says a recent writer on Japan, "between Japanese and foreign methods of adjusting culled flowers has often been remarked. With us the general idea is to produce a bouquet in which the richest variety of color can be obtained—a sort of crush-concert of hues in which individual form and beauty are almost lost. The Japanese florist, on the other hand, prefers to display the natural lines of stems and branches, and to exhibit the subtle shapes and colors of each bud and blossom in an open and well-balanced composition. The same subordination of color to form and the same simple naturalness as opposed to ostentatious artificiality, are to be observed in even the minutest details of Japanese gardening. Grouped masses of similar flowers are not wanting in some parts of the native gardens, but there is no attempt to arrange them into color patterns and geometrical designs.

We referred not long ago to the fact that perfume making from fresh flowers was becoming an established industry in our Southern States. A recent letter to the New York *Tribune* describes some of the processes employed in Florida, and declares that their results are so excellent that "now it is claimed that attar-of-rose can be made in Florida with as much success as in the gardens of Bulgaria." The two chief processes used are distillation, and absorption, or "enfleurage," the latter being resorted to in the case of the more delicate flowers, whose perfume is found to be injured by heat. It is based on the "established law of affinity which hydro-carbons have for perfumes. When these have been highly purified they catch, and in catching concentrate and intensify, the odors communicated to them." A perfume factory where this process is used contains multitudes of wooden frames with rims about three inches in depth, in which are set several sheets of glass. Each sheet of glass is spread with a layer of pure fat, and over this fat are sprinkled the petals from which the odor is to be obtained. The sheets are piled closely on one another in the frame, the frame is slid into a tight-fitting box, and in a short time the fat absorbs all the odor. The fat is then cut up into small squares and immersed in alcohol, when "the delicate essence at once parts from its coarser companion, and, uniting itself to the alcohol, is fit for the market." Another method is to strew the petals on cloths saturated with oil, and when the odor has been absorbed, to put the cloths in a press and squeeze out the impregnated oil.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY
THE GARDEN AND FOREST PUBLISHING CO.
OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, JANUARY 30, 1889.

The Nation's Forests.

THE first step in the effort to provide for the conservation of the forests on the national domain should be the withdrawal from sale of all forest-lands belonging to the nation. It will not be necessary to preserve and maintain all these forests permanently, but the extent of forest-territory which will be required by a practical plan of forest-preservation and management for our Western mountain regions cannot be at once precisely determined. A thorough examination of these regions, and of the agricultural country depending upon them for its water supply, will be necessary, in order to show what forests must be retained, and what tracts of timber can be put upon the market without injury to the important interests involved. Until such an examination has been made, none of the forest-lands now belonging to the United States should be sold.

The second step should be to commit to the United States army the care and guardianship of the forests belonging to the nation. There is in time of peace no other work of national defense or protection so important as this which the army can perform, and it is plain that under existing conditions the forests on the national domain will not be—indeed cannot be—adequately guarded and protected by any other means. The measures which have been tried, including those now in operation, or nominally in operation, have proved almost entirely ineffective. The forests on the public lands are pillaged by settlers, and by the employees of railroad and mining companies, without scruple or limit. Other instruments will have to be employed if the forests are to be preserved. Their complete and final destruction, with that of the soil which sustains them, is, under the present system, or want of system, only a question of time, and of a very short time.

The officers of the United States army are educated by the nation for its service, and they constitute a body of men not equaled by any other in our country in their equipment for guarding and protecting the great forest-regions belonging to the nation. They possess every kind of fitness for this work in greater degree than any other class of men, and if authorized by law to undertake this service

they would have the power and the means necessary for its performance, while everybody else is at present inevitably powerless and incapable. As there is likely to be very little work for the army hereafter in the care of the Indians, it will be available for this service of guarding the national forests. The work can be done well by the army, and it would cost nothing, or very little, while any other plan would necessarily be both ineffective and costly. This guardianship and defense of the nation's forests by the army of the nation should be continued and maintained until a sufficient number of adequately trained and equipped foresters has been provided by the national government for the administration of a complete and permanent system and policy for the management of the forests on the public domain.

This brings us to consider the third step. This should be the appointment, by the President, of a Commission to make a thorough examination of the condition of the forests belonging to the nation, and of their relation to the agricultural interests of the regions through which the streams flow which have their sources in these forests, and to report, with the facts observed, a comprehensive plan for the preservation and management of the public forests, including a system for the training, by the government, of a sufficient number of foresters for the national forest service.

The Commission should determine what portions of the existing forests on the public domain should be permanently preserved, and in what manner the remainder should be disposed of. The national forests can be so managed that they will be perpetually reproduced, and will yield forever an abundant supply of timber for the inhabitants of the adjacent country, and a revenue which will more than sustain the cost of the forest service. A National School of Forestry should be established at a suitable place in one of the great mountain forests on the public lands, and its equipment should be as thorough and adequate for its purpose as is that of the National Military Academy at West Point.

THE "Elizabethan home" has long been a synonym in American ears for all that is most beautiful in domestic architecture, and, at the same time, most comfortable and home-like. But exact observation and clear judgment have less to do with this feeling than traditional sentiment and the reports of tourists enchanted by the picturesque accessories of English country dwellings. The following description—quoted from the pages of the *American Architect and Building News*, where a recent address by the English architect, Mr. J. A. Gotch, is discussed—gives a more exact idea of Elizabethan architecture than those that are commonly presented to us.

"In planning these homes nearly everything was sacrificed to show. People who lived contentedly with their dogs in rooms carpeted with rushes, which were changed once a week, could hardly be expected to be very squeamish in regard to niceties of arrangement, and it is common to find the bedrooms opening from each other after the fashion of a New York tenement-house, without any corridor for reaching them separately, while in some very magnificent mansions the suites of rooms allotted to visitors could only be reached from the reception-rooms by crossing the court, which, it is needless to say, had no provision for sheltering from the rain or snow the festal clothes of the persons who walked through it. So inconveniently planned, according to our notions, are the Elizabethan mansions in this respect, that they can hardly be used at all by a modern family. One or two of them have been remodeled by the rather heroic treatment of building a corridor around the court-yard, like a cloister, so as to reach the farther bedrooms without going through all the others, but this darkens half the windows, besides spoiling the court. In other cases a portion of the house has been rebuilt, at a great expense, according to our ideas, but most of the Elizabethan palaces, splendid as they once were, have been allowed to go to ruin, simply from the impossibility of utilizing them for a modern family without very costly alterations. Even the reception-rooms, magnificent as they are, accord ill with the

habits of the present representatives of the families which built them. . . . In a few instances, as at Hatfield House, Lord Salisbury's favorite residence, the ancient mansions will probably be kept in habitable condition for many years longer; but the great majority, like Haddon Hall, the most beautiful of all, will inevitably be abandoned, sooner or later, by their owners, from the impossibility of being comfortable in them, and they will fall, one after another, into decay. Whether this will be a great loss to architecture is not altogether certain. The plans have been recorded in many books, so that we shall not lose the recollection of their stately and picturesque arrangement, but the details of the designs are rarely of a very high order of merit. The rich ceilings made of plaster modeled by hand are often the best portions. . . . But the wood-work is no better than that done now, while the carving, both on wood and stone, is of little value, either in design or in execution, and would hardly be noticeable except for the lavishness with which it is used. . . . Moreover, the houses of that period contained glaring faults. Symmetry being, in the minds of the architects of that time, necessary to correct taste, windows and bays were distributed almost without regard to the interior planning, and a bay illumining a great gallery might be balanced by one of equal size in the buttery. Where real windows could not be used, false ones were put in without compunction to preserve the symmetry of the composition, and Cobham Hall, one of the best examples, is . . . 'riddled' with sham windows, put in with real mullions and transoms and glazed, but closed behind the glass with a wall."

These facts are familiar to all who have really studied Elizabethan and Jacobean architecture. Nevertheless, an unreasonable admiration for it still persists in the minds of the public. Knowing that these houses have incomparable dignity and picturesqueness when seen in a general view amid the surroundings with which the passage of centuries has beautified them, even Americans often seem to think that there can be no more certain way of securing a beautiful and comfortable home than by imitating them as closely as possible. We do not say that the actual attempt is very often made, but it is occasionally made in a more or less ambitious and conscientious way; and we could point to one house at least—one of the very costliest country homes ever erected in this country—which has been copied room for room and stone for stone from an Elizabethan prototype. It should be needless to explain, now that our own domestic architecture has developed types of genuine beauty and of complete appropriateness to our own wants, that such efforts must be mistakes both from the æsthetic and from the practical point of view. If the ancient homes of England are proving themselves uncomfortable for habitation even in England, how shall they meet the needs of this country—how shall they suit our habits of life, which differ still more from those of the sixteenth century Englishman than do those of his descendants of to-day? Nor does a really cultivated taste find, as Mr. Gotch confesses, much to admire in the heavy, monotonous, and often clumsy and unrefined decorative motives, which were employed by the architects of the English Renaissance—their work in this direction is, in truth, far inferior, both in design and in execution, to the best that American architects now produce. And, of course, the general and, so to say, superficial charm which old English homes possess in their original situations, is entirely lost when they are transplanted to alien climes and deprived of all historic associations.

Since it was announced that certain improvements would necessitate the destruction of the thirteen trees planted on Washington Heights, in this city, by Alexander Hamilton, to commemorate the original states of the Union, much interest has been felt for their preservation, and a movement has been started to purchase enough land about them for a small park. The trees are Liquidambars, and, although they are called a grove in the newspapers, they really form a dense clump. They all stand within an area fifteen feet square, which means that they were too closely planted to permit of a healthful growth. Several of them are so choked and crowded that at this age their trunks are not more than six or eight inches in diameter, while the

trunks of the larger ones are about two feet in diameter. Even the best of them have no symmetrical development, and the tops of most of them show considerable dead-wood. We are not likely to have too many small parks, and it will be fortunate if some of the land about these trees can be devoted to public use. But apart from their historical associations these Liquidambars have no great value. Many single trees are better worth saving, and, indeed, if Alexander Hamilton had planted one tree where he planted the thirteen, it would now cast nearly as large a shadow as they do and it would be much more likely to survive another century.

White Huckleberries.

IN GARDEN AND FOREST of January 2d there was a notice of the occurrence of a form of *Gaylussacia resinosa* with white fruit in New Jersey. A similar case is known to me at Shelburne, New Hampshire, where a few bushes of *Vaccinium Canadense* bore flesh-colored or pinkish berries, instead of the usual deep-blue fruit. The flesh-colored berries were found at the same spot in two successive seasons, but I have no means of ascertaining whether their occurrence has been noticed for a greater length of time. In the berries both from New Jersey and New Hampshire we have simply albino forms not depending on the growth of a fungus; certainly in the case of the New Hampshire plants, which I examined carefully.

In Germany, however, there has been observed a white-fruited form of the common Blueberry, or *Heidelbeere* of the Germans, which is due to a fungus growth. As long ago as 1859 it was described by Döll under the name of *Vaccinium Myrtilus* var. *leuocarpon*, but, in 1879, Schroeter discovered that the white color was due to the growth of a fungus which he called *Peziza baccarum*, which, in its mature or ascospore form, consists of a small cup on a slender but comparatively long stalk which springs from a small, hard nodule, the sclerotium. Woronin, in a very interesting paper in the Memoirs of the St. Petersburg Academy, beautifully illustrated, as are all his writings, has recently given a full account of similar white berries found by him in Finland on *Vaccinium Vitis-Idæa*, *V. Oxycoccus* and *V. uliginosum*, three species also found in the United States, and of the fungi which produce the white color.

Woronin considers that the fungi on the different *Vaccinia* above named, although closely related, really belong to four distinct species of *Sclerotinia*. The hard nodules, or sclerotia, are found in the berries late in the season, and the cup-like, mature form is produced early in the spring from the *sclerotia* in the berries which have lain on the ground during the winter. The ripe ascospores in the cups germinate at once, and the germinal tubes make their way into the young stems of the *Vaccinia* in the neighborhood. They penetrate to the woody bundle at first, and afterwards produce a cushion-like mass of filaments under the epidermis, from which grow chains of necklace-like filaments, which cover the surfaces of some of the upper leaves and the young shoots and exhale an odor of almonds. Each joint of the filaments ultimately becomes separated from its neighbors by a peculiar structure, called by Woronin a *disjunctor*, and they fall apart and constitute what are called by botanists the conidial spores. The conidial spores, which mature at the end of May or early in June, are, through the agency mainly of flies and bees, carried to the pistils of the opening flowers. Those which are deposited on the stigmas produce long tubes, which, somewhat like pollen-tubes, traverse the styles, but, unlike pollen-tubes, do not attach themselves to the ovules, but make their way into the placentas. The mycelial tubes then grow and cause an atrophy of the young seeds and internal portions of the berries, although their general size and shape are comparatively unchanged. The tubes finally become indurated and form a compact mass, and the berries blacken and fall.

It is highly probable that we have similar diseases of Huckleberries and Blueberries in this country, and Woronin suggests that it is possible that the disease of the Cranberry, *Vaccinium macrocarpon*, in the United States, may also be due to the growth of some species of *Sclerotinia*, to which genus he refers the fungi described in his memoir. He also mentions similar sclerotoid forms on Cherries, berries of the European Mountain Ash, and a few other plants, and considers that it is probable that the common mould of Plums, *Oidium fructigenum*, is connected with some hitherto unknown sclerotium. W. G. Farlow.

Japanese Gardening.—I.

ONE of the best accounts of the aims and results of Japanese landscape gardening that have ever been written in English was published in a periodical which seldom comes beneath the eyes of the general public—the *Transactions of the Asiatic Society of Japan*. Therefore, although it bears date as long ago as November, 1886, a brief summary of it may not be unacceptable. It is itself, however, so condensed, as well as so full of varied and interesting information, that I can do no more than select passages here and there, with the confession that almost all those omitted are of equal value.

"Landscape gardening as practiced in Europe," says the author—Mr. J. Conder, a Fellow of the Royal Institute of British Architects—"is subjected to greater formalities of design than in Japan, and in theory it harmonizes less closely with the features and disposition of real scenery. It is more of a science and less of a fine art." Even in our most naturally designed gardens a certain element of formality is prescribed by the canons of European taste. "Houses being objects exhibiting formal and geometrical lines, it is maintained that such lines should be repeated to a greater or less extent in the adjoining garden, in order to produce an approximate combination." And this feeling expresses itself in details as well as in the general scheme; "trees and shrubs are often selected for their uniformity in size and shape, and grouped in equidistant rows and phalanxes," while it is unnecessary to refer to our use of formal flower beds and minor features. The Japanese have attained to no such skill in the cultivation of exotic plants as has been attained in Europe, "but the absence of such artificial refinements is considerably to the advantage" of landscape gardening as a fine art. "Constructing only with the materials native to the country, the designer is able to follow consistently the arrangements suggested by nature, the landscapes he seeks to reproduce being in all cases identical with the natural types that are familiar to him." As regards scale, the gardens of Japan are far less imposing than those of Europe. "There is little here to compare in gardens to our spacious English parks. . . . The Japanese artist confines himself to narrower and humbler lines, but it must be recognized that within his limits he produces results unrivaled in natural beauty and loveliness. . . . Unnatural regularity is generally most studiously avoided, but the variety obtained is the result of well considered arrangement, and by no means that of hazard."

The theory of the art, like so many other intellectual things, was derived from China, but greater simplicity prevails in Japanese developmets. "It is usual to divide garden compositions into three styles expressive of their general character, . . . the Finished, or labored style, Intermediate style, and Free, or bold style. In practice these styles are not sharply divided, but a garden, according to its rough or elaborated character, may generally be classed under one of the three heads, . . . and it is an important law that whatever character is decided upon should be consistently followed throughout." The Finished, or elaborate style, is the one least commonly employed. "There are other guiding principles, . . . such as suitability in character to the pursuits and rank of the proprietor . . . and the expression . . . of some predominating sentiment. The garden is regarded as a poem or picture intended to arouse particular associations and inspire some worthy sentiment. . . . If, for instance, a garden be designed for a poet or philosopher, its general disposition should express dignified seclusion, solitude, virtue, or self-abnegation." It is difficult for us, with our less strongly poetic temperament, to sympathize with such aims or even to see how they can be effectually carried out or clearly understood. But to the Japanese the thing seems clear and simple enough, and with the following paragraph even Europeans should be in heartiest accord: Gardens, it is said, should be undertaken from a genuine love of nature "and with a desire of enjoying the beauties of natural

scenery, and should be so arranged that the four seasons may each contribute in turn to their artistic excellence. They should be pleasant retreats for hours of leisure and idleness; and as one writer has poetically expressed it, 'places to stroll in when aroused from sleep.' . . . In western designs the idea of displaying wealth and luxury is paramount, and our gardens are principally regarded as resorts for the pleasures of society and fashion; whereas in Japanese gardens the prevailing intention is rather that of a place exempt from public haunts and fitted for unrestrained ease and meditation." Such ideas as The Happiness of Retirement, Modesty, Peace, Gentleness and Chastity, Connubial Felicity and Old Age, the Japanese strive to express in their arrangements. In part their success depends upon the emotions naturally excited by scenery of various kinds, but in part upon traditional historical or philosophical meanings which are associated with many of the arrangements adopted, and, of course, cannot be understood by foreigners.

Passing from theory to practice, Mr. Conder notes that the first step in the artist's education is to visit good scenery and make notes and sketches. These, of course, "cannot be closely followed in preparing designs, but will supply suggestions and lead to originality in composition. . . . Before proceeding to execute a landscape-garden a careful survey of the site and its surroundings is necessary. If it be a bare and level area, the designer is free to arrange his composition in any way that he may please according to its size, bearing in mind the locality and surroundings, and the character of garden suited to the particular proprietor. But if it be a site possessing natural facilities, such as fine trees in prominent positions, hillocks, a stream, or even a natural cascade, the artist will consider how such natural features can be utilized and worked into his design. . . . A neighboring view may be cleverly taken advantage of, and the garden so arranged as to harmonize with it, the distant landscape when seen from the rooms of the house actually appearing to form part of the whole composition. Aspect must be considered as well as prospect. . . . Great care is recommended in considering the scale of a garden. If a small garden be arranged on the same plan as one of a larger model, it will look weak and unsatisfactory; and . . . if a large garden be designed upon the lines of a smaller model, it will lose all its grandeur. . . . For example, the arrangement of two or three large rocks in front of a clump of fine trees in a large garden will look more imposing than a greater number of smaller ones. Multiplicity of detail within small compass is, however, necessary in a little garden, in order to give it interest and add to its apparent scale. . . . A garden is, above all, a place for summer enjoyment, . . . and must therefore, by all means, look cool and refreshing; but such coolness is not produced by planting trees too densely and crowding the area with many objects. A few masses of foliage, judiciously arranged in the background, may be made to impart a fresh and cool effect. The presence or suggestion of water is necessary; but it must be remembered that clean, shallow and running water looks much cooler than deep, stagnant or weed-covered pools. The total absence of litter and untidiness, added to the presence of water, produces the most refreshing effect. A garden, therefore, should have large, open spaces, cleanly kept, with stretches of white sand or gravel in the foreground and moss in the background. . . . In large compositions the distribution of areas and contours demands the first attention. In some cases advantage will be taken of natural elevations and depressions in the ground. Sometimes a site may possess a stream, cascade or natural inlet of water. Supposing no such facilities exist, the aspect and prospect which the plot possesses will be carefully studied, and the best positions for hill and dale, lake and waterfall, determined. It often happens that water cannot be obtained; and if the character of the scene to be represented requires it, it is not unusual to arrange the hills, rocks and plants in such a way that the idea of water may be suggested. Sometimes a stretch of bare, beaten, brown earth or of well-raked sand will indicate a lake or sea, and a meandering, pebbly bed a river, the surrounding rocks, plants and piles further assisting the delusion." No rules strictly direct such arrangements, yet several general guiding principles are respected, for a Japanese garden is "more than an artistic disposition of trees, flowers, shrubs and stones. It is a real picture composition, intended to represent some imaginary landscape. . . . The principle of suggesting to the imagination the idea of space by means of blanks and obliterations, so common in Japanese pictorial art, is followed also in horticultural compositions. A hill, it is said, should never be constructed touching an outer fence or boundary; a space behind it, however small, produces an

idea of greater extension of the garden. By a similar theory the spaces immediately behind the nearer hills should be left open and not filled with detail. There are five principal hills specified for gardens. . . . in the Finished style. Hill No. 1 forms the most central feature of the nearer distance. . . . As it represents a near mountain of considerable size, it should have broad and sweeping sides, and may have a pathway and a little house or pavilion upon it. Hill No. 2 should be placed adjacently to No. 1, a cascade and rocks often dividing the space between the two. It is secondary to No. 1, and should be somewhat smaller and of different character. Hill No. 3 is placed upon the other side of No. 1 near the base of its broad slope and more in the foreground; it suggests the idea of a lower hill divided from the main mountain by a depression. This depression may be supposed to be occupied by a hamlet, road or stream, in which case its sides should be clothed with a few thick-foliaged trees or shrubs to add to the impression of a sheltered and inhabited dale. No. 4 is a small hill generally introduced into the near foreground; it should have none of the characteristics of a large mountain, should be low, rounded and covered with much detail in the form of stones, shrubs and flowers. Hill No. 5 is in the remotest part of the garden, and, as it represents a distant mountain, it should be steep and mysterious without much detail."

This, then, in general terms, is the scheme upon which a Japanese constructs one type of garden, varying it, of course, in multitudinous ways to suit the suggestions of the site or the leanings of his individual taste. It may seem at first thought as though, while avoiding artificiality in one direction, the artist who works thus falls into it in another direction—our idea of a "natural" landscape arrangement is certainly not the wholesale creation of features which sometimes are not even suggested by the site, nor the simulating in miniature of large natural forms, nor the effort to make sand or gravel do duty for water or small shrubs produce the effect of trees. Could anything, we ask ourselves, be more unnatural than a small garden designed to imitate an expanse of mountain scenery, with bare earth instead of living water for its lakes and streams?

But it seems to me, after much reading upon the subject, that the Japanese aim is not more wholly different from ours than is the spirit in which this people looks at works of gardening art. It is often said that they have less imagination than Occidentals; but the statement refers merely to abstract imagination, so to say—to metaphysical, spiritual imagination. As regards material imagination—the picture-making power of the eye, the ability to recognize, appreciate and enjoy the beauty and sentiment of a thing which is not actually imitated or even portrayed in art, but merely suggested—the case is exactly the reverse. Here the Oriental imagination is much stronger than our own. Whether we try, in our garden arrangements, to be formal and architectural, or natural and free, we demand that the desired effect shall be actually, practically, materially obtained, that the things we see shall be literally themselves, and depend not at all for their significance upon the imaginative faculties of the observer. The Japanese, on the other hand, never desires anything but a strictly natural effect; but he is content that it shall be suggested rather than displayed. The elements before him are valued less for themselves than for their power to act upon his imagination and recall the forms of beauty which they typify rather than reproduce. We demand in a natural garden that it shall be a beautiful passage of scenery. The Japanese demands that it shall suggest a beautiful passage of scenery. His garden is to him less a landscape, properly so called, than a picture of a landscape; and he does not see anything more unnatural in a small picture composed of piles of earth, rocks and shrubs representing mountains, trees and lakes, than we see in a small painting on canvas when it represents similar objects. We know that an adequate statue of a man can be made within the compass of a few inches, and never think of questioning its truth or "naturalness" because of its size. It does not purport to be the man, but merely suggests the man, and our imagination accepts it without thought of its discrepancies in size and color. Thus the Japanese looks upon his little studies of mountain scenery, and finds them as thoroughly natural as works of art can be.

How soon an Occidental can learn to assume his standpoint, how thoroughly he can learn to appreciate the suggestive beauty of Japanese gardens—these are questions, of course, with regard to which only travelers can speak, and Mr. Conder does not touch upon them.

New or Little Known Plants.

Berberis Thunbergii.

ALTHOUGH one of the earliest Japanese plants known to botanists, having been collected by Thunberg, one of the first Europeans to explore the botany of Japan, *Berberis Thunbergii* has found its way into western gardens only within the last few years. Thunberg considered it identical with *B. Cretica* of south-eastern Europe, which, perhaps, is nothing more than a geographical form of the widely distributed and very variable *B. vulgaris*; while some later botanists have referred it to *B. Chinensis* of northern China, a very different plant, with slender pendulous branches, and long, drooping racemes of flowers and fruits. *Berberis Thunbergii* is, nevertheless, one of the best marked and most distinct of all the Barberries now found in gardens. It forms in cultivation a dense, although graceful, bush, some three feet high by four or five feet in diameter. The branches are stout, pendulous towards the extremities, deeply grooved, covered with bright red bark, and armed with simple, straight spines, half an inch long. The leaves are deciduous, tufted along the entire length of the branches, obovate or spatulate, rounded at the apex, quite entire, bright green above, paler on the lower surface. The flowers, which are produced in the greatest profusion along the whole length of the stems, are solitary or in pairs, or rarely in few-flowered umbels. They are rather large, with three or four acute red sepals and pale straw colored petals, sometimes streaked with red, and are almost odorless. The fruit is bright red, a quarter to half an inch long, elliptical, or nearly globose. It possesses an insipid and very disagreeable flavor, and remains upon the branches bright and fresh through the winter, and until the appearance of the new foliage in the spring. The leaves of this plant late in the autumn are tinged with brilliant shades of orange and scarlet.

Berberis Thunbergii was sent several years ago to the Arnold Arboretum from St. Petersburg, and is now often seen in American gardens. It has much to recommend it—hardiness, free and rapid growth, neat and graceful habit and foliage, brilliant autumn coloring, and showy and persistent fruit; and few shrubs are better suited to form low masses of foliage, or for dwarf hedges. It is not particular as to soil, and, like the other Barberries, is easily increased by division, from cuttings and from seed.

Our illustration upon page 55 represents a well grown specimen of *Berberis Thunbergii* in a garden near Boston, and shows the habit of the plant; while Mr. Faxon's drawing upon page 53 makes known to persons unfamiliar with them the foliage, flowers and fruit of this species, of which an excellent colored figure was published in the *Botanical Magazine* for 1882, t. 6, 646.

Cultural Department.

The Propagation of *Rhododendron maximum*.

Sir.—In 1885 a distinguished landscape-gardener remarked that whoever would produce *Rhododendron maximum* so cheaply that it could be freely used, would render a service to all planters, and this suggested some extended experiments at the Shady Hill Nurseries.

First, fresh seed of this *Rhododendron* were planted in boxes of carefully prepared soil in February. They came up promptly and abundantly, but difficulties began at once. This plant, when first germinated, and for some time afterwards, is the most delicate little atom of vegetable life that can be conceived of. It is exceedingly small, and is as transparent as water, of which, with a very thin film of more solid substance to inclose it, it seems largely composed. This delicacy of structure exposes it to the attacks of a minute fungus, which often kills a box of several thousand little seedlings in a single day. To save them from this devouring enemy, which always appears as soon as the plants do, it is necessary to transplant them into fresh earth immediately after the seeds germinate. This was done three times, and then the plants became a total loss from the persistent attacks of this fungus. We

transplanted many thousands, and finally, after the most patient and painstaking efforts, continued through two winters, saw all our labor end in failure.

The prime conditions necessary for the healthy growth of the seedlings of this species are, evidently, absolutely perfect drainage, plenty of fresh air, and a rather deep shade. The green-house did not supply these conditions. Then a bright thought occurred to one of the men watching the experiments, by which we hoped to supply the exact conditions of nature and let nature take all the care of the plants.

In April, 1887, we planted plenty of seed of this plant on the surface of old, mossy logs, which lay half submerged in the water of a springy bog, at the foot of a mountain. These logs soaked up water from below, and were never dry, even in summer. They were also in a rather deep shade, as tall trees stood about them on all sides. I had often noticed small plants of different *Ericacea* in abundance on top of much decayed stumps in such places, so that I planted the seed with some hope.

In November, 1887, the logs were covered with multitudes of little plants of our *Rhododendron*, but pitiful looking things they were. In size from one-sixteenth to one-eighth of an inch high, and still so watery and transparent that we had no expectation of their ability to survive the winter.

time, they can be grown rapidly and successfully. Four years ago Mr. Jackson Dawson, in an address before the Massachusetts Horticultural Society, explained in detail the method he has practiced with uniform success. The seed is sown in earthen pans early in January, in a soil of peat, loam and sand in equal parts. The sand should be sharp, but fine and clean, and entirely without iron or clay. Over the broken crocks, which should fill one-third of the pan, a covering of sphagnum or coarse siftings of peat is placed, and upon this two inches of the prepared soil is sifted, and then well firmed and watered gently. As soon as the soil is settled the seed can be sown quite thickly. It should then be covered with the slightest possible sprinkling of soil, after which a covering of fine sphagnum is put over it, a gentle syringing is given, and the pans are placed in a temperature of seventy degrees. After sowing, the seed should on no account be allowed to get dry; but at the same time saturation should be avoided. It will usually come up in from two to three weeks, and as soon as the first seedlings are seen the coarsest of the moss should be gradually removed, and when the seed is fairly up a slight sifting

Fig. 90.—*Berberis Thunbergii*.—See page 52.

In November last the seedlings were, to our surprise, half an inch high, with leathery leaves, and were safe and solid, and from that time on we knew it was plain sailing. This is a slow but a sure and an easy way to make this magnificent native *Rhododendron* as cheap as any ordinary shrub, and I hope it will be put in use by many nurserymen.

Somerville, Mass.

F. L. Temple.

[It is true that success in growing *Rhododendrons* from seed is almost impossible when they are started in a house devoted to a mixed collection of plants which require treatment entirely different from that needed by the delicate seedlings of the different species of *Rhododendron*. The device of our correspondent bridges over the most dangerous period in the growth of the seedlings, and when time is no object and where one has a swamp filled with moss-covered and decayed logs no doubt large numbers can be produced in this manner. But nurserymen are not always the fortunate possessors of swamp-land, and besides this, they are obliged to raise stock more quickly than is possible by the swamp-method. Although the seeds of *Rhododendrons* are very minute, and the plants in the first six months of their existence require the most delicate handling, yet if a house is devoted exclusively to their propagation, so that they can be watched and watered, shaded and transplanted at precisely the proper

of fresh soil among the young plants will help to strengthen them. As soon as they have made the first rough leaf, they should be pricked off thickly in boxes or pans of fresh soil prepared as for the seed, carefully syringed, and kept growing in a high temperature and moist atmosphere. Such delicate seedlings as *Rhododendrons* at this stage should never be transplanted in a shed or room where there is any draught, but always in a close, moist atmosphere, as the roots are so delicate that only a moment's drying makes them almost worthless. After five or six weeks the plants will have covered the surface of the ground, when they will again need transplanting, this time half an inch apart, and otherwise should be treated as before, always having fresh soil and clean boxes at each transplanting. At this stage, if everything has been carefully attended to, they will grow very rapidly, and will soon need transplanting the third time, and, if properly cared for, may be set two inches or more apart.

This frequent transplanting in fresh soil each time keeps the plants from damping and lays the foundation for a vigorous plant for the future. If *Rhododendron* seedlings are left long in the seed-box or pan, they are apt to be attacked by a minute fungus, which will often carry off

thousands in a night. The best remedy, at the first signs of its appearance, is to sift heated sand amongst the young seedlings, using a very fine sieve. This looks like heroic treatment for plants of this tender age, but it is very effective in destroying the fungus, and does not injure the young plants. About the first of September more air and less moisture may be given, so as to harden the plants preparatory to their removal to winter quarters, which should be a deep frame or pit in some sheltered situation. They may be put in this pit the first of October; or sooner, if the house is needed for other purposes. In this pit they should have plenty of air every pleasant day, but should be covered every night to keep them from frost as long as possible. This can readily be done in most seasons up to the middle of December or the first of January by a single mat; they can then be covered with mats or meadow hay, and will need to be uncovered only once in every two weeks for an hour or so to guard against damp or excessive moisture, which often will induce a growth or fungus even in a cold pit if it is kept long without airing. In the spring, about the first of May, the young plants can be transplanted into well-prepared beds of peaty soil, or a light, sandy loam of good depth. If dry weather sets in, they will require plenty of water, as they are not deep-rooted at this time; if water is handy, a good syringing may be given every evening as soon as the sun begins to leave the bed, until the middle of August, when all moisture should be withheld, so that the plants may ripen well before winter sets in. If they have been well cared for, they will be from six to seven inches high at the end of the second season.

At the approach of cold weather a slight covering of leaves between the young plants with Pine boughs or coarse meadow hay, over the tops, to keep the sun off, will carry the plants through the winter in safety. The following spring they may be planted in the nursery, where they can remain until used. The same treatment will apply to Azaleas, Kalmias, and other Ericaceous plants, only the Azaleas grow much more rapidly than the others, and at the end of the second season such species as *A. mollis* and *A. calendulacea* should have quite a number of flower-buds on them, while the Rhododendrons will not show signs of flowering until the fourth or fifth year.—Ed.]

The Fruit Garden.

MULCHING STRAWBERRIES IN WINTER.—Much has been written about this, and no one doubts the benefit of it. In northern Vermont, however, we can pretty safely depend upon a snow mulch from December 1st to April. This winter is an exception. We have had no snow yet, to amount to anything, and in the middle of January our roads are bare, and as smooth as the best Macadam. The fields have but a sprinkling of snow, and the strong Strawberry plants stick up through it; but though somewhat seared, they seem yet little the worse for the exposure. As regards material, the ideal mulch for almost everything is evergreen boughs; but it is not often practicable to get enough of them. Oat, wheat and rye straw are used, and the last is best of the three; but better still is bean straw. If evenly applied, it is not beaten down by the snow so as to smother or rot the plants, and it holds even the lightest snow in its open meshes, thus utilizing to the utmost all that comes.

PROTECTION OF TREES FROM MICE.—Binding the trunks with tarred paper is what is commonly advised for this purpose; but the paper is apt not to give complete protection near the ground. It also costs more and does not last so long as the laths and barrel staves that I have used for many years. These are cut in two in the middle, driven or pressed slightly into the soil, and tied with a single turn of strong cotton twine. They may be left on the year around, and in the fall are utilized by the codlin worms as an apparently safe retreat. But late in the fall they are tied again, being reversed, so that the spun-up worms are left exposed to a cold world, and are cleaned off very quickly by the birds. Quarter-inch board is preferable to barrel staves, on account of the bilge-curve of the latter, which does not allow them to be turned; but if the strings are cut a few days in advance, and the staves laid on the ground so that the inner sides are exposed, the birds will clean off the worms in a short time.

WHEN TO PRUNE.—It has a smart, snappy sound to say "prune when your knife is sharp," and for such pruning as may be easily done with a knife, it is well enough. But for the larger limbs that must often be amputated, pruning when your saw is sharp will not answer always and everywhere. Where all trees are so hardy that a cut, however large, never blackens or "bleeds," one may prune at any time with safety, while trees are not in leaf. But in the northern tier of states there are many trees planted that are more or less injured in their wood by hard winters. Such trees are best pruned after the severe weather is over, but then as early as possible, so that the wound will get pretty dry before the sap starts. This will not always prevent "bleeding" when a tree has been much hurt by low temperature, but it is the best that can be done for them.

WHAT TO APPLY TO THE CUTS.—I have tried grafting-wax, both solid and liquid, and various cements. Wax cleaves or crumbles off too soon. The best cement I have used is made by boiling pine-tar slowly for three or four hours, adding half a pound of beeswax to a quart of the tar. Have ready some dry and finely-sifted clay, and when the mixture of tar and wax is partially cold, stir into the above named quantity about twelve ounces of the clay, continuing the stirring until the mixture is so stiff, and so nearly cool, that the clay will not settle. This is soft enough in mild weather to be easily applied with a knife or spatula. But of late I have found that any thick ochreous paint, put on with a brush, answers every purpose, and can be applied faster and more easily than anything else. On large wounds it may need renewing, and if a red paint is used they are more easily seen.

CUTTING AND KEEPING CIONS.—I have always been best satisfied with the growth of cions cut in the fall. This, I know, is not so necessary in milder localities, but I believe it is best everywhere. It is often said that cions should be cut from bearing trees; and many believe that this favors early fruiting of the graft. I wish I could see some proof of so easy a method of bringing late-bearers forward. I think, if one is sure of the variety, there is no good reason why the cions may not be taken from the youngest trees—even from the nursery. To keep them well over winter, it is usually advised to pack them in damp moss or sand. It is difficult to get moss just right in dampness, and sand endangers the sharpness of the knife in grafting. The very best packing material is green-wood sawdust, just as it comes from the log. Cions nicely tied in bundles and labeled securely, and so packed, firmly compressing the sawdust under, over, around and between the bundles, well covered and kept cool, will come out in the spring in perfect condition.

Newport, Vt.

T. H. Hoskins.

Orchid Notes.

The most conspicuous objects in the cool house at present are specimens of *Ada aurantiaca*, the showiest of all cool Orchids, excepting *Epidendrum vitellinum*. It grows in masses, with tapering bulbs and narrow, deeply channeled, dark green leaves about one foot high. The distichous racemes spring from the base of the bulbs, bearing about a score of reddish orange flowers, in which the segments are compressed near the base and spreading at the apex. The whole flower is from one to two inches long, according to the variety. This is a strong grower and may always be depended upon to give a good crop of bloom. It requires an open soil with good drainage, and should have a plentiful supply of water at all seasons. Near the Ada and helping to relieve its brilliant hues, are plants of the Lily-of-the-Valley Orchid (*Odontoglossum bulchellum*). This is a most attractive species, growing in dense masses, with ancipitous, shiny bulbs and long, grassy leaves. The half pendulous racemes bear about a dozen flowers, which are pure white, excepting the prominent golden crest. They last a long time in perfection, and their usefulness as cut flowers is greatly enhanced by a delightful Hyacinth fragrance. Some three or four varieties of this species are known, the best being probably a very large form called Dormannianum. *Maxillaria picta* should be grown, if only for its powerful aromatic fragrance. This is a dwarf kind, with tapering, yellowish and furrowed bulbs and short, leathery leaves. The single-flowered scapes spring in abundance from the base of the bulbs—more than a score from one bulb. The flowers are cream colored, dotted with purple and chocolate. It does well in a cool house, with a good rest, after growth is finished.

Odontoglossum triumphans is a showy Orchid introduced nearly fifty years ago from New Granada, where it is met with in dense forests, in company with *O. Pescatorei*, but it is not at all plentiful. The bulbs are ovoid, compressed, and attain a good

size; the deep green leaves are about one foot long. The arching racemes bear from twelve to twenty flowers of good substance, and about three inches across, golden yellow, heavily blotched and barred with cinnamon brown and margined with pale yellow. The lip and column are pure white, with one large irregular blotch of yellowish brown on the anterior lobe. This is a handsome Orchid and a few plants will be found very useful to brighten the more sober tints of the varieties of *O. crispum*. It is robust and free growing, requiring an open soil with good drainage and a liberal supply of water at all seasons.

Lycaste lanipes.—Though not a showy Orchid this will be found very useful for cutting, as it produces abundant flowers from the base of the matured bulbs, and lasts a long time in perfection. In habit it resembles the well-known *L. Skinneri*; but the bulbs are larger and the leaves are of leathery texture. The creamy white flowers are four to five inches across, with a pure white lip beautifully fringed along its margin. It should be grown in a rich, open soil, in an intermediate temperature,

This is a very strong and free growing species, of noble appearance, with thick, fleshy stems, bearing broad, distichous leaves about two feet long, from the axils of which spring stout racemes two feet long, bearing a dozen large, greenish white flowers with a cordate, cuspidate lip of ivory white, and lasting about six weeks. This grand Orchid will repay liberal cultivation, as it delights in a rich soil kept open with nodules of charcoal. The roots quickly fill the pot, when the plant will be benefited with weak liquid manure. The best plants I have yet seen are growing among a collection of Palms and foliage plants and receiving the same treatment. The best form is *Superba*, a great improvement on the type, but unfortunately it is somewhat rare. A small growing and free flowering variety is named *Virens*. This is a very inferior form, but is often grown for its floriferous qualities.

Among the many choice varieties of *Lælia anceps*, *Hilli* and *Veitchi* may be noted as of especial merit. The former has large flowers of good substance, pure white tinged with pale

Fig. 91.—*Berberis Thunbergii*.—See page 52.

kept moderately dry after the bulbs are matured. It is a native of Guayaquil.

Angræcum sesquipedale.—This is an interesting and very striking Orchid introduced some sixty years ago from Madagascar, where it luxuriates on large trees with a maximum of heat and moisture at all seasons. It is a large plant, with broad, distichous, dark green leaves, very stiff and leathery. The large, star-like flowers are borne on axillary racemes, usually three in number, about eight inches across, very fleshy and ivory white. The cuspidate lip terminates in a spur or tail sometimes eighteen inches long. The flowers last about three weeks if kept somewhat cool and dry. This Orchid does well in a pot filled with large lumps of charcoal and a plentiful supply of sphagnum. It should be in the warmest house, and abundantly supplied with water during the growing season, and at no time allowed to become dry, or the loss of the bottom leaves will result. A fine variety of this called *Majus* comes into flower somewhat later, is more robust in growth, and the flowers measure fully eleven inches across.

Another fine Orchid flowering at this season is *A. eburneum*, which comes from the same locality as the plant last mentioned.

purple. The side and front lobes of the lip are broadly margined with amethyst purple, while the crest is a pale yellow. In *Veitchi* the segments of the flowers are narrow and smaller, pure white, with side and anterior lobes of the lip finely streaked and spotted with pale rose purple.

F. Goldring.
Kenwood, N. Y.

Ostrowskia magnifica.—The Garden contains a capital figure of this handsome new Campanulaceous plant. Herr Max Leichtlin, to whom horticulturists are indebted for the possession of living plants of it, has already stated that it is easy to grow, is as hardy as a weed, and thrives in any soil. It has erect stems about a yard high, with toothed, oblong leaves in whorls and a terminal head of flowers, each on a long stalk, semi-nodding, bell-shaped, four inches across, two inches deep, the corolla lobed and spreading, the stamens and stigma as in *Platycodon*. The color is purplish-lilac, with darker veins. It was discovered by Dr. Albert Regel in eastern Bokhara in 1884, and flowered for the first time in cultivation with Max Leichtlin in 1877.

Senecio Ghiesbreghtii.—In addition to its usefulness as a large, winter flowering shrub for the conservatory, this handsome Rag-wort may be grown in eight-inch pots, when its

stem attains a height of about two feet, with large, handsome foliage, and enormous heads of yellow flowers, which last a month or more. The plant is as easy to grow as *Paulownia imperialis*, but it is not quite as hardy.

Kew.

W. Watson.

A hardy shrub with beautiful foliage just now is the *Andromeda Catesbaei*. Its stems are deep green, its leaves a dark bronze, while its racemes of flower-buds, which are already a half inch in length, in preparation for spring, are of a rosy red color.

Germantown.

Joseph Meehan

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

V.—SOME OF THE EFFECTS OF EVAPORATION FROM THE LEAVES ON (1) THE PLANT, (2) THE SOIL, (3) THE ATMOSPHERE.

EFFECTS OF EVAPORATION FROM THE LEAVES ON THE PLANT ITSELF.—The amount of water which the plant loses by means of the leaves is, as we have seen, relatively large. Since, of course, it is only the water which escapes, the mineral matters which the root-hairs brought in with the water must remain behind. Therefore, the primary effect of the evaporation from the leaves is concentration of dilute solutions. The amount of mineral matter existing in leaves in autumn is appreciably greater than in the early summer before the work of concentration has proceeded far. The simplest experiment to prove this is the combustion of a leaf plucked from the tree in late spring or in early summer, and one taken from the tree just before the close of the season. The latter leaves a larger amount of ash, or incombustible matter, behind, than the former. Concentration by evaporation is an important factor in nutrition, as we shall see in a later paper.

EFFECTS OF EVAPORATION ON THE SOIL.—The only question to be considered with respect to this is, can the amount of evaporation sensibly affect the amount of water in a saturated soil? In other words, would it be possible to employ any plants for drainage purposes? The answer to this is not yet quite clear, for the experiments upon the subject have not been long enough continued, and in many instances they lack scientific accuracy, not so much in the manner in which the details have been stated, as in the disregard of disturbing conditions. The most interesting instances are those of the planting of Blue Gum, a species of *Eucalyptus*. This tree has long possessed a certain reputation for its supposed power to destroy, or at least to mitigate, the effects of miasm originating in marshes. It should be stated at the outset that the leaves yield a product known as eucalyptol, having more or less decided antiseptic qualities. As the distinctive odor of this substance is given off by crushing or by bending the leaf, or even by rapidly moving the leaf, especially on exposure to the sun's rays, it has been believed by some writers that the effects in reducing the deleterious influence of marsh-miasm may be wholly attributed to the eucalyptol-like volatile matter. But the plant has remarkable powers of giving off water in the state of vapor. The amount has been variously stated by different authors, but a fair average of the results of experiments on *Eucalyptus globulus* would make it not far from two quarts of water daily for every square yard of leaves. This amount, though large, would be considered by some engineers as too small to be a very efficient agent in the drainage of swampy ground, but, as may be seen by the accounts of success in the Roman Campagna,* especially at the "Three Fountains," there are plainly two sides to this question. A quotation from a work not readily accessible to the readers of this journal will indicate that in the country of which the species of *Eucalyptus* are natives, remarkable effects are attributed to the odorous emanations from them.

"That these enormous giants exercise an influence on the climate of the district cannot be doubted, the whole atmosphere being impregnated with a pleasant aromatic odour issuing from them. The odour is especially noticeable in the early morning, and it produces an agreeable feeling of invigoration, accompanied with a desire for exercise. The inhabitants of the locality all enjoy excellent health, and strict inquiries revealed the fact that no severe illness had occurred in the Karri District within the memory of the oldest inhabitant, while invalid visitors almost invariably improved in health."—Rattray and Mill's "Forestry and Forest-Products," 1885. From E. J. C. Brace's Prize Essay on *Eucalyptus* Plantations, p. 237.

Other plants, notably the common Sunflower, have been mentioned in connection with this matter of draining swampy land, and good effects have been obtained where the task im-

posed upon the plants has not been wholly out of proportion to the extent of foliage. In a detailed consideration of this question, which the present paper cannot attempt, attention should be directed (1) to the mechanical effect produced by the larger roots, serving, as they do, about the same office as the branches and twigs in an ordinary "brush drain," and (2) to the action of leafy branches in intercepting currents of air, both of which have a bearing on the hygienic improvement of wet land.

EFFECTS ON THE AIR OF EVAPORATION FROM THE LEAVES.—Every one knows that the atmosphere possesses the power, varying with the temperature, of taking up water and retaining it in the form of vapor. The total amount at any time is its absolute humidity.

When at any given time the atmosphere has taken up all the moisture that can be retained at that temperature, it is said to be saturated. Any proportional part of this amount expressed in percentage is its relative humidity.

Observers have shown that the absolute humidity of the atmosphere in a forest is hardly greater than that of the air over open ground. But, on the other hand, the relative humidity is not far from six per cent. higher in the former than in the latter case. Can a forest, by this slight difference in the amount of moisture which its atmosphere contains, or by the innumerable points of contact presented by the leaves, or by the cooling effect of evaporation from the leaves, affect the precipitation of rain at any time? Or, to make the question more general, do forests affect rainfall? This question, like almost any about which not enough is known, has provoked discussions which have been unnecessarily acrimonious. Even the highest authorities are very far from agreement in this matter. Ebermeyer, a distinguished and critical student of the subject, wrote thus in 1873:

"Forests increase the annual relative moisture of the air, but this influence is much more noticeable at high elevations than at low elevations. The precipitation of moisture (dew, cloud, rain, snow) takes place more readily on this account in wooded than in treeless regions, and the frequency and intensity of these precipitations increase with elevations above the surface of the sea. Moisture descends more readily and freely upon a wooded than upon a treeless mountain of the same height. Forests affect rainfall only so far as they increase the relative amount of water held in the air, and thus bring the relative amount nearer the point of saturation; thus, with fall of temperature in the forest, a part of the moisture is easily precipitated. . . . Forests make the climate of a country moister, and especially so in the summer."

Some later investigations in Bohemia, in European and Asiatic Russia, and in India, point in the same direction, but in our own country numerous comparisons may be fairly interpreted in exactly the other way. The question waits for further facts.

THE PRESSURE EXERTED BY SAP.—When a branch is cut in one of the early days of spring there is generally a flow of liquid from the cut surface which varies in amount during different periods of the twenty-four hours. An experimenter in the last century showed that this flow from the cut surface is not passive, but that the liquid is forced out, and he proved by a pressure gauge that the amount of pressure was very great. Similar experiments have been repeated both in Europe and in this country with substantially the same results. Some of the more interesting here were undertaken at the Massachusetts Agricultural College, in 1873, and showed that the pressure might amount to even three atmospheres. The food stored in the tissues of most of our forest trees during the summer is in the form of starch; this is converted, toward the end of winter, into some sort of sugar, thus passing into solution. This complex solution, together with the crude liquids brought in through the roots from the soil, constitutes the sap as it flows from a wound. The factors determining the pressure are (1) the osmotic force previously described and (2) the expansion of the air in the air-spaces of the woody tissues. At nightfall, or with a reduction of temperature, the pressure ceases or becomes negative—that is, there is an actual suction into the plant.

There are one or two phenomena observed in the flow of sap, which are as yet unexplained.

WATER-PORES.—On the tips of the young leaves of some plants, in warm mornings, drops of water can be seen, which seem at first like drops of dew, but immediately on their removal other drops take their place. In some cases, particularly in plants of the Calla Lily family, these drops follow one another rapidly, and the water may even escape in the form of a fine jet. The pores through which this water is forced are somewhat like stomata, or breathing-pores, but they are not in any sense true valves.

The Forest.

The Forests and Woodlands of New Jersey.—III.

TREATMENT OF HILL-SLOPES.—Some broad, beautiful slopes and hill-sides on the New Jersey side of the Delaware River have been irretrievably ruined by most unintelligent management. They were originally covered with a heavy growth of trees, and were thus protected from destructive washing and land-slides. There was an obvious and imperative necessity that such land should be left permanently under forest conditions. This could easily have been done without restricting in the slightest degree its productiveness. All the timber that it would yield could have been cut off when the crop would best meet the demands of the market, without any interference with the conditions required for the perpetual reproduction of the forest. It was only necessary to protect these steep tracts from fire and from pasturage. The ruin of such slopes is caused more frequently by pasturing them than in any other way. The woods are thus finally killed out, and then the soil begins to wash away where the strongest currents of water descend. Small gullies are found at first; and as the strong, elastic network of living roots decays, huge slices of the surface of the hill-side begin to slip down, and there is soon an unsightly mound at the foot of the slope, where the soil of broad and fertile acres has been deposited, or it has all gone into the river below.

Some such declivities are destroyed by the attempt to cultivate them, but this is idiotic and suicidal. When land is so steep that it must inevitably wash away and be destroyed whenever the forest is removed, the collective intelligence of the community should interfere if the individual owner is incapable of taking care of his own possessions. In many instances the injury to such hill-slopes, once started, extends to other farms, and destroys lands that were in their own conditions protected and safe.

Because such destruction of fertile and valuable land goes on in detail, a little here and a little there, nobody thinks about it. But along every considerable river flowing through a hill-country the permanent damage and loss of value amounts to hundreds of thousands of dollars. If the land thus destroyed along the whole length of the stream were carried out from one place it would make a great sensation. People would think about it, and something might be done to prevent it. In every region of steep, rolling land or hill-slopes, where the soil has any considerable fertility, the same process of destruction is constantly going on, and the owners of the land accept such ruin as if it were wrought by the direct act of God, or the resistless processes of nature, whereas it is caused solely by their own lack of intelligence. It is entirely unnecessary, and a very slight exercise of thought and judgment would suffice to prevent it.

PROFITS FROM WOODLAND.—The profit from woodland is varied greatly by different conditions, such as distance from market, facility of transportation, the relation of supply to demand, and other causes. In some parts of the state, as in Salem County, many owners think their woodlands yield no profit whatever. Some of them say that they keep their lands in forest only because the wood would not pay the cost of cutting it off. Others say there is no profit or benefit beyond the mere convenience of being able to go out and cut a sill or post when they want one; and some say that they preserve their woods for considerations of sentiment alone—that they like to see the trees, and to walk among them sometimes.

Estimates of the amount of profit from forest-lands vary, from nothing, as above, to ten per cent. of their value or of the whole sum invested. In some regions, where the soil is good and the growth of timber is consequently rapid, and where some local industry supplies a brisk market near at hand, some owners think their woodlands yield a profit of ten per cent. In other parts of the state, where all the conditions are less favorable, profits are estimated at one, two, three, four, five and six per cent. But the truth appears to be that there is very little accurate knowledge on the subject. I have found the widest possible differences between the estimates of men living in the same neighborhood, and even in regard to the same tract of woodland; some intelligent and experienced woodsmen affirming that it was worth six per cent., while others said of the same land that it would not be worth having as a source of income, even as a gift, and that woodland is an undesirable kind of property.

Very few, if any, owners have kept such accounts of the yield of the various products of their woodlands as would be necessary for the determination of the question of the amount of profit. The amounts named above are estimated only. It

would of course be of great service to the country if a few owners would keep accurate records of all cost and expenditures, on the one hand, for certain definite measured areas of forest, and, on the other, a complete account of all receipts of every kind. This would have to be continued at least through the whole term of the life of one generation of trees—that is, from the time when one growth of the timber is cut off until the next growth reaches maturity, and is, in its turn, all cut off and marketed. Such a record would have great interest and value as a contribution to our knowledge of economic forestry. Who will begin and continue it?

FOREST-FIRES.—Forest-fires are the greatest cause of injury to the forests and woodlands of New Jersey. In all parts of the state where there are large tracts of woodland the value of this kind of property as an investment has been seriously diminished by the liability to great damage or almost complete destruction of the woods by fires. Each successive burning of a forest impoverishes the soil more and more, and its capacity for reproducing a valuable growth of timber is thus gradually diminished, and in time almost completely destroyed. If any plan could be devised for the effectual protection of the woodlands of the state from fire their value would at once be greatly increased. The question how to defend the forests from fire is in this state, as in some other parts of our country, the most urgent of all our forestry problems. It does not seem likely that we shall obtain much help from legislation.

A considerable proportion of the most destructive fires are started by sparks from railway locomotives. There are several kinds of spark-arresting appliances which would, in part at least, prevent the escape of burning cinders from the engines, but the railroad people object to their use on the ground that they lessen the speed of their trains. Some of the railroad companies keep the whole breadth of their "right of way" clear of trees and bushes, and plow a narrow strip at the edge of it, on each side. This is a valuable precaution, and doubtless prevents many fires. But a high wind sometimes carries sparks beyond this barrier into the dry woods, and thousands of acres are burned over before the fire runs its course. In such cases it would be a good plan for the owners of forest-lands on each side of the railroad to clear a narrow zone all along the front of their property, and plow it every year, so as to prevent the possibility, under ordinary conditions, of fire being blown into the woods from passing engines.

This suggests the only means for preventing the unlimited or indefinite extension of forest-fires which would be at once practicable and effective. This is the plan of clearing and plowing narrow lanes through all large bodies of forest, at regular distances apart, at every mile, for instance, crossing each other at right angles, thus dividing the woodlands into protected blocks, each a square mile in area. The wood thus cut out, when not too remote from market, would probably pay the cost of the work of clearing these lanes at first; but where this is not the case, the expenditure would be returned many times over in the rapid increase in value of the woodlands of the state which would result from their comparative security from the ravages of fire. It is often observed that an old woods-road, having only the breadth of a single wagon-track, is sufficient to stop the progress of a forest-fire, and it is altogether probable that a lane, forty or fifty feet wide, kept clear of trees and bushes, and with one-half of its breadth plowed every year, would nearly always be found an effective barrier. If this should prove to be true in practice, then a system of such lanes, crossing the woods in opposite directions a mile apart, would have the effect of confining each particular fire within the limits of the square mile on which it is started, and the damage in each case would be comparatively slight. The proper breadth for such lanes, and their number, would be determined by practical experiment, as their value would be demonstrated by use.

The greatest obstacle in the way of the adoption of such a plan for forest protection is probably a certain indisposition on the part of the owners of woodlands to do new and untried things, a kind of inertia which is common to all classes and conditions of men. If some energetic owner of a large tract of woodland would put this plan into operation, his example would probably soon be imitated by others. It would be comparatively easy of application in the level regions of southern New Jersey, but its use would be more difficult in the mountains and highlands of the northern part of the state. Until some such practical method is adopted the progressive devastation and ruin of the forests in this state by fire will probably proceed unchecked.

Franklin Falls, N. H.

J. B. Harrison.

The Western New York Horticultural Society.

Annual Meeting at Rochester.

THIS Society is one of the strongest in the country, and its deliberations have always been of the highest order. The meeting last week was equal in every respect to the best that have preceded it, and it might well serve as a model for similar gatherings. It was well attended by intelligent and interested members and visitors. The papers were carefully prepared by experts in the subjects treated. The discussions were always pithy and practical. Business was dispatched with rare order and promptness. Each session began at the precise moment named on the schedule, and the interest never flagged for an instant until the close. Our report of the meeting is necessarily limited to a condensed summary of some of the addresses and discussions, but the proceedings were instructive from beginning to end. The venerable Patrick Barry, who for twenty years has served most efficiently as President of the Society, was unable to preside; but he sent a donation of \$2,000 as the nucleus of a fund whose income is to be used for the Society, under direction of the Executive Committee. Mr. W. C. Barry presided and read the President's Address, which was a record of horticultural progress during the year, and in spite of the depressed prices of staple fruits, it was hopeful in tone, as the following extract will show:

We hear a good deal about low prices, overproduction of fruits, and all that. This is nothing new; the same cry was not uncommon twenty or thirty years ago. In my opinion, prospects were never better. The consumption of fruits is increasing wonderfully all over the world, but it is natural that as we advance more regard should be paid to the quality of fruits and the manner in which they are placed in the market. The slovenly fruit-grower must go!

THE CHAUTAUQUA VINEYARDS.

This was the subject of a paper by Mr. A. S. Watson, who described the Chautauqua Vineyard district as extending for about forty miles along the south-easterly shore of Lake Erie, and towards the south reaching half way up the range of hills whose summits are from three and a half to five miles from the lake-shore, to which they run parallel. The surface of the district is gently rolling or level and never precipitous, and no section of the country of equal width can show greater diversity of soil. The strip along the lake is a sandy loam, easy to cultivate, quickly responding to fertilizers, and generally underlaid with clay. It varies from half a mile to a mile in width. It is considered inferior for farming purposes, is cheaper than the adjacent land, and its merits for grape-growing have been but recently recognized. Its advantages are ease of cultivation and capacity to withstand drought, while grape posts are more durable here than in the gravelly loam. Grapes produced here have a finer bloom, more compact clusters and better keeping qualities, but are later in maturing than on the next belt. The vines, too, are less susceptible to winter injury. South of this is a strip of gravelly loam, a stronger soil, more valuable for farm crops. It is a warm soil, and the rapid growth of weeds makes it more difficult of cultivation. It yields enormous crops of fruit and is more susceptible to the effects of drought. It matures crops earlier, and, therefore, is preferable for early varieties. Still south of this on the hill-slopes is a narrower strip, with a soil principally of clay, and the few vineyards planted here produce a good yield of excellent quality. The Catawba, Delaware and Isabella do better on this land than they do nearer the lake. The soil is not easily tilled, but the grapes have a beautiful bloom, ripen early, and have the best keeping qualities. Nine-tenths of the land in these three belts is well adapted to vineyard planting, but not one acre in forty is yet planted, and scarcely two-thirds of the vines planted have come into bearing. That is, thirty-nine-fortieths of the land is now devoted to farm crops, and the visitor riding along one of the perfect roads that traverse the district would naturally inquire, "Where are the Chautauqua vineyards?" And yet 700 car-loads of grapes were shipped from this region last season, which paid \$100,000 in freights to the railroads. Two and a half million ten-pound baskets were required to market the crop, and they cost \$75,000. For the young vineyards fifty car-loads of wire

will be needed next spring, \$5,000 worth of manilla rope will be needed for tying the vines, and about ten million vines will be propagated. The Concord leads all other varieties, largely in the number propagated, and following this in the order of recognized merit come Worden, Moore's Early, Pocklington, Niagara, Delaware, Brighton, Agawam, Lindley, Salem and Catawba. A new variety, the Moyer, is attracting much attention. It is hardy and healthy, resembling the Delaware in foliage, size and quality of fruit, and is earlier than Moore's Early. A large percentage of the labor in the Chautauqua vineyards is done by women and girls. Tying up the vines in spring, and harvesting the crop in the fine autumn weather, is invigorating rather than exhausting work, and of the thousands of women and girls who begin to gather the crop in September and continue the work for six weeks or two months, few leave without gaining in strength, and from fifteen to thirty pounds in weight. Several vineyards are successfully managed by women. It would seem that for women left with families and a capital of from \$2,500 to \$5,000, and dependent upon the income secured from this investment and upon their own resources for a livelihood, no more promising occupation can be suggested. A vineyard of five or six acres, in full bearing, with a comfortable cottage and packing house, can be secured for \$2,500.

FERTILIZERS.

Professor Caldwell, of Cornell University, began by stating that if dilute manure-water or water in which the three most important elements of plant-food—potash, phosphoric acid and some compound of nitrogen—had been dissolved, were passed through a stratum of pure, clean sand, it would come out as rich in all these ingredients as when it was poured upon the surface; but that if the same water was filtered through ordinary tillable loam, it would be found almost colorless and odorless, and analysis would show that the nitrogen, phosphoric acid and potash had been taken up and were held by the soil. Now, if clear water should be again poured through this soil scarcely any of the sulphate of ammonia, the phosphate or the potash would be removed. It would require 100 gallons of pure water to wash out of the soil what was left there by passing through it a single gallon containing this fertilizing material in solution. This property by which plant-food is fixed in the soil is of great advantage, and enables the farmer or gardener to manure when he will, with the assurance that the land will hold the plant-food till it is needed by the plant. For, although it cannot be washed out by water, the plant carries its own solvent, or the key to unlock what has been fixed in the soil for its use. A solution of plant-food can easily be too rich for the plant's use, but we need not fear, under ordinary conditions, any excess of fertilizer, for, when locked in the soil, it is only delivered to the plant in such quantities as are required. One form of nitrogen, however, and the form which it generally passes into when taken by the plant—namely, the nitrates—is not fixed in the soil, but can be dissolved out by rain so as to pass off in the drainage-water. The natural caution, therefore, in case the nitrates are used, is to apply them when the plants need them. That is, do not top-dress with nitrates in autumn for spring crops, and use small and frequent applications rather than apply the entire amount needed at once. While in a general way the farmer can put all the manure he has to spare on his land or in it, and then forget it till the crop comes to take it as necessity requires, with nitrogen he must be watchful, and always have a plant ready to catch it when nitrification takes place.

Professor Caldwell was followed by Joseph Harris, who made a most suggestive address, in which he urged upon fruit growers and gardeners the advantages of using more nitrogen and using nitrates as the cheapest and most available forms of this element. Gardeners, he said, should use more commercial fertilizers, instead of bidding against each other for stable manure, which is a by-product, with a price controlled entirely by the demand. The profit of using nitrogen, for example, depends upon the value of the crop. Consumers refused to take the chemists' valuation of food stuffs, but consulted their tastes. For the support of life the carbohydrates in corn might be worth as much as the same nutrients in peaches. But while these elements in corn were worth \$30 a ton, they were worth \$500 a ton in peaches. It might not pay to use nitrate of soda on meadows when the carbohydrates in hay were worth \$30 a ton, and yet it might be profitable to use nitrate on strawberries where these nutrients were worth \$750 a ton. It had been stated that nitrates would not pay in the peach orchard, and they would not pay when other crops were grown among the trees. Indeed, it was conceivable that nitrates might injure the peach crop where they were

allowed to encourage a rank growth of weeds, which drank up the moisture needed by the trees. He had used nitrates with success for peaches. He did not believe they encouraged a weak, spongy growth of the trees that would suffer in winter. If applied early, the trees would make a strong, early growth, which enables them to ripen their wood well and produce abundant fruit buds. As fruits and vegetables are improved in quality they need richer land, just as improved varieties of live stock repay for the best of treatment. Beyond any question, early vegetables need nitrates before the warm weather comes, when nitrification goes on more rapidly in the soil. As a matter of practice, he found no loss from applying the nitrates he needed at a single application, for summer rains did not fall in sufficient abundance to wash the fertilizer out through the drains. The so-called "complete fertilizers" in the market did not contain enough nitrogen in available forms, and as it had not been demonstrated that plants took up this element to any great extent in other forms than that of nitrates, he advised the use of nitrates directly, and, fortunately, nitrogen could be bought more cheaply in this form than in any other. He did not counsel the indiscriminate use of nitrate of soda, although he used it largely and with profit. But he thought that no gardener or fruit-grower could afford to neglect making a careful trial of this fertilizer.

FUNGUS DISEASES OF PLANTS.

Professor A. N. Prentiss, of Cornell University, in his report as chairman of the Committee on Botany, gave a summary of the losses to fruit growers in the different counties from plant diseases. These losses were comparatively light during the past year, and yet in the aggregate they amounted to hundreds of thousands of dollars. Professor Prentiss considers these diseases more dangerous foes than destructive insects. Concerning a large proportion of them our information is limited, and we have few remedies that can be trusted. Not only is the fruit destroyed by parasitic fungi, but the plants and trees are robbed of the vitality necessary to the production of remunerative crops. Decreased vigor in the plant means lessened profit from its fruit. Careful study and experiment in this special field by men of scientific training, is one of the most urgent needs of horticulture. Recent investigation of the black rot of the Grape by agents of the general Government seem to prove that copper sulphate can be successfully used as a preventive of this disease, and the same substance will check the growth of the downy mildew of the Grape leaf. Flowers of sulphur is the best known remedy for the powdery mildew of the vine. The apple fruit-scab not only disfigures the fruit and often makes a large proportion of it unmarketable, but the same fungus attacks the leaf, weakening the tree, so that even if the fruit escapes the scab it is small and imperfect. Experiments by Mr. E. S. Goff point to spraying with a solution of soda hyposulphite and potassium sulphide as hopeful treatment of this fungus. But for black knot in the Plum, which has caused the total loss of many orchards, cutting away the affected parts as soon as the disease appears, and burning them, is the only safe course known. It is now agreed that Pear blight is a bacterial disease, but no remedy has been suggested for it except the amputation of the affected limbs. Peach yellows is the cause of loss beyond computation every year, but almost nothing is known of its origin or character, and no remedy for it has been found. Professor Prentiss continued through a long list of rusts and blights which preyed upon small fruits, chiefly to enforce the lesson that research of the most thorough and patient kind is needed before fruit growers will be able to meet these diseases with any feeling of confidence that their ravages can be arrested or controlled.

THE CULTIVATION OF THE PLUM FOR MARKET.

Mr. S. D. Willard, of Geneva, read a most instructive paper on this subject, in which he insisted that success can only be gained when good trees of varieties suited to a particular location are selected; when these varieties are adapted to the local market; when the orchard is carefully cultivated and liberally fed, and when constant watchfulness is exercised against the attacks of insects and diseases. The Plum is capricious in its likes and dislikes, and very often a variety which does well in one locality will fail a few miles away on soil of apparently the same kind. Markets are quite as variable. In one, Damsons are more highly prized than choicer sorts, while in a neighboring town colored varieties are required to the exclusion of all others. The selection of varieties therefore depends on the proper solution of very many problems, and yet these points which are vital to success must be settled beforehand by the planter from such observations and information as are within his reach. To the inquiry, then,

what varieties should be planted for profitable orchard culture, Mr. Willard can only reply that the Lombard, Reine Claude, Quackenboss, Bradshaw, Purple Egg, Gueii, German Prune, French Damson, Peter's Yellow Gage and Copper have proved among the best for his soil and market, while of the newer sorts Stanton is one of much promise.

Against the curculio the jarring process has proved satisfactory. If spraying with the arsenites is tried, care should be taken to use a solution as weak as possible, because the foliage of the Plum is easily injured. The green aphid is often more destructive than the curculio even, sometimes defoliating entire orchards. Professor Cook feels certain, however, that the kerosene emulsion dashed forcibly upon the tree by a pump through one of the new spraying nozzles will overcome this pest. The orchard should be carefully inspected as often as twice a year for the black knot, and on its first appearance the limb should be cut off far below the diseased point. Good culture and an enriched soil will prove helpful against leaf blight. The plum is perishable, so that careful preparation for market is essential, and when the fruit is to be sold from retail stands it should be picked with stems adhering, closely sorted and carefully laid in five to eight pound baskets. Other things being equal, a clay loam is the best soil for Plums. Cultivation of the orchard should begin early and should not be deep. The new growth of thrifty trees should be cut back to one-half every year in vigorous trees, and no thinning out of the branches is needed. For home use Mr. Willard named as choice varieties, M'Laughlin, Reine Claude, Washington, Bradshaw, Peter's Yellow Gage and Stanton. The productive life of a Plum-tree averages from fifteen to eighteen years, but the Lombard, under proper cultivation, might last twenty-five years.

CANNING AND EVAPORATING FRUIT.

Mr. S. G. Curtice read a paper on the canning industry, which began in a small way a little more than thirty years ago, and has grown so rapidly that now fruits and vegetables are put up in this way not only for western mining camps and for winter use, but they are so cheaply and successfully preserved that they compete at seaside resorts and many other places with green fruits and vegetables in their season. No accurate data as to the total amount of business done by the canneries of the country are available, but the estimates made were so enormous that Mr. Curtice refrained from giving the approximate figures. In his own establishment last year \$236,000 were paid for fruits, \$70,000 for tin, \$14,500 for sugar and \$68,000 for labor. As to complaints of the overproduction of fruits, Mr. Curtice said that he never could obtain as much as he wanted of choice kinds—fruits of a particular color or flavor. He had given \$80 for the fruit on a single White Cherry tree, and more profit was often realized by the owners of a few trees in a city lot of Rochester than was yielded by many acres of farm land.

The evaporating industry is still younger, having begun in western New York some fifteen years ago. Mr. M. J. Doyle, who read a paper on this subject, stated that within forty miles of Rochester there were nearly 2,000 fruit evaporators, besides many small dry-houses on farms, and the business was still rapidly growing. Of apples alone, 25,000,000 pounds were evaporated here, and the total dried product of all kinds of fruits amounted to 37,750,000 pounds, for which producers received \$1,485,000. More than 4,000,000 pounds of dried fruit were exported from this region last year, and Rochester fruit is in demand at such remote markets as Australia.

NEW VEGETABLES.

Mr. E. S. Goff made a report on the new vegetables offered by the leading seedsmen of the country last spring and tested at the Geneva Experiment Station. Of Beets, Lentz Turnip (Bragg) is a strain of the old Bassano, as early as the earliest; the New Market Garden (Iowa Seed Company), a short, conical variety, of large size and quick growth, is not as early as Egyptian or Eclipse, but yields a larger crop than either. Mitchell's Perfected Carrot (Gregory) is hardly distinct from the Coreless Red, but it is worth notice as being of good size, fine form, almost as thick at the bottom as at the top, and without the pithy core found in most of the larger varieties. Among several excellent new varieties of Cabbage, Marvin's Savoy (Hallock) yielded twelve heads from twelve plants averaging nine inches in diameter and weighing six pounds each. This is an extraordinary production for the Savoys, which are decidedly superior to common cabbages in table qualities. Dreer's Earliest Snowstorm and Gilt Edge Snowball (Thorburn) lead the list of Cauliflowers in point of productiveness and neatness of the heads. None of the Sweet Corns were superior to older sorts, but the Ruby Sugar (Rawson), a tall variety

which continued to furnish boiling ears of the sweetest quality from August 10th until frost came on October 11th, would be a valuable acquisition but for one fault. Many of the ears have a dark red cob, the juice of which produces an almost indelible stain upon table linen or upon the hands. Emerald Gem (Henderson) and Perfection (Livingston) were the finest Musk Melons tested, all things considered. Two new Okras proved desirable varieties for the Northern States. These were Little Gem (Dreer) and New Dwarf Density (Thorburn). Both were early, dwarf and bore fruit of uniform size. Child's Celestial Pepper (Gregory) is distinct and attractive, remarkably productive, and as the plant bears both red and yellow peppers at the same time, it is quite ornamental. Among Squashes, the Sibley (Sibley & Rawson) and the White Chestnut (Gregory) are valuable additions to the old list, and the former is likely to prove a formidable rival of the Hubbard. Probably the most important novelty of the year is the Dwarf Champion Tomato (Henderson). The plant is dwarf and compact, with foliage little subject to rust, and fruit is smooth, uniform in size and of excellent quality. Of eighteen new varieties of Potato tested, the Rural New Yorker No. 2 gave the largest yield. *Stachys tuberosa*, the so-called new vegetable from northern Africa, was tested, and yielded small, fleshy tubers, which only attained the size of acorns. Its table qualities were not tried.

Besides the papers already mentioned, Mr. Geo. B. Ellwanger contributed one on "Hardy Herbaceous Plants;" Mr. George Savage read one on "Roses for Winter Forcing;" Mr. William Webster spoke of "Improvements in Farmers' Homes;" Mr. Charles S. Little discussed the "Cultivation of Aquatic Plants," and Professor A. J. Cook gave a practical address on "Insecticides."

The exhibition of fruit was notably good. Ellwanger & Barry alone showed sixty-three varieties of apples and thirty-six varieties of pears, while other members contributed almost as many more. No finer Fameuse, Fallawater or King apples were ever seen, and the plates of Anjou, Winter Nelis and other pears could hardly be excelled. One Anjou pear weighed twelve ounces. Mr. Barry showed eighteen varieties of hardy grapes, among them early varieties, like Brighton, and all were in capital condition. Several of Roger's Hybrids, Eumelan, Niagara, Jefferson and Vergennes, were included in the collection. Grapes have kept so well this year, that Catawbas were selling in Rochester for a lower price than at any time since they first ripened.

Cook's fruit-gatherer is a new machine, which was strongly recommended to all who have orchards of any considerable extent. Not only are apples and pears gathered much more cheaply with this implement—for about one-half the cost of hand-picking—but much time is saved, which is an important item. Apples often increase in size just as they approach the ripening point, and the gain in quantity, not to speak of quality, when the fruit is allowed to remain until its full growth is reached, is worth considering. This machine does its work so rapidly that the fruit-grower can wait until the fruit matures before beginning to harvest the crop, and several members asserted that such an implement is as necessary to Apple-growers as is a mowing-machine or reaper to farmers.

As an evidence of increasing interest in Peach culture in western New York, it was stated that Mr. J. F. White, of Mount Morris, has an orchard of 22,000 trees, covering 145 acres. The varieties with which Mr. White has had the most success are Waterloo, Alexander, Early Rivers, Mountain Rose (the earliest freestone), Fosters, Early Crawford, Oldmixon and Late Crawford.

Notes.

Erica carnea and *Daphne Mezereum* were blooming in the open ground in the Arnold Arboretum on the 19th of January.

The bean of the *Soja hispida* is in as great demand in Japan as our garden Beans are here; but though it has been introduced, and re-introduced, over and over again, to American gardens, it fails to meet popular appreciation. A little money buys a good deal in Japan, but the crop of Soja Beans in Japan last year is represented by \$20,000,000.

A remarkable Orchid, still in bloom at Rose Hill nurseries, is a white variety of *Lalia Pattinii*, so-called. There is some uncertainty as to the identity of this plant; it is supposed by some authorities to be a winter-blooming form of *Cattleya Skinneri*, which it strongly resembles. The colored variety was introduced some two or three years ago, but this white form appeared in a consignment imported by Messrs. Siebrecht & Wadley.

The showy Yellow Broom (*Genista*) is now being grown largely for Easter decorations, and increased demand is reported. Pot-plants, well grown, make a mass of bloom highly effective among other plants, and it usually pays the grower better to sell it in this form than to cut the flowers.

Under the modest title of Botanical Notes, Mrs. Mary K. Curran, the curator of the botanical section of the California Academy of Sciences, contributes to its Proceedings a paper (now issued separately) containing a large amount of varied and important information upon a number of California plants, derived, for the most part, from personal observations made in the field.

Styrax Obassia has not yet, we believe, flowered in American gardens, though the plant itself has been considerably distributed. The leaves are as large as those of the Witch-Hazel, and the flowers are of corresponding size. Like the ordinary Snowdrop-tree or Halesia, to which it is related, the flowers are white, with the addition of a grateful perfume. It flowered last year in England.

The cork trade in Spain was unusually good last year, the exportation to other parts of the Continent, as well as to England and America, having been greater than for several years past. The demand has been the greatest for the superior kinds of corks, such as those for champagne bottles. Gerona is the most important centre in Spain for the production of cork, hundreds of cork manufactories being scattered over the province. In the town of Palamos there are forty. From St. Felin de Guixols it is reported that the Cork trees have been suffering from the attacks of a pest which threatened to destroy them. A voracious caterpillar or worm has been attacking the Cork forests in millions during the past year or two. In a very short space of time it stripped the trees of all their leaves completely. These worms are now in their turn said to be attacked and devoured "by another insect, a species of beetle of a dark green color, and armed with a horn, with which it cuts the worms up. Still another insect, in the form of a crab (*cangrejo*), pursues the worms and destroys them; and thirdly, when the caterpillar has passed through its metamorphosis, and the butterflies have deposited their eggs, a third insect, until now unknown, attacks and pierces the bags containing the new germs, and destroys them; all of which will contribute, no doubt, to the complete extinction of these destructive caterpillars."

The competition annually opened to young designers by the Architectural League of New York dealt this year with "A Tomb for a Distinguished Architect." The competitive drawings have recently been displayed at the exhibition held by the League, and it was pleasant to see how much good taste, as well as scholarly accomplishment, they revealed. The design by Mr. Brite of this city, which gained the gold medal, was adapted to a site such as frequently presents itself in American cemeteries—a low hill-side crowned with trees; and his scheme showed an Ionic façade with angle-piers and two intermediate columns—behind which stood a large sarcophagus—fronting on a finely designed platform, with encircling seats backed by a retaining wall against the sloping bank. The silver medal fell to Mr. Enders, of Chicago, who showed a charmingly simple and dignified isolated mausoleum, without columns, but with steps and a seat-encircled platform in front. Both these designs, and all the best ones among the seventeen that were shown, adhered to classic types—a noteworthy and a promising fact in these days when Romanesque art so strongly attracts our artists. Although Romanesque art is undoubtedly better fitted than any other for many kinds of modern buildings, it is difficult to secure with it just that expression of combined dignity, refinement, quietness, simplicity and delicacy which is especially desirable in a tomb. Nor does an adherence to classic types necessitate monotony in form or feature. The drawings now in question were sufficient to refute such an idea, for there was much diversity, even between those which were most "scholarly." When we reflect that no work had been admitted into this competition by men more than twenty-one years of age, its results were extremely promising; and for several of the designs one may heartily wish realization in more solid material than pen and paper. Still more interesting than any one of them, however, was a design not in the competition, which had been prepared by Mr. St. Gaudens and Mr. Page Brown. It showed a temple-like structure with a projecting pediment borne by twelve caryatids, arranged in three rows of four each, which had been given the shape of winged angels. Here, Christian sentiment had been significantly displayed; yet the result was truly classic in feeling, and, executed as this sculptor could execute it, would be of wonderful beauty.

The Administration of Public Parks.

THERE has, of late years, been a gratifying growth of the sentiment in behalf of public parks in American cities. It is coming to be recognized that a city can hardly possess a more attractive feature than a good system of public parks, and often, even in cities of the second or third rank in respect to population, the foremost talent in the landscape-creative art has been secured to make designs for the great public grounds which, in beauty and in adaptation to their various purposes, can be approached by only a few of the most famous parks of Europe.

When, however, we reflect upon the kind of maintenance our parks receive, the prospect is not cheering. Important works of this kind have been sadly damaged and mutilated, and in some cases almost irretrievably injured, by failure in administration and management. The constant change in our system of municipal government is usually responsible for this. The lack of permanence in administration is our great bane. Lines of policy are entered upon, and after they are well under way they are abandoned at a great sacrifice, usually for no other reason than that they were instituted by another set of men, to whom their successors are opposed on grounds that have nothing whatever to do with the matter in hand. Good housekeeping, either on a municipal or a domestic basis, cannot be expected where there is an unceasing change of servants. The best artist may be engaged to report a project for a public park or system of parks. After a careful study of the situation he submits the plan best calculated to meet the topographical conditions and correspond to the peculiar needs of the population. The plan is accepted, the work is taken in hand, and all goes well for a time, when suddenly the authorities in charge of the work are replaced by other men. This change may come from political motives, it may be due to that spirit of false economy that every now and then pushes forward and aims its blundering blows at precisely the points where they will effect the greatest waste, but a

revolution of policy is threatened. Possibly the tact and skill of the artist whose design is imperiled may avert the calamity; there may be a man or two among the new authorities who recognize that, having given a lifetime to the study of such questions, he is most competent to speak, and they are therefore guided by his judgment, and have the character to influence their associates. But the average local politician is not of this stamp. His ignorance is paralleled by his conceit, and he deems himself competent to pronounce with positiveness upon any question presented to him. The danger is aggravated by the prevailing ignorance regarding the purpose of a park. One man has the idea that it must be a centre for all sorts of noisy sports, for festivities of the brass band, fireworks and barbecue order. Another's idea is that of a "pretty" place, a huge flower garden, spangled with gay exotics, striped with ribbon-borders, and beds of brick-colored geraniums uttering their chromatic shrieks on every hand. The true conception of a park—that of a place where the urban inhabitants can, to the fullest extent, obtain the genuine recreation coming from the peaceful enjoyment of an idealized rural landscape, in rest-giving contrast to their wonted existence amidst the city's turmoil—is farthest from their minds, and they will exert all their influence for the incorporation of their favorite discordant features in the scheme. In these ways the purpose of many a nobly conceived public park is threatened with perversion.

How can these defects best be remedied? Of course the greatest safeguard lies in the appreciation of the work by the public itself, for whose benefit the park is created. Once let the design be fully realized, and the public use of the park in the ways originally contemplated would be so thorough, and the enjoyment of it so complete, that any departure from the true purpose would be met by such an expression of sentiment that the desecration would be practically impossible. But, unfortunately, of all art processes, that of landscape-making is the slowest in its consummation, and it is during its successive creative stages that the danger is most threatening.

The landscape-gardener has a task more difficult than that of other artists. His imagination must grasp the available materials and estimate their potentialities, and then, taking a bold leap into the future, he must form in his mind a picture of the ultimate scene to be unfolded, and must dispose his materials so as to develop this ideal through slow natural processes. Besides the ultimate picture broadly conceived so as to present the greatest beauty at all hours of the day and every day in the year, he must also form an idea of the progressive aspects of his creation as the years go on, until the result is achieved, which, with proper care, will endure for centuries. In other artistic activity, realization follows close upon the heels of conception, but the finished picture of the maker of landscapes will not become an actuality for years; indeed, a century may pass before the artist's thought attains its full expression.

The work, therefore, of the true landscape-maker, is essentially unselfish; he can hardly hope to witness its completion, and his only delight is that of conception and of watching its growth so far as he may; the latter activity, akin to parental responsibility, is commingled with pain. Without wide sympathy, a love for the mass of his fellows, a perception of their needs and of how nature can best be brought to respond to them, his task would be a failure. It may be seen, then, that no other form of art-creation deserves more reverent care, more protection from thoughtless or mischievous hands, than that of such a master, whose canvas is the earth, and whose pigments are the objects themselves that the painter aims to counterfeit—the turf, the trees, the grass, the flowers, the rocks, the water, under the changing skies.

The chief danger comes during the progress of the work. The designer, of course, has in view the attainment of pleasing results as soon as possible, and the gradual heightening of these with the progress of the work as the

growing things take shape, although these are incidental stages, and the completed picture may be quite another thing than that out of which it is evolved. But, as in the growth of every organism, there are periods where ugliness temporarily prevails, especially in its beginnings; so it is in the creation of a landscape. In more advanced stages, also, there may be moments when the beauty of the scene might, for the time being, be heightened by making some change in the plan, but it would be at the cost of a lasting mutilation of the whole. To judge a painter's work while it is in progress, and to demand changes, because some effect of underglaze, for instance, that was intended to heighten the beauty coming from succeeding brush-strokes, chanced to be distasteful, would be the height of folly. But in the work of the landscape-maker effects equally transitory are more slow in passing, and are likely to become the pretext for demanding a change on the part of the ignorant or misunderstanding.

Therefore an essential thing in the administration of a public park is to provide some means by which the faithful execution of the original design can be assured. A public park, in order to be well administered, should have a management of the most permanent character possible. In Germany are to be found the best public parks in Europe, and a leading feature of German municipal government is its stability. While the power comes directly from the people, and the form is, therefore, fully as democratic as ours, there is in all departments a permanency of tenure for all officials, from the mayor down, equal to that prevailing habitually in our private business corporations. The result is, a continued harmonious administration of public works by competent and experienced men that assures the most economical and satisfactory results.

The adoption of such a system with us would be hardly practicable until experience had taught us the unsatisfactoriness of our present methods by more severe lessons than have yet been received. It seems possible, however, to attain a permanency of park administration in another way. There is an increasing tendency to intrust the management of public libraries, museums and like institutions to boards of trustees, incorporated bodies independent of the city government, but still public institutions sustained by public support. The parks of a city can as appropriately be administered in this way as can a public library or art museum. They form an institution by themselves, sanitary, educational and æsthetic in nature, and it is equally important that they should be kept free from the complications and uncertainties of local politics. The customary park commissions, although often admirably constituted, have the great drawback of a liability to sudden, and, perhaps, complete change of personality. Under such conditions the best results could hardly be looked for, and it is something of a wonder that our parks have been maintained as well as they have. Under well organized boards of trustees, like that, for example, which has built up the Boston Public Library, and has made it the most successful institution of its kind, we might hope for an escape from many of the dangers now attending park administration.

The Artistic Aspects of Trees.—VI. The Lombardy Poplar and the Weeping Willow.

GOOD taste is required for the grouping of all kinds of trees if the results are to have the harmony which is the only quality that, in the long run, can satisfy the eye. But if this is true of trees in general, it is doubly true of those which are eccentric in form or color, like the Lombardy Poplar, the Weeping Willow, the White Birch or the Purple Beech.

No tree has a more marked individuality or is more effective in the right place, than the Lombardy Poplar, but no tree looks worse when wrongly placed. If its constitution were more vigorous it would be well adapted to

street planting when the street is narrow, because with it a certain amount of verdure can be secured without too great an interference with sunshine. But the slender shadow it casts renders it, on the other hand, ill adapted for roadside planting where shade would be grateful. Nevertheless, as planted by the highways of Belgium, France and northern Italy it has dignity and beauty. Its stiff, aspiring form brings more accent into such wide, level, featureless landscapes than would the round, umbrageous forms of other trees. This gives no warrant, however, for planting it along winding roads or in mountainous or wooded districts. Nor does it appear well in isolation, unsupported by a long straight line of its fellows or by lower masses of foliage; nor when planted in groups; nor yet when its sharp top is seen rising here and there at random out of a wood. One or two Lombardy Poplars carefully set in a plantation just where they are needed to relieve its general softness and to break the sky-line with a touch of vigor and emphasis, are often most effective. On the border of the lake in the Central Park, not far from its western extremity, are two or three tall Poplars standing on a little promontory. Their effect is admirable, and no other tree in just this spot would have so good an effect. But perhaps the best place of all for the Lombardy Poplar is among other trees beside a low cottage. In many European villages it is thus seen, and in many beautiful pictures it gives dignity and individuality to a composition which, without it, would be tame and commonplace, for the tree is almost as effective in its own little scene as a village spire in the larger scene of which it forms a part.

Wholly different in character is the Weeping Willow, and yet its unusually pliant, drooping expression makes it as conspicuous as the rigid uprightness of the Poplar itself. As soon as it comes before the eye, it presents a striking contrast to the simple dignity of those trees which determine the general character of every landscape. Easy of cultivation, rapid of growth, not particular about soils or situations, and putting forth its leaves very early in the spring; attractive, too, to many eyes by reason of its super-sentimental air, the Weeping Willow has been planted everywhere, and opportunities do not lack, in nearly every country, for estimating its fitness to this situation or to that. Nevertheless, it is hard to say in what situation it looks best. It has not nobility enough to stand by itself, and it does not group harmoniously with any other tree. Once in awhile in a Japanese picture we see a small Weeping Willow planted by a cascade, which has a charming effect. This is because the lines of the falling water harmonize with its own, and because, so to speak, the cascade seems to give the tree an excuse for its abnormal habit. To group it with round-headed trees means contrast without harmony, and this is still more emphatically the case if there is substituted for soft, deciduous foliage, the stiffer, more horizontal forms of conifers. In a street its pendulous weakness conflicts disagreeably with the rigidity of architectural lines; and even when we think a great Weeping Willow looks well drooping over and protecting a rural cottage, we cannot but decide that some other tree would look better, expressing still more clearly the idea of protection through its greater sturdiness. A cottage with a Weeping Willow beside it looks better than a cottage bare of foliage; but an Elm or a Maple of equal size would replace the Willow to very great advantage. But the spot most often chosen for the Weeping Willow is one where it may droop over a stream or a sheet of placid water. Perhaps, however, this is the very place where its faults are most manifest. A Willow is, indeed, very often the best tree that can be chosen for the border of a stream or lake, but not a Weeping Willow. All the virtues of this tree—the delicate character of its spray, the tender, pallid color of its leaves, and their twinkling, airy grace—are possessed by other Willows which are free from its defects. The White Willow of Europe, for instance, now thoroughly naturalized in our Northern States, is much more individual

in color and texture than the Weeping Willow, and is an extremely graceful tree; yet it has great dignity, and harmonizes admirably with almost all the trees commonly planted. A glance at the illustration on page 67, which shows the border of a pond in Brookline, Massachusetts, where White Willows edge the water for a considerable distance, should be enough to prove its appropriateness for such a place, and to suggest that not only near water, but in all other situations where Willows are desired, White Willows or some other species of similar habit should be chosen in preference to the Weeping Willow. Of course, there may be rare cases where a Weeping Willow, especially a small one, has been well used by an intelligent planter; but, as a general rule, it will be found out of keeping with its surroundings. When this is the case, a tree must have extraordinary merits to justify its introduction; and this can hardly be affirmed of the Weeping Willow, which, at its best, is eccentric rather than beautiful, weak rather than really graceful.

A correspondent, who is familiar with the forests of southern Indiana and Illinois, calls our attention to the fact that in this region, which is celebrated for the richness of the forest-growth and the immense development attained by individuals of several species of trees growing upon the deep, alluvial bottom-lands, more clearing and thinning of the woods has been done during the past five years than in the fifteen years previous. A large proportion of the great Yellow Poplars (*Liriodendron*) have already fallen under the axe of the lumbermen. The wealth of these forests will be appreciated when the fact is realized that ten years ago it was not uncommon to find an average of three Poplars to the acre, with stems six feet in diameter and running up straight and clean for a distance of seventy or eighty feet to the first branches. These giants, now nearly all destroyed, grew in a forest in which the predominating trees were Beeches, Black Gums and Blue Ash, which were not surpassed anywhere in stately proportions and splendid vigor.

Japanese Gardening.—II.

I HAVE already tried to show through quotations from Mr. Conder's article in the *Transactions of the Asiatic Society of Japan*, what ideas generally control the formation of gardens in Japan, and have tried to explain that the Japanese considers his garden, with its miniature artificial hills, vales, streams and rock-arrangements, a truly "natural" work of art, because it typifies or suggests by imitations on a smaller scale the effect produced by large natural features. This is to say that the Japanese looks upon this art much as we look upon painting, not demanding that the same materials shall be used as exist in the scene portrayed, or the same scale preserved, but merely that the result shall be truthfully suggestive of something that might be found in the natural world.

Passing to matters of detail, Mr. Conder explains that whether water be actually present or be simulated by expanses of smooth earth or sand, "a garden-lake when constructed in a limited area should never be completely visible from any one point of view, but parts of the outline should be intercepted and hidden by shrubs and plants placed in suitable positions. We find here again the important principle of suggesting limitless space by the partial obliteration of bounding lines." And, it need hardly be said, this idea at least is common to good landscape-gardeners all over the world.

Great use is made of islands in such lakes, whether they be of water or of simulated water. Some of them are isolated from the shore and treated in a way to suggest that they are surrounded by the sea itself. Others are joined by bridges to the bank, and always their minor features have symbolic meanings, which are lost upon a European eye. In a few Occidental gardens great use is made of natural unhewn stones and boulders, but the practice is almost the chief element in Japanese gardening, and great care is given to the sizes and outlines of the separate stones, as well as to their general effect as a mass. "The sizes and proportions of the different stones employed govern, in many cases, the scale of the trees and shrubs used in juxtaposition. Some writers go so far as to say that stones constitute the skeleton of the garden, that their form and distribution should receive the first attention, and that the trees and shrubs should be placed

afterwards in such a way as to emphasize and 'support' these stones and connect them into one harmonious whole." Scale is nicely regarded—very large stones are not used in small gardens, nor small stones in large ones. "The principal boulders in an artificial landscape being arranged to represent natural rocks, it is often customary to describe their altitude by fictitious measurements applicable to the grandeur of real scenery. This custom not only helps to keep up the imaginary illusion, but no doubt assists the designer in a consistent preservation of the character of all subsidiary parts. . . . The chief thing to be kept in mind in arranging garden-stones is to make them appear as if Nature had placed them in position. Some of the wilder freaks of Nature must, however, not be copied, for if artificially imitated on a comparatively small scale, they would be suggestive of instability and danger, and destructive to the general repose required in an artistic composition. It is the immensity, antiquity and adamantine solidity of the overhanging rocks and towering pinnacles of natural landscape which reconciles us to their threatening appearance." How different indeed are such ideas as these from the ones that commonly direct the employment of stones in our gardens, where no thought of Nature is suggested by the rockeries, grottoes and palpably artificial cascades, and where beauty has seldom been considered in the choice of the elements of construction.

A long list of stones is given by Mr. Conder, each of which is considered appropriate to a given service—as for association with water, or for use in valleys or on mountains or beside roads—and each of which has its own symbolic significance besides. The use of turf in Japanese gardens, he says, is of comparatively recent introduction. "The level portions were formerly finished in beaten earth, kept carefully weeded, or spread with white sand or broken shells. The hills were partly covered with different kinds of green moss." Raised stepping-stones often traverse these earthy lawns, and they are kept a little damp for the sake of neatness and coolness. Or if sand is used, it is carefully raked, sometimes in patterns—as in waving lines that represent water. "Gardens consisting of such areas of naked raked sand, with only a few stones representing rocks and islands, are not uncommon." How little they would satisfy our taste! Yet the strong Japanese imagination can delight in the picture of a sea-coast or mountain-lake which they present.

"In connection with the temples there are many magnificent avenues and groves of fine trees, arranged with the same formality as is employed in Europe. Some of the avenues of *Cryptomeria* and of 'Enoki' (*Celtis Chinensis*) lining the country roads and temple approaches are hardly equaled in grandeur by any avenues in the West. But in landscape-gardening such arrangements are seldom, if ever, resorted to. In cases where trees are grouped together in numbers, they are generally of different species and specially selected to contrast with one another. Form and line receive primary attention. . . . Such contrasts as that which the rugged Pine, with its scrambling, angular branches, forms with the spreading Cherry, or the drooping Willow, with its curving boughs, are purposely designed. . . . Trees and plants should not be used in positions contrary to their natural habits of growth. For example, a hill-side plant should not be placed in a valley, nor should plants peculiar to low, sheltered spots be placed on high ground." Here again is a refinement quite foreign to Occidental gardening, which prides itself, rather, upon making plants grow in just those situations where nature had not placed them. "As a general rule, trees which shed their leaves and look bare during the winter should not be planted in the foreground of a garden. An exception . . . is in the case of the Plum tree, which, on account of its early blossoms, is placed in the front of the grounds."

"The habit of clipping and shearing trees and shrubs is a common one in Japan, but it is seldom done in a manner inconsistent with the general character of the particular trees thus dressed." What the gardener aims at, is to accentuate, not controvert, the design which nature had in forming a particular tree. The Pine, for example, "goes through a thorough surgical treatment in the nursery, with the idea of producing a shape of acknowledged beauty, as displayed in some of the finest natural trees. Its branches are bent, broken and bandaged, and bound with cords and splints, until it grows into the fancy shape desired." This shape is rarely at variance with forms that can be found in nature; yet dwarf trees are sometimes trained into curious, non-natural forms, the branches of the favorite Pine are occasionally cut into the form of balls and trained to grow in a pendant way, suggestive of a cascade, and now and then one may even see a shrub cut into the shape of a junk under full sail. But fantasies like

these, we gather, are executed on a small scale and not placed where they would disfigure a landscape effect. Low shrubs are generally cut into hemispherical forms, but this is to aid the imagination by representing "rounded masses of variegated greens placed upon the hillsides and between the rockeries. . . . Such spherical masses are frequently arranged in groups towering one behind another, so as to suggest the forms of green hills." That is to say, the eye then recognizes, not an artificially shaped shrub, but a mass of larger size seen at a fictitious distance.

In the placing of trees, great care and taste are, of course, displayed. They should stand near a veranda for the purpose of affording shade, and near bridges so that their shadow may fall upon the surface of the water and produce a pretty effect. Singular and suggestive names are applied to the trees which hold different positions in a garden, from the principal tree which occupies a foreground spot, and must be a large and fine specimen—usually an Oak or a Pine—to the "distancing tree," which must stand behind the furthest hill of the garden and be rendered indistinct in outline to aid the effect of remoteness.

Flowering trees are often massed together in large numbers in public gardens; but in private grounds, where a more delicate taste may be supposed to rule, they are preferably distributed "in such a way that they shall come between the foliage of evergreens." Flowers are profusely used in most gardens in such a way as to supply an abundance of color at all seasons of the year. But in some kinds or types of gardens they are absent or appear only in or near the water. Of course no landscape arrangement is disfigured by formal beds; but another part of the grounds, usually adjacent to the women's apartments, is often devoted to the flower-garden, and here the plants are thickly massed together, though without any attempt at geometrical pattern-making. The growing of flowers in this way is, however, regarded as a rather effeminate taste.

Many paragraphs in Mr. Conder's article are devoted to the lanterns which so prominently ornament Japanese gardens, and to the nature and arrangement of gateways, fences, water-basins, bridges and hedges, as well as to the kinds of trees, shrubs and flowers most generally seen. But there is no space here to follow his descriptions. It can only be added that, of course, the arrangement of hills and valleys described in my former article does not universally prevail. The so-called "Common Gardens" have no artificial hills, "but the stones and rounded shrubs are sometimes grouped so as to suggest mountain scenery. . . . Gardens of this type when level may be supposed to represent either a mountain-valley or a sea-beach; in the former case the surroundings should be steep, thickly planted and imposing; in the latter case the landscape may be open and placid." Gardens for tea-ceremonies have peculiarities of arrangement proper to themselves, and there are others in which a stream is the chief feature, and which are arranged so as to bring it to the best effect. Even narrow courts and passages are treated by the landscape gardener, in simple designs consisting of "a continuous row of stepping stones and an occasional group of trees and shrubs."

And in conclusion I may add that a compensation is found in Japan for that lack, which Mr. Conder notes, of large parks with roads, wide lawns and great plantations, such as we find in the West. Wherever one goes in Japan, we learn from other writers, the natural landscape has been touched up and assisted to greater beauty by the hand of man. One can never tell where nature ends and artificiality begins, so thoroughly have nature's intentions been respected and so artistically have they been developed. Where a real landscape is thus treated, of course no miniature simulations of scenery are introduced. These are reserved for spots apart from great natural features, although such features may afar off encircle them and blend with their own near beauties. Here they lie, like pictures in a frame, and as such are judged by the Japanese eye—less for what they are, though this may be something very charming, than for what they typify, suggest and stimulate the imagination to recall.

New York.

M. G. van Rensselaer.

"When you come upon a particularly fine prospect, and remark upon it, What a pity that great tree is there, how much finer this would be if it could be removed! you might be very much surprised to find, when the tree was cut down, that you no longer had a picture before you; for the highest type of garden is like a picture gallery and pictures require frames."

Pückler-Muskau, 1834.

New or Little Known Plants.

Cereus Pringlei.

ONE of the most interesting of Mr. Pringle's numerous Mexican discoveries is the great Cactus which now bears his name,* and which he found during the summer of 1884 growing upon the hills and *mesas* south of the Altar River in north-western Sonora.

The stems of this remarkable plant, which divide irregularly above the base into numerous large branches, do not attain the great height of its near relative, the now well-known *Sauwarrow*, the *Cereus giganteus* of Arizona and Sonora. They are sometimes, however, more than thirty feet high, and they are thicker and more ponderous than those of any Cactus known. The number of ribs is fewer than in *C. giganteus*, while the flowers, instead of being clustered about the summit of the stem, as in that species, are scattered along the ribs for a distance of two or three feet from the top.

Nothing more was seen of this plant until October, 1887, when Dr. Edward Palmer, the well-known explorer of Mexican botany, visited San Pedro Martin Island, in the Gulf of California, which he found covered with a forest of these trees, which our illustration upon page 65, taken from a photograph, for which we are indebted to Dr. Palmer, shows to be one of the strangest and most remarkable forests which has yet been seen in any portion of the North American Continent.

It appears from Dr. Palmer's notes that San Pedro Martin Island, is in the Gulf of California, eighty miles north-west of Guymas, in latitude $29\frac{1}{2}$ and longitude 113 west from Greenwich. It is an irregularly shaped rock about four and a half miles in circumference, with a central elevation of 1,200 feet above the level of the gulf. It is partly covered with a deep deposit of guano, which Mexicans and Yacqua Indians are now engaged in collecting for export. The *Cereus* is called *Cordon* by the Indians, who gather the fruit in great quantities. They take out the pulp and seeds and grind them together into a sort of flour. This is then mixed with water and made into *tomales*, or cakes, a tablespoonful of the paste being put between two corn husks and boiled. Dr. Palmer found these *tomales* not inferior to the pies of more civilized people.

The *Cordon* furnishes the only fuel and timber produced upon the island, which is destitute of other trees. The dry, hard ribs, the remnants of many forest generations, and practically indestructible except by fire, are found scattered over the surface in large numbers; they are carefully collected by the Indians, who manufacture them into the canes needed by the men in climbing over the precipitous rocks in search of the guano; they serve for the beams and door-posts of the workmen's huts and supply the fuel for their simple cooking. The largest plant observed by Dr. Palmer was thirty-five feet high, with a circumference at the base of the trunk of seven feet and six inches.

Dr. Palmer collected only eighteen flowering plants upon the island; among these Mr. Watson finds a new genus of *Compositæ*, and a bushy Fig, probably an undescribed species. The poverty of the collection is due in part, no doubt, to the late period of the year in which it was made, and when most annual plants would have entirely disappeared.

C. S. S.

* "*Cereus Pringlei*, Watson, *Proc. Am. Acad. Arts and Sci.*, xx. 368. Stems erect; ribs usually thirteen, very rarely more; areolæ contiguous upon the ribs, oblong or lanceolate, the younger densely tomentose and with an outer circle of nearly erect, more or less unequal, ash-colored spines (mostly six to nine lines long), and a central stouter one twice longer, all terete; the older areolæ naked, with about fifteen dark flattened spines, mostly widely spreading, about an inch long, and deciduous; flowers lateral and scattered below the summit of the stem, two and one-half inches long; the ovary and tube very densely covered with tawny hairs, nearly or quite concealing the lanceolate scales and outer sepals; petals spatulate, white, tinged with green or purple, six lines long; fruit globose, two inches long, bearing the persistent flower, and densely covered with globose cushions (four or five lines in diameter) of dense tomentum intermixed with more or less numerous white, bristly spines (one-half inch long or less); seeds black and shining, obliquely oblong-ovate, one and one-half lines long; hilum oblong, basilar."

Foreign Correspondence.

London Letter.

THE new plants of 1888 do not include anything of a sensational character. There are a great many Orchids, numerous hybrids of all kinds, and a few introductions of a miscellaneous character. But one cannot point to any of them as of very exceptional merit. The taste and demand for Orchids predominates over everything else, and, no doubt, has diverted the attention of collectors from other plants. Indeed, there are those who affirm that it does not pay to bother about introducing anything nowadays except Orchids, which is another way of saying that there is no demand for plants of other families. But a new plant of superior qualities for the garden is always certain to find general favor. As an instance I might point to *Impatiens Sultani*, which was introduced to Kew by accident a few years ago, and which is now in almost every

we find a long list of new additions, many of them decided acquisitions. Especially is this the case in regard to Orchids. It may be treasonable to say so, but is there not too much importance attached to the mere marking and size in the flowers of these plants?—a great many being dubbed varieties and distinguished by a three-barreled name on account of characters which in any other family of plants would be ignored. Plant-breeders contribute more than any one to the progress in the horticulture of to-day. It scarcely seems credible that a generation or so ago many botanists discouraged with all their might any attempt to tamper with the so-called specific characters of plants by crossing them. Darwin taught how important a light the work of the breeder of plants, as well as of animals, throws on the great secret of the origin of species. Nowadays almost every nurseryman in England tries his hand at crossing one species of plant with another. The result already is almost miraculous. Among stove and greenhouse plants we have Orchids, Nepenthes, Begonias, Crotons,

Fig. 92.—*Cereus Pringlei* on the Island of San Pedro Martin.—See page 64.

garden. *Aristolochia elegans*, *Boronia heterophylla* and *Nephrolepis rufescens tripinnatifida*, all introduced through Kew within the last five years, are also universal favorites. A large number of new plants are obtained through cross-breeding, and these absorb a good deal of the attention of horticulturists. There must be large numbers of beautiful plants still unknown in gardens. Even those fields which have already been explored by the collector will contain many good plants worth introducing, whilst such new countries as New Guinea, Madagascar and Burnah are sure to be rich in floral treasures of all kinds.

Last year's introductions comprise numerous Orchids, most of them interesting, a few beautiful, the best of them being the following: *Cypripedium bellatulum* (habitat not published), introduced by Low & Co.; *C. Elliotianum*, from the Philippines, and *C. Rothschildianum*, from Papua, both by Sander & Co.; *Spathoglottis aurea* (*Kimballiana*), Borneo; *Lassochilus giganteus*, Angola, Linden; *Disa racemosa*, South Africa, Kew.

Amongst stove plants there are none of any particular beauty, the most distinct and pretty being *Begonia Lubbersii*, from Brazil. There is no new greenhouse plant, and only the following first-class new additions to the herbaceous collection: *Lilium Nepalense*, Nepal, Low & Co., and *Ostrowskia magnifica*, Turkestan, Max Leichtlin. Two good, hardy flowering shrubs have been added. These are *Syrax Obassia*, Japan, Veitch & Sons, and *Stuartia Pseudo-Camellia*, Japan, Veitch & Sons. [The last named plant has been known in American gardens for the last dozen years.—ED.]

When we come to varieties of well-known plants, however,

Anthuriums, Caladiums, Rhododendrons (Javanese), and Hippeastrums; hardy plants may be instanced by Hellebores, Pæonies and Narcissus. It is remarkable that none of these crosses, however extreme, reveals any tendency on the part of the offspring to break away from the fixed characters of the genus. Another fact of equal interest is that no cross-breeding of species, however varied in character the different species crossed are, has produced anything more extraordinary than has been obtained by the cultivation and selection of the progeny of a single species. The Chrysanthemums, with their hundreds, thousands of forms, all from one species, according to some botanists, the Gloxinias, the Cabbages, Apples and many other well-known garden races, are cases in point. Certainly the breeding of plants is a most delightful and fascinating occupation. It is as yet in its infancy, but in England it is being pursued with zeal and patience, and the magnificent results already achieved point the way to still greater.

An exhibition of Chrysanthemums on the tenth of January is a novelty which a few years ago would have been considered absurd. But by dint of careful cultivation and the selection of late-flowering kinds a very creditable display was collected in the London Aquarium on that date. The kinds shown were the following: Belle Paul, Meg Merrilies, Gloriosum, Rolfe Brocklebank, M. de Calrol, W. E. Drover, Progne, Martha Harding, Golden Gem and Mrs. J. H. Jones. During the last month we have had very heavy and continuous fogs, which have damaged flowers of all kinds, Chrysanthemums included. Still the above display was most interesting, and is certainly a step in the right direction. There does not

seem any good reason why we should not have Chrysanthemums that flower from January to June, just as we have them now from July to January.

Growers of hardy plants here are turning their attention again to Hollyhocks, which a few years ago were as great favorites as Single Dahlias are now. Then came disease, and the stately, many-colored Hollyhock was almost given up in despair by English horticulturists. Modern growers say cow manure will keep away the disease from these plants.

Leaf Spots of Green-house Plants.

IT is usually the case, when black spots appear on the leaves of ornamental plants, that they are supposed to be due to the attacks of insects or the growth of fungus parasites. There is, however, one form of black spot to which my attention has been several times called, which, although due to a fungus, is not caused by a parasitic species which infests the leaves themselves, and the spots cannot be considered as indications of any disease, but merely as accidental disfigurements. The spots to which I refer are about as large as the head of a pin, and are scattered without order, and sometimes very profusely, over the surface of the leaves. They can easily be removed by mashing or be picked off, when they leave a slight circular depression, as a rule. A microscopic examination shows that there is no fungus mycelium, but merely a mass of ellipsoidal, orange-colored cells covered by a black, structureless membrane of a flattened, hemispherical shape, which adheres to the leaf by its free edge. In short, the black spots are nothing but the discharged spores of a species of *Pilobolus* with their sporangial cap.

The species of *Pilobolus* are small moulds which grow on dung of various kinds, and look like minute white or pale orange-colored, glistening sacks, with a black tip when mature. The spores are ejected with considerable violence, and I have known them to be shot off to a distance of several feet. It is only when the *Pilobolus* grows on the manured soil of hot frames and green-houses, or other small-sized compartments where plants are grown, that it is likely to attract popular notice. When plants are crowded in a small space over fresh manure the *Pilobolus* is likely to appear and discharge its spores over the leaves and stems of any plants which are near. Some years ago the Roses in a green-house at Cleveland were found to be thickly spotted with *Pilobolus* spores, and the black spots were supposed to be due to a new fungus disease. More recently the Roses in a small green-house at Whitinsville, Massachusetts, were similarly affected, and an examination showed the presence of a quantity of *Pilobolus*, whose spores not only formed spots on the Roses, but also on the wood-work of the green-house for a considerable extent. The most recent case to which my attention has been called was at Newton, Massachusetts, where the leaves of Geranium were thickly spotted by spores of *Pilobolus*. The spots, of course, are merely a form of dirt, and cause no disease of either Roses or Geraniums, for the *Pilobolus* spores do not develop on living leaves and stems. It is a little singular that, while this particular form of black spot has attracted the attention of gardeners in this country, it has not been noticed in European green-houses either as a supposed cause of disease or disfigurement to any extent, if one can judge by the absence of any reference to the subject in the common works on plant diseases.

W. G. Farlow.

Ferns.

DURING the dull days of mid-winter it is essential that sufficient ventilation should be given to this class of plants, for if the moisture in the atmosphere is condensed on the fronds to any great extent, the plants soon become disfigured. If the weather is severe, a little additional fire-heat may be given, so that the ventilators may be opened enough to allow the superfluous moisture to escape, though at the same time excessive firing should be avoided, the present being the season of rest for a majority of species.

Some judgment should also be exercised in the matter of watering, so that the deciduous kinds may receive no excess, which would be sure to injure their roots, and this would mean a weakened growth the following season. Of course the evergreen species will take much more water, and, in fact, should not be allowed to become actually dry at any time during the year.

These cautions are specially applicable to old-established plants, as young seedlings of many species can be readily

kept in a growing condition during the first year, or possibly eighteen months, of their existence, but the period of rest will become more marked during the second year. As the most suitable time for repotting most of the species will soon be upon us—that is, in February or the beginning of March—it may be well to give that matter some consideration here. In repotting some of the large plants, it will be found more convenient to reduce the old ball, so that the plant may be replaced in a pot of the same size, provided this operation can be done before active growth begins. Otherwise the result might prove a disappointment; and if necessary to increase the stock, division of the crowns or rhizomes, as the case may be, can best be made at the same time. The soil for potting should be rather coarse, but the plants should be potted firmly, and given free drainage, though until they begin to root freely water should be given rather sparingly, not allowing them, however, to become very dry.

The practice followed by some growers, of cutting off all the old foliage at the time of repotting, may not be very injurious to some species, and if the plants are infested with insects it is a very good way of disposing of much of the vermin; but in my experience this radical treatment has not proved entirely satisfactory, on account of the weaker growth resulting from it, so that the plants recover their beauty much later in the season than when a portion of the old growth is left until the new appears.

If it is desirable to raise some plants from spores, these may be sown at any time when they are ready, but the most successful sowing is usually that made about the beginning of March. After that time there is not so much danger of the young plants damping off, and being the natural season of active growth with many of the species, it is quite reasonable to suppose that they will make more rapid progress if sown at that time than at any other.

But apart from the economic side of the question, the raising of Ferns from spores will be found a most interesting diversion for any one so inclined, not only on account of their peculiar mode of development, but because novel forms and unexpected hybrids often appear in a collection of seedlings.

Girdling Grape Vines.

ON the 13th day of September last an excellent opportunity was afforded to a Committee of the Massachusetts Horticultural Society to observe the effects of the process of girdling the branches of the Grape for the purpose of hastening the maturity of the fruit. Among other vineyards, we visited one situated in the south part of the town of Concord. On the southern slope of a hill which runs down to the river we found a plantation of several acres of the Concord Grape. The elevation was about seventy-five feet above the level of the river. The plants in the eastern half of the vineyard had been girdled for this and the two preceding seasons, while those in the western half were growing in their natural way. The girdled plants were more irregular and thinner in foliage, and, upon general view, did not look as vigorous as the normal growth. A closer inspection showed that the girdling process had been severely practiced upon every fruit-bearing branch, producing a very marked effect in developing the size and hastening the maturity of the fruit. Though the season was so late and unfavorable that we found the Moore's Early, in this and in other vineyards, to be barely ripe, yet the girdled Concord were in quite as good condition. On the other hand, the Concord of normal growth were much smaller in size and hopelessly behind time. It was evident then, as the event proved, that the natural crop would be ruined by frost. Here was an instance of a crop saved by girdling, and of another, side by side, which was lost by neglect of this process.

Without going further, it is then evident that, under some circumstances and with some varieties, there are decided advantages in the process. Such excellent varieties as the Iona and the Jefferson may be hastened to maturity by girdling. But in ordinary seasons we should scarcely think it worth while to be at the trouble to hasten the Concord, when we have equally good varieties like the Worden and the Moore, which are early without this treatment. Yet there is a larger development of the fruit by the process, which is of much importance to the marketman. This is so material a consideration, that it would be likely to govern were it not for another consideration which must be taken into account. What will be the permanent effect upon the vineyard of a continuation of this process? In the instance before us the work had been so thorough, not to say severe, that the effect upon the future of the vine could be predicted with confidence.

Not only were the branches above the ring largely developed by the arrest of the descending sap and also the limbs below seemingly shrunk to the size of a pipe stem, but the renewal-caness appeared to have an enfeebled growth. It was evident that the saving of the crop was likely to prove a serious injury to the health of the vineyard. But this was an extreme practice, where the crop had evidently been treated as of prime importance, and the renewal-cane had been neglected. But this by no means determines whether a judicious use of this method may not often prove harmless and of great practical advantage. Our native Grape is so superabundant in the production of foliage that checking becomes necessary. The fact, also, that a large amount of old wood has to be removed every autumn, has a bearing upon this question. Add to these the consideration that the renewal-cane, under proper encouragement, will give a large supply of nourishment to the root, and it does not seem unreasonable to conclude that a moderate portion of the descending sap may be arrested just below

as near the light as possible, and during the months of December and January, when Orchid bloom is always welcome, large, bold blossoms of ivory whiteness and of good substance will develop themselves very rapidly and remain in good condition for several weeks.

Dendrobium Wardianum.—This is a winter blooming species, and its very free flowering qualities, combined with its easy culture, make it a most desirable Orchid. It is deciduous, and succeeds best at the warmest end of the Cattleya house, close to the light, either in pots or baskets. It does not enjoy too much pot room, its thin, aerial roots preferring the outer surface of the pot or basket which it occupies. When the growths are fully matured the plant should be removed to a much cooler and drier atmosphere, enough water only being given to keep the bulbs from shriveling. About the end of September and beginning of October the plant may be removed again to its blooming quarters, when large and very handsome blossoms, each measuring some three inches in

A Willow Walk.—See page 62.

the fruit without material injury to the vine. Indeed, the case which has been here cited, and many similar ones which are known, so far from disproving, rather go to prove that a well-considered and moderate girdling would often result in decided advantage. At all events, it is desirable that there should be continued experiments in this direction.

Orchid Notes.

Cælogyne cristata.—This is one of the most popular of all the white flowering Orchids, its blossoms being pure and very handsome. It made its appearance in European gardens nearly half a century ago and has always been greatly admired. Several varieties have flowered since its introduction, among them being the very rare *C. cristata alba* (*hololeuca*), with blossoms of the clearest white, and now only to be seen in select collections. Two other varieties, one called the Chatsworth variety and the other known as *C. cristata maxima*, are both large forms, the latter having broad, flat sepals and petals, and a large lip with a bright, golden-yellow crest. This also remains somewhat rare. In its native country it is found growing at an elevation of 6,000 to 8,000 feet above sea level, and where the atmosphere at all seasons is very cool. Large specimens of this *Cælogyne* are often met with, a fact which clearly indicates it to be a species of easy cultivation. When growth commences the plants should occupy a cool situation until the newly made bulbs are fully matured, after which they should be removed to the warmest end of the Cattleya house

diameter, will make their appearance almost the entire length of the pseudo-bulbs, during December and January, and remain in good condition for from four to six weeks. Imported plants of this *Dendrobium* arrive in the market during February and March and are easily established. With good drainage and very little potting material, they will yield quite a display of bloom the following winter.

Short Hills, N. J.

A. D.

Phalænopsis denticulata is a new species, flowering for the first time with us. It evidently belongs to the Sumatrana section, though robust in growth. It bears short, erect, few-flowered racemes; these are yellowish-white, barred and blotched with cinnamon brown; the lip is streaked with violet, the anterior lobe white and papillose. It grows very freely with us, extending its roots in all directions, delighting in abundance of water and strong heat.

Saccolabium giganteum.—This is a beautiful Orchid introduced from Burmah. It is easily grown and of robust habit, with an erect, stout stem, closely clasped by broad, ovate leaves about one foot long, dark green, with streaks of lighter shade. The flowers are produced on dense racemes, about a foot long and pendulous. They are pure white, speckled and blotched with amethyst. The lip is amethyst, with lines of a lighter shade. This plant is probably only a variety of *S. violaceum*, a species introduced more than a century since under the name of *Vanda densiflora*. In the latter the leaves are narrow and longer, while the flower is of a mauve violet on a white ground. A pure white variety of this is called *Harrisonianum*, and is somewhat rare. All of these

plants do best in baskets filled with sphagnum and large lumps of charcoal in the warmest house, with abundance of water at all seasons, not allowing them to become dry at any time.

Kenwood, N. Y.

F. Goldring.

Propagation of *Daphne Cneorum*.—This beautiful shrub has always been comparatively scarce, on account of its slow and somewhat difficult propagation by ordinary methods. To multiply it rapidly the following method has been successfully practiced: remove two or three inches of the soil about and among some strong plants, in open ground, in spring, and fill in carefully with very fine compost, almost to the tops of the branches, leaving, perhaps, two inches of their tips above the surface. This will necessitate, also, careful pegging down of the plants.

The next spring, just as soon as the frost is out, remove with the nicest care the compost, using a hose or a pail of water to wash away the soil from the thickest part of the bush, and there will be found multitudes of little white buds on the branches, each standing out from the surface of the bark like an excrescence, only held to the parent plant by a minute thread, and each bud supplied with a straight, white root, the whole looking like a seed of Clover when well sprouted, but still below the surface. This *Daphne* has a great many leaves on its branches, and in the axil of each one is a dormant bud. These minute buds rarely develop under ordinary circumstances; but the generous diet prescribed above causes many of them to push, in their cool and dark situation, into the shape described.

These miniature plants come to the surface and develop into strong and really independent plants, wherever they happen to receive enough light and space to encourage them. But the greater part would be smothered by the shade or crowded out, if unassisted. All that remains to do is to detach them carefully from their native stem, which the least touch of a fine point will accomplish, and plant them immediately in a prepared soil, fine but not too rich, in small pots or boxes, and to keep them in a cool part of the green-house, or in a frame.

One plant, three feet across, so treated, produced last season, in the nursery, over 1,000 of these young plants.

Somerville, Mass.

—F. L. Temple.

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

VI.—APPROPRIATION OF CARBON, OR ASSIMILATION.

FROM the previous papers in this series the following facts must be briefly cited: (1) The parts of the plants are perfectly continuous, and there exists an unbroken connection between the leaves on the minor divisions of the branches and the hairs on the ultimate divisions of the roots. (2) That all the active parts of the plant are impregnated with water, and so long as the loss by evaporation from the leaves is made good by receipt of water from the soil, the tissues remain unwithered. (3) By evaporation of water from the leaves, the dilute solutions taken in by osmosis through the root-hairs are concentrated. (4) That the active cells throughout the plant require, for their activity, oxygen and food.

We are now to inquire in what way the plant prepares for itself this food which is essential to its activity. The question will be simpler if we look first at the mechanism of the food factory itself, the green leaves and other green tissues exposed to light, afterwards considering the materials out of which the food is made.

Each green leaf consists of a framework made up of mechanical elements imparting strength to the fabric. This framework gives us the innumerable diversities of veining of leaves, and their distribution governs largely the shape of the leaves. Supported by the framework are the active cells by which the food is prepared. In most cases these are not closely packed together, but they have between them intercellular spaces of greater or smaller size. Over the whole is extended the delicate epidermis, with its breathing-pores, previously described. The active cells contain not only protoplasm, but also green plastids or chlorophyll-granules. The pigment which gives to these their characteristic color possesses peculiar optical properties, chief among which is that of modifying the refrangibility of the rays of light, so that all the so-called violet, indigo, blue, green and yellow rays are bent from their course, and appear as red rays. Again, the color of an alcoholic solution of this pigment, which by transmitted light is green, appears blood-red by reflected light.

By gaseous diffusion the gases of atmospheric air make their way through the epidermis, and come, in a dissolved state, into contact with the protoplasmic matter and the green

granules which it contains. In the atmosphere there is found, in very small amount, the gas known as carbon-dioxide. This gas and the water from the soil are the principal raw materials used in the manufacture of food. Formerly the amount of carbon-dioxide in the atmosphere was stated to be about four hundredths of one per cent., but recent investigations have placed the figure somewhat lower, or about three one-hundredths of one per cent. This incredibly small amount is the source of all the carbon which we find in the organic world. It is first appropriated by the green granules under certain conditions about to be noticed, and, once appropriated, its combinations undergo myriads of transformations, both in the vegetable and animal kingdoms.

The conditions for the appropriation of carbon by plants may be given in the following order: (1) A supply of carbon-dioxide adequate in amount, but still not largely in excess of what the plant naturally finds around it in our atmosphere. It is generally believed that at certain periods in the geological past the amount might have been somewhat larger than that which we find at present. It is not, however, necessary to hold that the percentage was very much greater, in order to account for the enormous accumulations of vegetable matter transformed into coal during the carboniferous period. Botanists think that plants obtain the carbon-dioxide directly from the atmosphere, and all the experiments upon the subject justify that conclusion; but it seems unlikely that plants are unable, under any circumstances, to obtain a certain portion from the soil. The late Professor Gray believed that plants possess the power of taking up some of their carbon-dioxide through their roots, but he frankly said, that as yet we have no actual proof that this is the case.

(2) The second condition for the appropriation of carbon is the presence of chlorophyll granules in active protoplasm. Protoplasm without these granules (or their equivalent, like that found in certain sea-weeds), does not have the power of effecting the change by which carbon is retained. Again (3), there must be exposure of the cells to light of proper quality and intensity, such as that furnished in the sun's rays. It is not necessary, for experimental purposes, that the light should be direct or diffused sunlight, for some of the common artificial lights answer, notably the brilliant electrical lights now in use. But, of course, in its ultimate analysis, all of these artificial lights are only sunlight more or less removed from its original source.

Lastly (4), the active cells must be kept at a certain temperature. The degree of temperature most favorable for most rapid appropriation of carbon is different for different plants, but, in general, it is not far from 85° to 90° Fahr.

When these conditions are provided, the manufacture of food proceeds with greater or less rapidity, the rate depending on certain minor factors. Its chief feature is the reduction of the carbon-dioxide in the presence of water by the elimination of a certain proportion of the oxygen of these two substances, amounting practically to that which the carbon-dioxide holds in combination. This oxygen is set free from its combination, and, for the most part, escapes from the plant.

We do not know positively what the resultant combination of carbon, hydrogen and oxygen is, but it is probably one of the simplest carbohydrates, capable of immediate transformation into other substances. It is easy to show that, under certain circumstances, a part of this food is changed into starch, even in the chlorophyll granule, and there held in its solid form. But the greater part is taken away from the source of manufacture and stored in some shape for immediate or for future use. A large portion of this food is changed at once into the permanent form of cellulose or cell-wall substance. Portions are changed in the laboratory of the plant into the numerous substances characteristic of the vegetable world, such as tannin-like matters, and so on. And since all these substances formed from inorganic matter are like plant-substance, the term assimilation has been applied to the process by which they are formed. But, lastly, a certain part is consumed at once in work; combining with oxygen, it is, so to speak, burned up in doing the proper work of the plant. This proper work of the plant—its lifting and growth, its transfers of material and the motions of its parts—must be regarded as very small when compared with that which is done by sunlight in the plant. This can be illustrated by giving an approximate estimate of the amount of carbon which plants accumulate during a given time. This accumulation expresses, of course, the amount of work done by the sunlight in breaking up carbon-dioxide, less the amount of food broken up by the plant in its own activities. The difference is well seen when we take an acre of forest and estimate its annual increase in carbon. This is about the same as that accu-

mulated by an acre of herbaceous plants, or of shrubs—namely, about one ton, or more nearly 2,600 pounds, of carbon.

This ton of carbon to the acre represents, when expressed in the terms of modern physics, a certain amount of "energy of position" derived from the transformed "energy of motion" of the solar radiance. In this state it is ready upon occasion to give forth again as energy of motion its energy of position. It is a wound up spring, a raised weight, a bow upon the stretch.

This ton of carbon to the acre represents, when expressed in terms of modern chemistry, the product resulting from the reduction of a highly oxidized substance—namely, carbon-dioxide. In this new form it is ready to undergo oxidation and to return thereby to the inorganic matters from which it was produced in the mechanism of the plant through the agency of the sun's rays.

When we reflect that the carbon-dioxide from which this carbon is derived exists as what is practically an impurity in the atmosphere, irrespirable by animals, and that after its abstraction from the atmosphere there is given back to the air the oxygen which is required by all organic beings for their respiration, some of the intimate relations between animals and plants become very clearly seen. Not only do plants prepare food for animals, but they produce it from matters which are deleterious to animals, giving back in this very process the oxygen which the latter need in large amount.

To those who are fond of looking at the organic world as a product of development from very simple beginnings, these relations between plants and animals are among the most interesting subjects for speculation. Animal life cannot exist under its present restrictions as regards food, without the aid of plants; hence, plants must have preceded animals in the order of succession. But if we take into account the fact that there are a few of the lower animals which are believed by some observers to have the power, by means of a certain amount of chlorophyll which they have in their composition, to act upon inorganic matter precisely as plants do, the question of development becomes all the more complicated and interesting. These exceptional creatures, if their life history has been rightly understood, share capacities belonging to both the animal and vegetable worlds. But it must not be forgotten that without the distinctive chlorophyll (or its active equivalent), the living matter of the organism which we call a plant has the same needs as that of the animal. In fact, large groups of plants, among which may be mentioned the Mushrooms and Moulds, are illustrations of this very fact; they cannot prepare food for themselves, but must have it prepared for them by other plants. In many cases, of course, this food may, through its consumption by animals, have passed through many changes before it is presented for the parasitic plant to consume; but these cases only serve to emphasize the general statement, which may now be repeated in concluding this paper: green plants produce all the food which they themselves and animals require. The apparently simple and yet exceedingly complicated process by which plants prepare from inorganic material the organic food demanded by all organisms, transforms inorganic matter into substance like the very substance of the organisms themselves, and hence the term assimilation is highly significant.

Cambridge, Mass.

George Lincoln Goodale.

The Forest.

The Forests of the Rocky Mountains.

IN a paper on "Rocky Mountain Forests," read at Atlanta before the American Forestry Congress, Colonel E. T. Ensign, of Colorado, estimated the forest-land in Colorado, Wyoming, Montana, Idaho, Utah, Arizona and New Mexico at about 95,000 square miles, or thirteen per cent. of the entire area. This includes, he said, all grades, light and heavy, valuable and inferior. The forests are mainly coniferous, and most of them are on the mountain slopes, from 4,500 to 12,000 feet above the sea. Some of the foot-hills and mesas have a scattering and inferior forest-growth, and many of the streams are bordered with Cottonwood and a few other deciduous trees. Large tracts in the mountains from which the ever-green forests have been burned are now covered with the Aspen (*Populus tremuloides*). Other extensive areas are wholly denuded of trees, and the rocky, seamed and storm-beaten surfaces are desolate and forbidding in the extreme. Crowned all are naked mountain-crests and snow-clad summits.

Except in a few favored places, the forests are not dense. Compact and heavy growths of Spruce are sometimes found at the highest altitudes, and on the slopes. The Yellow Pine, the most generally useful timber-tree, seeks a lower level than

the Spruce, and is usually confined to southern slopes in warm and dry situations. When the pine-forest has been destroyed it is often not reproduced, owing to the prevailing arid conditions. On northern slopes, the home of the Spruce, where snow and moisture are longer retained, a second growth is more likely to appear. The altitudes of the Rocky Mountain region, inclusive of the valleys, plains and plateaus, vary from 680 feet above sea level at Lewiston, Idaho, to 14,400 feet in Colorado. The approximate mean height of the Idaho and Montana ranges is 8,000 feet, of the Wyoming mountains 9,000 feet, of the Colorado and New Mexico system, south to the latitude of Santa Fé, about 10,500 feet. I have thus indicated the great altitude of the region. It extends from the British possessions to the Mexican boundary. At least seven-eighths of its entire area lies north of the latitude of Atlanta. As a result of its high altitude and northern situation, its snowy mountains and extensive forests, powerful rivers have their sources in this region.

During the few years covering the rise of the mountain territories gold and silver mining and live-stock growing have been their chief industries, but agriculture is likely soon to take precedence of the others. Its recent progress, fostered by great systems of irrigation, has been phenomenal. Great agricultural enterprises, similar in kind if not in extent to those of Colorado, have already been started in all of the Rocky Mountain territories. It is obvious that the demand for water, already very great, will be largely increased in the future. The recent action of Congress authorizing surveys to determine what lands of the mountain and plains region may be reclaimed with the aid of irrigation, the water-supply available for such a purpose, and where reservoirs, canals and other irrigation works should be constructed, should receive the closest attention. In view of the agricultural possibilities contingent upon such action, and of the need for the prevention of floods in the great rivers, this movement for the storage and utilization of water is of the first importance.

But what, it may be asked, is the immediate connection between the forests of the Rocky Mountain region and its irrigation systems? The forests are the principal natural agencies in regulating the flow of water. They prevent the premature melting of snows, and protect and nourish the sources of streams. Aside from their office in attracting moisture and causing precipitation, it is evident that these forests, by reason of their location and character, and of the surrounding physical and economic conditions, are of vastly more importance for the conservation of water than for any other purposes.

Railway building in the Rocky Mountain region, and especially in Colorado, offers a most serious menace to the existence of the forests, and it is rapidly increasing. After the tie-chopping legion come settlers, miners, lumbermen and charcoal-burners, all of whom, in addition to their direct havoc of the woods, prepare the way everywhere for fire. For ties only the young, partly grown trees are used, and the consumption for this purpose alone is enormous. And yet cedar and oak ties, from the southern and Pacific forests, can be had in Colorado at a cost not above one-third more than the native pine ties, and they are in every way better and last at least twice as long. Lumbering to supply local and ordinary demands would not, of course, be objectionable if it were properly conducted. Under existing laws, however, most flagrant abuses are perpetrated, and the forests suffer great and unnecessary loss. Mining operations require a great deal of timber, and in some of the older mining districts the supply is exhausted, and such material is brought from a distance at undue cost to the consumer. The charcoal-burner is as merciless as fate. He spares not the smallest growth; nothing escapes him. Smelters consume great quantities of charcoal in the reduction of ores, but it is not necessary, and at some of the principal works little, if any, charcoal is used.

The number of articles which can be manufactured from wood-pulp advantageously is increasing constantly. Pipes made from it and fitted with iron couplings are now recommended for conveying underground all fluids not strongly alkaline, or which are not used at a high temperature. These pipes are impervious to leakage and practically indestructible. They have been used successfully for distributing natural gas, and the non-conductive properties of wood-pulp will make it valuable for underground wire conduits. Vast quantities of Spruce and other trees are destroyed every year in the Northern States and in Canada to furnish the material for the wood-pulp factories and iron-pyrites used in the production of "chemical pulp" are in increased demand. Wood-pulp is imported also into the United States from Sweden and other North Europe countries in very considerable and rapidly increasing quantities.

Recent Publications.

Review of Forest-Administration in British India, for the year 1886-87, by B. Ribbintrop, Inspector-General of Forests to the Government of India, Calcutta, 1888.

It appears from this report, which has just reached us, that the department controlled during the year which it covered 811,824 square miles of forests, or an increase over the amount reported a year earlier of 3,340 square miles. Some idea of the difficulties the Indian forest officers have to encounter appears in the statement that during the year no less than 1,171 cases of prosecution on account of damages of one sort or another were taken to the court, an increase of seventeen per cent. over the previous year. Convictions amounting to seventy-two per cent. of the number of prosecutions were secured.

Much attention is given to protecting the forests from fire, which has always been their most serious enemy. The whole area controlled by the department has not been brought under the fire-protection system, which, however, is being extended as rapidly as practicable. The total area under protection in all the provinces was 20,335 square miles, and of this protected area, 1,644 square miles were burned over during the year, or eight per cent., a result which is considered satisfactory, and shows the enormous difficulty of protecting forests over large areas from fire, especially in the case of forests of coniferous trees. The Indian forest administration has always been hampered by certain rights of pasturage in the forests acquired by the entire population through long custom, and the reserved forests suffer seriously from this cause, especially during dry seasons, when they are called upon to furnish more than usual quotas of pasturage. As an example of the effect of pasturage upon the forest, the case of two compartments in the mountain district of Darjeeling is cited; one field has been closed to cattle during a period of twelve years, while the other had been pastured during the same period. Seedlings and young trees abound in the former, while in the latter young trees or saplings are very rare, and no seedlings exist.

The following extract refers to Bombay, and is worth careful consideration on the part of the Commission of the Adirondack forests, who recommended the expenditure of considerable sums of money in planting trees upon the exposed rocky hills in the northern part of the state:

"The Conservator of the Northern Circle speaks very hopefully of reproduction in all forests where fires and cattle are excluded, and notices that the general experiment in the state of the reserves has been commented upon very frequently by outsiders, and this with special reference to hills which were formerly bare, but are now gradually covering over with a bushy vegetation, the advance guard of a higher order of plants. . . He expresses his conviction that the forest department could, by simple and inexpensive means, restore timber to all the bare hills of the Deccan, provided that fires and cattle are excluded, and the work of natives not interfered with in an irrational manner."

The gross revenue during the year covered by this report reached a total of \$5,016,000, which is the highest figure yet arrived at by the department. The net profits, however, fell slightly below those of the previous year, although the net revenue per square mile of forest increased from \$8.80 to \$9.24. The expenditure of the department includes the formation of new plantations covering 3,939 acres, and the cultivation of 39,924 acres of plantation made previously.

Periodical Literature.

In *Harper's Magazine* for February Mr. John Habberton writes sympathetically and encouragingly of "Bulb Gardens In-doors," explaining the charms of Hyacinths, Tulips, Narcissus and kindred flowers, and discussing their relative claims upon the amateur's attention. Many of his hints and counsels are very useful, and his enthusiasm, evidently based on successful personal experience, ought to encourage his readers to enter upon what is certainly the most satisfactory branch of house-gardening. We must, however, take issue with him when he recommends double Tulips as better than single varieties for in-door gardening. He is doubtless justified by practical considerations. The single Tulip, as he points out, is apt, when grown in this way, either to fail to develop its form in perfection or to lose it soon after it has been attained. "The double Tulip, with several times as many petals, proves that in 'union is strength' by retaining its form much longer." But when he adds that "there is little or no choice between single and double varieties as to beauty and range of color," he is surely misleading—that is to say, if by "beauty" he means

the form as well as the color of the flower. In all flowers of this character beauty of form is the most characteristic quality, and to double a Tulip, a Narcissus or a Hyacinth is to decrease its value in the eyes of the true lover of floral beauty to an almost incalculable degree. Who would not be shocked by the idea of a double Bermuda Lily or Lily-of-the-Valley? Yet the form of a well-grown Tulip is almost as beautiful, and quite as insistently demands respect at the hands of the horticulturist. With Roses the case is different. Some florists' Roses, indeed, are, like double Tulips, mere showy, formless masses of crowded petals. But in others—as in the best varieties of Tea Roses—while the exquisite simplicity of the form of the wild single Rose has been lost, a new type of form as beautiful in its own way in every stage of growth, and much more sumptuous and superb, has been achieved. The fact that the difference between double Roses in this respect is so often ignored both by cultivators and by purchasers speaks badly for the condition of public taste, but by no means excuses the praise too often given to double flowers. One glance at the exquisite drawing by Mr. Hamilton Gibson of a single Tulip and a single Daffodil, which helps to illustrate Mr. Habberton's article, should prove to the reader the folly of tampering with forms that Nature has made so perfect. If single Tulips cannot be well grown in-doors, let double ones be accepted as a makeshift. They can be nothing more than this, for even beauty of color suffers when the petals are so crowded together that their delicate streakings and shadings cannot be clearly discerned. All of Mr. Gibson's drawings, as one might expect, are very charming, and if the most important among them—the "Window Garden"—shows a result of such ideal beauty that few people can hope to reproduce it in their homes, it is well that enthusiasm and vigorous effort should be excited by a realization of what the best success may mean. The little drawing of *Freesia refracta alba* is particularly pretty.

Correspondence.

The Mistletoe.

To the Editor of GARDEN AND FOREST:

Sir.—I clip the following from an English horticultural journal: "The orchards of Worcestershire supply large quantities of the interesting parasite (Mistletoe), and though considered by some difficult to grow, it is not so. The way to propagate it is to obtain the berries, choose a suitable tree—Apple for preference—select a gnarled bough, and press in the berries in a notch where birds are not likely to pick them out, or cut a slit on the under side of the branch for the reception of the seed. Many an amateur who has an orchard cultivates his own Mistletoe, and a tree with the plant growing amongst the branches is exceedingly picturesque."

Will you kindly tell me whether the Mistletoe can thus be cultivated in America, and how far north it is hardy? Year by year at Christmas time there is a demand for it in our large cities, but the supply is small, and purchasers are often displeased with what they get, as it has a withered appearance in both the leaves and the fruit. This appearance is occasioned, I am told, by packing and transportation from distant places, and I think perhaps American amateurs or tradesmen might do well to grow it for themselves, if the thing is feasible.

Watertown, Conn.

F. R. D.

[The American Mistletoe (*Phorodendron flavescens*) is found from southern New Jersey to southern Illinois, and southward. It appears to be most common in some parts of Kentucky and Tennessee, where it does considerable damage to various trees, notably the Black Walnut, which is often killed by the excessive multiplication of the Mistletoe upon its branches. It is not known that any attempt has been made in the United States to cultivate the Mistletoe.—Ed.]

Poison Ivy.

To the Editor of GARDEN AND FOREST:

Sir.—Gray, in his "Manual of Botany," fifth edition, under *Rhus Toxicodendron*, L., Poison Ivy, Poison Oak, says the entire leaved form is *R. radicans*, L. Wood's Class-Book of Botany, 1875, separates the species into *R. Toxicodendron*, L., Poison Oak, Poison Ivy, and *R. radicans*, L., Climbing Ivy.

It seems to me that the division of these forms into species is eminently proper, if one may be permitted to generalize from a local herborization. So far as I have observed, *R. Toxicodendron*, with rhombic-ovate, variously notched, sinuate or cut-lobed leaves, is virulently poisonous. *R. radicans*, which

is either a low shrub, or a climber by rootlets over rocks and ascending trees, but with always entire leaves, is either not poisonous or else little virulent. The knowing this distinction in properties and this relation of forms may bring comfort to those who would otherwise live in a condition of timidity.

Along the shores of Buzzard's Bay *R. radicans* is excessively abundant. At Nonquitt it forms dense, low thickets about a tennis-court, occurs in the scrub growth about the cottages, along various paths frequented by nurses and children, about the play-grounds along the shore, and in the woods, climbing trees to a height of many feet, and with a stem of over an inch in thickness. In playing tennis the balls often fall amidst its growth, and are recovered by ladies and children indiscriminately, but I have yet to learn of a case of poisoning. The children ramble at all times amidst its growth, and remain unpoisoned. Those who are especially subject to Ivy poisoning in regions where *R. Toxicodendron* is the leading form, at Nonquitt last summer escaped poisoning altogether, although often fearful on recognizing contact with the dreaded plant.

Although perhaps the specific differences, as usually considered by botanists, are scarcely sufficient to separate these two forms (although I have noted no intermediate or connecting forms), yet this one difference in quality (or quantity?) would render it desirable to recognize in our manuals and local floras these two forms as if distinct.

South Framingham, Mass.

E. Lewis Sturtevant.

"When to Employ the Landscape-Gardener."

To the Editor of GARDEN AND FOREST:

Sir.—May I add a postscript to your recent editorial? It is not long since the American public first began to give thought and money to securing well-designed houses. We had first to realize that our dwellings were not what they might be, and, secondly, to learn that if we would do better we must ask the help of men specially trained to design happily and to build well. As respects the surroundings of our houses, even most of us who have employed architects are still in the first or unawakened stage. We simply have not perceived that our surroundings might be pleasanter or more in keeping with our abode. While we spend freely to fill the house with things of beauty, we probably leave the spaces round about it wholly bare, or if we attempt something better than nakedness, we do so without thought of general effect—without regard to any such principles of design as guided the architect in his shaping of the house. Not until we come to see that the surroundings of the house as well as the house itself should be designed—that house, approaches and surroundings should be planned together—shall we be likely to call upon the landscape-gardener.

Recent Plant Portraits.

PSEUDOPHŒNIX SARGENTI, *Revue Horticole*, December 16th; a reproduction of the figures published in GARDEN AND FOREST, vol. i., pp. 353 and 355.

RODRIGUEZIA FRAGRANS, *Gardeners' Chronicle*, December 29th. "This Brazilian Orchid is an old inmate of our Orchid-houses, and best known under the name of *Burlingtonia fragrans*. Its delightfully fragrant white flowers, with yellow centres, are grateful everywhere, but from the neat habit of the plant it is especially acceptable in collections where the space is limited and the house is small. Like the rest of the genus, it thrives best and is safest in baskets suspended near the glass of the roof, and after the pseudo-bulbs are fully matured it should be carefully but sparingly watered, sufficient only being given to keep it plump and healthy. During its inactive season, a place near a ventilator in the Cattleya-house, in which it is growing, or in some other part of the house, where there is a good air, not too heavily charged with moisture, assists in ripening its growth."

SYMPHYANDRA HOFFMANNI, *Gardeners' Chronicle*, December 29th; a native of Bosnia, where it was discovered in 1883; a free-blooming, hardy plant of the Campanula family, with white flowers, and well worth a place in the garden. The figure is from a plant which flowered for the first time in England in the Royal Gardens at Kew.

PINUS COULTERI, *Gardeners' Chronicle*, December 29th.

ECHINOCACTUS TEXENSIS, *Gartenflora*, December 1st.

ZYGOPETALUM SANDERIANUM, *Gartenflora*, December 15th.

CATTELYA RŒZLII, *Revue Horticole*, December 16th.

Public Works.

The Legislature of Minnesota having been petitioned to set aside a certain piece of ground for the purposes of a state park, the matter was referred to a committee consisting of Mr. H. W. S. Cleveland and Mr. J. D. Ludden. The following is a brief abstract of the report, which will be read with interest by all persons who look upon the preservation of natural scenery as a matter of real public importance:

After careful examination of the subject and consideration of future issues and interests involved, we have arrived at conclusions which can only be appreciated by a statement of the conditions which have led to the result. The Mississippi River, between St. Anthony Falls and the mouth of the Minnesota River, flows between high and precipitous banks, which are intersected at irregular intervals by deep transverse ravines, forming the beds of brooks. The largest of these is the valley of the Minnehaha, which is the outlet of the chain of lakes of which Minnetonka is the head. The others are simply the water-sheds of adjacent uplands. The character of the whole region is picturesque, and the effect of its topography is increased by a luxuriant growth of trees. It is yet possible to preserve nearly the whole of this historic region, and we appeal to the state of Minnesota, for its own honor and its own interest, to follow the example of the state of New York in the preservation of the Adirondacks and Niagara Falls, and to secure the whole area to be forever preserved. We ask that an area on the east side of the river extending from the grounds of the State University, or as near that point as possible, to a point opposite the lower end of Pike Island, and on the west side, from Riverside Park to the military reservation at Fort Snelling, and of such width on each side as will include the natural features of the banks and ravines, be secured as the property of the state, and that the whole intermediate space, including the river and its islands, shall thenceforth be preserved as public domain, connecting, as it necessarily and appropriately would, with the park systems of St. Paul and Minneapolis, and forming in itself a park of such unique character, comprising such features of grand and picturesque natural scenery as could nowhere else be rivaled. A broad avenue should extend for the whole length of each tract on the side farthest from the river, and the cost of these avenues, as well as the improvement of the park itself by diverging roads or paths to points of interest, should devolve upon the cities to which they respectively pertain.

The Park Board of this city passed a resolution at a recent meeting to set apart, in one of the new parks, sufficient ground for a botanical garden, if the friends of that enterprise should raise an adequate amount of money for its endowment within a period of two years. It is said that the Park Commissioners have good reason to hope that public spirited citizens stand ready to contribute the necessary funds if the garden can be established under an administration similar to that of the Museum of Natural History and the Museum of Art.

Notes.

The ninth edition of Mr. William Paul's well-known book on Rose-culture—"The Rose Garden"—has just been published in London.

Mr. E. S. Goff, horticulturist of the New York Experiment Station, has accepted the professorship of horticulture in the University of Wisconsin.

The average number of persons who have visited the Museum of Natural History in this city on the evenings when it has been open has exceeded 1,000.

Iris reticulata is now being forced near New York for the Easter trade. There is no reason why it should not be a success, though its capabilities in this direction are as yet untested.

A species of Phylloxera has been injuring Pecan trees in Mississippi. Dr. Riley has not identified it with any known species, but it is closely allied to a Hickory plant-louse named by Dr. Fitch *Phylloxera caryæcaulis*.

Of the newer grapes, Moore's Diamond was commended at the late meeting of the Western New York Horticultural Society for vigor of vine, productiveness, good quality and earliness. The Moyer and the Mills were highly spoken of.

A new white Rose is The Queen, a sport from Souvenir d'Un Ami. It will hardly supplant The Bride and Niphetos, in the trade at least. Apart from its fragrance it will not compete with The Bride, which many growers declare their most profitable Rose.

The double-flowered Chinese Blackberry has been forced successfully this winter, producing wreaths of white blooms about two inches across, which bear a strong resemblance to Polyantha roses. It is easily grown, but requires too much room in a green-house to pay the commercial grower.

The Rocky Mountain Columbine (*Aquilegia chrysantha*), which has been somewhat neglected of late, is now being grown largely with a view of bringing its merits before the public. It is a very handsome perennial, one of the handsomest of its tribe, and an admirable plant for the rockery or herbaceous border.

Houghton, Mifflin & Co. are to publish the miscellaneous scientific papers of Asa Gray, which are being selected and arranged by Professor Sargent. The first volume, containing the reviews of works on botany and related subjects, written between the years 1836 and 1887, is now in press, and will appear early in the spring.

A specimen of the Californian *Pinus Sabiniana* growing in isolation on a lawn in the Botanical Garden at Kew now measures thirty-five feet in height, and at four feet from the ground girths five feet six inches. From an illustration of it recently given in the *Gardeners' Chronicle*, it seems to be a symmetrical and beautiful specimen.

Many trees in western Massachusetts were broken down by the formation of ice on their branches during a rain-storm on the 6th of January. A correspondent writes that in some cases every twig was encased in ice half an inch thick. Accurate weighing of one of the broken branches in the village of Ashfield Plain showed that there were fourteen pounds of ice to one of wood.

The material benefit which French conquest has conferred upon Algeria shows clearly in accounts of the extent to which systematic irrigation has already increased the cultivable area of the country. In the district called the Oued Rir, the once-fertile oases had been almost buried under desert sands when the French took possession; now, by means of irrigation systematically carried out with the water of the native wells and of numerous artesian wells that have been sunk, these oases have been reclaimed to the number of forty-three, and are estimated to bear 520,000 Date-palms and 100,000 other fruit-trees which already produce profitable crops. The population of the district has meanwhile doubled, while its condition is vastly more prosperous than before.

A correspondent of an English horticultural journal writes that the thick fogs which recently spread over the neighborhood of London did serious damage to hot-house plants. "Before the fog came we had cut some six dozen good flowers (from a plant of *Camellia alba*), but not one since; nor are we likely to do so again; for although the trees were nicely set with buds and half expanded flowers at the time the fog set in, all of these turned rusty and fell off. . . . A plant next to it—a red variety well set with buds—has so far passed through the ordeal without loss of buds or flowers. Amongst Orchids the *Calanthes* show no ill effects. . . . A plant of *Saccolabium giganteum*, with two spikes of flowers on it, suffered injury at the ends of the trusses, where the flowers were not fully open, all of them turning to a brown color and having to be cut off. *Azalea Indica*, white and colored—a few of which were gently forced—have withstood the fog well."

The largest artificial cascade ever planned is doubtless the one which was partly built in the grounds of Wilhelmshöhe near Cassel, the summer residence of the local dukes, but better known in our time as the place where Napoleon III. was confined after the battle of Sedan. The park is a large and fine one, with very beautiful Beech-woods and many passages of the most charming natural scenery. But it likewise includes a make-believe mediæval castle and many singular devices. The cascade was begun in the first years of the last century, and was intended to consist of a series of regular steps leading down the whole side of the mountain upon which the park was created to the vicinity of the castle below. The plan proved too ambitious for accomplishment, and only the upper part of the cascade was built, the steps starting from a statue of Hercules, which is thirty-six feet in height, and into the head of which visitors may ascend to spy out the landscape, literally through the giant's eyes. Yet though this completed portion is only a third of the whole, it measures 800 feet in length, the steps gradually widening as they descend between masses of forest verdure.

In the latest Bulletin from the Iowa Experiment Station, Mr. R. P. Speer points out certain structural differences which are said to exist between such Apple trees as Duchess of Olden-

burg, Letofsky and a few other varieties from Russia which have endured the trying climate of the North-west, on the one hand, and the ordinary American Apples and those from west Europe on the other. The flowers of the former have larger and thicker petals, shorter and more stocky pistils and stamens, larger stigmas, anthers and pollen grains; their leaves are thicker; their wood, bark and bud-scales have a finer texture; and their roots penetrate more deeply beyond the frost-line. These physical peculiarities of the hardy trees are protective against summer drought and winter cold. Having been developed in a region of short summers, they ripen their wood early, their cambium layers do not contain so much liquid, and are, therefore, less subject to scalding of the bark on the south-west side when freezing temperature quickly follows warm weather in early spring. The questions suggested by these studies are interesting, and it is to be hoped that further investigation will enable Mr. Speer to give more definite facts in support of his theory.

In a recent number of the *American Florist* are printed trade reports with regard to holiday sales of flowers from forty-seven towns in the United States. In almost all cases the report is satisfactory in so far as quantity is concerned, though there are numerous complaints about the quality of the flowers as having been affected by unfavorable weather. In many places the demand for the costliest kinds of Roses seems to have been very large, while in others the cheaper kinds of flowers were in greater requisition. The trade in Christmas trees and in greens for church decorating is evidently increasing from year to year, and the finer greens—Holly especially—are more and more in demand. But the most interesting fact to be gathered from these reports is that the public is turning away from baskets and set pieces and learning to prefer boxes of loose flowers, which may be arranged at home. "Four-fifths of the call was for loose flowers," writes one correspondent; "A notable decrease in the demand for baskets and bouquets," writes another; a third "The demand for loose flowers exceeded everything; but few baskets were made up," and a fourth, "The demand for baskets is yearly on the decrease," while thirty-four reports out of the forty-seven include similar statements, and only four speak of an increased demand for set pieces. Had the holiday trade, as a rule, been bad, these changes might be explained by the fact that a reasonable quantity of cut flowers may be more cheaply purchased than even a small basket arranged by the florist. But as things have stood this year they seem to denote a growth in good taste and in the appreciation of the true beauty of flowers, which is indeed of promising import.

Mr. Sylvester Baxter, who is contributing an interesting series of letters on "Archæological Campaigning in Arizona," to the *American Architect and Building News*, speaks as follows of the neighborhood of Las Acequias, where Mr. Cushing is now pursuing his explorations: "The new camp is pitched in a pretty little hollow amid a clump of old Mesquite trees. The hollow is that of one of the ancient reservoirs and the moisture retained there makes it a favorable place for the luxuriant growth of the Mesquite trees. . . . The name conferred on the ancient city, Las Acequias, comes from the great irrigating canals that spread out fan-like among the ruins, and reach away to various parts of the plain to supply the other cities of the group. . . . It must have been an enormous labor to excavate them in those times, with nothing but crude stone implements and baskets for the transportation of the earth." When emigration sets in "the landscape undergoes a rapid transformation in the course of a few weeks. . . . The Mesquite trees are cut down and burned in piles above their roots, whose ramifications are followed by the smouldering combustion, leaving the ground ready for the plow, when that instrument shall eventually be brought into requisition, which will probably not be for two or even three years, for the mellow, rich soil needs no plow at first. A seed-drill rapidly sows the grain when the ground has been cleared, and the only labor then required is to irrigate and harvest. The next year even the labor of sowing is unnecessary, for a luxuriant volunteer crop springs up from the self-sown, ripened grain, and often, the second year, there is still another volunteer crop as abundant as the first! The growth of Sage-brush or Greasewood is cleared off with slight trouble or cost; a stout bar or beam is dragged across the land by a pair of horses, one attached to each end. The bushes are displaced by the powerful leverage at their bases as the beam is dragged over them. The team then follows the same course in a reverse direction, either yanking up the bushes by the roots or breaking off the brittle wood close to the ground. The brush is finally gathered into great piles and burned, making a strong, clear flame that shows across the country for a great distance."

The Soil and National Development.

CIVILIZATION means, or should include, foresight, the perception of essential and controlling conditions, adaptation of means to indispensable ends, and the defense and preservation of vital national possessions. All wealth is drawn from the earth itself. All the means which sustain human life come out of the ground or the sea. The principal source of permanent wealth for this country, and of sustenance for its people, is in its soil. No matter how great our mineral wealth may be, or our income from exports of manufactured articles, agricultural success is for us an indispensable condition of national power and permanence. The soil is our most valuable possession, and it is the only one of our important national possessions which is in danger of being seriously and permanently impaired in value. Under present agricultural methods a great proportion of the soil of this country is being rapidly exhausted of its fertility.

A large part of our agricultural population is still, to a considerable extent, nomadic, multitudes of farmers expecting to leave their land after they get about all they can out of it. They do not regard the land which they now till as a permanent possession. They think they may yet go to some other part of the country and there find better land. Many of them do not wish always to be farmers, but hope to find something better than their present occupation, a way to make money faster, and with less hard work. The illusory expectation of finding better land somewhere else is a factor in the unsettled and uncertain state of mind of many thousands of farmers regarding their occupation. It should be considered and analyzed by thoughtful men.

So far as the soil is concerned, most farmers might as well stay where they are. It is their methods which are at fault. Any temporary improvement of individual fortunes which might result from a migration to newer regions would be at the expense of the impoverishment by which such farmers have destroyed the soil which

they now wish to leave. But the essential feature in this matter, surpassing all others in importance, is the fact that, compared with the demand for new land, the total possible supply or quantity remaining available in this country is very small. Practically it is already exhausted. Considering the vast immigration which we receive, and the increase of our population by birth, the area available for agriculture which still remains unoccupied is insignificant. It is not a factor of importance in our agricultural problem.

Our people cannot all live in cities. If men will not themselves cultivate the soil, they must still eat what is brought out of it, and the subsistence and civilization of the entire population must depend at last upon the fertility of the land. We cannot advance much farther in civilization, or national development, until the nomadic methods of agriculture by which the soil is now mercilessly exhausted and ruined, shall give place to a practical and enlightened policy which will preserve permanently unimpaired the fertility of cultivated lands.

When Nature is allowed to retain undisturbed possession of a region she plants it with a crop which reproduces itself forever, and which perpetually augments the fertility of the soil out of which it grows. There is much talk in New England of lands being exhausted and abandoned, and of farms being sold at prices which would not reproduce the buildings on them. The buildings are sold for less than they cost, and the land is given away. But none of this land should ever have been cleared or cultivated. It should have been kept in forest, and if it had been so kept, would have been more valuable to-day than any of the adjacent cultivated lands.

One of the most effective agencies in the process of eliminating all fertility from land is excessive pasturage. Unless there is a radical change in agricultural methods, it will only be a very short time in the life of the nation until many millions of acres will be so exhausted that the soil will yield no return for agricultural labor. Population will begin to press closely upon the means of subsistence in large regions of our country. These are not remote or merely possible evils. They are already real dangers, which threaten us with a speedy culmination of our prosperity, and with arrest of our national development. The process of the exhaustion of the soil of the country will not only limit our national expansion in wealth and power, in character and genius, but will change the type of our civilization, and the development of conditions analogous to serfdom will be as inevitable as "the process of the suns." The most important changes in human history are often produced by the gradual and unobserved shifting of forces, of the very existence of which the mass of men are unaware.

A Piece of Vandalism.

THE press of New England has recently called the attention of the public to the destruction of a venerable Oak tree growing in the town of Woodbridge, near New Haven, in Connecticut. The tree was a very famous one, widely known throughout the state, and a familiar and valued landmark for the navigators of Long Island Sound. The following notes with regard to this tree have been furnished by Professor D. C. Eaton, of Yale College, and in a future issue we hope to publish its portrait:

A large party of New Haven and Woodbridge people gathered under the Oak on Friday, October 13th, 1882, to celebrate its venerable age. There were speeches by Ex-Governor English, Hon. N. D. Sperry (a native of Woodbridge), Rev. Mr. Marvin, of Woodbridge; Rev. Dr. Todd, of New Haven; Judge Pardee and a few others (myself included). The opinion was freely expressed that the tree was at least a thousand years old. I found a branch four and a half inches thick which had been sawed off, high up the tree, and on this branch I counted eighty-nine rings. The girth of the tree at five feet from the ground was twenty-two feet, at one foot from the ground twenty-seven feet; the diameter, therefore,

about ninety inches, or at the lower place of measurement 103 inches, and by the rule of three I made the age of the tree a little short of 900 years, and so could very well call it about a thousand. Taking the lower diameter the result would be 1,184 years. Last December the tree was cut down, and it was found that the trunk was a mere shell, the sound wood from five to twelve inches thick.

Last Wednesday I drove out to Woodbridge, and persuaded one of the proprietors to let me have a large piece of the wood from the trunk. I brought away, also, a small branch, and some leaves and acorns, and send you a part of all of them.

You will see that the tree was of the species *Quercus tinctoria*, the Black, Yellow, or Quercitron Oak, leaves, acorns, timber and yellow inner bark all concurring in their testimony. One of the pieces I send is a transverse section of the main trunk, passing from the bark inward as far as the wood was sound. I send also a bit of the half decayed wood from still further inward. The larger slice shows fifty-seven rings in the outer five inches, and forty-one rings in the next five inches, the innermost part showing about five and a half to the inch. The bit of deadwood from somewhere in the interior of the tree is nearly four inches broad, and shows about thirty-one rings, an average of eight to the inch. I conclude that the tree must have had periods of rapid growth and other periods of slow growth; but I do not see that we can put the average rate higher than twelve rings to the inch for the last sixty years, and eight to the inch for the previous life of the tree. This would give us 40 x 8 and 12 x 5, or 380 years for the whole life of the tree. With ample allowance for unestimated irregularities I cannot now believe the tree to have been as old as 500 years, probably only 375 to 400 years. The tree stood at the corner of two country roads about four and a half miles from New Haven, on the top of a long hill, about 300 or 350 feet above tide level. It was a conspicuous object for miles around, and was constantly visited by many lovers of nature. The owners are having it sawed up into boards for sale, and it is expected that many people will secure relics of this venerable Oak.

It is almost incomprehensible that any man could be found in New England sordid enough to destroy a tree of such imposing dimensions, venerable age and widespread fame, that it should draw about it the most distinguished men in the state to celebrate the marvel and the mysteries of its existence. The thought naturally arises that the celebration had been organized for the express purpose of increasing the value of the tree to relic-hunters. But whether this is true or not, there is some consolation in the fact that the tree was hollow, and that the amount of material it affords will not go far to gratify the cupidity of the man who destroyed it. It is devoutly to be hoped that no one will be found willing to buy an atom of the wood of this tree, and in this way or in any other countenance this piece of vandalism.

Ten years ago the forests covering the western slopes of the Big Smoky Mountains in Tennessee were considered as inaccessible and remote from market as any in this country; and a serious proposition to convert them into lumber would have been regarded as purely chimerical by persons who had seen those rocky wilds. A powerful Scotch company has, however, been operating in these mountains during the past two years, and the rocky and precipitous beds of the Pigeon, the Little Pigeon and other streams which flow west from the Smokies have been partially cleared out and improved, and timber cut from their banks is now manufactured in immense quantities at the mills in Knoxville. Much of the best and most accessible Yellow Poplar has been cut down already, and what has not been cut is controlled by this company, who have had for some time agents at work quietly buying up every good tree at prices ranging from fifty cents to one dollar each. These trees, it must be remembered, are the finest of their kind, with tall, straight shafts six to ten feet in diameter, running up without a limb for eighty or one hundred feet. They represent the undisturbed growth, under conditions of soil and climate perfectly favorable, during a period of not less than 500 years. Five hundred years' growth, under the changed conditions made by man, will not serve to build up their like. The last stronghold of the great

deciduous forests of eastern America, the richest, most varied and most valuable found on the surface of the earth, with the exception, perhaps, of the little known forests of western and south-western China, has been invaded, and its destruction is now a question of time alone.

The Yellow Poplar only has suffered so far, but in these same forests are Ash trees of a height and girth which even the bottom-lands of the Ohio and the Mississippi have never produced; Birch of a size and beauty unknown elsewhere, and above these, and near the summits, Spruces unmatched, except by those which grow, or once grew, on the banks of the Columbia. The amount of lumber contained in these forests of Spruce and Birch is comparatively enormous, and certainly nowhere else is there so much, or so valuable, Red Birch. The inaccessible position occupied by the Spruce, and the small demand up to the present time for birch-lumber, have saved these forests so far. Their destruction, however, will not be delayed much longer, and sooner or later a way will be found to transport to the saw-mill the most inaccessible tree growing on the remotest slope of the Alleghany Mountains.

There is a bill before the Legislature of this State to authorize the City of New York to expend \$300,000 in improving and extending the menagerie in the Central Park. This bill ought to be defeated. There is not room in the Central Park for a Zoological Garden. The present collection of beasts is not a credit to the city; it injures the park as a park, interfering seriously with those purposes for which it was created, and thus injuring the people who frequent it. New York ought to have a Zoological Garden commensurate with its population, wealth and commercial importance among the cities of the world. There is no better educator than a good Zoological Garden, and none of the equipments of well-ordered modern cities are superior to it in attractiveness and in the general interest and intelligence it creates. Provision should be made now for the location of a garden of this character in one of the proposed new parks; but instead of spending more money on the existing menagerie, the sooner it can be cleared away, and the space it now makes offensive devoted to trees again, the better.

The Landscape Gardener.

IRRESISTIBLE forces are drawing vast populations into the cities. Here, in the busy centres of the great towns, life is lived at high pressure—at such pressure that men are continually compelled to seek rest and refreshment, either in suburban home-life, or in frequent flights to the country, the mountains or the sea. It is to meet this want that millions of dollars are spent upon public country-parks, and other millions upon country seats and seaside seats, summer hotels and summer cottage neighborhoods; while, near the cities, the same want causes the region of detached and gardened houses to continually expand. This modern crowding into cities results in a counter invasion of the country; and it is just here that the special modern need of an art and profession of landscape-gardening is first felt. How can we add roads, and many or large buildings, to natural landscape, without destroying the very thing in search of which we left the city? How shall we establish ourselves as conveniently as may be, and at the same time preserve all the charms of the scene we have chosen to dwell in? How may we rightly work to bring more and more beauty into that scene?

Questions like these are not easily answered, and many other problems arise equally difficult of solution. How shall we arrange the roads and buildings of a new suburb so as to make it a thoroughly pleasant place to live in? How shall we secure all possible convenience and beauty in the door-yards and gardens of a neighborhood? How shall the railroad station-yard and the church-yard, the public school-yard and the public square

be made as pleasant as possible to look at, to linger in or to play in? How shall the public park, to which many hundreds or thousands will resort at one time, be so made and preserved as to be to all city dwellers a revelation of nature's beauty and peace?

Only special study and long observation will fit a man to solve successfully these problems of landscape gardening. Says Mr. Ruskin: "Art, properly so called, cannot be learned in spare moments nor pursued when we have nothing better to do. To advance it men's lives must be given, and to receive it, their hearts." To the art of preserving, enhancing or creating out-of-doors beauty, whether natural or formal, the landscape-gardener gives his days. One week will find him plotting the half formal ways and plantings of a city-square, and the next may see him working to bring out and to emphasize all the beauty a piece of park-land can be induced to yield. One day he is designing a garden-terrace for a stately country-seat; another day finds him suggesting ways of perfecting the charm of a rocky wilderness by the seashore, or the beauty of a meadow or pondside or woodside in the country; while a third day may be given to the planning of the plantations which are to make some ugly, wind-swept field a pleasant place. He shares with the architect the designing of homesteads—fits the part called the house to the surrounding parts, plans the necessary approaches, and works out such appropriate changes in the surrounding scene as trained taste and experience suggest. He plans, with care, the roadways and the foot-paths by means of which the people shall enjoy their country-park without harming it; he studies sites and surveys preparatory to laying out new suburbs or new neighborhoods of summer-cottages; he devises the surroundings of hotels, hospitals and public buildings—everywhere endeavoring to supply every convenience of arrangement, and, at the same time, to preserve or to create as much as possible of beauty, be it picturesque or formal.

Boston.

Charles Eliot.

The Kentucky Coffee-tree.

THE specimen of the Kentucky Coffee-tree, of which a view appears in our illustration upon page 79, is, by far, the largest and handsomest I remember to have seen. It was planted in 1804, directly in front of the historical Verplanck mansion, at Fishkill-on-Hudson, occupied for some time by Baron Steuben during the Revolution, and the scene of the first meeting of the Society of the Cincinnati.

This tree is now seventy-five feet high, and the short trunk girths, three feet from the ground and below the point where it forks into two main stems, a little more than ten feet. One of the main stems was struck by lightning in August, 1887. The damage inflicted was considerable; it has, however, now partially recovered, although it hardly seems probable that the great rent torn by the lightning can ever entirely heal over, or that the tree can ever regain all its old vigor and beauty.

The Kentucky Coffee-tree (*Gymnocladus dioica*), although occupying a comparatively wide area in North America, is nowhere common. The most northern limits of its distribution are in the Province of Ontario and in southern Minnesota; it is found from western New York and southern Pennsylvania as far west as eastern Nebraska and the Indian Territory, although east of the Mississippi River it has not been noticed anywhere south of the central part of the State of Tennessee. It is always found scattered among other forest trees, upon rich hillsides, or on the bottom-lands of rivers. The trunk is erect and rather slender for its height, rarely attaining a diameter of two feet and a half, and is covered with dark, gray-brown, conspicuously furrowed bark. The branches are all erect, not spreading, giving to the tree, even when old, a narrow, ovoid outline; the branchlets are unarmed, very stout, covered with thick, coarse bark, and entirely destitute of spray—a peculiarity which led the French botanist Lamarck to give to this tree the name *Gymnocladus*, formed from two

Greek words, *γυμνός* and *κλάδος*, meaning "naked" and "branch." The leaves, like those of the other plants of the Pea family, are alternate; they are two to three feet long, unequally twice-pinnate, with four to seven pairs of pinnæ, which are seven to thirteen foliolate, with the exception of the lowest, which is reduced to a single leaflet. The leaflets, which stand vertically upon the stems, are an inch or an inch and a half long, ovate-acute, stalked, membranaceous and pale green. The flowers are polygamo-dioecious—that is, upon some plants there are perfect flowers, with well-developed pistil and stamens—and upon other plants male flowers only, with perfect stamens, but rudimentary pistils.

They are borne in slender, terminal racemes, which, upon the male plants, are four or five inches long and more compact than those of the perfect flowers, which are ten or twelve inches long. The flowers are long stalked, pubescent, greenish white, an inch long, with an elongated, tubular disc, a calyx of five oblong petal-like sepals, and four or five small, oblong, equal, spreading, imbricated petals, inserted, with the sepals, upon the summit of the disc. There are ten short, included stamens, those opposite the sepals being rather longer than the others. The anthers are two-celled, introrse, and open by two longitudinal slits. The pistil, which, in the male flower, is reduced to a small conical process, consists of a sessile, hairy ovary contracted into a slender style, obliquely dilated into a terminal stigma, with two spreading lobes covered with stigmatic hairs. The fruits, of which three or four are sometimes developed upon one raceme, are oblong, somewhat falcate, chestnut-brown pods, with thick, hard walls, six to ten inches long by two inches broad, containing a thin layer of sweetish, yellow-green pulp surrounding the obovate, slightly flattened, long stalked seeds, which are half an inch in diameter, and covered with a hard, dark chestnut-brown shell. The embryo, with fleshy cotyledons, and short, erect radical, is surrounded by copious, horny albumen.

The wood of the Kentucky Coffee-tree is quite heavy, although not very hard, strong and coarse grained, the layers of annual growth being strongly marked by one or two rows of large, open ducts. In color it is light rich brown, tinged with red, the thin sap-wood, which turns into heart-wood generally at the end of five years, being much lighter. It is very durable when placed in contact with the ground, and is therefore sometimes used for posts and fence-rails. It is occasionally used, also, in cabinet-making, as it works easily and can be made to take a good polish. It is liable to check, however, in drying, and the grain is rather coarse for fine work. The seeds were sometimes used as a substitute for coffee before and during the Revolution by the inhabitants of the then remote regions west of the Alleghany Mountains—a fact which has given to this tree its popular name. It is said that the fresh leaves, macerated and sweetened, are sometimes used to poison house-flies, but I have never been able to substantiate this statement to my satisfaction.

The Kentucky Coffee-tree has a good deal of value in ornamental planting. It is an excellent street tree, possessing the merit for this purpose of not putting forth its leaves until late in the spring. The foliage is light and graceful, and in winter this tree is always a conspicuous and interesting object, with its upright branches and thick branchlets. It requires a deep, rich and rather moist soil. It is never a fast growing tree, but this peculiarity is not a disadvantage in the case of ordinary street-planting.

The tree from which the very fine specimen log in the Jesup collection in the American Museum of Natural History was cut, grew in Missouri, not far from St. Louis, and, although only eighteen inches in diameter, was 105 years old. This, perhaps, should be taken as about the average rate of increase of this tree growing naturally in the forest, although the Verplanck specimen, which was probably several years old when it was planted in 1804, has grown much more rapidly.

The first description of the Kentucky Coffee tree appeared, with a figure of a raceme of the male flowers and of a leaf, in Duhamel's "*Arbres*," i., p. 107, t. 52, published in Paris in 1755, in which it was referred to Bonduc of Plumier, the *Guilandina* of Linnæus. It had been introduced into France several years before, as Duhamel speaks of trees already large, although they had not flowered at that time. From France it was sent to England, or, more probably, it reached that country directly from America; and in 1753 Linnæus, in the first edition of the "*Species Plantarum*," referred this tree to his genus *Guilandina*, calling it *G. dioica*. Lamarck many years later separated it from *Guilandina* and established for it his new genus *Gymnocladus*, changing unfortunately the specific name to *Canadensis*. One of the rules of botanical nomenclature, however, insists that in cases where a plant is transferred from one genus to another it shall retain the specific name originally given to it, provided, of course, that this specific name shall not have been previously given to another plant in the new genus. If this rule, which was established long after Lamarck's time, had been followed in the case of this plant, it would have been called after its removal from *Guilandina*, *Gymnocladus dioicus*, the gender of the specific name being changed to agree with that of the generic name. Karl Koch (*Dendrologie*, i., p. 5) first adopted the name of *Gymnocladus dioicus* for our tree, and his lead and that of Baillon (*Histoire des Plantes*, ii., 87) had now best be followed, and the name *Gymnocladus Canadensis* given up for the less familiar *G. dioicus*.

It was believed for a long time that the American species was the only representative of the genus *Gymnocladus*, but fifteen years ago a second was discovered in China, and is now known to be widely distributed through the central part of the Empire. It is the *G. Chinensis* of botanists, the *Fei-tsao-toa* or fat Black Bean of the Chinese, the seeds of which are largely used by the Chinese women in washing their hair and heads. Very little, however, practically, is yet known of this tree, which has not been introduced into the United States or Europe.

Our illustration is from a photograph made by Mrs. Winthrop Sargent, of Fishkill. C. S. S.

New or Little Known Plants.

Rosa humilis,* var. *triloba*.

THIS pretty freak of our common low Wild Rose was detected by Miss Jennie E. Whitesides, of Harmonsburg, Pennsylvania, in 1881, growing upon a sandy bank near that place, whence it was transferred to her garden. Since June, 1886, it has been in cultivation at the Botanic Garden at Cambridge, where it has for three years perpetuated the abnormal character of its petals. Aside from the interest which attaches to it on this account, the figure is also of value as illustrating very clearly the characters which distinguish *Rosa humilis* from other eastern species. The slender habit, the open foliage, the very slender, straight spines, the narrow stipules, and the nearly constant and often free toothings of the outer sepals, are characteristic of this species. In this form it is found in the dry, sandy or rocky localities which it prefers, from New England to the Mississippi and southward to the Gulf States. As in all the species of the group, the pedicels, hip and calyx-lobes are more or less glandular-hispid. And like every other Rose, it is subject to variation. When growing in wetter localities it may be somewhat stouter in habit, the spines thicker at base, the stipules more foliaceous, and, of course, there may be found anywhere specimens or young shoots with enough of scattered prickles. But it never takes on the taller, stout and bushy growth, and the broad-based, recurved spines of the northern *R. lucida*, nor the peculiar foliage and densely prickly covering throughout of the *R. nitida* of New England swamps. S. W.

**ROSA HUMILIS*, Marshall, *Arbust. Amer.*, 136, *R. lucida* of Gray's Manual, Wood, etc., in part.

[*Rosa humilis*, next to *Rosa Caroliniana*, is the most common Rose in the elevated mountain region of Virginia, eastern Tennessee and Carolina. Here, unlike our other Roses, which frequent open situations, it is found growing only in the shade of the forest, generally on steep slopes, and usually in very rich soil. As it appears growing in such situations it is one of the most distinct of all the American Roses, with its very slender stems, sparse, open foliage, and few long, slender spines. C. S. S.]

Cultural Department.

Nerines.

THESE plants have suddenly come to the front in England as useful autumn and winter-flowering bulbs. Ten years ago they were scarcely known in English horticulture, only two species, viz., the Guernsey Lily (*N. sarniensis*) and Fothergill's Amaryllis (*N. curvifolia*) being at that time represented in a few collections. Now, however, eight of the ten species acknowledged by Mr. Baker (Kew) are in cultivation, and, besides these, there are a great many hybrids and improved varieties, most of which are of first-rate merit. The principal growers and breeders of Nerines are the Guernsey nurserymen and amateurs. Chief among the latter is Mr. Mansell, who has raised some beautiful hybrids, *N. Manselli* being the best of all, species and varieties included. Messrs. Henderson, of London, raised some good hybrids about six years ago. Lately Herr Max Leichtlin, of Baden-Baden, has taken an interest in Nerines, and, as is the case with almost everything he takes in hand, he has done much to improve them and make them known.

Dean Herbert raised about half a dozen hybrid Nerines, which, however, appear to have been lost long ago. All the species are natives of South Africa. They do not appear to be abundant in any part, as collectors find a difficulty in obtaining the bulbs in any quantity. The oldest and best known species, *N. sarniensis*, was for a long time supposed to be a native of Japan. It was cultivated in Paris as early as 1634, and in London in 1659. In the Channel Islands it has been cultivated at least 200 years, the bulbs being sent to English and other markets under the name of Guernsey Lilies. Tradition had it that a ship which had come from Japan and was wrecked near these islands had on board a quantity of the bulbs of this Nerine, which were washed ashore and soon established themselves. But there are no Nerines native of Japan; the two plants known in gardens as *N. Japonica* and *N. aurea* being species of the genus *Lycoris*, which is not unlike Nerine, though really nearly related to Zephyranthes.

The cultural requirements of Nerines are of the simplest kind. The point of chief importance is that of the growing and resting periods. The flower spikes are developed in the last three months of the year, usually just preceding the foliage. Growth continues all winter, usually finishing in April, when the leaves turn yellow and fall off. It is not advisable to repot the plants often, a pot-bound condition being favorable to the production of flowers. The bulbs may be allowed to crowd (they produce offset bulbs freely), and a pot nine inches across will often hold as many as twenty bulbs, all huddled together. Under good treatment almost every one of these bulbs will flower annually. In repotting, the whole mass of soil, roots and bulbs should simply be transferred intact to a larger pot. The right time to repot is immediately after the flowers have faded. A light loam, or a mixture of loam and peat, with a little sand, may be used. Whilst making growth, weekly waterings with liquid manure should be given. The temperature at this time ought not to fall below 50° at night nor below 55° during the day; air should be given on all favorable opportunities. A position near the glass and exposed to full sunlight is indispensable. In America, where the winter sunlight is brighter and more continuous than in England, Nerines ought to thrive perfectly. After the leaves have faded the plants should be placed in a dry, sunny position, exposed to all the summer sunlight, and *never watered*. The crop of bloom in the autumn is dependent on a strict observance of this point. As soon as the flower spikes show themselves water should be given, and from now till growth is over the soil must be kept moist.

Seeds are ripened freely, and these, if sown as soon as ripe, ought to produce flowering plants in about three years. All the kinds hybridize freely with each other. Probably, however, the greatest improvement may be looked for from seeds of the largest and best colored seedlings and hybrids already obtained. The following are the best of the species and hybrids:

N. Sarniensis.—Guernsey Lily. Already very well known. The scape is developed in August, and is about one foot long, bearing an umbel of from ten to twenty bright, rose-crimson flowers, each one and a quarter inches long, with red filaments half as long again as the corolla.

Var. *Plantii* has longer scapes, deeper colored flowers, and

even larger in the flowers. This is, perhaps, the finest of all the forms of *N. Sarniensis*.

N. curvifolia.—This is the largest flowered and handsomest of the species, and is also the parent of all the best kinds of garden origin. The scape is about a foot and a half high, the umbel twelve-flowered, six inches through, large, bright scar-

Fig. 93.—*Rosa humilis*, var. *triloba*.—See page 76.

is a better plant than the type. It is one of the best of the Nerines.

Var. *profusa* has bright scarlet flowers, with narrower segments.

Var. *corusca* is distinguished by its broad foliage, large umbels, and large, bright, scarlet flowers. A major form of it is

let, glittering in the sunlight; each flower is one and a half inches long, with broad, reflexed segments, and long, projecting filaments. I have seen a specimen of this in a twelve-inch pot, bearing sixteen grand heads of flower. Certainly nothing could be finer. The flowers are developed in September and last about a month. *N. Fothergilli* is a large flowered

form of this. It is generally known as *N. Fothergilli major*. *N. Moorei* is a most beautiful plant of recent introduction. It is like *N. curvifolia*, but has bright green leaves, a compressed scape nine inches long, and a nine-flowered umbel of large, bright scarlet flowers. It blooms in the latter end of September.

N. Manselli is the largest and best of all. It is a hybrid or seedling of doubtful parentage, though probably *N. curvifolia* was one parent. The leaves are twice as broad as those of any other Nerine, and they are developed along with the scape. This is one and a half feet to two feet high, stout, bearing an umbel fully six inches through, and composed of from twelve to eighteen flowers. These are one and a half inches long, with broad recurved segments, and colored bright, sparkling rose. They are developed in November and last into January. I saw a magnificent inflorescence from Guernsey on the seventh of this month. This plant is certain to become a great favorite. It has very few equals among winter flowering plants, whether stove or green-house.

N. flexuosa.—A free flowering, pretty species, which produces its flowers and leaves together in October. The scape is tall, sometimes flexuose. The umbel is composed of from ten to twenty flowers, which are declinate, with crisped segments, and colored pale pink. The stamens and style are curved. There are several varieties of this, all of them pretty, but small flowered when compared with the better kinds.

N. pulica.—This is remarkable for its ivory white flowers; they are borne in four to six flowered umbels on scapes a foot long. The segments form a ball which is semi-erect, one inch long and three-quarters of an inch across. There is a tinge of rose on the keel at the back of each segment.

N. atrosanguinea is a hybrid from *N. Plantii* and *N. flexuosa*. It has a scape sixteen inches high, the flowers two inches across, with wavy segments, the colors being deep salmon-rose.

N. Cami was raised from *N. curvifolia* and *N. undulata*. The umbels are ten-flowered, the scapes a foot long.

N. amabilis has a scape a foot high, with a large umbel of bright pink flowers.

N. excellens has a twelve-flowered scape, and is one of the best of the rose-colored kinds.

N. Meadowbankii has flowers as large as *N. curvifolia*, and colored glowing scarlet, while those of *N. elegans* are salmon-rose. There are other hybrids which can be well recommended as first-class kinds.

Kew.

W. Watson.

Tea Rose, The Gem.

THIS variety has been previously mentioned as being possibly an old sort presented to the horticultural public under a new name. Some growers have pronounced it identical with Marie Van Houtte, while others were of the opinion that while it greatly resembled Marie Van Houtte in some points, yet they were inclined to esteem The Gem superior to that variety. It should be stated, in justice to the introducer of The Gem, that it was not presented with a positive voucher as to its origin, but merely offered as an apparently valuable addition to the list of Roses for forcing, and though he had an idea that it might have been a sport from Perle des Jardins, yet he was unable to make a positive statement to this effect. Judging from the style of the plant and form of the bud, however, this opinion does not seem to be well founded, and we are led to offer the opinion that it may have been an unnamed seedling which was accidentally distributed.

But, be this as it may, The Gem has not yet proved such an acquisition as was anticipated, and after one season's trial it is not spoken of with much enthusiasm. However, it should not be utterly condemned because it is not a brilliant success as a forcing Rose, for its sphere of usefulness may be found in another direction, that is, when planted out-of-doors for summer use. It showed some good flowers last season under such circumstances. One great objection to The Gem has been found in its color, which is not decided enough. By artificial light, however, its yellowish white petals appear to much better advantage than when seen by daylight.

In size few of the flowers equal those of a good Perle des Jardins, though occasionally buds are seen that would compare favorably with buds of that variety. In form it is inclined to be globular, the petals being rather short, and sufficiently numerous to make the flowers quite double.

The Gem seems strong and vigorous in constitution, with bright, handsome foliage, and it holds its leaves well when forced, giving the plant a more attractive appearance than some other more useful varieties. But the fact remains, so far as it has fallen under my observation, that the flowers have not proved to be so marked an improvement upon other roses

in beauty and general utility as to render it of much value to the commercial grower; and though it may improve as a better knowledge of its cultural requirements is gained, yet it does not now promise to be a profitable venture. The public taste in the matter of Rose-buds is of a much more exacting nature than it was a few years ago, so that color, size and fragrance must all be taken into consideration; and besides all these, for the benefit of the grower, free production of bloom is insisted upon as a necessary qualification W.

January, 1889.

The Green-house.

AS most green-house plants are now in active growth a rather higher temperature must be maintained than that used in December and January; a night temperature of 50° to 55° in the cool green-houses and 65° to 75° in the warmer ones will be about right. But in very cold weather, rather than drive the fires hard to maintain heat in the pipes, the temperature should be allowed to fall 5° or 8°. Hard firing is injurious to green-house plants and favorable to the development of red spider.

Ventilate in fine, warm weather, moderately and carefully, a little at a time and early in the day, and shut up gradually and early in the afternoon. In this way considerable sun-heat is saved, and this natural heat is far better for plants than is artificial heat of any kind.

While Callas, Carnations, Roses, Streptosolen, Leptosyne and some other plants now in bloom, if copiously supplied with water, delight in the bright sunshine, there are many others, for instance, Calceolarias, Cinerarias and show Pelargoniums, that are benefited by a slight shading from warm sunshine; and bulbous plants, as Hyacinths, Tulips, Ornithogalum, Narcissus, Amaryllises, and the like, last much longer if slightly shaded when in bloom. Gloxinias love a place near the glass, but at the same time perfect shade from sunshine.

With most cool green-house plants, such as Cytisus, soft-wooded Heaths, Acacias, Chorozema, Hardenbergia and many others, so long as an abundance of water and free ventilation is supplied, shading is never necessary at this season. But it is well to shade stove plants, including Marantas, Anthuriums, Dracenas, Dieffenbachias, Palms, Medinilla, Ixoras and many others. Most Orchids, Ferns and Selaginellas should also be shaded. But while a thin shading is desirable, a heavy shading is injurious. Cheese cloth, tiffany, or some other light linen cloth fixed to rollers, and arranged so as to be raised and lowered at will, is the best; but for those who have not time to attend to this shading some sort of paint for the glass should be used. Turpentine or naphtha whitened like milk with white lead, and applied with a whitewash-brush, adheres very well, but can be easily washed off at any time. Linseed oil and white lead make a capital shading, but it is almost impossible to wash it off again.

A moist atmosphere is absolutely necessary in our warm green-houses, and in order to keep the plants in healthy condition, clean and free from insects, they must be syringed at least once a day. Tepid water is best for this purpose, and syringing should be done in the morning before warm sunshine reaches the house, and again in the afternoon just as the sunshine is passing away. And in order to still further moisten the atmosphere of the house and counteract in a measure the evil effect of hot pipes, water should be sprinkled around freely on the benches and floors.

In the cooler houses where less fire-heat is used less water will be needed, and in the green-houses where plants are in bloom—and these should be collected in a house by themselves as much as possible—syringing should be almost discontinued, to save the flowers from disfigurement. D. A.

Boston, Mass.

Orchid Notes.—*Angracum Chailluanum* is a rare species introduced some twenty years ago. It produces a slender stem, with leathery, dark-green leaves about eight inches long, deeply notched at the apex. The flowers are borne on pendulous racemes, are pure white with narrow segments, the lip being prolonged into a yellowish-green spur about four inches long. This plant grows freely on a block of wood or in a basket filled with sphagnum moss. The warmest house suits it best, and it requires a liberal supply of water.

Phajus irroratus is a charming and very rare hybrid (I believe the entire stock is here) between *Calanthe vestita* and *Phajus grandifolius*, and presents the intermediate character of these plants, with conical-ovate bulbs, and dark-green, lanceolate, plaited leaves. The erect racemes bear about a dozen flowers, three inches across, of a creamy yellow flushed

Fig. 94.—The Verplanck Kentucky Coffee Tree.—See page 75.

with rosy pink. The roundish lip is creamy white stained with yellow. This Orchid is rather a delicate grower, and does best in an open compost of peat and loam in an intermediate house. *P. irroratus purpureus* is the result of a reverse cross from the parents named above. It is more plentiful

and a far stronger grower, very much resembling *P. grandifolius* in its growth, and equally free. It produces a stronger raceme, and the flowers are somewhat larger than those of *P. irroratus*. The sepals and petals are white; the lip is of a dull rose-color with a pale yellow throat. This plant may be

treated in the same way as the commoner kinds, and, being a gross feeder, will be benefited by occasional waterings of liquid manure.

Kenwood, N.Y.

F. Goldring.

Plant Notes.

The Origin of the Double-flowered Horse-chestnut.

AS it seems very desirable to put on permanent record the origin and history of curious forms and garden varieties of cultivated trees, I have thought that the following résumé of an article which was published in the *Belgique Horticole* so long ago as 1854 should be given in GARDEN AND FOREST. Neither Loudon nor any other writer whom I have consulted appear to have been aware of the facts mentioned below. As the work to which I am indebted for the information is not generally accessible to lovers of trees, a brief statement of the real facts of the case can hardly fail to be of interest.

The editor of the *Belgique Horticole*, in an early number of that periodical for 1854, stated, in the letter-press accompanying a very good figure of the Double-flowered Horse-chestnut, that the origin of the form was unknown. Shortly afterwards, Monsieur Auguste-Napoleon Baumann, nurseryman, Bollwiller, wrote to the editor that the tree in question originated as a branch-sport in the garden of Monsieur Duval, at Geneva, at which town the writer stayed from 1819 to 1822, studying botany under De Candolle. M. Baumann had noticed a branch of the parent tree clothed with larger and more deeply-colored leaves than usual; he called the attention of the gardener to this particular branch, and the following spring when the tree was in flower, M. Baumann was sent for to see it. That portion of the tree which had excited his curiosity the previous year was laden with splendid inflorescences in which the stamens were changed into petals—the flowers had become double. Grafts were sent to the famous Alsatian nursery, and probably the vast majority of the specimens now in cultivation have been propagated from the stock raised at Bollwiller, in 1822.

A writer in a recent volume of the *Revue Horticole* calls attention to the hardness of the tree, and M. Charles Baltet, in his paper "*De l'action du froid sur les végétaux*," definitely states that the Double-flowered Horse-chestnut did not suffer in France during the very severe winter of 1879-80.

Kew, January, 1889.

George Nicholson.

Monsieur Naudin contributes to the *Revue Horticole* an account of two interesting new plants. The first is his *Saccia elegans*, a name bestowed upon a shrubby plant of the Convolvulus Family, raised from seeds sent to Antibes by Dr. Sacc, an agricultural chemist residing at Cochabamba, in Bolivia. Unlike most Morning Glories, it is an erect shrub, growing to a height of six feet or more; the flowers are lilac, and hang in long clusters from near the extremities of the branches. This very ornamental plant is not hardy in the south of France, although in Algeria it succeeds admirably, and has ripened seeds. It may be expected to flourish in some parts of southern California.

Monsieur Naudin's second novelty is *Sicana odorifera*, a remarkable Cucurbitaceous plant from Brazil, with climbing stems twenty-five or thirty feet long, attaching themselves to the smoothest surfaces by means of tendrils, the ends of which flatten out and present an exceedingly adhesive surface to any object with which they come in contact. This plant is monoecious, with yellow flowers, which, when fertilized, produce cylindrical fruits the size of a large Cucumber, or of a small Musk Melon, and becoming red or orange when fully ripe. They are edible, although many persons dislike them on account of their strong aromatic odor. They are used, it is said, to free dwelling-houses of flies, which are unable to support their peculiar odor.

The *Sicana* requires more heat than the Cucurbitaceous plants in common cultivation. It produced two fruits, however, at Antibes the past season, in spite of the abnormally cold and wet season, and M. Naudin believes that in an ordinary season it would fruit abundantly. These fruits, although fully grown, did not entirely ripen, and unless M. Naudin can succeed in ripening them artificially, further experiments with this interesting plant must be deferred until a fresh supply of seed can be obtained from its native country. M. Naudin believes that the region in which this plant can be cultivated can be extended by selection. "I have just spoken," he says, "of the possibility of obtaining, sooner or later, varieties of the *Sicana* better suited to our climate than the plants first introduced. Whether it is considered the result of acclimatization or not, the fact remains that the constitution of the exotic Cu-

curbitaceous plants which we have cultivated for a long time in our gardens has been sensibly modified. The plants which I have raised from the seeds of species brought from the tropics have been invariably more difficult to raise and later in ripening their fruit than individuals of the same species raised from seed produced in France, and adapted, to a certain extent, by long cultivation to their surroundings. It is to be hoped, therefore, that the same change may be operated with the *Sicana*, and perhaps with several other species."

It is probable that the long summers of our Southern States will make the cultivation of this very interesting, and perhaps valuable, plant possible there.

Principles of Physiological Botany as Applied to Horticulture and Forestry.

VII.—NITROGEN.

ALL living matter (protoplasm) contains a certain proportion of nitrogen in combination—the living matter of animals is derived directly or indirectly from the living matter of plants, and, therefore, the appropriation of nitrogen by the latter is a question of great importance and general interest.

By far the larger proportion of the nitrogen appropriated by plants is absorbed in the form of some combination. Experiments on an extensive scale, and very carefully conducted, have been correctly interpreted as showing that, under the conditions of the experiments in question, none of the nitrogen absorbed came from that which exists, uncombined, in the atmosphere. But there are certain facts in regard to the nutrition of a few plants which render it highly probable that, under some circumstances, the free nitrogen of the atmosphere may be utilized to some extent as a source of this element. While, therefore, the general statement found in the textbooks—namely, that the nitrogen of plants is not obtained from the free nitrogen of the air—is undoubtedly correct in the main, it should be qualified to some extent for at least a few of our cultivated plants. It is necessary to consider first the general statement, and pass thence to the puzzling exceptions.

In the experiments instituted to settle this vexed question, series of plants were cultivated under conditions by which they were afforded all the materials necessary for healthy nutrition, with the sole omission of combined nitrogen. These trials were made in numerous ways, and with every possible precaution, but always with the result of showing that the plants growing in our ordinary air did not derive therefrom any of the free nitrogen. It is seldom that experiments in any field of research are checked by as many precautions to avoid error as characterized the series referred to, and therefore the results have been generally and properly accepted.

The forms of combination most favorable as nitrogenous food for plants are different for different plants; for instance, for some, the ammonium salts are best, while for some others, nitrates serve a better purpose. The following statement presents briefly the general facts relative to this point: The Beet and Tobacco thrive best when combined nitrogen is afforded them in the form of ammonium salts, and the same is true of the Sunflower. But, usually, nitric acid, in any of its diffusible combinations, answers every purpose. These combinations may be with ammonium, potassium, sodium, calcium and magnesium. It may be said that, as a rule, these combinations offered to the plant must not present an alkaline reaction, but there are some exceptions to this.

Whence do our wild plants obtain in nature their supply of these substances, which, of course, our agricultural and horticultural plants procure from the liberal amounts presented to them in the form of manures? Leaving for subsequent consideration the question of utilizing, in some cases, the free nitrogen of the air, it may be said that the supply appears to come first, from the minute amount of combined nitrogen present in the air and brought down in falling moisture. These combinations are in very small amount, and are properly termed traces, since the minute quantity cannot be accurately determined. By electrical disturbances in the atmosphere, combinations of the free nitrogen, with oxygen on the one hand and with hydrogen on the other, are effected. A second source is probably the nitrogen which enters into combination during the evaporation of water at certain temperatures. A third source is found in the products which result when organic matters, perhaps in a state of decay more or less complete, are acted upon by weak electrical currents. This may possibly explain, in part, the good effects of vegetable mold incorporated with the soil.

At this point should be noticed, in passing, the important

fact that many organic matters containing nitrogen are decomposed by the action of minute organisms into nitrous and afterwards nitric acids. This process of nitrification, as it is called, probably takes place whenever the ammonium combinations in manures are placed upon arable soil. There are, however, a few organic combinations of nitrogen which are not decomposed in the soil in this manner—for instance, scraps of tanned leather. These remain unaffected even after long periods of time.

With regard to the difficult inquiry as to whether any plants whatever can make use of the free nitrogen of the atmosphere, we have the results of many careful investigators who have been impressed by the peculiar relations of Peas, Beans, Clover and other plants belonging to the natural order Leguminosæ. In comparing Cereals, like Indian Corn and Wheat, with Peas and other leguminous plants, Professors Atwater, Hellriegel and others have found some interesting and puzzling facts. For instance, in experiments by the latter, plants of the Grass family were found to require a generous supply of some salt of nitric acid, in order to grow thriftily and yield a satisfactory amount of grain. But when Peas were cultivated under similar conditions, there was a distinct increase in the amount of nitrogen in the plants above that which was supplied to the plants during the experiments.

Recent observations have shown that certain leguminous plants possess on their roots tubercles, which are alleged to contain minute gemmules belonging to the vegetative threads of a fungus. By some, these organisms have been termed bacterial forms, and they are thus described by one of the most assiduous investigators of the subject, but the later conception is, that instead of being bacteria they are yeast-like gemmules. Be that as it may, it is highly probable that these organisms have the power not only of breaking up nitrogenous matters, but the far more extraordinary power of effecting combinations of the nitrogen of the air which has been absorbed by the soil, and thus placing nitrogen combinations directly within the reach of the roots of the plant. And it is even suspected, upon good grounds, that the fungal forms may assist in effecting absorption of other substances from the soil, and thus play an important part in all root absorption. Among the more recent observations of interest in regard to this matter is the curious discovery that although nitrogen compounds may and probably do easily escape from the soil where they occur, there is, in some instances at least, a marked increase in the amount contained in the soil, which is ascribed with plausibility to the presence therein of similar micro-organisms unconnected with the roots of plants, by which the free nitrogen of the air in the soil is brought into combination. But in what way this combination is brought about is not yet satisfactorily explained by any hypothesis yet proposed.

The amount of combined nitrogen brought down by rain and the like has been variously estimated, but the problem presents peculiar difficulties, since the observations must cover long periods of time. Moreover, there are local conditions which must necessarily modify results, and hence it is manifestly unwise to rely on observations taken at any one point. The most trustworthy results are probably those made at Rothamsted, in England, which have been extended over many years. To be sure, the determinations have not always been made by the same methods, but, this aside, the general results may be relied upon. The following are among the estimates furnished by this station:

1. "The nitrogen existing as nitric acid and ammonia in the rainfall of one year is not far from 3.3 pounds per acre. The proportion of this calculated as ammonia is between 2.3 and 2.6 pounds per acre, the rest being given as nitric acid."

2. "We may probably take 4.5 pounds per acre as the best estimate we can at present give of the total combined nitrogen annually supplied in the Rothamsted rainfall."

It will be seen from the above estimates that the amount of combined nitrogen falling in rain-water is far too small for the demands of our cultivated plants, and hence, in the case of the latter, manures must be supplied.

Concerning the destination of the nitrogen compounds taken into the plant, observations have been numerous, but the results are not wholly accordant. The statement given below represents perhaps as well as may be, the present condition of knowledge in regard to the matter, but it must be understood that much of what follows is conjectural. The nitrates or nitric acid absorbed by the roots are changed in the plant into ammonia compounds which unite with the earliest formed carbohydrate (in the leaf probably) to constitute the proteid or albuminoid compound. In the formation of this there is also a trace of sulphur required. This union of nitro-

gen is not, however, confined to foliage alone; it may be supposed to take place in any active cell.

The nitrogen compounds thus formed in the plant are of various kinds. The principal ones are chemically termed albuminoids, and resemble in many of their properties the white of egg (whence their name). In amount these compounds differ in different plants, in different parts of the same plant, and in the same part at different seasons of the year. The following percentages are cited from a trustworthy source:*

Red Clover, in full blossom,	3.7
Carrot-root,	1.5
Carrot-leaves,	3.2
Winter Wheat,	13.0
Field Beans,	25.5

Of these amounts about 15 or 16 per cent. may be reckoned as nitrogen.

Besides the combined nitrogen, there is always to be found a small amount of free nitrogen in the intercellular spaces, and dissolved in the cells of plants.

It is yet uncertain in exactly what way the nitrogen compounds in the plant are finally broken up. The course has been traced out in a few instances, which can better be examined in another paper of this series, when we glance at the numerous changes which organic matter, as a whole, undergoes while in the plant.

Correspondence.

The Yosemite Valley.

To the Editor of GARDEN AND FOREST:

Sir.—Your editorial in GARDEN AND FOREST of January 2d on the Yosemite Valley interested me very much, as I passed one of the pleasantest weeks of my life there only last May, and if it is allowed to an Englishman to criticise, I should like to give my impressions of the present system of management in the valley. I have been all over Europe and a good deal of India and the United States, and I certainly have never seen a spot, except the Yellowstone Park, so well worthy of being preserved forever in a state of nature as the Yosemite.

I quite agree with you that the system of leasing the park to a company who have practically an absolute monopoly, both of the means of conveyance and the hotels of the valley, is not, in some respects, a good plan, and though I cannot speak too highly of the civility and excellent accommodation we received, and the goodness of the horses, drivers and carriages supplied by this company, yet you feel all the time that you have got to do as they like and not as you would like yourself. The present system is all very well for travelers who wish to be put through, in a large party, in five or six days, and to see the regulation sights at the regular hours, and who are able and willing to pay about \$100 for it; but for travelers who, like myself, prefer not to be herded with a number of other more or less congenial companions, and who, either on horseback, on foot, or in a small party of two or three in a carriage, wish to go their own way at their own time, the system is not at all suited, and many, I am sure, are deterred from going there on account of this monopoly. Why should it not be possible for the Commissioners to allow outsiders, under proper regulations, to take their own, or other people's hired horses and carriages, into the valley, without having to pay fabulous sums for tolls and fodder? And why should not a little more of the open competition, which is always so advantageous for those not in the ring, be allowed? With regard to the fencing and cultivation which is going on, it must be remembered that it would be very difficult and costly to bring hay for so many horses from a distance, if none is cut in the valley.

It is not only the valley itself which needs conservation and protection from the depredations of sheep, cattle, cutting and burning, but also the magnificent range of forest which extends from a little beyond Grants all the way to Wahwona and on to the valley. Though I have seen the finest forests in the Himalaya, Mexico and the Alps, the drive through this unequalled coniferous timber filled me with almost as much wonder and delight as the valley itself. At present it is intact, or nearly so, and it may not be too late to take measures for keeping it in a state of nature; but if once settlers and lumbermen get in, half the beauty and pleasure of the Yosemite trip will be destroyed, and California will have lost forever what is now a unique pleasure ground.

The efforts of GARDEN AND FOREST to bring the people of the United States to a sense of the value of their forest property are worthy of the very highest praise and support. I have

* The tables in Johnson's "How Crops Grow," 1868.

seen so much of the fatal effects of the destruction of forests in other countries, that I only hope they may be successful; and I could not help thinking on many occasions during my recent journey in America, that every bushel of corn and wheat which is now being exported from the United States, at prices which leave little or no profit either to the grower or the carrier, represents an amount of timber, of virgin soil and of virgin forest, which would be worth, probably in the lifetime of its present owners, far more than all the corn and wheat which may be, in the meantime, produced by its destruction and waste. Forest-fires are even more ruinous, for they seem to rage annually over a large part of the Rocky Mountains and Pacific States, and I cannot help thinking that very strong measures will, sooner or later, have to be taken to stop them. The prevention of burning has been one of the most difficult tasks of the forest-department of India; but it can be done, even when the feeling of the local population opposes it; and though freedom is a very good thing, yet it seems to me to be going too far, when you allow the inhabitants of the head-waters of a great river to make the country uninhabitable for hundreds of miles below them, by burning or allowing to be burnt the forests on which those rivers depend, in a great measure, for their regular flow of water. The fearful devastation lately caused in China by the overflow of the Hoangho River is a good instance of this, and we might expect the same thing in Bengal, if the forests of the Himalaya had been treated as the forests of China have, and as I am afraid some of the forests of the United States are in a fair way to be dealt with, if the eyes of the people are not opened in time.

Cirencester, England.

H. J. Elwes.

To the Editor of GARDEN AND FOREST:

Sir.—In my letter published in GARDEN AND FOREST of January 16th, I referred to localities in Rhode Island where the Tulip-tree is found indigenous. I omitted, however, to refer to a locality where it grows naturally in Massachusetts, but so near Rhode Island that it might properly have been spoken of in the article alluded to.

I discovered a number of these trees in June, 1887, in a rather scattering wood on the north-eastern shore of "Wal-lum Pond," a sheet of water in the north-western corner of Rhode Island, and running over the line into Massachusetts. The trees were in the latter state, but close to the line of division. I saw a considerable number of them, varying in size from the seedling a foot high to trees forty feet high or more, but none very large, and being with other trees, they had little room for development of top. I was not looking for them, nor should I have been much more surprised to see a band of native "Nipmuck" Indians spring from the woods than I was to see these trees. The pond is almost wholly surrounded by forest, and is, indeed, in the midst of a wild forest-region.

A note from Mr. Jennings, of our recent topographical survey, gives the altitude of this pond as 575 feet, which height makes the occurrence of this tree there of still greater interest. Some of the trees growing with the Tulip-trees, or near them, are Birches, Oaks, Beech, Maples, Ash, Hemlock and Pines, with an undergrowth of Laurels, Viburnums, Cornus, etc. Near by is *Viburnum lantanoides*, a very rare plant in Rhode Island.

I think this region has been but little explored, or the existence of the Tulip-trees would have been noticed before.

Providence, R. I.

L. W. Russell.

To the Editor of GARDEN AND FOREST:

Sir.—A recent note from one of your correspondents states that the wood of Burr Oak in North Dakota is brittle and shaky, and of little value, and throws doubt on the use of cultivating it here.

While it is true that most of the oak grown in this region is short, brittle and shaky, some of it has been found as durable for axe handles, rollers, etc., as much of the hickory found in the market.

I think there is reason for studying carefully the circumstances under which the toughest wood here is naturally produced. The growth of some trees here is vigorous.

In northern Minnesota, near Aitken, on the well sheltered and alluvial bottoms of the Mississippi, I have seen the Burr Oak four feet in diameter at four feet above the ground, and seventy feet to the first limb. In Manitoba, along the Pembina Mountains, near Nelsonville, I have seen valuable groves of this timber.

My impression is that the exposure to fire and wind is the principal reason for the poor quality of most of the oak timber grown here.

I shall be glad to furnish next season samples of leaves, fruit, wood and soil of the Burr Oak from different localities, with full notes, to any one who will study them and publish the results.

St. Paul, Minn.

H. B. Ayres.

Periodical Literature.

The following extracts from an exhaustive article in the January *Bulletin of Miscellaneous Information*, issued by the authorities of Kew Garden, upon the plant (*Erythroxylon Coca*) which produces *Cocaine*, is of general interest now that this valuable anæsthetic has come into such general use:

"In recent years the well known Coca plant has received considerable attention, owing in a great measure to the valuable properties which have been ascribed to one of its alkaloids called *Cocaine*, as a local anæsthetic. Coca wine and various other preparations of coca leaves are now largely in use. The plant itself has been noticed and described by botanists and travelers for more than three hundred years.

"The earliest detailed account appears to be that given by Nicholas Monardes in the third part of his '*Historia Medicinal de las Cosas que se Traen de Nuestras Indias Occidentales que Serven en Medicina*,' which was published at Seville in 1580, after the author's death. This was translated into Latin by Clusius while delayed by adverse winds at Gravesend on his way to Belgium, where the translation was published at Antwerp in 1582. In 1580 an English translation of the third part, in addition to that of the two earlier parts previously printed, was also published by John Frampton, a London merchant. The Kew library possesses a copy of this book, which is printed in black letter; its title is 'Joyfull Newes out of the Newe Founde Worlde, Wherein is Declared the Virtues of Hearbes, Trees, Oyles, Plantes and Stones.' A condensed translation from the Spanish of the three parts is given by Clusius in his '*Exoticorum Libri Decem*,' 1605, which is usually quoted as the earliest authority on Coca.

"The account given by Monardes of the Coca plant and its uses are tolerably minute. He describes the methods of using Coca when traveling, either in the form of balls, or of a paste made by chewing the leaves with lime made from shells, or the leaves alone. 'For the use of these little Balls taketh the hunger and thirst from them; and they say that they receive substance there by, as though they did eate meate. At other times they use them for their pleasure, although they labour not by the way, and they use the same Coca alone, chewing it and tossing it in their mouths, from one side to another, until there be no vertue remaining in it, and then they take another.'

"The Coca plant, although known for some time previously to European botanists, was first defined as a species, according to modern principles of nomenclature, by Lamarck, in the *Encyclopédie Méthodique* (1786), from specimens brought from Peru by Joseph de Jussieu. Cavanilles figured and described it from the same specimens, and we have also a representation of it in the inedited plates of Ruiz and Pavon. The first figure of the Coca plant published in this country appeared in the *Companion to the Botanical Magazine* (1836), Vol. ii., t. 21, with a description by Sir William Hooker, from specimens gathered by Mathews in the environs of Chinchao, Peru. A full account of the uses and property, mode of cultivation and commercial value of Coca in its native country had been given previously in the same work (p. 161), in a translation from the second volume of Dr. Poeppig's '*Reise in Chili, Peru, und auf dem Amazonenstrom*.'

"At that time and for many years afterwards Coca leaves were looked upon merely as the source of a stimulant to the nervous system, employed by the inhabitants of Peru and Bolivia in very much the same manner and for the same purpose as the Chinese use opium and the East Indians chew the betle. The published statements from Monardes onwards respecting Coca appear to establish the fact that its use by the Indians of the Andean region enable them to accomplish such severe labor as no European could perform. Von Tschudi refers to the effect the use of Coca had on himself, in greatly assisting respiration and in enabling him to ascend high mountains without fatigue. Dr. Weddell, Spruce and Markham, and numerous other travelers and scientific observers, agree in ascribing to Coca marvelous sustaining power, although many of them are careful to point out that Coca used in excess produces highly injurious effects, like the immoderate consumption of other stimulants or narcotics.

"According to De Candolle the original home of the Coca plant in South America has not been clearly defined. He states that early authors, such as Joseph de Jussieu, Lamarck

and Cavanilles, had only seen cultivated specimens. The specimens gathered by Mathews in the ravine of Chinchao might have been beyond the limits of cultivation. Those from Cuchero, collected by Poeppig, were said to be wild, although the traveler himself was not convinced of this. 'It is by no means improbable,' he says, 'that the seeds may have been dropped by birds.' André speaks of Coca in the valley of the river Cauca, in New Granada, as 'in abundance wild or half wild.' On the other hand, Triana, a reliable authority on such matters, does not admit that the species is wild in New Granada. At present we have the Coca cultivated to a very large extent on the Andes in the Argentine Republic, of Bolivia, Peru, Ecuador, and the United States of Colombia (New Granada). It is also cultivated in the mountainous parts of Brazil, and there are specimens in the Kew Herbarium collected from the head waters of the Rio Negro by Spruce, in 1854. The largest plantations, called locally *Cocals*, are said to be in the province of La Paz, in Bolivia. Weddell estimates in a good harvest the produce of Coca leaves per acre at about 900 pounds. The total production of Coca is something like 40,000,000 pounds, worth at 1s. per pound a value of £2,000,000. Almost the whole of the production is consumed in South America.

"In the Andes the Coca plant succeeds best in the mild, but very moist, climate of the lower mountains, on elevations between 2,000 and 5,000 feet above the level of the sea. The thermometer at this elevation does not often fall below 60° Fahrenheit, and the climate is free from any great or sudden changes. It appears that Coca, like Coffee, succeeds best on mountain slopes, where the soil has perfect drainage. Swampy land is very unsuitable, and so, also, according to Poeppig, is land strongly impregnated with lime. From the experience gained in cultivating Coca in other parts of the world, it appears that the plant thrives in warmer localities than were at first supposed suitable for it. In many tropical countries it will grow at sea level, provided there is sufficient moisture in the air and the rains are pretty evenly distributed through the year. It will not thrive at the higher elevations at which Coffee grows in either the East or West Indies. An elevation midway between those mentioned above will probably prove most suitable, regard being had to the fact that the lowest minimum temperature does not fall below 65° Fahrenheit. Shade is said to be unfavorable to the development of the alkaloids in the leaves. Dr. Rushby has made repeated analyses of shade-grown and sun-grown leaves, with the result that the latter were invariably found much richer in total alkaloids. Plants appear to be generally raised from seed, and when eight or ten inches high they are put out in their permanent places during the rainy season. The care or cultivation suitable to Tea or Coffee plants would appear to be also those necessary to the cultivation of the Coca plant. The crop is a leaf crop similar to Tea, and there would appear to be nothing special in the requirements of the plant, which is found to be hardy and easily managed.

"In Peru the plants begin to yield the first crop of leaves in three years after planting, but in poor soils the plants are often left until the fifth year. The full-grown shrub yields a harvest every thirteen or fourteen months; but as the ripeness of the leaves, which is proved by their breaking when taken in the hand and bent, depends very much upon the soil and situation and the age of the plants, in many large plantations the collection goes on throughout the year. In some favorable localities two or three good crops are gathered in the year.

"In Tea the very young leaves only are gathered. In Coca, on the contrary, the largest and most matured leaves are sought, as these contain most of the alkaloids which render the Coca leaves a marketable product. After being gathered, the leaves in South America are usually dried in the sun on platforms. They are then heaped up to undergo a slight amount of sweating, and are then ready for use.

"Now that Coca is being cultivated experimentally in other countries than South America, it is important to bear in mind that the standard of best Coca leaves is likely to change. To a manufacturing chemist the best quality would mean simply the quality that would yield the largest percentage of crystallizable Cocaine, obtainable in the easiest manner, while the same Coca might be considered for domestic consumption (amongst the natives of South America) one of the lower grades. It is highly probable that the amount of Cocaine forms no element in the Indian's estimate of the quality of Coca any more than the percentage of nicotine establishes the quality of a particular grade of tobacco. Coca leaves are classed by the Indians as *Najas dulces* (sweet leaves), and *Najas amargas* (bitter leaves). The former are made sweet by the abundance of alkaloids other than Cocaine, while in the

latter the bitter flavor of Cocaine is the predominant one.

"Since the discovery of the anæsthetic properties of cocaine the demand for Coca leaves in South America has considerably increased for export purposes. A distinct loss in the alkaloids generally, as well as in cocaine, has been noticed during the transit of leaves to this country, and latterly, in consequence, it has become the practice to extract the alkaloids from the leaves in South America and export to the United States and Europe a crude preparation which is largely taken up by the manufacturers of cocaine. The demand for Coca leaves has therefore fallen off, and it is probable that the cultivation of the Coca plant in our tropical colonies may never assume large proportions. Small and exceptionally fine samples of Coca leaves may find a limited market in this country and on the Continent; and possibly in India and eastern countries it may be worth while to grow sufficient leaves to meet the local demand for cocaine. Beyond this it is scarcely possible to go, if it is borne in mind that South America is able, without further extension of cultivation, to produce such enormous quantities of Coca leaves that the one-eightieth part would be sufficient to swamp the cocaine markets of the whole world. In a letter dated January 25th, 1888, Messrs. Burgoyne, Burbidge, Cyrian and Farries reported that the commercial value of 'Coca leaves yielding total alkaloids of .80 per cent. would be about 6d. to 8d. per pound. At present it is difficult, they say, to get a true valuation on account of absence of demand. . . . The average price last year (1887) was about 8d. per pound, taken all around.' In a letter dated the 9th of November, 1888, Messrs. Burgoyne state, 'Very few parcels of Coca leaves now come before us of the market, as the manufacturers of cocaine either deal directly with the shippers of the leaves or buy the crude extract for manufacturing purposes. The demand for the alkaloid increases, and the price of the leaves varies from 10d. to 1s. 6d. per pound. In the absence of statistics of stock here we cannot say what the probable future of the article is with regard to price.' In a further letter dated the 5th of December, 1888, Messrs. Burgoyne kindly forwarded the following interesting information respecting Coca leaves in the United States: 'We have just heard from New York that the stock of Coca leaves in that city consists of 10,000 pounds of Huanuco leaves and 40,000 pounds of Truxillio leaves. These were all imported this year and are good green leaves. The Huanuco leaves are the kind used for making cocaine, but since the large quantities of the crude cocaine arrived from Lima on the European markets there has not been such an active inquiry, and the price has declined to twenty-two cents (eleven pence) per pound. It is a well known fact that they cannot be imported under twenty-six cents (thirteen pence) per pound, and when the small stock of 10,000 pounds is gone, higher rates will no doubt be obtained for Huanuco leaves. The Truxillio leaves, on the other hand, are only used in pharmacy and for Coca wine. They are as strong as the other kind in alkaloid, but the product will not crystallize. The stock in hand, viz., 40,000 pounds, is a large one, and the price may probably go down to fifteen cents (seven pence half-penny).'"

Recent Plant Portraits.

Botanical Magazine, January:

BROWNEA MACROPHYLLA, t. 7033; a New Grenada tree of the *Leguminosæ*, only known in flower through a specimen which has grown under glass in the late Mr. Crawford's garden near Cork. The splendid heads of scarlet flowers are ten inches across, but they are produced directly from the main trunk near the ground, and are of comparatively short duration, characteristics which must somewhat lessen the value of this tree as an ornamental plant.

OLEARIA INSIGNIS, t. 7034; a representative of a genus which, in New Zealand and in some parts of Australia, replaces the Asters of the northern hemisphere. *Olearia insignis* is a low, stout shrub, with handsome, white flowers, occupying rocky river banks in the northern part of the Middle Island of New Zealand.

ROSA INCARNATA, t. 7035; a native of widely separated districts of France, belonging to the group of *R. Gallica*, of which it has been often considered a form. It is, nevertheless, incredible, as Sir Joseph Hooker points out, "that a plant growing wild in several parts of France, and which was recognized in English gardens 248 years ago, and named and described in a standard work 117 years ago, should have, as it were, passed entirely out of the knowledge of horticulturists and botanists till the latter half of the present century." Yet this is the history of this very handsome Rose, with large and brilliant flowers.

Notes.

None of the encyclopædias tell us what plants furnish the briar tobacco-pipes. It is said the Heath of the south of Europe (*Erica Mediterranea*) furnishes the best.

One objection to the Worden Grape is that its skin is too tender to bear transportation well. A grower in western New York has found that this difficulty is overcome if a vine-leaf is placed under each cluster.

It is proposed to place a bust of the late Professor A. E. de Bary in the hall of the new University building in Strasburg. Contributions are solicited from his former pupils and friends, and may be sent to his successor, Professor Graf Solms-Laubach.

The climate of Afghanistan is so very dry that without irrigation nothing can be grown below an elevation of 3,500 feet, at which point dew first begins to form. During the summer season the people live chiefly on Melons, which are grown in such quantities that syrup is made from them.

The attention paid to forestry is increasing in England. Among other proofs we may note that during the winter Professor Boulger will deliver, at the City of London College, a course of ten lectures on this subject, with especial reference to the examinations of the Surveyors' Institute, and will follow them up in the spring by a course of practical demonstrations in the country.

In the year 1887 1,140 public lectures on the culture of fruit trees were delivered in Belgium, twelve on the culture of forest trees, and six on Tobacco-culture. The relative amount of forestry instruction seems unduly small; but it should be remembered that special schools exist in Belgium for the instruction of foresters, and that these public lectures were addressed to a mere general audience.

A writer in a recent number of the *Saturday Review*, of London, says: "We cannot admit that the very best American apple ever possesses a tittle of the flavor of good English fruit. But that cannot affect the economic question (of increased fruit-growing in England) at all, because the number of persons who can distinguish excellence of taste is, and must be, always very limited. Market prices, except for limited amounts of exceptional products, will always be ruled by the supply of fair average commodities."

The officers of the Pennsylvania Horticultural Society announce that in order to make the monthly meetings more interesting and secure a larger attendance, they have made arrangements for a series of essays on horticultural subjects, one of which will be read at each meeting. The first of these papers, "The History and Future of the Pennsylvania Horticultural Society," will be read by Wm. A. Reed, M.D., at the meeting on Tuesday, March 19th, 1889. At this meeting, and at each subsequent one, there will be an exhibition of new and rare plants.

The *Revue Horticole* wonders why the White *Platycodon grandiflorum*, a beautiful plant, well known in America, is not grown in the vicinity of Paris. A greater wonder is that, known in America, it is not more popular than it is. Both the white and the original blue are admirable border flowers, and are excellent for cutting. And then they have the character, so dear to the American flower-gardener, of knowing how to take care of themselves. Once in a garden, they rarely die. *Platycodon* was once among the Campanulas, and it yet often goes under the name of Siberian Bell-flower.

An interesting article in a recent number of the *Illustrirte Garten Zeitung*, of Vienna, is devoted to the *Leguminosæ* of the western prairies. Especial mention is made of the "Tuskee," or Prairie Turnip (*Psoralea esculenta*) and the attempts which were made to introduce it into Europe as an article of food at the time of the potato famine some forty years ago. In 1849 the Academy of Sciences in Paris considered two treatises upon the tubers of this plant, which were said to contain eighty-one per cent. of starch. A certain Monsieur Piquot tried hard to bring it into favor under his own name as "Piquotiana," and sold the seeds in bottles at a price equivalent to nearly \$2 for fifty seeds. But all efforts to establish it as an article of diet were unavailing, as was the case with many other tuber-bearing plants at the same epoch.

In Mr. W. R. Bliss' interesting book, "Colonial Times on Buzzard's Bay," recently published by Messrs. Houghton, Mifflin & Co., there is a sentence which proves that the early

settlers had a keener sense for the value of woodlands than was shown in later years, or is often found to-day. When the so-called "Rochester Propriety" was established in 1679, "the value of the great forests . . . was recognized by the order that their shall be no Tymber of any sort conveyed or carried a way out of the Lymits of Scippican under the penilltie of twentie Shilings for every Tree or part of a tree so used." To protect the production of turpentine, which was a chief industry of the district, another decree prohibited "any person from boxing or shiping or milking any pine tre or tres on the common on the penalty of payeng Ten Shilengs for every tre." And in another place we read, "So valuable was the right to gather turpentine regarded that it was specially mentioned in deeds of woodlands granting 'All ye privildge of milking of pine trees.'"

A Japanese correspondent of the *Revue Horticole* has begun in that paper a series of articles on the horticulture of his native land. The first article recites certain facts with regard to Japanese landscape gardening which were recently given to our readers from another source. As far as history tells, it is furthermore said, the first garden was established in Japan in the reign of an emperor who lived in the middle of the ninth century of our era. In 900 another palace-garden was laid out by the Emperor Ouda, who is notable as having been the first to introduce the culture of the Chrysanthemum, afterwards adopted as the royal symbol. The remains of a garden planned by his son are still to be seen at Kioto. During the twelfth, thirteenth and fourteenth centuries the art seems to have reached its highest development, and in 1378 was established the Ghinkakouji Garden at Kioto, which is still the finest specimen of landscape gardening in the empire. After that time the art remained stationary, owing to the civil wars which distracted the country. But when peace was made in 1580 the Shogun of the moment proved a noteworthy patron of gardening, as was likewise his contemporary, the famous *savant*, Rikiyu. The many plants introduced by the Portuguese towards the end of this same century gave an impulse also to horticulture properly so-called, and it was further helped, towards the beginning of the seventeenth century, by the introduction of conservatories, and quickly advanced to a point never before attained. Mr. Yoshida's explanation of the way in which the Japanese regard their landscape gardens tallies with that which has already been given our readers. "To imitate nature," he says, "would be a very simple thing, and would demand no effort of the imagination. But the question is how to represent lofty cascades of which the source is so mysterious, and high mountains covered with walls of trees on inaccessible rocks?" To represent, not to imitate; to make a picture of a landscape, not an actual landscape; this, in truth, is the chief aim of the Japanese artist.

Catalogues Received.

- A. BLANC & Co., 314 N. Eleventh Street, Philadelphia, Pa.—Cacti.
 A. BRIDGEMAN, 37 E. Nineteenth Street, New York.—Garden and Farm Seeds.
 WILLIAM BULL, 536 Kings Road, Chelsea, London, S. W., England.—Flower and Vegetable Seeds.
 W. ATLEE BURPEE & Co., 475 and 477 N. Fifth Street and 476 and 478 York Avenue, Philadelphia, Pa.—Garden, Farm and Flower Seeds.

The Defense of National Property.

THE greatest obstacle in the way of effective action for saving the forests on the nation's lands, is the lack of a clear understanding of the situation and of what it requires on the part of the people of this country. The problem is specific, limited and particular. It is not merely a topic for leisurely discussion and contemplation. One of the most important possessions of the nation is in imminent danger of extinction. An exigency now demands immediate and effective action, and the only alternative is ruin.

The plan presented in this journal three weeks ago, and to which we now recur, requires the immediate withdrawal from sale of all the public lands in the mountain forest-regions of the country, and the employment of the Army of the United States to protect these forests from injury and spoliation until a permanent policy for their care and preservation can be put in operation.

An emergency confronts us, and the employment of the army for this work of national defense is a necessity. If one of our great seaboard cities were demolished by a foreign foe, the loss to the nation would be far less than that which would result from the destruction of the forests on the lands now belonging to the nation. Or, if hundreds of millions were exacted as the price of escape from bombardment and obliterating flame, the subtraction from the nation's wealth which this would require would be trivial compared with the permanent extinction of the very springs and sources of national wealth and revenue which would be caused by the destruction of these forests.

The overwhelming and unanswerable argument for the adoption of this plan, and for the employment of the nation's army for the defense of the nation's property, is the fact that it is the only method which can be made efficient and successful. It is obvious that so much time would be required to prepare any other administrative machinery and put it into operation, that the forests would be extinct before the completion of an elaborate arrangement for their defense. But here is the best available machinery for the protection of this invaluable national property ready

to our hands in the thorough organization and intelligent efficiency of the Army of the United States. Its officers are superior men, who have been trained at the expense of the nation, and they are already in its paid service. There is not at present any other service so important as this in which the army can be employed.

As for official or Government work in forestry in this country, nothing could be attempted that would so strongly tend to vitalize and popularize it, as the success of the scheme which we have proposed. Official persons often justly complain that they are not sustained in their work, as they should be, by public interest and sentiment. There is no other way in which intelligent and public-spirited citizens can so efficiently co-operate with all that is vital in the forestry work of the national Government, as by urging the adoption of the plan we have presented—the immediate withdrawal from sale of all the public lands in the mountain forest-region of the West, and the employment of the United States Army to guard these forests until a plan for their permanent administration has been completed.

New Varieties.

MONSIEUR ANDRÉ, in a recent issue of the *Révue Horticole*, calls attention to the difficulties which confront the purchasers of plants who are obliged to rely, in making their selections, upon the glowing and interested statements of value with which new plants are habitually put upon the market:

"Plant-buyers, no matter what class of plants they are interested in, must often find themselves confused if they consult the catalogues of dealers. The immense number of new varieties now obtained on every side, and named and described as possessing every desirable quality and virtue, must cause a well-nigh hopeless embarrassment. If they are not fortunate enough to possess some work upon gardening containing authoritative lists of the different varieties of garden plants, they must buy on the strength of the catalogue descriptions, and then be compelled to throw away, as worthless, a large part of what they have bought, or else continue to cultivate inferior forms. The way to prevent this is simple; and it can, with a little trouble, be arranged. It is only necessary to establish, for the different classes of ornamental plants, juries of approval, of the same character as the pomological congresses, which have successfully established the nomenclature and the merits of cultivated fruits. Monsieur Godefroy-Lebeuf has recently suggested such a plan in the case of Orchids; but every new plant, no matter of what class, should be submitted to a jury of specialists to determine if it merits recommendation, if it is not already cultivated under another name, or if it is really worth cultivation for any particular purpose or special reason. The question is certainly somewhat complicated, but it can be solved to the satisfaction of intelligent producers of new plants and of all plant-buyers."

American plant-buyers suffer, perhaps, more than those of any other country, from exaggerated statements regarding new plants, which too often appear in trade-catalogues, because Americans are, as a rule, more easily misled by glowing advertisements than Europeans, and because in America trade-catalogues are too often the only sources of information about new plants and horticultural matters generally, with which plant buyers provide themselves.

An international jury, or a number of juries, to pass upon all new plants originated in England, France, Belgium, Holland, Germany and the United States, might, perhaps, be impracticable, but there ought to be no very serious or insurmountable difficulty in organizing such juries in Europe, with an American jury of American specialists to confirm, so far as the United States is concerned, the action of their European associates. It is pretty evident that the vast numbers of varieties of garden-plants which are now produced every year must, sooner or later, necessitate some such plan as this, and the sooner it can be perfected, and put in good working order, the better it will be for every one interested in horticulture. The producers of valuable varieties would gain as much,

and perhaps more, from the endorsements of such juries as the people who buy plants, for they would buy all the more if they could feel assured that they were getting what they were asked to give their money for.

Private letters from Philadelphia indicate that there is a chance, if the financial support of public-spirited citizens can be obtained, to put into execution at last the long-cherished plan of acquiring, for public uses, the site of Bartram's Gardens, the first botanical garden established in the United States, with the house built by John Bartram, the famous Philadelphia botanist, and many of the trees planted by him. This spot has for years been the Mecca of botanists and horticulturists. There is no other more interesting to them, and none so filled with associations connected with the early development of botanical science in America.

This opportunity is an important one, therefore, and we trust that it will be improved. The public spirit and civic pride of Philadelphia's leading men are known all over the civilized world, and there can be no doubt that as soon as this matter is once understood they will not consent to see this spot, at once so valuable on account of its historical associations, and so convenient and suitable for a public breathing-place and pleasure-ground, given up to the demands of commerce. The land should be acquired in such a way, or on such terms, as would permit some permanent special supervision of it by some body of men who would be specially interested in the historic character of the place—the University of Pennsylvania, or the Academy of Natural Science.

If it becomes merely one of the city parks, under the general management of some branch of the city government, it would inevitably lose all its distinctive or special character and interest.

The taste for museums and in-door collections of all kinds, and the habit of giving large sums for their establishment and maintenance, are valuable and encouraging features of our national character; but we must strive to make the out-of-door life of the inhabitants of our great cities more attractive, healthful and interesting; and places of historic or other special interest should be utilized for purposes of this kind whenever it is practicable.

The name of Bartram's Gardens should be preserved, and in order that it shall have any significance or appropriateness, should be maintained in as near the condition as its first owner left it as is practicable. Whether any other features of a botanic garden would be practicable is, we suppose, rather doubtful. But the name of a distinguished man is a precious possession to a great city and a potent influence in popular education and the development of civic patriotism. We hope to hear that definite steps have been taken to purchase the old garden and to perpetuate the interest of the place.

The Daily Mirror and American, published in Manchester, New Hampshire, calls attention to the fact that the statement, recently made in our columns, that six million feet of Spruce timber were to be cut this winter from the immediate vicinity of Mount Washington, give a very inadequate idea of the damage which is being inflicted upon the forests of northern New Hampshire.

"The Connecticut River Lumber Company, whose headquarters are at the Connecticut lakes, will probably put into the streams this winter nearly a hundred millions of Spruce. The Brown Lumber Company, of Whitefield, and the Berlin Falls Company will cut twenty million feet each, the Kilkenny Lumber Company half as much more, and half a hundred other firms and individuals will contribute very much to the destruction of the forests north of Woodsville and Conway. Instead of six million feet, which a stranger might infer from the statement made was the total output of our northern mills, it must be several hundred millions. But this only emphasizes the fact that one of the chief glories and sources of wealth of our northern counties is fast disappearing before the woodman's axe to return no more, for the mountain sides

from which this timber comes do not reproduce a growth as land does in this part of the state, and when once stripped they remain bare. With the forests departs much of the beauty, the grandeur and the attractiveness which have made our mountains famous as health and pleasure resorts. When the woods have been cut away, the White Mountains are about as bleak and barren a section of country as we know of, and when there are no timber lots left the charm that was formerly theirs will be wanting. Even the Profile, the Franconia and Crawford Notches and Mount Washington would lose much of their glory and beauty with the destruction of the forests in which they are set, and the territory about them, when stripped of trees, would be one to shun.

"It is but a few years, comparatively, since nearly all these forests were owned by the state, and it was a terrible mistake when they were sold for a song to speculators. Most of the timber lands in Pittsburg, and many in other townships, were sold for twenty cents an acre during Gov. Harriman's administration. Perhaps this was all they were worth to sell at that time, for with the nearest railroad forty miles away no one could realize much by clearing them; but some one ought to have been far-seeing and wise enough to have concluded that in a few years they would be worth a hundred times what they sold for, and that the state could not afford to sell them at any price. Other immense tracts have been sold for even less per acre, or given away to Dartmouth College or some of our academies, which have turned them over, for a nominal price, to the lumbermen."

These statements are quoted, not only because they emphasize the words of Mr. Harrison in another column of this issue, but because they invite attention to the broader fact that what has happened in New Hampshire is now happening in other parts of the United States. Valuable forests are being frittered away in the South and in the West without any adequate return. But the experience of New Hampshire, expensive and disastrous as it has been, may yet have some value as a warning to the people of other states. On no part of this continent today are there any forests so remote from existing means of transportation that they will not soon be called upon, if they have any value whatever, to give up their quota to supply the wants of our rapidly increasing population.

Some Old American Country-seats.

I.—THE GORE PLACE.

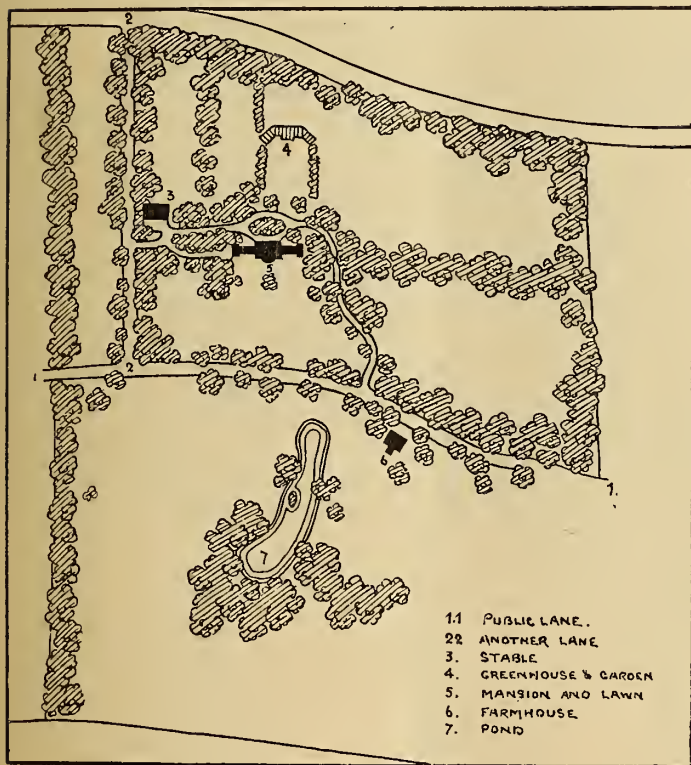

JOHN WINTHROP, first Governor of Massachusetts, had his country-place. It lay upon Mystic River, and was called Ten Hills. The pleasures of life there were certainly peculiar, wolves and prowling Indians being frequent visitors; but now that several of the ten hills have been even destroyed, Winthrop's frontier "paradise" can only be imagined, not described. Unfortunately the same must now be said of almost all the mansions and gardens of the later aristocratic time which preceded the Revolution. The rising tide of population has swallowed up the handsome establishments of Tories and patriots alike. The Craigie house, which the Longfellow family preserves in Cambridge, is now almost the sole surviving representative of the terraced and high-walled stateliness of the colonial days.

Boston and her surrounding sister cities grow continually. Farm after farm and garden after garden are invaded by streets, sewers and water-pipes, owners being fairly compelled to sell lands which are taxed more and more heavily. Before destruction overtakes the few old seats now remaining, it will be well to make some sort of record of their character and beauty.

About eight miles from the State House, one of the roads of the Charles River valley, after passing through a somewhat squalid manufacturing district, suddenly becomes a rural lane, which winds its shady way first past the low-roofed farm-house and then past the lawn and mansion of what is plainly an old estate. The accompanying picture on page 91 shows the house as it appears from just within the trees which shade the lane. The grass sweeps up to the walls of this long, south front. No line of any sort breaks the flowing breadth of the lawn, for the approach-road, which leaves the lane near the farm-house, goes around through the trees to the door in the north front of the house. The simple but well-proportioned building is set off against a background of foliage, and the ends of the low wings are shadowed by tall Pines and Chestnuts, whose brothers, forming noble masses at the sides of the lawn, support and frame the house, and, joined with it, compose

one satisfying picture. On the further side of the lane is an open field and a winding pond, whose distant further end is lost in the shadow of a Pine-wood, from out the edge of which a White Birch leans over the water. Larches, too, and small Beeches, grow in the edge of this distant wood, and enliven the darkness of the Pines in spring and autumn, while here and there above the tops of the trees appear the crests of low hills, a mile or two away beyond the river.

This strikingly peaceful and lovely scene, so religiously preserved by its present owner that he can say that only the gales have harmed it since he came into possession more than thirty years ago, impresses the most casual passer-by, and teaches owners of country-seats a lesson of first importance. Here is not one rare tree, not a single vegetable or architectural wonder, not one flower-bed or ribbon-border; only common trees, grass and water, smooth ground and a plain building. The scene is interesting, impressive and lovable, and it is this solely by reason of the simplicity, breadth and harmony of its composition. This is real landscape-architecture of the purest type, in comparison with which all modern arrangements of specimen fancy trees must always appear ineffective as well as inappropriate.

Sketch-plan of the Gore Place.

The lands about this mansion, once a part of the so-called Beaver Brook Plowlands, were first owned by the beloved first minister of the colonial church of Watertown, the Reverend George Phillips. After his death, in 1644, certain of the Garfield family became the owners, and when Mr. Christopher Gore bought "the forty-acre lot," about 1791, he entered upon lands which had been the home of excellent people during a full century and a half. Mr. Gore was sent to England in 1796 as one of the Commissioners under Jay's treaty, and one wing of his house having been burned in his absence, he caused the present mansion to be built of brick and made ready for his return in 1804. It is said that he brought with him an English landscape-gardener, and certainly the old place bears every mark of the distinctive style of Humphrey Repton, whose book on landscape-gardening was published just before Gore's visit to Europe. The brick house, which is painted white, contains many finely proportioned rooms. Two doorways open upon a long platform on the north front. Between these doors stretches a hall dining-room, with a marble floor, and fire-places at each end. The large bay in the south front contains an oval drawing-room; on one side of this room is a breakfast-room, and on the other a parlor; the east wing contains a billiard-room, the west the kitchen and offices.

The carriage-turn, and the whole north side of the house, is crowded with large trees; many Hemlocks, whose soft boughs sweep the ground at the edge of the drive, several Umbrella

Magnolias among the Hemlocks, some large Lindens, and many very tall White Pines. Just beyond is the flower-garden, carefully sheltered and quaintly laid out in geometric fashion, with great banks of shrubs at the sides, plenty of smooth grass, and large beds crowded with perennials in rich, old-fashioned array. A small enclosure for deer adjoins the garden; two smooth and open hay-fields are close at hand, and around all this forty-acre home-lot stands a dense belt of forest-trees, shutting out the commonplace world and affording a pleasantly shady walk of something like a mile in length.

Mr. Gore lived to be Governor of Massachusetts and United States Senator. One of the later owners of the place, Mr. Theodore Lyman, 2d, made the pond beyond the lane, and built the present approach-road, and both he and the present owner planted many trees; but every proprietor since Mr. Gore's time has respected the character which was impressed upon the scene in the beginning; nothing to-day appears incongruous or out of place. If the Governor himself could walk about this country-seat to-morrow he would certainly be very proud to own it his.

Boston.

Charles Eliot.

Winter in the Pines.

IN a winter ramble there is much revealed that is hidden or passed by in summer. The leaves have fallen from the deciduous trees, and we see more clearly their shape and size. During my woodland walk to-day I measured a tree and found it to be over nine feet in diameter. Its gnarled branches and scarred trunk told of the centuries that had come and gone since, as an embryo, it first sent out its little plumule to the light. This old monarch is but a common Chestnut (*Castanea vulgaris*, var. *Americana*), but its great horizontal branches, each one as large as a fair-sized tree, give it an immense expanse of shade, with a venerable and protecting expression which would be marked even outside of the Pine Barrens, where, it is imagined by people unacquainted with our forests, that only scrub Oaks and scrubby Pines abound. In the immediate vicinity of this large tree were several Oaks from three to five feet in diameter. And beautiful Hollies, and Laurels and Cedars and Pines, were all around, which, together with the unusual warmth of this January weather, conspired to give the impression of a sub-tropical land. Grape-vines had climbed to the tops of the tallest trees, and not contented with one support, they had reached out and clasped others, binding them together and forming dense bowers beneath. Other woody climbers were also here. The Virginia Creeper and Bittersweet and various species of Smilax were abundant.

Birds twittered and sang and watched us from evergreen boughs, and woodpeckers and creepers were on the naked trunks and branches, always keeping us in view with the same angle of observation, no matter how often we made them revolve around the trees, or tried to circumvent them. Not so with the little Chicadee, however; he was willing to be on quite familiar terms, following us with his merry music, hanging and clinging to small twigs just above our heads, with back down, but all the time keeping a sharp, inquisitive watch upon the invaders of his domain.

Leaving the big trees and the bright moss that carpets the ground beneath them, and the prickly Smilax that hedges them in, we turn toward the more open barrens. Here, amid a goodly forest of trees from one to two feet in diameter, we find many old charcoal beds. The forest must have grown up since the sooty burners left this region. They usually make a clean sweep of the wood over quite an extensive tract, except perhaps a few trees that are left to shade the huts where they live during their forest raids. And this, no doubt, is the reason that we occasionally find small groups of large trees scattered here and there throughout southern New Jersey.

Probably there is not as much demand for charcoal now as there was fifty years ago. Still large tracts of timber are annually burned to supply the demand. But in New Jersey, for some reason, probably because the soil is so productive, no arid wastes are left, but young trees immediately spring up in the place of the old, and in a quarter of a century or so there will be quite a respectable forest to hide the former devastation. In the old charcoal beds to-day a glad surprise awaits me. The little *Draba verna* is in full bloom, standing thickly over the blackened spots, where the direct rays of the sun have more powerful effect than on the surrounding light soil, and bring the little plants forward as if in a hot-bed.

Dr. Gray was inclined to the opinion that this plant was not indigenous to our soil. If not, the seed must have been distributed in these forest fastnesses through the agency of the early charcoal-burners, or possibly birds may have been the agents, as I have often seen our little field sparrow (*Spizella*

pusilla), and the pine linnet (*Chrysomitris pinus*), and the thistle bird (*C. tristis*), eating seeds from plants growing on the roadsides and in fields.

Passing on through these open barrens, we soon reach a dense Cedar-swamp, which for several seasons past I have promised myself I would explore in the winter. Along its borders we find the rare local *Helonias bullata* growing in large clumps, with leaves fresh and bright, somewhat resembling those of the old-fashioned White Lily (*Lilium candidum*); but the leaves are more shining and larger, and withstand the frost better than the Lily. And very beautiful they are here in mid-winter, standing up in great rosettes, and looking more appropriately placed and beautiful than they ever do in a garden.

What I saw within the gloom of the Cedars must be told in another letter.

Vineland, January, 1889.

Mary Treat.

History of the White Lilac Industry.

FOR a long time it was generally, and even now is by many, believed, that to obtain White Lilac flowers during winter, the plants should be forced in a dark place. Such, however, is not an absolute necessity by any means; it is practically a question of heat, and, given this, White Lilacs can be easily produced in fully-lighted houses. The varieties mostly grown for this purpose are Charles X. and Rouge de Marly, both of which are cultivated in enormous quantities in France, and also in England, for forcing. Formerly Covent Garden was supplied almost exclusively from France, but now many English establishments are devoted to this special branch of the flower-trade. In some of these a system prevails by means of which the bushes to be forced are retarded to such an extent that the flower-market is furnished with fine White Lilacs (forced) long after unforced bushes in the open air have ceased flowering. The exact means adopted to secure these results are not divulged by those who practice them; the rough-and-ready plan of stripping off all the leaves of established plants in the open air, and so causing a second growth and a crop of flowers in autumn, is, however, not the one adopted by the Covent Garden growers. The white-flowered forms are not used for early forcing, they are not sufficiently vigorous, and the two red-flowered ones above-mentioned are almost invariably used. The red coloring matter, however, exists in such a quantity in some—for instance, Andenken and Ludwig Späth, a handsome dark-colored form of recent origin—that, even in the dark, white flowers cannot be produced.

In connection with this subject, the historical notes of M. Héring, in a recent volume of the *Journal de Botanique*, are of especial interest. As early as 1820 we learn that several French gardeners had tried the forcing and bleaching process, but not with any degree of success. Their plan was to make towards Carnival-time a deep hole, put fermenting material in the bottom, and cover the top with boards and straw. By this means in a fortnight or three weeks they obtained flowers which had lost a portion of their redness, but which were far removed from the snowy purity of those produced at the present day.

When hot water began to be successfully used for heating plant-houses a new era commenced in the Lilac industry, and in the winter of 1858 Paris society had its floricultural sensation in the pure White Lilacs, grown by M. Laurent, a Parisian florist. His plan was to take bushes from the open ground, plant them in a house which was kept day and night at a temperature ranging from 86° to 95° Fahrenheit, and under these conditions it took less than three weeks to get flowers. Madame Furtado, at the *Chateau de Roquencourt*, and M. Lavallée, at the *Chateau de Segrez*, among others, began to force Lilacs, and the latter, during his Presidency of the *Société Nationale d'Horticulture de France*, exhibited to the Society perfectly White Lilac which had been produced in a fortnight in full light in a house heated from 95° to 105° Fahrenheit.

The Marquis de la Ferté, *Chateau du Marais*, tried the cultivation in an Orchid house (in full light), with a temperature of from 59° to 68° Fahrenheit, but the flowers did not change markedly in color; the heat was insufficient, and the same results were noted at Segrez whenever the thermometer was not allowed to rise above 68°. Even in the dark, with comparatively low temperature, flowers become rose-tinted. So far M. Héring.

A few words may be written, however, about forced colored Lilacs. As is evident enough from previous remarks, the bushes must not be subjected to nearly so much heat if normally-tinted flowers (and for these, too, there has arisen a

large demand) are required. For pot-culture it is best to graft or bud the desired varieties on stems of *Ligustrum ovalifolium* or of *L. vulgare*. The plants thus treated make short, stubby growth, and set very freely, but they will not bear early forcing. *Syringa Chinensis* makes a delightful pot-plant, and this species it is usual to bud on two-year-old seedlings of the common Lilac (*S. vulgaris*). This operation takes place at the end of July. The next spring, as soon as the growth is as long as the finger, it is stopped, and by autumn a fine head is formed. Early the following spring the little trees are potted and the pots plunged in the open ground. An abundant water supply is necessary to induce a vigorous growth. In the middle of July the pots are taken out of the ground and less water given, in order to ripen the shoots. In November the pots are covered with some material to prevent frost from breaking them, and the plants are ready for removal to the forcing-house as required.

Kew, February.

Cultural Department.

Hybridization of Gladioli.

IN 1885 I prepared to raise Gladiolus-hybrids by planting a row of the species *G. purpureo-auratus* among rows of Gandavensis varieties for the sake of convenience in hybridizing the flowers. Similar plantings of *G. dracocephalus* were made. Many flowers of *G. purpureo-auratus* and of *G. dracocephalus* were used as the pistillate parents. Some hybrids were attempted in the reverse order, using Gandavensis varieties as the pistillate parents, with but little success, and as the resulting seed was not kept separate, no notes can be given on this cross. The stamens were removed from all flowers to be hybridized while in the condition of unopened buds. The pollen was removed from the cells of the anthers with a sharp-pointed stick, and transferred directly to the stigmatic surface. This, in practice, was found the simplest method with Gladioli, although with most plants a camel's hair brush is best.

The hybridized seeds were planted in April, 1886, in shallow boxes, and so grown throughout the summer. About mid-summer, when the leaves attained a considerable height, fine sifted cow-manure was spread over the soil in the boxes to the depth of half an inch or more. This proved beneficial as a mulch and source of liquid-manure at each watering. In autumn the bulbs were sifted out of the earth and kept in boxes, as they have been in succeeding winters. The second year the seedlings were planted thickly in rows in the open ground.

I was informed by Mr. W. E. Endicott, who has had large

Fig. 95.—Diagram of the Perianth of Gladiolus.

were planted as one lot. The seed proved highly fertile, and yielded as many plants as do seeds of ordinary Gandavensis varieties.

About twenty-five hybrids of *G. purpureo-auratus* bloomed in 1887, the second year from seed, and were essentially similar to those which bloomed last summer. Many bulbs accidentally overlooked when digging in the autumn of '87, grew finely last summer, which is strong evidence of the hardiness claimed for the hybrids, as the winter of '87-'88 was extremely severe.

During the summer of 1888, 175 purpureo-auratus hybrids bloomed for the first time, and careful notes were taken of each plant.

Before discussing the hybrids, a few preliminary notes are necessary. In the Gandavensis varieties (the ordinary Gladioli of gardens) the segments of the corolla are arranged on two anthotaxic* plans. The first and most numerous arrangement is that shown in A fig. 95. The uppermost segment of the perianth is without, overlapping the adjoining segments; the lowermost within, embraced by its contiguous segments; the upper pair of laterals are overlapped by the lower pair of laterals; the lower pair of laterals overlap their adjoining segments. The other arrangement of the segments is shown in B fig. 95. The uppermost segment overlaps the adjoining

* "Anthotaxy, denoting flower arrangement. A name formed on the analogy to phyllotaxy, or leaf arrangement." Asa Gray, "Structural Botany," Part I., p. 141.

laterals; the lowermost overlaps its laterals; the lower pair of laterals is wholly within, and the upper pair of laterals is wholly without their adjoining segments. A single spike may be composed of flowers of the first arrangement (*A*) wholly, or it may have flowers of both arrangements in varying numerical proportions; but the first (*A*) as far as noted always predominates. Flowers of the second arrangement (*B*) may be the first, last, or scatteringly intermediate on the spike. The two arrangements are fundamental in the flower, they are not brought about by twists in the segments. The arrangement of the cells in the ovary coincides with the varying relative position of the segments.

In *G. dracocephalus* all the flowers, in the large number examined, were arranged as in *B*. The same is true of *G. purpureo-auratus*. Only a few flowers of *G. Saundersii* were observed when this character was in mind; but those were of the second arrangement. *G. psittacinus* is the only species where a variation of the arrangement was noted. In his species most of the flowers were arranged as in *A*; but a very few were found of the type of *B* in the diagram.

The existence of two plans of flower-arrangement on a single spike in a true species would be anomalous, and I consider its occurrence in hybrid Gladioli due to the inheritance of mixed blood; the arrangement (*A*) being due to certain ancestral species, and the arrangement (*B*) to other ancestral species. This suggestion is borne out, in fact, by the hybrids of *G. purpureo-auratus*, for, as noted below, both arrangements are found in the hybrids, although the form *B* only is characteristic. It is quite possible that, by following this character out one might be able to trace the origin and kinship of species and garden-hybrids of Gladioli.

The species *Gladiolus purpureo-auratus*, used as the pistillate parent, is well represented in the illustration upon this page. The flowers are deep, tubular, and bell-shaped. The ar-

range of the segments is as in *B*. On the central lower petal is a narrow blotch, and on the adjoining laterals broad, elongate blotches of dull maroon-crimson. At the base of the blotches, near the centre of the flower, the color heightens to a rich crimson over a very small area. This rich color is an important fact in the result obtained in the colors of the hybrids, where the whole blotch is commonly a rich crimson. On the margin of the blotches is a lip-like splash of golden yellow (not shown in the figure). The color of the rest of the flower is a pale greenish-yellow. The plant grows to the height of about four feet, with foliage narrower than in *Gandavensis* varieties. The flower-spike grows in a graceful subarcuate fashion, quite distinct from that characteristic of *Gandavensis* varieties or of any species with which I am acquainted. The flowers are arranged rather far apart on the stem; they all face in one direction, and in view of the arcuateness of the flower-stalk, and pendant, bell-shape of the flowers, their interior is not easily seen. The corms of *G. purpureo-auratus* are not very large. They bear bulb-lets at the base, and, in addition, small corms at the tips of the characteristic running root-stocks, one of which is shown in the figure. The species is distinct, and different individuals vary little. The only variation noted was a specimen which had a richer yellow than common in the lip bordering the maroon blotches.

The *Gandavensis* varieties used as the staminate parents were a choice lot of named varieties and seedlings.

The quality of the *Purpureo-auratus* hybrid seedlings was of a high order. Of the 175 which bloomed, ten per cent. were plants worthy of a place with the best

named varieties. Thirty-seven per cent. were well worthy of general cultivation. Fifty-three per cent. were of medium quality, indifferent or poor. In estimating quality, color was considered of first importance, and, after it, form and arrangement.

All the flowers, without exception, were colored—white,

Fig. 96.—*Gladiolus purpureo-auratus*.—See page 88.

pink, red, crimson, maroon, etc.—thus showing the *Gandavensis* blood. In many the color was of a peculiar magenta-pink, quite similar to that often seen in *Magnolias*. This color existed in none of the *Gandavensis* parents and was distinct from any that I have seen in *Gandavensis* varieties. Twenty-six per cent. of the hybrids were marked on the lower segments by the characteristic shape of the blotch in *G. purpureo-auratus*; but, instead of being dull maroon-crimson, in most cases it was rich crimson, the color found at the base of the blotches in the species parent. This is an interesting and striking fact. Only eighteen per cent. of the hybrids had the characteristic *Gandavensis* stripe on the lower segments, and fifty-three per cent. had markings which in shape were a combination in varying proportions of the linear stripe of the *Gandavensis* and the blotch-like stripe of *Purpureo-auratus* flowers. The yellow splash at the margins of the maroon blotches in *G. purpureo-auratus* is largely inherited by the hybrids, but is often wanting. It was noted in nearly half of the seedlings. Not infrequently the form of the yellow splash is retained, but the color is replaced by white. The arrangement of the segments in most of the flowers was that figured in *Balone* like the species parent; but exceptions were frequent in which the arrangement *A*, found so predominantly in the *Gandavensis* varieties, also existed, but always in a few flowers only of a spike. The form in eighty per cent. of the flowers was sub-open or flaring, being close to the form which would be made by modeling a pattern half way between the two parents in shape. Some were widely flaring, remotely resembling a full blown *Magnolia* in shape. A few flowers (eight per cent.) were deep bell-shaped, like the *Purpureo-auratus* parent. A few others (nine per cent.) were close to the *Gandavensis* parent in shape. The size of the foliage and habit of the plants was half-way between the two parents in ninety per cent. of the hybrids. A few (ten per cent.) tended toward the greater size and rigidity of the *Gandavensis* parents. The corms bear small corms at the tips of the stoloniferous underground side-stems, thus following the character of the species parent. The percentage in which this character occurred was not ascertained, but it was generally present.

Out of 175 hybrids flowered, only three closely resembled the *Gandavensis* parents, two were close to *G. purpureo-auratus*, but they showed the foreign blood by being shot with red. Mr. Endicott, in a recent paper,* noted that he had only had two plants showing pure blood from many hundred seedlings raised from *G. purpureo-auratus*. This statement, with my own observations, leads to conclusions of great interest and importance. It proves the complete union of the parents in the hybrid offspring, there being very rarely or never individuals which copy either parent to the complete exclusion of the other. It proves, also, the extreme potency of foreign pollen on *G. purpureo-auratus*. This would not be expected, as the pollen of its own species would be supposed, on all common principles of fertilization, to be prepotent.

In the hybrids, the shade of color, the crimson central blotches and the flaring form of the flowers may be considered the new characters developed by the mixed blood. They are the characters due to the cross, of which traces only can be found in either parent. The hybrids, in a most remarkable degree, were, roughly speaking, half way between the two parents in form, coloration, marking, habit, etc.

Mr. Charles Putnam, of Salem, raises many *Purpureo-auratus* hybrids. He uses for the pistillate parent the variety known as *Lemoinei*, which is itself a hybrid between *G. purpureo-auratus* and *G. Gandavensis*. His staminate parents are *Gandavensis* varieties. The seedlings which he raises are largely very close to or nearly identical with *Gandavensis* varieties, which is further proof of the complete union of parents in the offspring, as his seedlings are three-fourths of *Gandavensis* blood and only one-fourth *Purpureo-auratus*, and therefore would be expected to lean toward the *Gandavensis* parent.

Mr. C. Sander has originated a hybrid between *G. dracocephalus* and *G. Gandavensis*, which promises to produce a line of hybrids of much importance.

G. dracocephalus is a tall, strong-growing species with hood-shaped, yellowish green flowers, netted with very small linear red dots. The only approach to a stripe in the basal segments is the omission of the red, leaving a pure yellowish green line. The species produces very large bulbs and an abundance of bulblets. With high culture I have grown this species and its hybrids to the height of six feet. A few of the hybrids were given me, and in 1885 seed was saved from which during the past summer ninety-six seedlings bloomed.

The flowers were naturally fertilized, and, judging from the results, probably largely by *Gandavensis* pollen. The type species was fertilized with *Gandavensis* pollen, and perfect seeds matured, but as unfortunately they were planted with seeds from the hybrids, no notes can be given on them separately. None of the hybrids approximate to the *Dracocephalus* type, but many come close to the *Gandavensis*, indicating, as was probably the case, that the blood was three-fourths *Gandavensis*. The great value of the hybrid is the strength, size and floriferousness of the plants and the unique form and marking of the flowers, due to a combination of the characters of both parents.* One of the most important features of these hybrids is that a large percentage bear flowers entirely free from stripes in the lower segments. This is a character due to the *Dracocephalus* blood, and will be highly appreciated by *Gladiolus*-growers, because of the possibility it offers of obtaining flowers of whole colors. The characteristic carmine stripes of *Gandavensis* varieties make often, and it might be said commonly, an inharmonious contrast with the ground color of the flower. Several crimson, pink and red *Gladioli* of this cross of various shades, and of great beauty, bloomed, and were distinguished by the fact that the colors were pure and the stripe wholly absent. This is suggestive, as other species having no stripes or blotches, and desirable markings would doubtless tend to give to hybrid offspring their special features, as is so clearly seen in hybrids of *G. dracocephalus* and *G. purpureo-auratus* when crossed with *Gandavensis* pollen.

One seedling of much interest was produced. The pistillate parent was *G. purpureo-auratus*, the staminate a *Dracocephalus* and *Gandavensis* hybrid. The result was a flower combining the characters of all three parents in a marked degree. The form was a combination of that characteristic of the *Purpureo-auratus* and *Gandavensis* parents, with sharp, pointed petals; color, dull magenta-red, bearing the characteristic *Purpureo-auratus* and *Gandavensis* blotch in the three lower petals. On the margin of the blotches, in the middle of the two lateral petals, was a blotch of distinct mottled yellowish green. In the centre of these blotches was a line of clear yellowish green. This color and the mottling were the only *Dracocephalus* characters noted, but they were so distinct and are so characteristic of the species that no doubt can be entertained of their origin. Four other *Gladioli* from seed of *G. purpureo-auratus* were noted, which, in color and peculiar hood-like form, showed the blood of the triple parentage.

The complete combination of parents in plant-hybrids is shown in a marked degree in the fine hybrids sent out by V. Lemoine, of Nancy, under the name of *Montbretia crocosmiaeflora*. I have grown five of his hybrids, and they are all directly intermediate between the parents, which are *Montbretia Pottsii* and *Crocsmia (Tritonia) aurea*. The combination is seen in the color, size, form and habit of the inflorescence. Some swing toward one parent more, some toward the other, and there is a brilliancy of color in several of the hybrids far exceeding that of either parent.

The hybrids of *Gladiolus purpureo-auratus* and *G. Gandavensis* and of *G. dracocephalus* and *G. Gandavensis* are entirely fertile, and the seed grows easily. The *Montbretia* hybrids, above noted, also seed freely, so that there seems here to be none of that whole or partial sterility attributed to true species-hybrids in plants and animals.

The pollen of *G. purpureo-auratus* is much less active on *Gandavensis* varieties than the reverse cross, and attempts to make this cross were attended with little success. The same is true of crosses tried with *dracocephalus* pollen. In a lot of about 250 *Gandavensis* seedlings, bloomed for the first time last summer, only three or four showed signs of *Purpureo-auratus* blood, although the flowers had quite as good a chance to be naturally fertilized by *Purpureo-auratus* pollen as did that species with *Gandavensis* pollen. Insects must have passed freely from one species to the other in order so effectually to cross-fertilize the *Purpureo-auratus* flowers. No *Gandavensis* seedlings showed traces of *Dracocephalus* blood.

To sum up the deductions. The species *G. purpureo-auratus* is very readily fertilized by *Gandavensis* pollen. The offspring of *G. purpureo-auratus* and *G. dracocephalus* crossed with *G. Gandavensis* are vigorous and readily set fertile seed. The hybrids are a direct combination of the two parents in color, form, habit and root, but with some new characters developed by the mixed blood.

It is sometimes thought, with garden-plants long in cultivation, from which seedlings have been raised in abundance and for a considerable time, that we have reached the end of the striking variations possible. Such a statement has been

* "The Species of *Gladiolus*," by W. E. Endicott; GARDEN AND FOREST, No. 31, page 363.

* A few of these hybrids were shown at the Massachusetts Horticultural Society last August, and were noticed in GARDEN AND FOREST, No. 28, p. 336.

made in regard to Gladioli. As a general conclusion this may be said to be emphatically incorrect. The limitations of hybridization, as regards what species may be crossed by what other species or even genera, are entirely unknown, and this is now the most inviting field for horticultural experiment. A keen pleasure is assured to the individual who shall strive to break the bonds of varietal variation, and by infusing new blood gain valuable and novel plants for the cultivator, and a furtherance of our knowledge of the conditions and effects of hybridization.

Boston.

Robert T. Jackson.

Window Plants.—This is the season when complaint is most often made that window plants look sickly and that their leaves turn yellow and fall. Insects often cause the trouble, and in some cases it is because leaves are not kept clean. But more commonly too much water is given. When the pots are insufficiently drained the water remains stagnant about the roots. Roots need air, and when this is excluded no food is absorbed,

dividing a stemless crown much fewer plants could have been obtained. But we still had the crown to divide, in addition to the long trunks, so that one plant made many rooted sets.

This method gives four or five times as many young plants as the ordinary one, and why can it not be applied as well to such herbaceous plants as Delphiniums, Hollyhocks, Aconites and Clematis? Of course it would be advisable to cover them in gradually as the stalk grew up, and not all at once, a method which might kill some plants.

Somerville, Mass.

F. L. Temple.

Orchid Notes.—*Calogyne cristata*. This is one of the best known of the tropical Orchids, and is a general favorite everywhere. It can be successfully grown and flowered in almost any kind of green-house, or in any soil, provided it be well drained. We grow large numbers of these Orchids, and they are now making a wonderful display of bloom. The flowers will last a long time when cut, add gracefulness to the heavier kinds when used in a vase, and relieve the rich colors

The Gore Place, Waltham.—See page 86.

the reserve material in leaf and stem is soon exhausted, and the plant is starved. Window-plants should have no water when the soil is damp. A plant is in a healthy condition when it is allowed to dry out until water is needed, and this demand should be made twice a week or oftener, according to the size of the pot and of the plant, the rapidity of transpiration and of evaporation from the soil. An aerated soil is essential to success with window plants, and it is just as necessary for the health of shrubs and trees. Last June a dam built across a little brook which runs through my meadow raised the water level of a pond, half a dozen square rods in extent, about two feet. A thrifty Tulip tree stood ten feet from the bank, but in a few days every leaf turned yellow and fell. So many of its feeding roots were shut out from air by the water that saturated the soil about them that the tree died of starvation.

Trenton, N. J.

S.

Propagating Herbaceous Pæonias.—Four years ago some frames in the nursery were built where there had been a bed of herbaceous Pæonias, and after the frames had been filled with rich and light soil some weak shoots of Pæonias were seen pushing up from roots left in the soil. These plants were left for three years, when they were dug up and found to be set eighteen inches deep.

They had pushed a stalk through all this covering, and the stem, which in plants set near the surface would have been an annual one and would have died back to the crown of roots in autumn, had become a perennial trunk, full of axillary buds, and having strong roots directly under and feeding these buds, while the crown of roots at the bottom was also strong, but not so strong as when planted near the surface.

The benefit to the propagator from this remarkable change of habit of the plant is that a long stem full of buds and roots is produced which has only to be cut into short sections with the shears to furnish a large number of well-rooted plants. In

of the more showy. When grown in baskets, the plants are useful for hanging in the dwelling-house. It is very little trouble to grow this plant, which needs to be repotted only once in three or four years, though it is benefited by an annual top-dressing of chopped leaves and moss. We grow them in a cool house, where the sash is kept down from June till September, and they are treated to a good drenching of water once or twice a day, until the bulbs are matured. The plants make fine stout bulbs, thoroughly ripened, and sure to give good spikes of bloom. The pure white variety, Alba, is at present somewhat rare, but, happily, it grows as freely as the type, and bids fair to become very plentiful in a few years. Another good variety, named Citrina, has long, narrow bulbs, more slender and bronzy green foliage. This flowers fully a month later than the species, and on that account it is a valuable kind, as it prolongs the flowering season till early spring. If possible it is more floriferous than the type; one plant with us has 112 spikes, which will yield some 600 flowers.

Dendrobium Endocharis is a charming little plant, the result of a cross between *D. Japonicum* and *D. aureum* (*heterocarpum*). The flowers, freely produced from the sides of the bulbs in twos or threes, are milk white, with a purplish striated blotch at the base of the lip. It has a delightful primrose fragrance, and grows freely in a pot or basket filled with a mixture of fibrous peat and moss. It requires a cool house, and should be kept moderately dry after growth is matured.

Kenwood, N. Y.

F. Goldring.

Doronicums as Pot Plants.—Although the proper place for these showy Compositæ is the hardy flower-garden, they are also suitable for use as winter-flowering plants. If lifted with care in autumn, potted, and placed in a cool house, in the earlier months of spring an abundance of bright yellow flowers will be the result. Besides their beauty, the flowers have the additional value of lasting well when cut. With the above treatment we now have *Doronicum Caucasianum* in full bloom.

This species does not exceed twelve inches in height, and does well in five-inch pots, making it a useful pot plant. *D. plantagineum excelsum* is also showing flower-buds. This is much taller in habit, and under liberal treatment it grows four or five feet high, with flowers four inches across. *D. Austriacum* and *D. Clusii* are equally desirable. After flowering in pots the plants may be placed in the border for the summer, and a second, and even third, crop of flowers will be produced if the soil is rich and abundant water is supplied.

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

VIII.—THE CHANGES WHICH ORGANIC MATTER UNDERGOES IN THE PLANT.

THE preceding papers have outlined the mechanism by which organic matter is formed by plants. It has been shown that the green parts of plants possess the extraordinary power of constructing out of inorganic materials, taken from the air and soil, matter which is essentially like the very substance, of which both the framework and the living parts are made. It is now necessary to see what are the changes by which the simplest organic matter is transformed into various complex substances found in the plant.

For this examination a very brief review is essential. The efficient agent in the change by which inorganic materials are converted into organic matter is, as we have seen, the chlorophyll-granule (or its green pigment), which imparts to our ordinary plants their characteristic color. In some striking instances, this green color is hidden by other coloring matters which occur either in the shape of granules or as dissolved pigments; but wherever a leaf accomplishes the work of changing inorganic into organic matter, it does so through the agency of its chlorophyll, or some equivalent of chlorophyll. Moreover, in these granules, or in the cells which contain them, is effected also the equally important, but even more mysterious, change by which nitrogenous compounds are brought into combination with the simpler organic matter, and the whole substance endowed with life. The absolute necessity of sunlight, or light of substantially the same quality as sunlight from some indirect source, in the first step in the production of organic matter, has been commented on, but attention must now be called to the fact that many, if not indeed all, of the subsequent changes and combinations, can go on without light.

The radiant energy which falls upon the plant as sunlight is received by the cells which contain chlorophyll, and in the presence of the requisite inorganic materials upon which it acts, is transformed into another form of energy, which is retained. Chemically, this transformation in the plant always accompanies reduction of highly oxidized compounds, in which process a portion of the oxygen is released. The newly transformed energy is now to be turned to other forms (or, as one may say, different kinds of work) within the plant. Putting the same idea into the language of chemistry, we say that the newly constructed organic matter (formed by reduction from highly oxidized materials, carbon-dioxide and water) is now to be modified in many ways. But the principal ways are the following: (1) the construction of new living matter, (2) the building up of new parts, including the repair of waste, and (3) the performance of such kinds of work as lifting, and transfers of all sorts. And when, after watching the expenditure of the treasured energy, or the consumption of the stored-up organic matters, we look at the ultimate products resulting therefrom, there meet us only the inorganic materials with which we started. In other words, we have followed the course of sunlight in its marvelous activities, and have come back to the point of departure. But between the first point, when we have before us sunlight acting on the green plant containing chlorophyll and employing carbon-dioxide and water in the presence of a small amount of dissolved earthy matter, as its raw materials, to the last point, at which, after all the products have been utilized and all the work done, we have only the raw materials back again, the distance is very great. Between these points the changes may be simply innumerable. Their multitude and complexity are best realized when we reflect upon the diversified products of the vegetable kingdom which man turns to account for his needs. All the timbers for shelter, the fibres for clothing, the starches, sugars, oils, nitrogenous matters and condiments for food, the perfumes, the dye-stuffs, tanning materials, gums, resins, and drugs in general, form but a small proportion, since these are only the very few of which man has yet discovered the uses and employed for his wants. Their multiplicity is so great that only a few characteristic changes of a general nature can be selected for pres-

ent observation. For this purpose, in our hasty glance at these changes, or what is called metastasis, or metabolism, we must note that there is a building up, and there is likewise a pulling down—a treasuring and an expenditure of energy; and one of these is discernible in all the greater changes which go on within the plant. But there are a few changes which appear to be on a single plane, that is, there is no marked modification in the chemical composition of the materials, but simply a re-arrangement of their constituent atoms. In the plant, constructive metabolism, in its widest sense, includes the storing up of sunlight and the subsequent utilization of the formed materials in the making of new parts; on the other hand, destructive metabolism includes all those retrograde changes in material by which the stored energy does any sort of work.

For convenience it is well to look first at the organic products which contain no nitrogen. These may be roughly grouped into three classes, (1) the carbo-hydrates, (2) the fats, and (3) the vegetable acids.

1. The carbo-hydrates are of two general sorts, (1) the starch group and (2) the sugars. Starch is the first visible product of assimilation proper; that is, it is the first substance which we can detect as a solid in the assimilating cells, but in all probability it is not first body formed; it is likely that some form of sugar is the primary substance produced in the work of a green leaf. Starch has the same elementary composition as cellulose or cell-wall material, but its physical characters and chemical reactions are different from those of cellulose. Under certain circumstances cellulose may be employed as food by the seedling; but such cases occur only in instances like that of the hard seeds of dates, etc., in which there is also a further supply of more easily utilizable food. Cellulose is used for building, not as food. Starch, on the other hand, is one of the principal forms in which food is treasured by plants. It is accumulated in underground parts, as roots and tubers, and above ground in leaves, stems and seeds, taking on characteristic shapes and markings. In many instances these distinctive characters enable one, by the use of the microscope, to detect cases in which starch from one source has been substituted by accident or design for another sort. One of the most interesting discoveries of modern times is the fact that these grains of starch accumulate through the intervention of colorless granules of living matter, which, as shown in the first paper of this series, are substantially the same in origin as the chlorophyll, or green granules, by which organic matter is constructed under the influence of sunlight.

There are many substances which are identical in atomic composition with cellulose and starch, namely, *inulin*, or the substance in which much of the food is stored in certain plants of the Sunflower Family, and *dextrin*, which occurs in much sap at the time when rapid building of new parts is going on. To the same group belong certain gums—for instance, Gum Arabic. These which we have mentioned are only a very few of the bodies allied to cellulose which are found in plants, but this brief reference to them may indicate the importance of the fact that out of precisely the same proportions of three elements, viz., carbon, oxygen and hydrogen, it is possible to derive substances so diverse in their appearance and physical properties. By comparatively slight changes in the chemical composition these are transformed into other substances, which will be discussed in the next paper.

Cambridge, Mass.

The Forest.

Forestry in New England.

THE extracts which follow are from an address delivered before the Massachusetts Horticultural Society, at Boston, on February 9th, by Mr. J. B. Harrison, Secretary of the American Forestry Congress:

New England has in her own territory a conspicuous illustration of the value of an extensive tract of mountain forest, and of the evils which result from the destruction of the woods. The White Mountain region of New Hampshire was, in its natural condition, remarkable for the amount of beautiful scenery in a limited area—that is, for the number, interest and variety of its separate, complete landscapes. Each picture or scene was large enough to make the impression of individual and satisfying beauty, and there was little waste space between them. There was merely for each one a natural and charming frame.

I have time to-day to mention but one of the functions of this mountain forest—that of a place for summer rest and recreation; for sylvan peace and shade, coolness, beauty and refreshing change for men and women weary of the heat

and dust and noise and wearing care of life at home and in the towns. The preservation of these mountain woods for this use was of vital importance to the people of the nation in general, and the inhabitants of New Hampshire possessed in them a source of perpetual revenues. As population, wealth, leisure and the disposition to seek change of scene in summer increase in our country, these mountains and valleys have been thronged by an ever-changing multitude of guests, glad to have the opportunity of paying liberally for the comforts and luxuries of life while sojourning at the great mountain hotels. The region was worth more to the state than the richest gold mines would have made it. The one condition of a permanent and most liberal income was the protection and preservation of the forests. They are, in very great proportion, already ruined. They have been cut and burned away in most unintelligent disregard of their value. In consequence, the charm of the region is in great measure destroyed. The value of the hotel property will be seriously impaired, and many of the places which were once the loveliest are now desolate and hideous. The hills themselves are crumbling and dissolving, and a blight and curse are settling upon important parts of this sanctuary of beauty and peace. It might have been preserved uninjured forever; and yet it might have yielded another great revenue from the timber which it produces, most of which could have been cut, at proper times, without impairing the value of the forests in any way. All this would have been practicable, if we had been sufficiently civilized.

I have not time to speak of the loss by the destruction of this great source of timber supply, nor of the injury to the streams which have their sources here, the disastrous floods and the depleted summer flow, or the effect on the industries and subsistence of thousands of men and women in the great mill-towns between these mountains and the sea. The injury to New Hampshire agriculture is to be recognized, though it is less important, because most of the state is unsuited to cultivation, and should have been left permanently under forest conditions. Some portions of the hill-country of western Massachusetts, have, in a considerable degree, the same character as the mountain region of New Hampshire, and should be taken care of accordingly.

Men who own small tracts of woodland, especially successful lumbermen of towns and cities who have recently acquired them, are apt to thin and prune and drain and clear away the undergrowth, and, in short, to change as completely as possible all the conditions under which the trees had lived hitherto, and then wonder that the trees do not thrive. One thing necessary to most trees in this part of the country is shade. In New Hampshire, as in many other regions, the southern side of ravines and the north side of hills grow up to trees whenever they are protected from cattle and fire. But where the ground slopes to the south it remains bare. The trees will not grow, the young plants being scorched to death by the sun, and this is true of some of the level country where the land has been exhausted by tillage. Of course the forest would skirmish around and would cover such places in time, conquering them slowly from the edges, but such object-lessons are instructive, if we have eyes to see them. The chief things required for the successful management of such tracts of woodland is to protect them from fire and from pasturage, and then let them alone, mostly. The trees will do best under the conditions which produced them and have always nourished them hitherto.

The destruction of the timber of a forest by fire is a trivial loss compared with the permanent injury to the soil itself, which always results from forest fires. The burned land produces only inferior trees, and repeated burnings destroy the soil itself. We already have deserts of our own in this country created by this process, where the soil was before remarkably fertile. But, taking our whole country together, pasturage is a worse enemy to the forests than even fire, because it is everywhere. It operates more slowly, but it brings a ruin just as certain and complete, and where forest land is pastured there can be no permanent forest. If it is necessary or desirable to grow timber or trees in Massachusetts and New England, it is indispensable that some lands should be set apart for tree culture, and protected entirely from pasturage. The pasturage of woodlands is a feature of existing agricultural methods, in which a change might well begin, which should be extended to the whole matter of pasturage, and its relation to the fertility of the soil and to the profit and loss of farming. There can be no considerable advance or improvement, except by giving up some existing practices and methods, and adopting better ones in their stead. A little synthetic observation would convince thoughtful men that pasturage has too

large a place in our present methods of agriculture, and that it is a wasteful and costly process, especially in its effect on the fertility of the soil. I think it would be an important step in a real advance in civilization if in Massachusetts and New England the pasturage of domestic animals were to a great extent gradually, and not too gradually, relinquished. This belief is sustained by more reasons than can be presented to-day. To feed cattle in-doors would enable farmers to save and utilize all the manure. In pastures it is largely wasted, and is often even an injury to the grass upon which it is dropped.

Forestry and arboriculture are chiefly economical subjects. Where tillage is more profitable than the production of timber or trees, the land should be cultivated. Where wood-products are the most profitable crop, there forest conditions should, of course, be maintained. But considerable intelligence, instruction, observation and forethought may be required to determine what lands are really available for profitable agriculture. A great deal of land is filled and pastured in Massachusetts and New England which should never have been cleared or cultivated. When farms are abandoned it means that they should never have been farms. The land would have been more valuable under permanent forest conditions.

Our agricultural methods are steadily impairing the fertility and productiveness of a large proportion of the soil of our country. It is tilled and pastured to the last degree of exhaustion, and about everything that people can think of is done to hasten the process of impoverishment. A little while ago I saw the great wheat country of the Red River of the North all ablaze with the burning straw over hundreds of square miles.

We are not worth so much as we think we are. Much of our agriculture impairs and exhausts the capital invested in land. Methods that exhaust the soil of a country cannot rightly be regarded as civilized methods. The *wants* of our people are increasing. More and more is required to make life comfortable, interesting and satisfactory to the inhabitants of this country, while we deal most ignorantly and carelessly with the soil, which is the great store-house from which nearly all our wealth and means of subsistence must come.

I think that in Massachusetts and New England forestry and arboriculture should be considered largely in their relations to agriculture and to the permanent fertility and productiveness of the soil. It is important to observe that, while no method or system can reasonably be recommended which would be permanently unprofitable, yet much experiment is often necessary here in tree-planting and culture, as in other fields, and we cannot expect that each particular step or effort will in itself be profitable, or will yield a satisfactory return for the capital invested. No considerable advance is easily or quickly made, and changes are necessarily attended with some inconvenience.

There is no way of learning all about these subjects at once. People who read and study good papers and books on forestry are likely to know more about forestry and arboriculture than anybody else.

But the great need is, not that the people of Massachusetts and New England should accept any particular opinions or judgments regarding these subjects, but that they should examine these subjects with a new degree of attention and interest, especially in their economic aspects and relations. We do not need a sentimental fashion of talk about trees and tree-culture, but we do need, as a means to a most important end, to have the people of Massachusetts and New England think about trees, talk about them, read about them, write about them, until there is a tree-feeling in the air, and such a reverberation of sensible and practical teaching on the subject as will compel general attention.

Correspondence.

Shrubs for Shady Places.

To the Editor of GARDEN AND FOREST:

Sir.—Please give a list of shrubs which will flourish under the shade of deciduous trees.

Boston, January, 1889.

E. A.

[The number of shrubs which can be grown under the shade of trees depends largely upon the density of the shade. If the trees under which it is desired to carpet the ground are growing close together, or if they are trees which produce a dense shade, it will be found difficult to establish a satisfactory growth of other plants under them. The Periwinkle is the best plant to use under such circumstances. It is an evergreen, very hardy, and, when once established, it will flourish in deep shade. The difficulty in

establishing this or any other plant in ground filled with the roots of old trees is found in the dryness of the soil, from which the tree-roots absorb all the moisture, rather than in the absence of light. Periwinkles or other shrubs used in this way will require, therefore, careful watering until they are fully established. When the shade is not dense almost any shrub can be successfully used under or among trees. The common Privet, the Barberry, Wild Roses, the native Cornels, Viburnums and Blueberries can all be used for this purpose. Rhododendrons, although they will not bloom in the shade, are good under-shrubs, and so is the Mahonia in those parts of the country where it is hardy. The growth under the dense forests of the southern Alleghanies, especially in the neighborhood of the streams, is often carpeted with a beautiful evergreen *Andromeda* (*A. Catesbaei*), which is one of the best of the shade-supporting plants. It is hardy in New England with a little careful protection. There could be found probably no better dwarf under-shrub for the Middle States than the European *Hypericum calycinum*, the so-called Rose of Sharon—a low, dwarf plant, which produces large yellow flowers during the summer, and which is very generally planted in England under trees, and always delights Americans who visit English gardens. This plant is not, unfortunately, very hardy in northern and eastern New England.

It is desirable, when possible, to plant the under-growth at the same time the trees, which are to shade it, are planted. If this plan is adopted the shrubs get a secure hold upon the ground, and become established before the trees are large enough to shade the ground, or to draw from it all its moisture. If this plan is adopted there is hardly a shrub which cannot be used in this way, although it must be remembered that there are few plants which can produce flowers abundantly without sunlight.—Ed.]

Mutilating Street Trees.

To the Editor of GARDEN AND FOREST :

Sir.—The people of St. Louis have for some years been in the habit of pruning and pollarding their trees, chiefly Ailanthus and Sycamore, but Maples and Elms in many instances. This treatment is usually given to young trees as soon as they have reached the height of the second-story windows, but for the past three or four years a severer method has been practiced, and trees that have struggled successfully with the vicissitudes of a city life until they have attained considerable size, have been topped off down to branches at least four inches in diameter. One row of some twenty or more Sycamores has been mangled to this extent by the neighborhood-carpenter. Will you kindly state what effect this is likely to have on the vitality of the trees? F. C. P.

St. Louis, Mo.

[The appearance of American cities and towns is seriously injured by the way in which ignorant and irresponsible men are allowed, in so many cases, to mutilate shade trees. Sometimes the cutting is done to satisfy the unreasonable demands of the various corporations operating wires; sometimes it is to gratify the whims of individual property owners. We can never hope that the streets of our cities and towns will be ornamented with handsome trees or properly protected from the summer sun, as long as the governing bodies delegate their authority to cut or prune trees to irresponsible agents of private corporations, and allow individuals to hack down every tree standing in a public thoroughfare which may be disagreeable to them. In every city and town there should be a responsible officer, familiar with trees and their requirements, whose special duty should be the planting and care of the street trees, and this officer should superintend the planting of all such trees, and their care and pruning, upon a system which should secure the greatest benefit to the greatest number. Until some plan like this is adopted, in accordance with popular interest and popular demand, there is little use in giving advice in cases like that in St. Louis, as described by our correspondent. Cutting off large branches from a healthy tree reduces its vitality, and, of course, should never be

permitted. Severe pruning may be resorted to when a tree is in a feeble or perishing condition, when such an operation may stimulate vigorous growth. A wound made by cutting off a branch, unless it is immediately protected by a coating of coal-tar or of paint, is liable to be attacked with dry rot and other fungus-growth, and from the affected surface, the decay will gradually penetrate the whole tree and finally destroy it. It is merely a question of time when trees subjected to the treatment described by our correspondent must perish. There can, of course, be but one opinion as to the appearance of a street in which the trees are mutilated by the ordinary city laborer.—Ed.]

To the Editor of GARDEN AND FOREST :

Sir.—In your issue of May 3d, 1888, you kindly inserted an account of cases of inflammation of the skin of the hands and face of a florist and some of his assistants, which was attributed to the irritating action of some plant. *Primula obconica*, the only one handled by them for the first time that season, was held in especial suspicion as the possible offender. The cutaneous disturbance therein described, *dermatitis venenata*, subsided in a short time, and the skin of the three affected persons has remained in a healthy condition until recently. Within the last two or three weeks, however, they have all manifested a recurrence of the same symptoms, an eczematous inflammation of the hands and face, and in about the same degree as last year. They now feel assured that the trouble is caused by *Primula obconica*, for the condition did not develop until a few days after this plant was first offered for sale in the shop, where it was freely handled by them. The proprietor informs me that his hands and face became affected immediately after making it up into dinner-table decorations. He states also that some of those engaged in cultivating it have complained to him of a similar inflammation of the skin, which it has produced upon them. His other assistants in the shop, who were not thus affected last season, remain exempt this year.

It is desirable to know if other cultivators or florists have had a similar experience with this newly-introduced plant, or if other species of this large genus have exhibited irritating properties.

Harvard Medical School, Boston.

James C. White.

Editor of GARDEN AND FOREST :

Sir.—Will you kindly inform me whether *Cypripedium insigne* is best propagated by seed or by division of the roots, and when the division should be made?

Plainfield, N. J.

C. D. W.

[Raising Orchids from seed is a work requiring great skill and patience. The seeds are very fine, resembling chaffy dust. *Cypripedium insigne* is best propagated by dividing the crowns after it has done flowering, and care should be taken that each portion of the plant has some good roots attached. Each division should have two or three growths.—Ed.]

Recent Publications.

Contributions to American Botany, No. xvi., Sereno Watson. Proceedings of the American Academy of Arts and Sciences, vol. xxiv., and now issued separately.

Mr. Watson's sixteenth contribution to North American Botany is mainly devoted to the enumeration of a collection of plants made by Dr. Edward Palmer, in 1887, in the neighborhood of Guaymas, in Mexico, at Muleje and Los Angeles Bay, in Lower California, and on the island of San Pedro Martin, with descriptions of new species and critical notes. In the short introduction to this paper Mr. Watson calls attention to the fact that "the peninsula of Lower California and that portion of the Mexican mainland which borders the intervening gulf, though reputed a sterile land, have always, whenever they have been explored, yielded a rich harvest of novelties to the botanical collector. Much, therefore, was expected from so keen and careful a collector as Dr. Palmer, when he undertook to spend a season at Guaymas, and from that point to explore such other places as might be accessible to him. Though the season of 1887 proved very unfavorable on account of its dryness, the result has, nevertheless, been very satisfactory. Of the 415 native species collected, eighty-nine species—or more than one-fifth—are wholly new, and many others are of great interest in various respects.

"The larger part of the collection was made about Guaymas

itself, which town lies on the eastern side of the Gulf of California, in the State of Sonora, in latitude 28° N., and 250 miles south of the United States boundary. It is hemmed in closely by very rocky hills and low mountains (of 1,200 to 1,500 feet altitude), intersected by narrow valleys. The artificially watered gardens, with their irrigating ditches and brush fences, protecting and favoring the growth of numerous native plants, the rocky islands in the harbor, and the valleys and mountains around, were all alike searched."

"Muleje, upon the western side of the Gulf, ninety miles from Guaymas, is described as in a dry, barren and mountainous region, where, except in the very short, rainy season, the only green vegetation to be seen is along the banks of a small creek. This place was visited early in June, and again late in December. Of the forty-nine species collected there, twenty-four occurred elsewhere, mostly at Guaymas. Los Angeles Bay, also on the peninsula, about 200 miles north-west of Guaymas, was visited at an unusually favorable time, after a rain which was the first that had fallen in twenty-two months, and when vegetation was in full bloom. The surrounding country is very mountainous, some of the ridges having an altitude of 2,000 to 3,000 feet. About a month was spent here (from November 22d to December 20th), and 112 species were collected, of which twenty-three had been found previously by Dr. Palmer. The remaining station was the island of San Pedro Martin, lying about eighty miles north-west from Guaymas, of which a view has already appeared in this journal.

"The characteristics of the flora of the region bordering the Gulf of California, so far as shown by this collection, are for the most part those common to the flora of the whole arid region of the interior, from south-eastern California, Arizona and New Mexico southward into Mexico, distinct in a great measure from that of California proper on the one side and that of the Gulf States on the other. Nearly or quite two-thirds of the species range northward beyond the Mexican boundary. In the mountains about Guaymas we find a considerable number that are identical with or allied to species that have recently been collected by Pringle and Palmer in the mountains of Chihuahua. We have here also probably the northern limit on the Pacific coast of the tropical or sub-tropical genera *Rhizophora*, *Hæmatoxylon*, *Portlandia*, *Citharexylum*, *Pedilanthus*, *Ficus*, etc. The proportion in which the several orders are represented in the collection is remarkable. Of the 415 species, one-fourth are equally divided between the *Gramineæ* (50) and the *Compositæ* (50). Another fourth includes only the four orders, *Leguminosæ* (44), *Euphorbiaceæ* (32), *Malvaceæ* (17), and *Solanaceæ* (15). These are followed by the *Nyctaginaceæ* (15), *Convolvulaceæ* (13), *Asclepiadaceæ* (10), and fifty-three other orders with still fewer species. The important orders, *Ranunculaceæ*, *Rosaceæ*, *Saxifragaceæ*, *Umbelifera*, *Ericaceæ*, *Cupulifera*, *Conifera* and *Orchidaceæ*, are wholly unrepresented. Excluding the *Cyperaceæ* and *Gramineæ*, there are only five endogenous species in the entire collection."

Mr. Watson proposes the new genera for plants collected by Dr. Palmer: *Malperia* in *Agerateæ*, for an erect annual near *Hafmeisteria*; *Pelucha* in *Pelucheniæ*, a shrubby plant related to *Pelucha*; and *Pattalia*, an *Asclepiad* of the *Metastelma* group. Among the new species are apparently several plants of very considerable interest. Among these are three species of *Figs*, one with edible fruit, and a new *Palm*, referred to the small genus *Washingtonia*, of which the type is the now well-known *Fan Palm* of southern California. A few of Dr. Palmer's new plants which seem to possess real horticultural value have already been drawn, and will be figured from time to time, as opportunity permits, in the pages of this journal.

Mr. Watson's paper ends with the description of a few new species of plants lately found in the United States, chiefly in California.

Periodical Literature.

The January issue of *Hooker's Icones Plantarum*, being Part I. of the nineteenth volume, is of more than usual interest to American botanists, containing, as it does, the portraits of a number of plants of the Bahama Islands, which in their flora are closely united with the southern extremity of Florida. The Bahama plants figured are *Phialanthus myrtilloides*, a representative of a Rubiaceous genus confined to the Island of Cuba, with the exception of the present species, which is found also in the Bahamas; *Mimosa Bahamensis*, one of the few plants endemic on the Bahamas, the fruit now first made known by Eggers' collecting; *Acacia acnifera*, another endemic Bahaman species, which, as Mr. Baker points out, is closely related to the now widely-distributed *A. Farnesiana*

of our Texano-Mexican region; *Acacia choriophylla*, a small tree, now only known from these islands; *Salmea petroboides*, a Helianthoid *Compositæ*, a Bahaman representative of a large West Indian and Mexican genus; *Buxus Bahamensis*, a Bahaman species, now first described, and related to the Jamaican *B. Vahlia* and the Cuban *B. retusa* and *B. gonoclada*; and *Pinus Bahamensis*, a tree forty feet high, and described by Baron Eggers as forming dense woods on the Island of New Providence. *P. Bahamensis* was first described by Griesbach from a cone preserved in the Kew Museum, which Dr. Engelmann suggested ("Revision of the genus *Pinus*," p. 25), should, perhaps, be referred to *Pinus Cubensis*, a view which the present figure abundantly sustains. Indeed, judging from this figure, the Bahama plant, with the exception of the somewhat stouter mucros on the scales of the cone, is exactly identical with specimens of *Pinus Cubensis* from the Florida Keys, in which the leaves are in threes, while on the trees on the mainland of the North American continent they are often in twos.

This part contains figures of a number of Indian species of *Liparis*, and a continuation of the new Chinese plants now in course of elaboration in the Kew Herbarium. There is an excellent figure also of the great Peruvian *Ranunculus* (*R. macropetalus*), which sometimes attains a height of four feet, with large, globose-campanulate flowers, which are believed to be red. This is the species which M. Raimonde says is given by the Indians to their children "*pour les faire parler plus promptement*."

In the February number of *Scribner's Magazine* Mr. Austin Dobson writes a charming gossip article on "Old Vauxhall Gardens," the famed resort of English fashion during the latter half of the eighteenth century. The pictures from old prints which accompany his words assist them in showing that, while Vauxhall was undoubtedly an admirably designed place of recreation, it had little of the character which we usually associated with the name of garden. Miss Burney called it "formal," and so, in the extremest sense, it was. The garden covered about ten acres, and was divided by a Grand Walk, at the end of which stood a statue of Aurora, afterwards replaced by a "grand Gothic obelisk." "Beyond the end of this walk was a *ha-ha*, which separated the gardens from the hay-fields then adjoining it. Parallel to the Grand Walk ran the South Walk, with its triumphal arches; next to this again was the covered alley known indifferently as the Druid's, or Dark Walk. . . . and last came a fourth walk open at the top. Other walks, the chief of which was the Cross Walk, traversed the garden from side to side, and in the quadrangle formed by the Grand Walk, the Cross Walk, the South Walk and the remaining side of the grounds was a space of about five acres. This, which lay to the right of the entrance, was known as the Grove." The Grove was furnished with an elaborate music-stand, a building called a "Turkish Tent," and upon occasion, with supper tables in the open air. Colonnaded arcades flanked many of the walks; pavilions and statues were everywhere scattered about, and at one end of the Cross Walk stretched a large picture representing ruins and running water. Many other details are given by Mr. Dobson, but these may suffice to show the general lines upon which this famous garden was formed. As a garden, we repeat, it is not very interesting to read about, but the many notable persons whose footsteps can be traced within its borders, and the many mentions made of it in last-century literature—all these collected and gaily annotated by the author, serve to provide a most entertaining chapter.

Recent Plant Portraits.

STREPTOCARPUS PARVIFOLIA, *Botanical Magazine*, January, t. 7036; a native of the Cape of Good Hope.

MACODES JAVANICA, *Botanical Magazine*, January, t. 7037; a scarlet-flowered, terrestrial Orchid, the beauty of which "resides in deep green, velvety leaves, the light-green, longitudinal nerves of which are united by groups of transverse, snow-white, irregular streaks, much like those of *Dichorisandra mosaica*, but more delicate."

SCUTELLARIA ALPINA, *Révue Horticole*, January 1st.

CAPPARIS SPINOSA, *Révue Horticole*, January 1st.

SOBRALIA ZANTHOLEUCA, *Gardeners' Chronicle*, January 5th.

JACIADENUS CARINATUS, *Gardeners' Chronicle*, January 12th; "this is a pretty stove annual of the Gentian order. . . . The flowers are produced in autumn, and last over a month without fading. The corolla tube is white, from two to three inches long, the color of the lobes being bright purple. The plants like a well drained soil and plenty of moisture at the root always."

Notes.

Flowers of the Hepatica, gathered in the woods near Boston, were displayed before the Massachusetts Horticultural Society on the 26th of January.

Monsieur Hémie de Vilmorin, one of the best known and best liked horticulturists in Europe, has been elected President of the Botanical Society of France.

From a note in a recent number of *Le Moniteur D'Horticulture* it appears that M. Bleu, a well-known Parisian Orchid-grower, has succeeded in obtaining a cross between *Odontoglossum Roezlii* and *O. vexillarium*. Two specimens, showing slight variations themselves, have now flowered, the plants being only four years and nine months from seed. They are intermediate in character between the two parents.

Cherokee Roses in small quantities are at last to be seen in at least one Boston florist's window. It is surprising that they are not grown more frequently, for there is scarcely a flower which is more lovely. From the florist's point of view, however, the plants take up too much space, as they must be planted out and well established before good crops of flowers can be had from them, while only one crop, lasting from four to six weeks, is produced annually.

The Annual Report of the School of Forestry connected with the Indian Forest Department, and situated at Dehra Dun, shows that seventy-five students were under instruction during the year 1887-88. Of these, fifty-six were supported by Government, nine were deputed by native states and ten were private students. The copies of the examination papers joined to the Report indicate the thoroughness of the scheme of instruction, and show that a high standard of education is aimed at for the future guardians of the Indian forests.

Monsieur Joly, of Paris, has recently published a pamphlet in which he describes a famous Black Hamburg Grape-vine which grows on the estate of the Marquis of Breadalbane, in England, and is believed to have been planted in 1832. Its stem, at one foot from the ground, measures two feet in circumference, while its branches cover an area of some 4,275 square feet, and during the year 1888 it yielded about 3,000 bunches of grapes. These facts denote a vine almost equal in size to the famous one at Hampton Court, planted in 1769, which is likewise of the Black Hamburg variety.

At the meeting of the Society of American Florists in this city last summer a resolution was adopted setting forth the advantage to the trade of flower-pots of uniform size and shape, and a copy of the resolution was sent to all the potteries in the United States. In response to this call the Whilldin Pottery Company has already placed the standard pot upon the market, and other manufacturers will, no doubt, follow the example. Besides the evident gain from uniformity, the rim at the bottom of these pots saves a great deal of the loss from breakage when they are set down smartly on the bench to settle the soil. The added band stiffens them at the top, and they can be packed more closely and securely.

At a late meeting of the Massachusetts Horticultural Society a resolution was adopted authorizing the President to appoint a committee of five to consider the subject of national and state forestry, the need of further legislation to protect the forests on our national domain, and the best means to promote a greater interest in arboriculture. Dr. Walcott named as the committee, Charles S. Sargent, John Robinson, J. D. W. French, Francis H. Appleton and Leverett M. Chase. The appointment of similar committees by the horticultural and agricultural societies of other states would tend to encourage a more careful study of forest problems by thoughtful men, and their recommendations would doubtless prove of practical value.

So rapidly were the mountain sides in the neighborhood of Cape Town being denuded of their flowering plants by the reckless hands of cockney pedestrians, that the local government not long ago passed stringent laws for their preservation. Now botanists and tourists complain that these laws are so very stringent as to interfere with all lawful pleasure as well as all scientific research. "Here," says a correspondent of the *Gardeners' Chronicle*, "is the text of the definition of 'forest produce' which may not be touched under penalty: 'Game, fish, minerals, stones, earth, trees, timber, firewood, wattles, kraal wood, branch wood, slabs, chips, sawdust, plants, grass, reeds, thatch, rushes, bedding, peat, creepers, fibres, leaves, moss, flowers, ferns, fruits, seeds, roots, bulbs, galls, spices, bark, gum, resin, sap, charcoal, honey, wax, shells, horns, ivory, and generally anything growing or contained in the forest'!!! Anything else? Could it not be enacted that the respectable subject or botanical stu-

dent should be blindfolded before going up, to further atone for the stupidity of a few 'snobs' who could easily have been stopped without enacting such absurdities?"

A correspondent of the *Gardeners' Chronicle* makes the complaint so often heard in this country, that the trees on the streets and in the open spaces of London are annually mutilated by the saw and bill-hook of the ignorant pruner. He adds: "In my neighborhood—a south-western suburb—the young trees on the common were last year pruned in much the same fashion as a Currant-bush, and this has been the rule since they were planted in 1885. The result is seen in little conical heads, full of small twigs, the general outline of a tree being a *fac simile* of those of a German toy. It is possible by banishing the 'pruners' for all time, that the trees would throw out vigorous branches, and grow into picturesque objects, affording shelter from the rain and sun to the many young and aged persons who make use of the common, and become a pleasant picture to a district rapidly gaining in importance."

Mr. Flinders Petrie discovered not long ago in Egypt the remains of a number of Roses which had been bound into a garland and buried with the dead. The tomb from which they came was one of those which contained the encaustic paintings recently described and illustrated in *Scribner's Magazine*, and date from between the second and the fifth centuries after our era. Monsieur Crépin has examined these Roses, and recently read a paper relating to them before the Royal Society of Belgium. The nine blossoms he had secured were all imperfect, but evidently belonged to the same species. So far as he could judge, they resembled most closely a Rose cultivated in Abyssinia to-day, which was described by A. Richard under the name of *Rosa sancta*, as it is grown in the vicinity of temples. *R. sancta*, which is very similar to *R. centifolia* or *R. Gallica*, appears not to be a native of Abyssinia, but to have been cultivated there from a very distant period. Nor could the Roses found in the tomb have been of native origin, as no Rose grows wild in Egypt. But the flowers were doubtless obtained near the place of sepulchre, as Roses were largely cultivated in Lower Egypt and exported thence to Rome. The only native Rose known in this east African region is one that occurs in the mountains of Abyssinia—*R. Abyssinica*—believed to be a variety of *R. moschata*.

In a recent number of the *Revue Horticole* the following sensible words were printed: "Whatever may be the degree of intensity in the coloration of foliage, it can never play the same rôle as flowers in the summer decoration of a garden. A mass of *Coleus* or *Achyranthes*, a basket-bed or garland of one sort or another or a mosaic pattern in bright foliage, may be usefully employed in a decorative composition of considerable extent; but they cannot produce the same attractive and gay effect as flowering plants used in a mingled way or in distinct groups. Recently we saw an example that was pushed to an extreme point—a basket-bed entirely composed of *Coleus negro*, with dark, almost black, violet-purple foliage, and bordered with *Achyranthes*, the leaves of which showed a net-work of green and yellow. The impression made by this basket was inexcusably mournful. One vaguely imagined the existence of a *tumulus* under this mass of flowerless plants, and some sort of funereal urn would not have seemed inappropriate in the middle of it. This was certainly not the effect that had been desired, and we might cite many other cases where an injudicious use of colored foliage had produced negative or disagreeable results. The general rules to follow may be summed up thus: Reserve colored foliage for spots which are to be seen from a distance, in masses, and plant near the house and in all other much-frequented spots those flowering plants which, in addition to their elegance and their varied bloom, usually disseminate a grateful odor."

State Forest-lands of New York.

THE Annual Report of the New York Forest Commission for the year ending September 30th, 1888, recommends legislative action to exclude railroads from state-lands, to enable the state to acquire forest-lands by purchase, and to encourage a system of tree planting and forest culture. The proposal that all building of railways on state-lands within the forest-preserve shall be prohibited, and all existing laws permitting state-land to be taken as a right of way for railroads shall be repealed, is entirely judicious, and its practical bearings are important. There has been too much railroad building on the state forest-lands already, and no more should be permitted. The Commission recommends the appropriation from the state treasury of a certain amount for the purchase by the Board of Land Commissioners, upon the recommendation of the Forest Commission, in the name of the state, of forest or wild lands, at a price not to exceed one dollar and fifty cents per acre, and in amount not to exceed in expenditure the annual appropriation for such purchase. If the state can acquire an absolute title to any considerable quantity of land on these terms, and can take care of it afterwards so that forest conditions shall be restored and maintained upon it, this would be a step in the right direction.

The Commission asks for an appropriation to encourage and begin "a system of tree planting and forest culture," and thinks a beginning could be made at a comparatively small expense. Undoubtedly the beginning could be made so small that it would cost very little, but if the system were continued and extended it would probably be at once the costliest and the most useless enterprise ever undertaken by the state of New York. The scheme is a visionary one, and the work which it proposes is unnecessary. If the denuded tracts are protected from fire, from pasturage and other injuries, nature will reclothe them with forests much more rapidly than it can be done by tree planting under the direction of the Forest Commission. The proposal illustrates the need of some degree of special knowledge and training in the management of forest interests of such importance. An appropriation for such a purpose

would not only be thrown away, but would tend to divert attention from the real requirements of the Adirondack region.

The Commission also desires to obtain authority to lease portions of the state-lands to individuals who wish to appropriate to their own use and enjoyment pleasant sites for residences on land which belongs to the state. This is a mischievous proposition. No authority to lease the state-lands for such purposes should be given to anybody. Some arrangement for hotels and lodging-houses for sheltering the multitudes of people who use the region as a summer-resort is, of course, indispensable, but beyond this there is no good reason for permitting residence on the state-lands. If a few persons are to be admitted to such residence, there is no sufficient ground for excluding others, and in a few years the best portions of the forest-region owned by the state will thus be wrongfully appropriated to private uses, and the value of the wilderness as a sylvan resort and sanitarium will be seriously impaired. No facilities should be granted for increasing the number of residents on the property of the state. Those who are there already, the "custodians" on the islands in Lake George, and the squatters on sites along the shores of the Adirondack lakes, should be required to vacate these places at once, no matter how much wealth, or social and political influence, they may be possessed of.

A joint committee of the Board of Trade of Minneapolis and the Chamber of Commerce of St. Paul recently adopted a resolution, which they will present to the Legislature, regarding the extension of the park systems of the sister cities. It is proposed to form a great River Park extending for a considerable distance along both banks of the Mississippi, and including the islands in its stream. The idea is to take a strip of shore averaging some 300 feet in width, but extending further inland at certain points where ravines and water-courses occur; to construct a stately boulevard, on the inward side of which residences will be built, and to preserve all the land between it and the water as ornamental grounds. Boulevards already exist on the St. Paul side, which would form a continuation of the new one and unite it with the remainder of the park system of the town. The existing State Park, on the Minneapolis side—which includes the Falls of Minnehaha—and the Fort Snelling military reservation, which may easily be opened to the public, can likewise be connected with the new work. The boulevard can be so disposed as to afford not only extensive views of the river, but glimpses down its steep banks in certain spots; and at the foot of these banks there are places which can be effectively laid out, and sometimes even give room for accessory drives, while their slopes are already beautifully wooded with a variety of large trees. Mr. Cleveland has sketched a plan to show what the general effect of the scheme would be, and even from hearsay one can understand why local journals predict in its accomplishment the grandest park in the world. The wonderful beauty of the Riverside Park, in New York, is too well known to be insisted upon; and although the upper waters of the Mississippi have not the grandeur, of course, of the Hudson near its mouth, they are very beautiful, and a vast gain will spring from the fact that not one side merely, but both, can be utilized. Too many charming river-fronts have already been sacrificed in America to the supposed needs of trade or to mere shiftless neglect; and it will be a serious mistake if the authorities of Minneapolis and St. Paul do not preserve their own in the manner now suggested. As Mr. Cleveland points out, the thing must be done now if it is to be done at all. If time is lost, buildings will intrench on the desired locality and the fine forests along the river will be ruined past repair. These wooded tracts, as Mr. Cleveland writes, instead of being the richest ornament, will become the most unsightly portion of the suburbs, "and future generations will only deplore the want of forethought which might have saved without cost such features

of natural beauty as no money could purchase and no art could presume to imitate."

Mr. Carl Schurz is well known as an ardent advocate of change in our national policy in many matters connected with the tariff, taxation and trusts, and yet in his recent address before the Commonwealth Club of this city, he declared, as the result of his deliberate judgment, that the forest problem was more important in its ulterior consequences than were other economical questions. "If I had the power," he said, "to choose for the country between an immediate reduction of tariff duties on the one hand and the introduction of an effective forest policy on the other, I should say, 'Let the people be burdened a little longer by protected interests, for at a future day they can change their system and retrieve their losses,' rather than let the destruction of our forests go on at the present rate, for that destruction may bring on a train of disaster from which the country may never recover." It is not the purpose of *GARDEN AND FOREST* to take part in the discussion of questions which divide the political parties of the country. The words of Mr. Schurz are quoted to invite attention to the estimate of the paramount importance of the national forest problem made by a man who has some knowledge of European forests, and who, as Secretary of the Interior, has been in a position to gain special information as to the wanton waste of the timber on our public domain.

The movement to preserve the celebrated prehistoric ruin of Casa Grande, in Arizona, deserves to succeed, and as there appear to be no antagonistic interests, it ought to be an easy matter to secure the requisite Congressional action. Fortunately, the structure stands on a "school section," and the territory of Arizona could be compensated by the cession of another section of the public land. Casa Grande stands in the midst of a region that was extensively cultivated under irrigation by the ancient inhabitants, and, after centuries of fallowness, it is now coming under cultivation again by similar means through modern enterprise. It is a rich soil, well adapted to semi-tropical horticulture, and the preservation of this ancient monument will add to the attractiveness of the section. The movement to save Casa Grande originated with Mrs. Mary Hemenway, of Boston, to whose public spirit science and philanthropy are already deeply indebted.

The Terrace Garden at Wellesley.

THE Terrace Garden at Wellesley, Massachusetts, which is shown in the illustration on p. 103, is by far the finest example of an "Italian garden" with clipped trees and hedges that exists in America. Indeed, so far as we know, it is the only important example of this style to be found here. In the year 1851, we may read in Downing's "Landscape Gardening," Mr. H. H. Hunnewell, of Boston, selected a portion of an old family estate of many hundred acres on the bank of Wellesley Lake, and laid out a country place of some two hundred acres, about forty of which were devoted to ornamental grounds in the vicinity of the house. These forty acres consisted of a "flat, sandy, arid plain which . . . was more or less covered with a tangled growth of dwarf Pitch Pine, Scrub Oak and Birch, all of which were cut down and plowed up." The ground was then prepared for planting, a nursery was established for which the stock was chiefly imported from England, and the place quickly assumed a cultivated and promising aspect. "The house . . . was then built, having . . . on one side a fine extent of simple and dignified lawn, and on the other a French parterre or architectural garden with fountains, bordered by heavy balustrades, surmounted at intervals by vases, with steps leading through a series of terraces to the lake, a fine sheet of water of about a mile in extent having a peculiarly varied and beautiful outline. From this French parterre stretches off on the right the ornamen-

tal or English pleasure-grounds, a part of the same view. . . . From this we pass along the lake to the Italian garden. . . . To Mr. Hunnewell we believe is due the merit of having first attempted to clip our White Pine, and the result shows that it bears the shears quite as well as the Hemlock or Yew; though in this garden are equally successful specimens of clipped Norway Spruces, Balsam Firs, Arbor Vitæ, the English Maple, the Beech, and Scotch Firs. From the Italian garden we cross the avenue into a wood through which winds a walk, planted on either side with a very extensive and satisfactory pinetum, containing all the rarest and newest Conifers and evergreen shrubs, which, with the slightest protection from the winter's sun, seem to thrive exceedingly well. Among other features of this place . . . are various vistas through different avenues planted for this purpose—some of Purple Beech, others of White Pine—all of which will in a few years become very interesting and effective."

The editor of the second edition of Mr. Downing's works wrote this in 1858, when the place had been in hand but seven years. Its success was already so well established and its beauty so great that he could take it as his text for declaring that "if two places of the same size were commenced the same day by persons of equal taste, knowledge and means, one a wood and the other a naked plain, at the end of ten years the naked plain would be the finer and more satisfactory."

Although his description dates from thirty years ago, it might be couched in the same words, though with increased emphasis, were it penned to-day. During the intervening years Wellesley has remained in Mr. Hunnewell's hands, and his reputation among American horticulturists is so wide-spread that there is no necessity here to explain that the place has constantly received the most loving and skillful attention. It is indeed a wonderful place to have been wholly created in less than forty years, and no stronger evidence of its owner's devotion to it could be cited than the way in which the Italian garden has flourished. Perfect results are absolutely necessary if topiary works are to be anything but ragged and hideous deformities. To fail to produce absolutely symmetrical, full and luxuriant forms is to spoil the trees that Nature had designed, and leave nothing but ruins in their stead. But at Wellesley there are no failures and no ruins. A great variety is shown in the formal shapes as well as in the species of trees selected; but in each case the form has been admirably attained, and the species has been made absolutely docile beneath the shears. It is hard to say which tree gives the best result, clipped thus to a smooth wall of green; but the White Pine, most interesting from its novelty in such a shape, is, perhaps, paramount also in soft delicacy and beauty of surface. This, in its natural estate the most picturesque of our native trees, seems the tenderest and most charming when it assumes the form of a solid mass of foliage. The hedge to the left of the foreground in our picture is of Hemlock, while the White Pine shows in the dark tree, cut into three stages, near its extremity. The hedge with the conical masses rising from it that leads away from the centre of the foreground is of English Beech; another White Pine, again cut into several stages, shows near the broad walk by the lake, and the slender pyramidal trees on the second terrace are Norway Spruces. Admirable results, strange as it may seem, have been obtained by clipping the European Larch, which had not before been used in this way. In early spring the compact masses of pale, tender green of this tree are particularly charming. The immediate vicinity of the lake and the classic shape of the boat-house give somewhat the illusion of a real Italian scene, and its effect as one comes upon it in the midst of characteristic New England scenery is very striking. Whether it is an entirely harmonious effect—whether such a garden is a thing to be desired in a rural situation in America—is a question that may be left to individual tastes to decide. Such gardens certainly should not be used everywhere or very often; but those

who have seen Mr. Hunnewell's garden must be glad that one exists in this country. To hundreds of visitors it must have given their first and only sight of the "topiary work" about which they had read so much in books of travel and description, and the man whose skill, patience and taste have supplied his country with a unique work of art is a real benefactor.

The pinetum of which so much was expected thirty years ago, has more than fulfilled all that was hoped of it. It is now by far the most interesting collection of Coniferous trees cultivated in America. The sandy subsoil is admirably suited to the growth of these trees, which have flourished wonderfully under Mr. Hunnewell's generous treatment. The collection is interesting on account of the large number of fine specimens which it contains, and, more especially, for the lessons about trees which it has taught those persons who have been privileged to watch its development. Where trees are concerned, a record of failure is not less valuable than one of success.

The collection contains many specimens of great beauty and interest. Some of the finest and the largest specimens of the Douglas Fir, raised from seed collected by Dr. Parry in Colorado, may be seen at Wellesley. There are fine specimens of *Abies concolor*, *Picea polita*, *Abies Nordmanniana*, *Picea orientalis*, *Abies brachyphylla*, *Abies Veitchii*, *A. Cilicica* (a tree too rarely seen in our gardens), *Picea Aganensis* (the *P. Alcockiana* of most gardens—a tree, by the way, which Mr. Hunnewell considers one of the most promising of all Conifers), *Thuja Japonica*, *Pseudolarix*, and, indeed, every Conifer which has been found capable of supporting the New England climate.

It is pleasant to know that the members of Mr. Hunnewell's family have built themselves country homes in the vicinity of his own, and that so long as the course of nature permits the witnesses to his life-long love of horticulture to survive, the hands of his descendants will give them fostering and loving care.

Sweet Cassava in Florida.

OF recent additions to the food plants of this country perhaps none deserves as much notice as the Sweet Cassava (*Manihot Aipi*). It seems to have been proved beyond question that on the southern border of the United States there are considerable areas admirably adapted to growing this remarkable plant as a staple article of home consumption, while in Florida, at least, its manufacture into starch, tapioca and glucose ought to become a leading industry. A considerable crop was grown in that state in 1885, and parties were about to engage in its manufacture, when a phenomenal frost destroyed nearly all the seed in the state. Such a reverse can be easily guarded against, however, and the fear of its recurrence will not deter any one from planting Cassava according to his ability or inclination.

In the winter of 1887-88 only a few persons in Florida had any seed for planting. Through the efforts of one of the agricultural journals of the state this seed was widely distributed and great interest aroused in the new crop. This winter Cassava-seed is advertised extensively, and it is probable that a large quantity will be planted and that the manufacture of it will be undertaken before the end of the year. An analysis of the Florida root made by Professor Wiley, of the Department of Agriculture, shows it to contain seventy-two per cent. of starch, while Bolivian Cassava has only a fraction over fourteen per cent. of starch. Professor Wiley thinks that good Cassava starch can be made in this country, and that the manufacture of glucose from Cassava will prove even more profitable.

It may here be remarked that the name Cassava is said to belong properly to the product of the *Manihot* rather than to the plant itself, but in the latter sense it has become too well established in this country to be set aside. In tropical America the plant is known as *Manioc* or *Mandioc*. It should be observed, however, that the plant there cultivated almost exclusively, and from which the tapioca of commerce is derived, is the *Manihot utilissima*. This plant, though very similar in botanical characters to *M. Aipi*, has some very obvious differences. Its roots contain a poisonous principle, which, however, is dissipated partially on being grated, and entirely by the heat employed in converting the starch into tapioca. Its roots

are of uniform texture, and do not boil soft, while those of the Sweet Cassava do boil soft except as to an axial bundle of tough fibres.

A small quantity of Florida Cassava-seed was obtained by a few Louisiana farmers last spring, and those who have reported results express themselves as highly satisfied. But we must look to Florida growers of Cassava for that extended experience with the crop which is necessary to a correct knowledge of its requirements and profitableness. In the southern portion of the state certain contributors to the agricultural press have had this plant under observation for many years, and to their efforts is mainly due the awakening of interest in this crop.

The Cassava plant is closely related to the Ricinus or Castor Bean, which it resembles in general appearance. It is a handsome plant, not having the coarse, rank aspect of Ricinus. It does not bear much seed, and it is not propagated from seed, but from cuttings of the larger stems, very much as Sugar-cane is propagated. It is a tuberous-rooted perennial, and though the top is killed by a moderate frost, if the stems are cut so as to leave a few eyes at the base (there are no eyes on the tubers), and these are protected by a light mulching or covering of earth, the top will be renewed each successive year. In south Florida the top has been known to remain green for three consecutive seasons.

Before it is time for frost the stems that are half an inch or more in thickness should be cut, laid in piles and covered with earth. It is said, also, that the stems may be kept where they will become quite dry without having their vitality impaired. When ready for planting, in January, February or March, the stems are cut in pieces about six inches long. These are planted four or five feet apart and three or four inches deep. The crop receives shallow culture till sufficiently grown to shade the ground and hold its own against weeds. It may be left to grow for two years with advantage, thus requiring a minimum amount of culture. The roots should be dug only as wanted for use, as they decay soon after being exposed to the air. Cassava requires mellow, well drained land, and responds readily to manuring. Florida's sand hills seem to be specially adapted to this crop, better, perhaps, than to any other.

As to the quantity of Cassava root that may be obtained from an acre of ground, no satisfactory estimates have as yet been made. It must vary greatly under various conditions. A single plant grown in Polk County produced fifty pounds of roots, the top measuring eight feet in height and ten feet in breadth. It had been highly manured. A person who has given special attention to the Cassava thinks that from ten to fifty tons of roots of one year's growth ought to be obtained from an acre of land, according to its quality. This is little better than conjecture, but certainly the plant yields enormously under favorable conditions.

The uses to which Cassava may be put are almost too numerous to mention. By manufacture it may be converted, with scarcely any waste, into starch, tapioca and glucose, and into substances of minor importance. If it will furnish a substitute for wheat flour, that should head the list of its uses in a region where wheat will not grow. Professor Wiley thinks it is too deficient in nitrogen to serve that purpose, and that it should rank in nutritive value with the Irish Potato. Probably it may best be used in combination with flour and meal. In the Tropics Cassava flour is used extensively for making a large wafer or cracker, which is quite palatable, and keeps without injury for months. Florida housewives have used it for making bread, puddings, custards, fritters, jellies, etc.; also as a vegetable it is used in all ways in which Irish potatoes are used.

It is as food for stock, however, that Cassava has excited most interest in Florida. It is greatly relished by cattle, horses, hogs and poultry, and seems to be a very wholesome article of food. The great tubers, sometimes three or four feet in length, may be taken from the ground at any time of the year and used as food for man or beast. It will thus be seen that the acquisition of Cassava promises to be a great boon to the people of the extreme south, while its manufacture should supply the place of at least one importation—that of tapioca.

Jacksonville, Fla.

A. H. Curtiss.

"It is in this way that the artist-painter modifies his picture (a picture so much simpler than the artist-gardener's), making this part prettier or more like nature, correcting a shadow here, putting emphasis there,—how then should the landscape gardener, who must work with such refractory and uncertain materials and bring unity out of a whole collection of pictures, hope to succeed at the first attempt!" *Pückler Muskau.*

Foreign Correspondence.

London Letter.

"A SCHOOL of scientific and practical horticulture" is the most important item in the programme of our Royal Horticultural Society for this year. Chiswick is to be devoted to experimental and test gardening, and is to be made ornamental as well as useful. If the Society can succeed in carrying through all that is aimed at in the Chiswick gardens, every one interested in horticulture will be gratified. There is a strong section of the Society in favor of departing entirely from Westminster to Chiswick, arguing that a horticultural society should appeal for support, not through flower-shows and city offices, but through solid work in the laboratory, *i. e.*, the garden. American readers will be interested to hear that in future first-class certificates will not be awarded by the Royal Horticultural Society to plants that are not of exceptional merit as garden-plants. A second-class certificate, called an award of merit, will be given to plants worthy of commendation. After all, the value of these certificates depends on the discriminative knowledge of those who award them, and the committees appointed being composed of leading horticulturists, both professional and amateur, we may feel confident that none but first-class plants will win their approval. It is also intended to certificate strains and not individual plants in such cases as seedling Begonias, Fuchsias, Primulas, etc. A healthy sign is noted in the desire shown by nurserymen and others to get certificates for their new plants. Many of the nurserymen who used to hold aloof from the Society now submit their new plants for its approval.

At the meeting held on the 15th inst. the following plants were exhibited and received first-class certificates: *Vanda Amesiana*, to which I have recently referred. Messrs. Low & Co., who introduced it, state that their collector saw plants with over 100 expanded flowers, and one upon which no less than 185 flowers were counted. The species is very distinct, and bears evidences of proving a most useful garden Orchid. *Primula Sinensis*, Swanley Mauve, is remarkable for the size and substance of its pale, mauve flowers; some of those shown measuring more than two inches across. Mr. Cannell has succeeded in obtaining a strain of Primulas remarkable for vigor and size of flower. He and the Messrs. Sutton have been most successful in Primula breeding. Some interesting information, both historical and cultural, on *P. sinensis* has recently been collected and published by Dr. Masters, in the *Gardeners' Chronicle*. The power of the plant-breeder when relying solely upon seminal variation is well exemplified in the success with this Primrose. The prototype is a poor plant, with flowers smaller than those of *P. poculiformis* or *P. obconica*, and correspondingly small foliage. Mr. Cannell's Swanley Mauve is only one of thousands of forms which have been the outcome of cultivation and selection on the part of the horticulturist. I do not think the importance of looking after seminal variation under cultivation is properly grasped as yet by horticulturists generally, yet it is a fact that better results are thus obtained than by hybridizing alone.

Mr. Frank A. Morgan, whose article in the *Nineteenth Century* on "Fruit-growing" you recently referred to, is not considered an authority by English professional men. Mr. Morgan gauges the whole question by his experience in a fruit-market, and quotes fancy prices paid by a few extravagant cockneys as a basis upon which to argue the question of fruit-growing for the whole of England. Mr. W. N. White, who has had twenty years' experience in the London Fruit and Vegetable Market, and is a grower as well, says: "I have, at the present time in my warehouse, apples from Herefordshire which cannot be sold at a shilling per bushel; I have also apples from Berkshire and Oxfordshire which cannot be sold at two shillings and sixpence per bushel, and yet a fortnight ago, I sold American apples as high as eighteen shillings per bushel, though I think it only fair to say that plenty of American apples are being sold at three shillings per bushel, and that during the past month of December I have received no less than 16,500 barrels, representing 50,000 bushels of apples from America. Some of your correspondents will say that this proves their contention that these can be grown in England. Permit me to inform them that they could not be grown in England, and that the worst apple I am at present receiving from America is superior to the best of any I am getting from the home country." Testimony from growers of great experience all tends to prove that fruit-growing in England is a poor panacea for agricultural distress. Mr. Morgan has urged, in a leading society journal, that we have only to plant the fields with fruit-trees, and engage a few laborers to

look after them, to ensure an abundant supply of such fruit as shall beat the foreign produce out of the English market!

BAMBOOS.—The two beautiful illustrations of Bamboos in Ceylon, which appeared in your issue of the 9th instant, would have delighted General Munro, who paid considerable attention to the cultivated Bamboos at Kew, where a large collection of both hardy and tropical species is grown. In the Palm house we have a clump of *B. gigantea* (*Dendrocalamus giganteus*) and another of *B. vulgaris*, with canes sixty feet high and five inches in diameter. In the gardens of the Duke of Northumberland at Sion House, situated on the Thames, just opposite Kew, is an equally large specimen of *D. Brandisii*. The quick growth of these canes—eighteen inches in a day—is most interesting; the shedding of the beautiful sheaths from the newly-developed cane, so well shown in your figure 85, being suggestive of the hatching of eggs. None of these giants have been known to flower here. The pretty *Arundinaria falcata* is cultivated for the decoration of rooms, some of our principal plant-furnishers growing it by the hundred solely for this purpose.

Grown in nine-inch pots the canes attain a length of six feet to eight feet, branch freely towards the top, arch over in the most graceful and plume-like fashion, and, being clothed with soft green, lance-shaped foliage, they form most useful decorative plants for large halls. When they get shabby all that is required is liberal treatment in a hot, moist stove for a few weeks, and they are as good as ever. Apparently the hardy Bamboos are little known with you, probably because your winters are too cold. Here *B. Metake* is a grand mass twelve feet high and as much through, the foliage of the richest green, and the habit as graceful as a fern. It is outside in a moist, shaded corner, and receives no protection whatever. *B. mitis* is another graceful, hardy kind; so, too, is *B. nigra*, *B. viride-glaucescens*, *B. hybrida*, *B. Simonii*, and about half a score of others under garden names. These get no protection, and are beautiful all through the winter. They like moisture and plenty of rich manure. M. Latour Marliac, a French nurseryman, has lately introduced a number of beautiful kinds of reputed hardiness, some of which have variegated foliage, or striped canes. The singular square-stemmed Bamboo (*B. quadrangulata*) is also quite hardy at Kew.

HERBACEOUS PÆONIES have suddenly sprung into favor here. Nurserymen are collecting and propagating them, and amateurs are inquiring into the merits of the many kinds offered. Except in the old-fashioned country gardens these plants were scarcely to be met with until lately. They are big, rich in colors, artistic enough to please the æsthete, and as easily kept as weeds. Not a little of their beauty is in their foliage in spring, which, as it pushes up, unfolds to view the richest of coppery and bronze colors. I know one famous garden where the proprietor prefers the foliage to the flowers, planting his Pæonies for spring effect. If we could grow the Montans no doubt many would prefer them, but they thrive in comparatively few localities in England. At Kew, for instance, they lose more growth in winter than they make during summer.

Kew.

New or Little Known Plants.

Japanese Chrysanthemum—Medusa.

EVERY one who has raised many Chrysanthemums from seed has occasionally found flowers with drooping florets, and such plants are rare in collections chiefly because they have not been considered worth propagating. As long ago as 1816 a Chrysanthemum, with long, white, streaming florets was described in England by Sabine. Delaux has sent out one or two varieties of this form, although of different colors, but they did not prove to be favorites with the public and they no longer appear on his lists. The plants which produce this type of flower have not generally been of vigorous growth, and have not proved capable of much improvement. The one illustrated on page 101 came to this country from Japan, where some of the tasseled forms are said to be much admired in the Neesima Collection, which included the Mrs. Alpheus Hardy and other noteworthy varieties. It is better than any of this class which we have seen—pure white in color, and, as the illustration shows, not without a certain grace of form. It is certainly interesting as a curiosity, and it may be found of use as a parent of new forms when crossed with other varieties.

Cultural Department.

Green-house Plants—I. Correas.

THE genus *Correa* is composed of about half a dozen very variable species, all natives of Australia, where they are known among the colonists as "Native Fuchsias." They belong to the order *Rutacea*, and are nearly related to *Boronia*, *Crowea* and *Eriostemon*. They form compact shrubs, usually about six feet high, though at least one has been seen as high as thirty feet. Under cultivation, however, they rarely exceed a yard in height. All the known species have been in cultivation in England, where, from about 1820 until a few years ago, the *Correas*, along with many other Australian plants, were among the most popular of green-house flowering plants. Several reputed hybrid *Correas* were raised in England, and numerous varieties were known, so that at least a score of named kinds may be found mentioned in old lists. For garden purposes it will be most convenient to call the kinds by the names under which they are grown, as it is somewhat difficult to understand why botanists refer *C. cardinalis*, *C. Backhousiana* and *C. pulchella* to *C. speciosa*, the plants known in gardens under these names being abundantly distinct.

Correas are among the most beautiful of hard-wooded green-house plants. They are easily managed, form nice shapely bushes and blossom freely every spring, often continuing in flower till midsummer. They are rarely seen in modern collections, having been crowded out by quicker growing and more gaudy-colored plants. A beginner often fails with them through treating them as if they were *Fuchsias* or *Pelargoniums*, and, growing disgusted with their behavior, discards them as worthless. And yet a well-grown *Correa* when in full flower is a perfect picture of elegance.

When propagated by cuttings these should be about three inches long, and composed of ripened wood of the last year's growth. They should be planted in very sandy peat and placed in a close frame, where the temperature is about 65°. Here they ought to be rooted in about two months. Grafting is, however, the most common method, as good plants are obtained more quickly, and the weaker kinds thrive better when grafted on a strong-growing stock than when on their own roots. *C. alba* forms the best stock for all the kinds except *C. cardinalis*, which should be grafted on a sturdy variety of *C. speciosa*. The stocks should be young, and the grafts similar to the pieces preferred for cuttings. Side graft-

ing, close to the base of the stock, and allowing the top to remain, always proves successful. February is the most favorable time for this operation. The worked plants should be placed in a close frame where the temperature is about 60°, and if looked after they will be united in about six weeks. The top of the stock may then be pinched out, leaving the lower part till after the cion has made a little growth. The young plants should be grown in an intermediate and somewhat close temperature, and kept bushy by pinching out the tops of the strongest shoots. In winter a temperature of not lower than 45° at night should be maintained. In April the plants should be re-potted in a mixture of peat two parts, leaf-

mould one part, and a good addition of silver sand. The soil should be pressed in firmly. During summer a sprinkling of water overhead should be given twice daily. Some of the kinds branch freely and keep compact in habit, whilst others must be frequently stopped to prevent them from becoming leggy. The plants require sufficient water to keep the soil moist, without its ever becoming saturated. They like plenty of sunlight, shading only for an hour or two at midday during summer. As the plants get larger a shift into a larger pot every two years or so will be sufficient. By judiciously staking the young plants, handsome bushy specimens can be grown in about four years. Of course the plants flower freely and regularly every year from the first. Small specimens in four-inch pots make pretty table plants. The flowers are useful for cutting, and last several days in water. The robust growing kinds such as *C. alba*, *C. Laurenciana*, *C. Backhousiana* and *C. speciosa* will thrive well when planted in a bed in a sunny position in an ordinary conservatory. Large examples of these kinds have been grown by treating them in this way at Kew. They bear cutting back heavily without suffering; this treatment is recommended for leggy or unshapely specimens.

Fig. 97.—Japanese Chrysanthemum—Medusa.—See page 100.

The following are the best of the cultivated kinds:

C. cardinalis; introduced by Veitch in 1856. It has an erect, somewhat thin habit, the branches dark brown and shining when old, tomentose when young. The leaves are one and a half inches long, half an inch broad, recurved at the edges, dark green above, pale and wooly on the under side. Flowers drooping on the ends of the numerous small branches, one and a half inches long, tubular, bright scarlet, with segments reflexed, greenish yellow; anthers exserted, yellow.

C. speciosa-major; introduced in the last century. An erect, bushy species, covered with a rusty tomentum, branching freely, and crowded with oblong leaves one inch long.

Flowers on short axillary branches, tubular, one and a quarter inches long, erect or drooping; color, deep crimson, with bright green on the scarcely reflexed segments. An easily grown and handsome plant, the best forms of it almost equaling *C. cardinalis*.

C. ventricosa; very similar to the last mentioned, the only difference being in the form of the flowers, and which is described by the name.

C. pulchella; introduced by Low in 1824. It forms a compact shrub, about two feet high, freely branched, crowded with cordate-ovate leaves one inch long, which are wooly when young, smooth and dark green when old. The flowers are pendent, tubular, one and a half inches long, the segments spreading; color uniform, bright rosy red, calyx green, stamens exserted, yellow.

C. magnifica; a compact, much-branched shrub, about two feet high, with orticular leaves, every part covered with a brown tomentum. Flowers not always drooping, tubular, one and a quarter inches long, white, covered with minute stellate clusters of scale-like hairs. This is probably of garden origin, the result of a cross between *C. alba* and some other species.

C. Laurenciana; the largest grower of all. The type is not particularly handsome, having leathery leaves, one and a half to two inches long, smooth, shining above, tomentose beneath; flowers in pairs or threes on the ends of short branches, greenish. It attains a height of thirty feet in Australia. A large red-flowered variety of this has been discovered in Australia by Baron von Mueller, but although frequent attempts have been made to introduce it, this evidently magnificent shrub remains still unknown in gardens. Seeds of it do not appear to be obtainable.

Other species are *C. alba*, which has small greenish-white flowers, and is grown principally as a stock for grafting the weaker kinds upon; *C. amula*, with orbicular leaves and purplish flowers, sometimes met with in gardens under the name of *C. Colvillei*; *C. Backhousiana*, with ovate, thick, felt-like leaves, and tubular, yellowish green flowers; *C. longiflora*, very likely a form of *C. speciosa*; *C. Brilliant*, of garden origin, with long tubular flowers, and *C. Harrisii*, a hybrid of inferior merit. Those here described at length are really beautiful and useful plants for the green-house, where they flower from December to April, and even longer.

Kew.

Roses.

Shallow Benches or Solid Beds for forcing Roses.—The question, Which possesses most advantages for Rose forcing, solid beds or shallow benches raised up from the ground, is still discussed among growers; and each plan has earnest advocates.

That both systems have advantages, under different conditions, has been frequently proved, but how to decide which method is the better adapted to particular circumstances has been a knotty question with many cultivators.

It has been stated in favor of the bench system that the condition of the roots was under better control, and that in consequence the plants were not likely to take so long a rest between crops, and the output was thereby increased, and also that there was less risk of over-watering.

Of course, it is quite natural that the evaporation will be much more rapid from a bench containing from three to four inches of soil than from a solid bed on the ground level. This is a strong point in favor of the bench system. Another advantage will be found by cultivators whose places are situated in large cities in the saving of soil by this method, this being a point of much importance where the supply of good soil within easy reach is limited, as frequently happens in such cases. And in any case there is much less labor to be performed in the preparation of the benches than in that of the solid beds. But there are other things to be considered. Prominent among them is the fact that many of the Roses used for forcing produced better flowers the second year than the first, as, for instance, Catherine Mermet, The Bride and Bon Silene, and it is undoubtedly easier to keep these plants in good condition during the summer months, when they are planted out in a solid bed than when they are planted on a bench exposed on all sides to the air, and liable to be heated all through by the sun to a much greater degree than is necessary for the welfare of the Roses.

It seems, therefore, that it would be wiser to adopt an intermediate practice rather than to condemn either system entirely, and use the bench plan for those varieties most sensitive at the roots, as Niphetos, Papa Gontier, Duke of Connaught and others of similar characteristics, and the solid-bed method for the stronger-growing more permanent sorts.

But the solid beds would often produce a better result if more care were given to their preparation, especially in regard to drainage, as a bed placed directly on a hard sub-soil is almost certain to become too wet during the winter.

A better practice is to make the total depth of the bed from fifteen to eighteen inches, all of which should be above the level of the ground, and to prepare it as follows, with such modifications as the circumstances may require:

Fill in the bottom of the bed to a depth of eight or ten inches with broken bricks, stones, clinkers or coarse cinders, and on this place a layer of good sod, grass side down, after which the bed may be filled up with the usual mixture of soil and fertilizers. A bed prepared on this principle will usually keep in good condition for several seasons, and may be refilled with soil without disturbing the drainage. And in the construction and preparation of benches for a similar purpose, due regard should also be had to drainage, as it will be found that a little care in this respect will be well repaid.

A good way to accomplish this is by building the bench of lumber six inches in width, with a space of from half an inch to an inch between the boards, as these spaces are readily covered by using the rougher soil in the bottom of the bench, thus forming a ready means of egress for the water.

Chestnut lumber will be found to last the longest for benching, but as this is not easily procured in all localities, it is not very often seen in use for this purpose, though where it has been thoroughly tested the report is usually favorable. W.

Shrubby Begonias.

THE great variety now to be found in Begonias has placed them in the front rank as decorative plants. Growing as they do without coaxing of any kind, always bright and cheerful in appearance, handsome either in foliage or flower, or both, they deserve a wider appreciation than is now accorded them.

In the spring of last year I made a selection of the best kinds, including many of the new French hybrids, and for the past two months, or since *Chrysanthemums* are out of bloom, they have been truly beautiful. They were treated as follows: Small plants in two-inch pots (two of each variety) were re-potted into four-inch pots about the middle of April last, and kept in a partially shaded green-house, without fire heat, until the end of May. They were then shifted into six-inch pots and the points of the shoots were pinched out so as to make them bushy. The soil used was a rich sandy loam of light texture. A few days afterwards they were placed out-of-doors in a shady place having a north-west exposure, watered as required, and finally shifted into eight-inch pots at the end of August, and removed to the green-house where they are to-day. The night temperature has been kept at an average of 55°. An occasional watering with liquid manure has been given, which helps materially to keep up a uniform growth. Several of the plants are now covered with bloom, while others have long scapes of brilliant coloring standing boldly out from the foliage. Some of the most striking kinds are to be found in the list which follows:

B. Gloire de Sceaux.—Bushy habit, with medium-sized, deep purple-bronzed leaves of a most exquisite shade; the flowers, literally covering the plant, are of a lovely peach-pink color.

B. Rubra (coccinea).—A very old species, with richest coral-scarlet flowers, flowering freely as small plants, but at its best when grown into large plants.

B. Incarnata. (Insigne).—Flowers large, deep flesh pink, plant bushy and very showy.

B. Diadema.—A distinct species, having palm-shaped leaves of bright sea-green, marbled with olive-green and spotted with white; flowers white.

B. Alba picta.—A little gem, having narrow lanceolate leaves, dotted all over with white spots. The flowers are greenish white, shaded with bronze, in panicles from the under side of plant.

B. Olbia.—Olive-green, metallic shaded leaves peculiarly formed and disposed, flowers very large, greenish-white, produced from the axils of the leaves on the main stem; an effective kind.

B. semperflorens rubra.—Bright, shining green foliage, with large panicles of carmine-red flowers. Another variety of *semperflorens*, *Amelia*, has larger and brighter flowers.

B. discolor, MADAM LENNET.—Leaves olive-green, marbled with gray-white, flowers large, deep pink.

B. discolor, M. HARDY.—Leaves deep reddish-bronze, marked with white, flowers rose.

B. PRESIDENT BONNEVILLE.—Leaves marbled silver, on bronzy shaded ground, flowers silvery pink, very handsome.

B. Manicata aurea.—One of the oldest species, with distinctly mottled yellow and green leaves; a very effective and beautiful plant.

Pearl River, N. Y.

John Thorpe.

Orchid Notes.

Stauritis (*Vanda*) *gigantea*.—As its name implies, this Orchid is of giant growth and noble appearance, but is only suitable for large houses. It is not by any means as attractive as *S. Batemanni*. The stout stem is closely clasped by dark green leaves about two feet long, tough and fleshy. The axillary racemes are very stout, pendulous, and bear twelve to eighteen thick, fleshy flowers, about three inches across, of deep yellow, blotched and spotted with reddish crimson. The small lip is incurved and channeled. This plant was introduced, thirty years ago, from Burmah, but it rarely blooms, though now it flowers here every year. It did not do so until it was nearly three feet high. It requires strong heat and abundance of water during growth.

feet long, bearing numerous bright yellow flowers of good size. The sepals and petals are wavy and specked with red. It is a native of Guatemala, and requires the temperature of the intermediate house, with very little potting material, which may consist of lumps of charcoal and a little moss. It should be kept moderately dry during the winter.

Angraecum citratum is a choice and attractive little Orchid, and the freest bloomer of the genus. It is dwarf and compact, with oblong, lanceolate, dark-green leaves, from the axils of which spring the slender, pendulous racemes, sometimes two feet long, closely set with pale, yellowish-white flowers in two rows. Sometimes as many as fifty flowers are on a raceme, and when four or five of these are borne on one plant it forms a very charming object, which remains in full beauty a long time. This plant was introduced, about twenty years ago, from Madagascar, and should be grown in moss and chopped leaves—in baskets—placed in the warmest house with a good supply of water, and should at no time be dry.

Lycaste (*Colax*) *jugosa* is an attractive little plant, with ovate, pointed bulbs and lanceolate, acuminate leaves. The erect

The Terrace Garden at Wellesley.—See page 98.

Phajus maculatus is a showy Orchid of strong growth, making a fine decorative plant, but of little use for cutting, as the flowers are as easily damaged as those of a Camellia. It forms large, ovate bulbs, terminated with ovate, lanceolate, plicate leaves nearly three feet long, dark green, copiously spotted with yellow. The scapes—generally two—are about two feet long, and bear fifteen to twenty bright yellow, fleshy flowers. The lip is streaked with reddish-brown, the middle lobe much crenated and margined with the same color. This plant is not seen as often as its merits deserve. It grows very freely in ordinary stove-plant soil, with the usual treatment of these plants. But when growth is finished it should be kept in a comparatively cool house. The variety *Intermedia* differs from the type only in the foliage, which is devoid of variegation.

Oncidium Cavendishianum.—An extremely useful species, lasting a long time in perfection, and especially useful for cutting. It belongs to the bulbless section, with thick, fleshy leaves, which are broad and about a foot long. From the base of the leaves springs the strong panicle, three to four

scape appears with the young growth, and bears three to four very handsome flowers, with sepals and petals of a creamy white—the latter barred and blotched with chocolate-purple. The small lip is of velvety texture; white, streaked and dotted with dark purple. It is a native of Brazil, and grows best with us in the warmest house, with copious supplies of water, and potted in peat and moss. Thrips are very troublesome to this plant, and a sure preventive is always to water overhead.

Kenwood, N. Y.

F. Goldring.

Epidendrum Endresii is one of the prettiest of dwarf-growing species but is now rarely seen. It is remarkable for its free flowering and lasting qualities, remaining fully eight weeks in good condition on the plant. The flowers of a well-grown plant are most beautiful, their snow-white sepals and petals contrasting agreeably with the lip, which is blotched with violet. In Mr. Wallace's collection at Paterson, New Jersey, a strong plant in fine health is now flowering, having a number of spikes covered with blossoms from the apex of thin grass-like stems. It is a native of Costa Rica, and thrives at an altitude of 6,000 to 8,000 feet, where it is cool at all seasons.

Many attempts have been made to import this plant in quantity, but every consignment, no matter how it may be packed, is almost worthless on its arrival, and very few plants survive the close and impure atmosphere to which they are subjected on their passage to this country. This Orchid will, in all probability, therefore, remain a rare plant for years to come. It grows very freely at the coolest end of the Cattleya-house in a shady situation, and should occupy a basket or pan suspended as near the light as possible, in a mixture of clear sphagnum and rough, fibrous peat, with ample drainage. In full sunlight its thin, fleshy stems will soon become weak and perish.

Summit, N. J.

A. Dimmock.

Some Choice Narcissus.—The beautiful little *N. Cyclamineus* has proved to be of easy culture. Collected bulbs flowering with us for the second season, show a marked improvement, both in size and quantity of bloom. Let us hope that this little gem, after having been lost to cultivation for more than 250 years, has come at last to stay. *N. triandrus*, from Portugal, is now opening in abundance its pretty, pale, pendent flowers. This is often considered hard to keep, but thrives well here under the treatment given to others of its class in a soil of two parts loam to one of peat. The varieties of *N. Bulbocodium* give a display for several months, commencing with var. *monophyllus*, which is white and of the characteristic "Hoop Petticoat" form. Var. *citrinus* comes next, with pale yellow flowers, which are just now at their best. *N. Bulbocodium* is the last in order of flowering, and comes a month later. We have also a form of *N. Bulbocodium* from Portugal which is quite distinct, no two bulbs producing flowers alike, but differing principally in the cut-off appearance of the corona. To the above may be added *N. serotinus* and *N. juncaefolius*, making an interesting collection for those who have small space at their disposal. All the above-named do well in five-inch pots at a temperature of 50° to 55°.

Passaic, N. J.

E. O. Orpet.

Principles of Physiological Botany as Applied to Horticulture and Forestry.

IX. CHANGES OF ORGANIC MATTER WITHIN THE PLANT (Continued).

WE have already seen that the first product of assimilation proper, that process by which the plant converts inorganic materials under certain conditions into organic matter, is probably some form of sugar. In the last paper it was pointed out that this primary substance bears peculiar relations to starch, the first visible solid product of assimilation. We are now to examine the physiological relations of the group to which sugar belongs and see in what way this is utilized by the plant as food.

There are three chief groups of sugars found in plants. They differ from each other in the proportions of hydrogen and oxygen which they contain, and they possess somewhat different physical properties. They are known as (1) the directly fermentable, (2) the indirectly fermentable, and (3) the non-fermentable; that is, they sustain different relations to certain microscopic organisms by which the process of fermentation is carried on.

The sugars of the first group may be represented by grape sugar, sometimes known as glucose, which occurs to the amount of five to thirty per cent. in certain ripe fruits. It is crystallizable, but lacks the high degree of sweetness which we associate with the type of the second class, namely, cane sugar. This latter is the sugar of the sugar cane, and of the sugar beet, and of sorghum, but it is generally associated with a certain amount of other forms of sugar, and by the very process of extraction a portion of the cane sugar may be more or less completely transformed into the less desirable kinds. The third group is represented by a substance which may be procured from certain Acacias, etc. Sugars of the last group are wholly incapable of ordinary saccharine fermentation; those of the second ferment only after they have become acted on by some agent which partially modifies their original character, while those of the first are very easily, and, as one may say, directly fermentable under almost any conditions. But all of these, like members of the starch series, are capable of undergoing oxidation, giving up thereby a portion of their energy of position, which reappears as energy of motion. The ultimate products of the complete conversion of these substances are carbon dioxide and water, the inorganic materials from which they were first brought together by the agency of the plant under the influence of the sunlight.

It should be borne in mind that the few sugars here

mentioned are only representatives of classes, and that these classes by no means exhaust the list. Moreover, it should be remembered that the sugars occur in different amounts in different plants, and, as is the case with many other substances, in different amounts in different parts, and, in the same part, at different periods of its development.

The second great group of substances containing carbon, hydrogen and oxygen, but no nitrogen, is that of the vegetable fats or oils. These are of very complex composition, and do not need to be here commented on from a chemical point of view, further than to take note of the fact that they contain relatively less oxygen than the substances before mentioned.

The fats or oils sustain peculiar relations to the living matter of the plant, especially while the latter is in a state of rest or of suspended activity, as in the case of ripe seeds. It is interesting to observe that the seeds of by far the greater proportion of species contain their food stored up, not in the form of starch, but of oil of some sort. In many cases the oil is capable of drying when exposed to the air, as is the case with that of flax seed (linseed oil), while in others it does not thicken rapidly, if at all. Oils of the first sort are extensively used in ordinary painting. The so-called volatile oils, such as the fragrant oils of the different members of the Mint order, are closely related to the turpentine, and are not to be confounded with members of the group of true fats.

It is a curious fact that in some, if not most, cases thus far observed, the fats or oils of seeds are in part transformed into other carbo-hydrates, such as starch, before they are utilized by the seedling. Thus the seed-leaves of the Castor-bean have been shown to take from the general supply a certain portion of the oil as such, and during conveyance to other parts, or somewhat later, to transform at least some of it into starch, which can be detected in the form of characteristic granules.

The third group of these substances free from nitrogen comprises the vegetable acids, such as Tartaric (in grapes), Malic (in apples), Citric (in lemons), and the like. Most of these are found in different proportions, and are never free from admixture, so that we may find even more than two of these in the same fruit, some of them occurring, perhaps, in mere traces only. One of the vegetable acids most frequently found is Oxalic, which is generally combined with calcium to form crystals of calcium oxalate, abundant in plants. In other cases it unites with potassium. In most instances there is also more or less of this acid remaining uncombined. It is difficult to form a clear conception of the direct use of these acids to the plant, except so far as they play an important part in the protection of the plant or some of its organs, as, for instance, its fruits, from unwelcome guests. This aspect of the subject will be examined at a later period, when we come to glance at the methods of dissemination of seeds.

Among the less important substances, which may be alluded to in connection with those now examined, are various astringent matters; for instance, members of the Tannin group. These occur in almost every part of the plant at some period of its growth. Widely different views have been entertained as to the origin and the probable use by the plant of these substances, some investigators holding that the members of the tannin series are waste matters, while others believe that they are reserve materials. In some cases they seem to have a very plain function in defending the plant from its enemies, but this, which is only a specialized office, will be incidentally referred to later. Associated with the tannin-like bodies are the curious principles which occur in certain barks, such as æsculin, in the bark of the Horse-chestnut, etc.

From the extremely long list of other substances free from nitrogen, only the following can now be noticed in passing: (1) the ethereal oils, compounds of carbon and hydrogen, and (2) the resinous matters, which are much the same as the last, but are combined with more or less oxygen. Both of these classes of substances are obscure in their origin in the vegetable laboratory, and in most cases it is difficult to hazard any reasonable conjecture as to their work in the plant. Probably they always have or have had some office of attraction (as is clear in the instance of the perfumes of certain flowers), or of defence, as is seen in innumerable cases. But we may possibly get a hint as to their office and occurrence when we remember that during the life of a given species its surroundings must have changed in many ways, and that possibly attractions and modes of defence required at an earlier stage are now no longer useful to the plants under existing conditions. And it is well known that a great many peculiarities of all sorts persist long after the conditions to which they were adapted, or which may have called them forth, have passed away.

In concluding this sketch of the substances free from nitrogen, we are now able to say that they fall naturally into two

classes—those which serve as treasuries of energy and those which subserve some minor but doubtless important end. We turn next to glance at that group of substances in which is found the vehicle of all these activities which present themselves when the energy treasured in the plant is released and manifests itself to us in some other way.

Cambridge, Mass.

George Lincoln Goodale.

The Forest.

The Forests of Michigan.

The first report of the directors of the State Forestry Commission of Michigan is a remarkably interesting and valuable document. It includes the law establishing the Commission, an account of a forestry convention at Grand Rapids, at which there seems to have been a much larger proportion of practical and sensible talk than is usual at such meetings, a list of trees and shrubs found in Michigan, and a large number of useful illustrations, which show the appearance and habit of growth of some of the principal trees of the state. The most important portions of the report are the brief and admirable discussions by Professor W. J. Beal of such subjects as forest-management in southern Michigan, forest-fires, the succession of forests in northern Michigan, cutting and removing logs for lumber, a lumber-camp, new uses for certain kinds of timber and the amount of pine yet remaining in Michigan.

The law provides for sending questions to the township-supervisors of the state regarding the area of forest-land, the origin and extent of fires and resulting damage, and the need of additional forest-legislation. The answers are not always very important, but the practice of sending out such questions has great value as a means of popular education regarding forestry subjects.

There are interesting communications from Professor A. J. Cook, Eugene Davenport, A. C. Glidden, A. A. Luce, T. T. Lyon (President of the Michigan Horticultural Society), Geo. D. Moore, W. K. Sexton, Professor V. M. Spalding, B. W. Steere, A. S. Kedzie, J. H. Moores, Geo. C. Nevins, and Hon. John T. Rich, Commissioner of Railroads. There is pretty uniform testimony that pasturage destroys the forest. But one gentleman says: "It is customary to pasture timber-lots. I consider it no injury to the trees, and but little benefit to the stock, except in the way of shade." If his judgment is correct, domestic animals might as well be kept out of Michigan woods.

There are several pages of apt quotations from this journal. The officers of the Commission are: Hon. Franklin Wells, President; Hon. Henry G. Reynolds, Secretary; Hon. Wm. B. McCreery, Auditor; Dr. W. J. Beal, of Agricultural College, and Hon. Chas. W. Garfield, Grand Rapids, Directors.

If every public library in the country could have a copy of this report it would vitally aid the work of popular education regarding forestry. An appendix contains the laws of Michigan relating to forests.

We make the following extracts from an address by Col. E. T. Ensign, of Colorado, at the Forestry Congress at Atlanta, last December, on the Colorado Forestry System.

The Colorado State Forestry Association was the first fruit of systematic local agitation of the forestry question. After its organization followed the enactment of a forest law in 1885. It created the office of State Forest Commissioner, and made the County Commissioners and Road Overseers through the state forest-officers for their own districts. The Commissioner has an annual salary, office equipments and traveling allowances. The county officers are paid *per diem* by the counties for services rendered. These officers are charged with the oversight of the public forests, they are to guard them against depredation and the outbreak and spread of fires, and they are to promote the culture of forest trees.

There are penalties for the willful or careless setting of forest fires, and for failure to extinguish camp-fires. The county officers must post notices conspicuously along the highways, warning travelers to put out their camp-fires, and citing penalties for failure to do so. Arboriculture is taught at the State Agricultural College, and provision has been made for the establishment of four experiment stations in different parts of the state. Forest-fires have become less frequent and destructive, and federal officers are aided somewhat to protect the timber on the national domain. Special effort has been made to show the intimate relations between the mountain forests and the streams of the state and its irrigation system. The forestry system of Colorado is an effort to improve local forest conditions. It deals with new methods, and seeks

to adapt itself to conditions unlike those existing elsewhere. It should be maintained until a more efficient system can be devised and put in operation.

Correspondence.

Forest Changes in Rhode Island.

To the Editor of GARDEN AND FOREST:

Sir.—When Roger Williams entered the Narragansett country and landed at what is now Providence, he had passed through a Pine and Cedar country. The slopes of the Moss-hassuck, of the Blackstone and Seekouk were heavily covered with Pine and Cedar. The stately Pine towered high and spoke to the winds; the Cedars were large and thick. There was Oak, but not in abundance. Now, confining myself to the region north of Providence, for a few miles of which I am familiar in ministerial work, I find that wherever the Pine has been cut down, not the Pine, but the Oak, has appeared. In Lincoln township there is abundance of Oak. Let us suppose ourselves in Pawtucket, a city adjoining Providence; we reach the end of Dexter Street, and for half a mile have woods. Much of it is little, scraggy Oak, in outer appearance like the Oak-forests I have often surveyed in central Illinois. Ascending the hill towards Saylesville, we see rising out of these puny Oaks perhaps twenty tall Pines, isolated and magnificent, and as graceful as any I ever saw. They stand alone like the pillars of the Temple of Jupiter Stator, monuments of a splendid arboreal age, when all those hills and valleys were filled with their brethren. In Saylesville itself, south of the bleacheries, and all alone, stands one of the most perfect and magnificent Pines in Rhode Island, its spreading branches a dark, rich, beautiful green. Above, around the rising hill, is the Oak. Between Saylesville and Pawtucket is a forest, a few tall Pines, but invariably where there has been a cutting is the Oak. Now, why is it that in this section of Rhode Island Oaks succeeds Pine? The Pines disappear. Tall and stately, and beautiful and strong, they have no successors. I tremble for that grand, unparalleled tree in Saylesville. It stands unique, and if your widely read journal can induce some Rhode Island photographer to take its picture I shall rejoice. It may be removed at any time from business necessity.

Providence, R. I.

Henry H. Northrop.

[The changes in the character of the forest-growth noticed by our correspondent in the neighborhood of Providence are gradually going on in many different parts of the country. They represent the bad effects which invariably follow ignorance in the management of the soil, whether it be the rich Corn-land or Cotton-land of the west or south, or the Pine-producing drift of New England. We are paying now, and dearly, for the mistakes made by earlier generations in the treatment of the soil in the first settled parts of the country, and we owe it to ourselves and to the generations which are to follow us, that the same charges are not made against us by our children's children. Land which produces large Pine trees does not produce vigorous or valuable Oaks. If the forests that once covered the gravelly plains and hills which surround Providence had not been disturbed by man; if the trees had not all been cut off and the surface soil licked up by constant burning, they would have been composed principally to-day of large White Pines and Cedars, as they were two hundred years ago. Fire and exposure are fatal to seedling White Pines. It is found that the seed of this tree does not germinate in soil which has recently been burned; and that the seedlings, when the seeds do germinate, perish when they are too much exposed to the sunlight, as is the case when the forest has been entirely cut away. The fact, however, that White Pines germinate freely and grow rapidly on abandoned pastures and old fields in many parts of New England, shows that the changed character of the soil consequent upon burning has more to do with the inability of this tree to reproduce itself upon ground recently cleared of a forest of Pines, than the exposure to light which follows clean cutting. The nature of the Pine and the Oak being understood, it is not difficult to see why, under the methods of forest-mismanagement which exist in this country, the latter is gradually taking the place of the former. An acorn may be carried by animals into the

midst of a Pine forest. It has the power of germinating and of existing almost indefinitely in deep shade. A feeble shoot only, perhaps, appears above the surface, hardly increasing perceptibly from year to year, while below the root goes on extending deeper and deeper. At the end of a century, perhaps, the Pines which shaded the Oak and checked its upward growth are destroyed, either by fire or by the axe. The Oak is broken off close to the ground, or fire consumes what appears above the surface. The Oak, however, has what the Pine does not have—the power to send up shoots from the stump—and the great root, which has been growing for years, at last has the opportunity to assert itself, and send up a strong, stout stem, or a cluster of stems, which occupy the ground, and so change the character of the next forest-crop. It is not probable, however, that there could have been enough Oaks growing in this way in any forest of Pines to change at once its character, and seedling Pines would appear among the Oaks, especially if the ground had not been burned over. But fires, if they do not do the damage the first year, are almost sure to come, sooner or later, and as they destroy the Pines and do not destroy the Oaks (for an Oak can be burned several times without destroying the vitality of the stump), every time a piece of ground is burned over the hold of the Oaks is strengthened as that of the Pines is weakened. This is why land which once grew large and valuable Pines now only produces small, stunted and worthless Oaks. This is what has been going on for a century or more all over New England and everywhere in the White Pine belt of the north. Mismanagement in the south is converting the valuable forests of the Long-leaved Pine into comparatively worthless forests of Old Field Pine. In Kentucky and in Tennessee mismanagement is gradually changing the forests of valuable White Oaks into forests of worthless Black Oaks, and all through the mountain forests of the West, Spruces and Firs and Pines are being replaced by miserable Aspens. Mismanagement growing out of disregard of the simplest laws of nature and of economy is slowly destroying the fertility and changing the character of the plant-covering of the whole North American continent. Such forces of nature work slowly, and the results, perhaps, are hardly noticed from generation to generation of men. But at length people, like our correspondent, begin to ask themselves, "Why is it that this land which, when it was first known, was covered with great forests of Pine, now only bears a feeble growth of stunted Oaks, and what has become of the fertility for which this region was once so famous?" It is easier to find the answer to such questions than it is to suggest the remedy for the conditions which give rise to them. But with such examples before our eyes as all the earliest-settled parts of this continent afford, there seems little excuse for the condition of things which already begins to prevail even in those regions where the balances of nature have not yet been seriously, or at least not irreparably, disturbed.—ED.]

To the Editor of GARDEN AND FOREST:

Sir.—It would not be safe, in my opinion, to trust to the innocuous character of that variety of *Rhus toxicodendron* with entire leaves upon such negative evidence as that presented in the communication published in your journal of February 6th. It is, of course, generally impossible for the physician to determine which variety has produced the cutaneous inflammation in individual cases, as the patient is almost always ignorant of such distinctions in the forms of leaves, even if able to recognize the plant at all.

I have in my office mounted, dried specimens of all the varieties of foliage of *Rhus toxicodendron* and *R. venenata*, and have frequently asked intelligent patients to point out which of the forms was the culpable agent in their case, and have seen no grounds for regarding the lobed leaflets of *R. toxicodendron* as more virulent than those with entire edges. I was certainly acquainted with one vine of the latter variety, which had been cultivated upon a building in ignorance of its nature, which severely poisoned at least two or three persons in one season. The great majority of persons are not affected by either variety.

It is interesting to know that persons "especially subject to Ivy poisoning" escaped last season, as described by your correspondent.

Boston, Feb. 7th.

James C. White.

To the Editor of GARDEN AND FOREST:

Sir.—In a recent number of a western horticultural journal I find the following: "Have you ever walked along the street of some city and observed the fragrance arising from the baskets of certain 'Rose seed' or 'Lavender bloom' venders? Well, when you do see them, don't invest in these wares unless you enjoy being fooled. The articles are offered for placing among clothes, and are 'warranted' never to lose their fragrance, but a dozen times a day the venders retire for a bit, and in some unobserved place squirt perfume over their stock to keep an odor about it. Anything that rattles in the envelopes does duty for the seeds or dry leaves."

Here in New York such frauds are common, and it seems as though there should be some way to prevent ignorant purchasers from being thus imposed upon. Not long ago I saw several peddlers on Twenty-third Street who were actually offering "Attar-of-Rose seed" for sale—the seed, that is, not of a plant, but of a perfume! There could hardly be a more transparent deception, yet it seemed to find many victims. From curiosity I ranked myself among them, and bought a ten-cent package of what looked like Pumpkin seeds. In twenty-four hours, of course, the strong scent which the package had emitted was wholly gone. On the other hand, the Lavender which is often sold on our streets in autumn seems to be the genuine article, may be bought either in dried twigs or in a powdered form, and keeps its delicate, fresh odor for a considerable length of time.

New York City.

W. K. G.

To the Editor of GARDEN AND FOREST:

Sir.—It may be interesting to note that *Nymphaea odorata* occasionally grows out of water. At Baur's Lay, on Buzzard's Bay, in 1888, pools which are such in spring, but which in summer are absolutely free from surface moisture, so as not to even dampen the shoes in walking over them, abounded with this plant. The leaves were large, but not unusually large, short petioled and healthy. The blooms had very short peduncles and the flowers were far larger than those that were found in water near by. It is not uncommon to notice the *N. odorata* blooming luxuriantly on the edges of ponds where the water has retreated, but this is the only instance I have observed of their growing when the ground was dry, without moisture in reach of discovery by digging with a jack knife.

It is not generally understood that some marsh plants will thrive far better in proper soil, different from their natural habitat, than in a state of nature. This instance given above is an analogous illustration with a water plant. It would be well for some of our cultivators to make a trial of growing the Pond Lily in the same manner as the Calla is now treated.

South Framingham, Mass.

Recent Publications.

Gartenkunst und Gaerten Sonst und Jetzt. Von H. Jaeger, Berlin, Paul Parey.

This book, the title of which may be somewhat clumsily translated as "Gardening Art and Gardens in Former and in Present Times," is one of the most valuable to the student of the subjects with which it deals that has yet been published. Its author holds the position of Royal Garden Inspector at Eisenach, and had published in 1877 a "Handbook of Gardening Art" for the practical instruction of members of his profession, which, we believe, is regarded in Germany as one of the best works of its class. The present work is primarily a popular history, not a theoretical or practical treatise. Yet the author's long personal experience in the planning and conservation of gardens, and the didactic habit of mind characteristic of the German intellect in general, have combined to bring within its covers many pages and incidental paragraphs of a theoretical, explanatory, and directly instructive sort. The reader, therefore, may learn from it not only what have been the efforts of gardeners in every age of the world, but how those efforts resulted from the point of view of abstract beauty, and also how they may best be utilized as precedents for modern practice. It is primarily a history, but, likewise, as its sub-title indicates, a general guide-book for the gardener, architect and amateur. The architect, especially, may learn much from its pages, for seldom has a treatise been written in which the respective qualities and claims of architectural and of gardening art are so systematically considered in the only right and proper way—that is to say, not separately, as the qualities and claims of two

rival arts, but together, as those of sister arts, each of which is dependent upon the other and neither of which can be properly practiced or appreciated if the other is left out of mind. Moreover, while most extended treatises on the history of gardening have been issued in large and costly tomes, this one forms but a single volume of about 550 pages of large octavo size, and costs less than \$5. Of course its illustrations are not so beautiful as those in more sumptuous and costly books; but they are very well selected; their number (250) makes up for their lack of size; the recent development of photographic art has permitted the inclusion of pictures of many gardens not hitherto familiar to the student's eye, and the numerous plans are clearly printed and sufficiently large to be easily understood. In short, the book is the most useful one of its kind of which we know; none in French or English exactly fills its place as being at once scholarly in point of view and popular in tone, and the gardener, architect or amateur who can read it in German is to be envied by his less fortunate fellows.

The introduction is one of the most interesting chapters in the book. It explains, among other things, that in all the earlier ages of the world, when a great part of the earth's surface remained in its primitive condition, formal gardens were exclusively created, natural gardens taking rank as works of art only when the savage beauties of nature had been so far subdued that a modified return to them meant novelty and refreshment for the soul of man. The first chapter deals with the gardening art of Egypt, Asia Minor, Persia, and Greece and its colonies. A long chapter on Roman Gardens follows, and a necessarily shorter one—for here the subject itself is less rich and sources of information are slenderer—on mediæval developments. The Italian Renaissance is then taken up, and its period of full bloom—when such men as Michael Angelo and Giulio Romano concerned themselves with the laying out of gardens—is fully treated. The spread of Italian ideas and their degeneracy into baroque, puerile and grotesque phases is then followed; next Dutch gardens are discussed, and then, at great length, the famous French period. The eighth chapter deals with the rise of true landscape-gardening in England. The ninth is devoted to the art of China and Japan, and the influence it had upon English development. Then this development is followed as it spread over the continent of Europe. Modern German gardens follow, then modern gardens in the rest of Europe, and in non-European countries, especially in America. German gardens in their estate to-day have a chapter to themselves, as do the useful gardens of the world—botanical gardens, cemeteries, winter-gardens, etc. And in a final chapter the present condition and the prospects of gardening art are theoretically considered. From this brief summary it will be guessed how rich Herr Jaeger's book must be in historical material. It is impossible within the limits of a mere review to summarize any of its historical chapters. Next week, however, we shall print some extracts having reference to American gardens, which we think will be of peculiar interest to our readers. And meanwhile we may quote a few counsels of a general sort which Herr Jaeger puts into particularly effective shape.

One of the great mistakes of modern theorists and practitioners, he says, is that they feel themselves obliged to take sides with one or the other of the great camps into which the gardeners of all time may be divided. They feel it incumbent upon them to declare distinctly in favor of the formal or of the natural style of gardening, and to exalt their chosen style to a degree which means the total denial of all worth or beauty in the other. In former times the same spirit has often manifested itself, as when, during the bloom of English landscape-gardening, countless beautiful old formal gardens were destroyed—in England itself and on the continent as well—to make room for novel arrangements often less harmonious and appropriate, and therefore less desirable in the given situation, than the arrangements they replaced. To-day almost every artist and amateur likewise professes himself a champion of the natural style, and refuses to consider the claims of architecture to a semi-architectural environment in the landscape. But the true aim of gardening art to-day, writes Herr Jaeger, should be "to unite both gardening styles—the pictorial (natural) and the symmetrical (architectural or formal)—or to use them alternately, as the exigencies of the site and of the dominant building demand the one or the other." His preference seems to be for a combination of both; not for a mixture of the two, in a disorderly, inartistic scheme, but for such a juxtaposition of contrasted elements, properly connected together and gradually leading the one into the other, as will properly support a building by symmetrical features and yet give true landscape beauty in remoter portions of the domain.

A certain measure of symmetry and architectural dignity in a garden is, indeed, naturally desired by the civilized eye; and when it is not supplied in right artistic ways is almost sure to be grasped in ignorant and inartistic ways. Theoretically, we ask only for natural effects in our gardens, and might be surprised to hear that we are always trying, in spite of theory, for symmetry and formality in line and color. But what other explanation can we give of the universal intrusion into our public and private gardens of geometrical ribbon-beds and borders, and of masses of exotic plants whose foliage is strictly architectural in character?

In this connection a final paragraph may be quoted from Herr Jaeger's pages. As bright-foliaged plants, he says, "form a contrast with the green of the main plantations, they ought to be very sparingly employed in their neighborhood. But to-day many gardeners and proprietors confuse rarity with beauty, and plant more of these bright-hued plants than is desirable—and sometimes such as are wholly insignificant intrinsically, or actually ugly. In general, the effort to introduce unfamiliar plants into a garden is a fashionable folly which can easily prove very dangerous to beauty in the result."

In conclusion, it is proper to say that Herr Jaeger's treatise has been somewhat severely criticised during the year since it appeared with regard to certain matters of historical detail. Dutch writers have accused him of patriotic bias in exaggerating the rôle which German artists played in Holland; and Austrian writers have accused him of unpatriotic bias in exaggerating the rôle which French artists played in Germany. Both accusations are based upon his account of certain individual gardens. But it must be remembered that the history of old gardens is often difficult to decipher, as they have largely lost their original estate under the successive retouching of generations of gardeners. And the main point, for the American reader at least, is not to know just who laid out this or that old garden, but to grasp the general course of the art, and the differences between its typical manifestations in this country and in that. As supplying a basis for such knowledge, we find Herr Jaeger's book all that a student could ask, while it is very pleasant reading even for those who have no serious desire to retain and put in practice the information it supplies.

Periodical Literature.

Bordeaux, which is one of the principal centres of the Vanilla trade, imports, according to the *Gardeners' Chronicle*, over 5,000 pounds annually. Most of the Vanilla imported comes from the French colony of Réunion, where the culture is of comparatively recent date. By the local dealers Vanilla is classified into four qualities. The pods of the first measure from seven to nine inches long; they possess the characteristic perfume in a greater degree than the other sorts. The Vanilla-vine, it is stated, is at times covered with efflorescence of a silvery brilliance, producing a crystallization similar to that found in the pod, and which in good specimens covers the outside of the pod. This is called Vanilla-vine, and is in great demand in the Bordeaux market. Two different methods prevail for preparing the pods for market. The first consists of harvesting the capsules after they have lost their green tint. Woolen sheets are spread upon the ground, and when thoroughly heated by the sun the pods are spread upon the sheets and exposed to the sun for a certain period; they are then put into the boxes, covered by a cloth and exposed to the sun. The fruit should assume a coffee color in twelve or fifteen hours after this last exposure. If this color is not obtained, the Vanilla is again submitted to the heat of the sun. This process occupies about two months, at the expiration of which the Vanilla is packed in tin boxes containing about fifty pods each and securely packed.

The second process consists of tying together about a thousand pods and plunging them into boiling water to bleach them, after which they are exposed to the sun for several hours, and then coated with oil or wrapped in oiled cotton to prevent the pod from bursting. During the drying the pod exudes a sticky liquid, the flow of which is promoted by gentle pressure of the pods two or three times a day. In the course of preparation for market the capsule loses about one-quarter of its original size.

The latest mail reports from Mauritius estimate that the out-turn of the coming crop in that island will be a small one, and will probably not exceed 34,000 pounds. The present market price in London for Vanilla is very good, ranging from eight shillings per pound for common to twenty-three shillings for fine sorts.

Notes.

During 1888, 100 car-loads of Lima Beans were shipped east from Santa Barbara, California.

Colonel E. T. Ensign has just been re-appointed to the office of Forest Commissioner of the State of Colorado, his present term being about to expire.

M. Godefroy-Lebeuf's new book upon *Cypripediums* is dedicated "*À la Gloire de la Maison J. Veitch & Sons, de Chelsea.*" The first part has just appeared.

Mr. H. A. Siebrecht, the well-known florist of this city, has been collecting plants in the West Indies. He writes that he has found a number of promising novelties in the mountains of Grenada.

The first number of a new Portuguese horticultural journal, "*O Floricultor*," has been issued. It is published in Oporto, and in Portuguese, with the exception of one column, "*pour les 'Etrangers.*"

At a ball recently given in New York, one apartment was exclusively decorated with Apple blossoms, another with Magna Charta Roses, a third with Orange trees in pots, and a fourth with Jonquils and blue Roman Hyacinths.

A German horticultural paper states that during the year which has recently closed no less than ninety-six new varieties of Roses were introduced into the European trade. Thirty-one florists shared in their introduction, and the list includes thirty-seven varieties of Remontant Roses and thirty-one Tea Roses.

The so-called "joss-sticks," the burning of which supplies incense for Chinese religious ceremonies, are made of the powdered leaves of *Lindera fragrans* mixed with the powdered roots of *Biota*. *Lindera fragrans* is a shrub of the true Laurel family (*Lauraceæ*), and its Chinese name means "Incense Leaves."

The Council of the Royal Horticultural Society of Great Britain intends to hold a Conference of Rosarians at the Chiswick Gardens on the 2d and 3d of July next. An exhibition of the species and varieties of Roses will be given the first day; and papers on Roses and their culture and origin are invited, and will be read and discussed during the second day.

The Royal Society of Agriculture and of Botany of Ghent will hold on the 23d of next November a grand international exhibition of Chrysanthemums, in honor of the centennial anniversary of the introduction of this now popular flower into Europe. Prizes are to be offered for the best specimens of primitive types, and for the best seedling varieties not yet in commerce.

The February issue of the *Kew Bulletin of Miscellaneous Information* is devoted to a list of the hardy herbaceous annual and perennial plants which matured seeds in the Royal Gardens last year. The seeds are available for exchange with other botanical establishments, but are not sold to the general public. This list makes a useful, although, of course, only a partial catalogue of the plants of this class cultivated in the Royal Gardens.

Flowers of the Japanese Apple (*Pyrus baccata*) have appeared this week in the window of a Broadway florist. Judged from the specimens displayed they seem to lack substance for winter forcing, and are less beautiful at this season of the year than might have been expected. The flowers of this tree are always more beautiful in bud than when fully expanded, and the branches should be cut before the flowers open if their real decorative value is to be obtained.

The twenty-second biennial meeting of the American Pomological Society was held at Ocala, Florida, on Wednesday, Thursday and Friday of last week. The attendance was large, all parts of the country being well represented. In the discussions, which were of the most interesting character, special attention was given to the fruits grown in Florida. The officers elected were: President, P. J. Berckmans, of Georgia; Vice-president, T. T. Lyons, of Michigan; Treasurer, B. G. Smith, of Massachusetts; Secretary, A. A. Crozier, of Iowa. Members were entertained with generous hospitality by the Horticultural Society of Florida, at whose invitation the meeting was held in that State. The exhibition of semi-tropical plants is said to have contained the most complete and best classified collection of citrus fruits ever made in Florida.

At a recent meeting of the Royal Horticultural Society of Aberdeen it was stated that one acre of Mushrooms in "our own country" (the exact locality not stated) had produced a

crop valued at about £1,450, of which more than £950 was clear profit, while near Leeds one-sixteenth of an acre had produced 3,000 pounds of Mushrooms, which means a crop worth about £1,600 to the acre. Another speaker, on the same occasion, treating of the forestry needs of the country, said that so long ago as 1457 proprietors were ordered by government to plant trees; that in 1503, in Scotland, a fine of £5 was imposed on any one who cut down a tree, so entirely had the land been denuded of wood; that thirty years later stringent regulations were passed with regard to the extent of land which the larger proprietors were annually to plant with forest trees, and the death penalty was affixed to the third offense in the way of tree-cutting. But the last decree of an analogous nature was passed in 1661, since which time no legislation has dealt with the subject.

According to the *Carpenter and Joiner*, New York is now the largest mahogany market in the world. Thirty years ago Mahogany was known commercially as "St. Domingo," from the island of St. Domingo, and "Baywood," or "Bay Mahogany," from the vicinity of the bay of Honduras in Central America. The Central American wood was soft, of light weight, and characterless; in later years it has practically ceased coming to this market, but one cargo having arrived at the port of New York during the last six years. St. Domingo Mahogany exists in name only. The original growth of this wood on the island of St. Domingo has long since been used, and the importation of small lots at exceedingly long intervals are only of the small and stunted growth, crooked, stained and defective. Individual logs of good size and quality can be secured only occasionally. The island of Cuba furnishes considerable quantities of a smaller size, more especially valuable for small work, which is hard and of good texture, but the great bulk of the mahogany used in later years is supplied from the forests of Mexico. Southern Mexico produces not only our largest and most beautiful grades of mahogany, but also some of the softer and less desirable grades, somewhat resembling the Baywood or Honduras Mahogany of olden times.

The schedule of prizes offered during the current year by the Massachusetts Horticultural Society, amounting to \$6,000, has appeared. One-half of the amount is offered for plants and flowers; \$1,700 for fruits; \$1,000 for vegetables, and \$300 for gardens and green-houses. There are also "prospective prizes" derived from the "Benjamin B. Davis Fund," for the originators of seedling fruits, flowering plants and vegetables which are not awarded until a satisfactory trial, extending through several years, has established the real merit of the variety. Such prizes as these last are calculated to develop horticulture in the most practical and useful manner. There are some curious anomalies in this schedule of prizes which will strike all practical horticulturists. For example, a \$3 prize is offered for four bunches of Radishes; \$4 for six pots of Roman Hyacinths; while the best specimen plant among the Indian Azaleas can win only \$4—no great inducement to any one to run the risk of ruining a good plant, which may represent twenty years' careful cultivation. Prizes of \$3 for ten cucumbers and of the same amount for a peck of Dandelions are certainly liberal, when the highest prize four Heaths can get is only \$8. The largest and best collection of blooms of hardy trees and shrubs may win \$6, and on the same day twelve Beets or twelve stalks of Rhubarb may aspire to carry away \$3 each. "Stove and green-house flowering plants," if they are not Orchids, do not get much encouragement, but on the 25th of June "two distinct named varieties" can carry away \$10, and on the same day twelve Beets, if they are good ones, can earn \$3. Beets seem to be favorites in Boston. The successful cultivation of Chrysanthemums is held to be most worthy of reward, as the highest prizes offered by the Society for flowering plants go to the best collection of twenty named varieties. Aesthetic considerations have, nevertheless, due weight when the garden prizes are in question, for \$60 goes to the "best House of Orchids in bloom," while the fortunate owners of the "best Strawberry-garden or the best vineyard of one acre" must each be contented with \$50.

The Adirondack Forests.

THE complete destruction of the Adirondack forests is inevitable if existing conditions and methods of treatment are to continue. Unimportant improvements in the details of their management may be made from time to time; such improvements have been made within the last few years, and others are now proposed; but the processes of destruction are much more rapid and extensive than the effect of these comparatively insignificant means of amelioration, and there is at present no reason to expect that any effective provision will be made for the permanent protection of any part of this important region. Nothing can be done, indeed, without a thorough change in the system of control and administration of the forests on the state lands. The methods now pursued interpose no serious check to the influences which will extirpate the woods in a comparatively short time. If the devastation of the region, already far advanced, is completed, centuries of time will be required for any process of restoration.

The destruction of the North Woods will produce a change in the flow of the principal rivers of the state, and in the water-supply of the Erie Canal, which will cause widespread disaster to the interests of the people. There will be uncontrollable freshets at the times of heaviest rain-fall, and when the snow melts in the spring; the channels of the rivers will be choked by debris brought down from the hills; and in summer, when a full volume of water is most needed, the flow will be insignificant. If this ruin is consummated it will be a most serious blow to the prosperity of the state and of all classes of its people.

Not less important is the value of the region in its relation to the health and life of the people of the country, as a place of resort for the inhabitants of the towns, and for all who need the restorative and vitalizing atmosphere and influences of a region of sylvan beauty and peace. As our population becomes more dense, the need and value of wild, rough tracts, incapable of cultivation, will be greatly increased. Beyond the arrangement required for the subsistence and comfort of the multitudes of visitors, no settlement or inhabitancy should be permitted in any part of the wilderness. If the forests are destroyed the entire charm

and attractiveness of the region will be eliminated, and a scene of hideous desolation will be substituted which no one will ever wish to look upon.

The only plan by which such injury can be averted, and means provided for the permanent conservation of these invaluable forests, is the acquisition by the state of the entire Adirondack region. While portions of it remain in the hands of private owners, injuries to state-lands adjacent to their holdings cannot be prevented. But it would be senseless and wicked to expend the money which would be required for this purpose while the present system of control continues. It has proved entirely inadequate for the protection of the forests on the lands which already belong to the state, and it would be the extreme of folly to acquire property at great cost when there is danger that it might soon be dissipated and destroyed.

Unless a system of permanent control under competent direction can be put in operation, the people of New York may as well relinquish all thought of saving the Adirondack forests, and all interest in the subject. There can be no adequate or successful administration of a great forest-preserve while its management is subject to the possibility of frequent change because it is treated as a portion of the political patronage of the state government. Unless the care of the forests on the state-lands can be placed in the hands of men of such known and obvious character and qualification for this work as will inspire general confidence, no system of administration can be successful, and competent men will not accept a place of such responsibility and importance while their work is always liable to interruption by the agencies of partisan politics. The inadequacy and failure of the present system of control and administration are inherent in the system itself, and are inseparable from its relation to partisan change and caprice. The evil is not to be remedied by merely changing the persons who administer a system which is essentially vicious.

If the people of the State of New York have enough regard for their own interests to lead them to insist upon the adoption of a system embodying the essential features of competent direction and security from partisan interference, it will be safe and wise to acquire the whole Adirondack region by purchase. If they have not this perception of the importance of the object in view, and of the means which are necessary for its accomplishment, the forests will be left to their fate. The methods now employed are wholly useless and ineffective.

How Trees Grow Tall.

THERE is no question more often asked of persons who are supposed to have some knowledge of trees than one relating to the manner in which the trunk attains its height. It is difficult to convince people, sometimes, that the trunk itself does not elongate and stretch just as the body of a growing child elongates, and that a mark made in the bark at a given distance from the ground will always remain at exactly that height, no matter how tall the tree may become. A correspondent of the semi-weekly *Tribune*, of this city, raised this question some fifteen years ago, and the answer which Professor Asa Gray wrote is so admirably clear, and such an excellent example of his method of dealing with scientific subjects in a clear and simple way, that we reproduce it for the benefit of our readers, among whom there are some, it is pretty safe to assume, who do not very clearly understand, even if they have ever given the subject any serious consideration, how trees grow tall.

"When I was a boy a thrifty Balm of Gilead Poplar before my father's house, barely large enough for the purpose, was used to hang a gate upon. I remember that the passers-by said: 'That is all very well now, but as the tree grows, the gate will go up.' The gate, as I remember, served for years, and did not 'go up.' When I was a boy, a long row of Lombardy Poplars on the side of the road leading to Hamilton College was used for fence posts, rails being mortised into

their trunks. After I had come to manhood, and had come to be a sort of authority upon such matters, one day, when in the neighborhood, this question was brought up, and the prevalent opinion expressed that the trunks of the trees in such a case must needs separate the rails more widely, and carry them all further from the ground. This opinion was shared by some very intelligent men, who had walked past these trees day after day for many years. I proposed that we should examine the fence, then at least twenty years old. We did so. The lower rail throughout remained next the ground; the upper, apparently, was no higher than the first; the growing wood had formed itself around the ends of the rails, sometimes in remarkable protrusions, forming deep sockets for the rails.

"As for the analogy of the tree with the man, 'born, say, one foot long, and growing till he is six feet high,' but still keeping the same head at the top—that is just what the tree does not do. Let the large bud at the summit of last year's seedling Horse-chestnut tree represent the head, and let Mr. Harrison notice what becomes of it in the spring, when the new growth is made. Or, let him examine a Horse-chestnut tree of five or six years' growth, and notice by the set of rings on the bark, left by the bud scales as they fell, just where the head was each year. He will see that the tree has the advantage of a fresh head each year—a new growth story after story, each on the top of the preceding one; whereas, in the man, the 'one small head' had to 'carry all he knew' year after year. On the other hand, the man is alive all through; the older parts of the tree are dead and buried in the interior.

"The heart-wood of any tree is dead, therefore cannot grow. If the lower part of a trunk has increased in length, say doubled it, in a given number of years, either the central wood must have been torn asunder or stretched, or the outer layers have successively slid over the inner ones. An examination of the structure of the wood as clearly shows that neither of the latter alternatives has occurred, as ordinary observation shows, against the first alternative.

"Can our correspondent bring any one clear case of evidence that a limb has been raised by the subsequent lengthening of a trunk below, excluding all cases such as that formerly referred to in the *Tribune*, where a tree growing on a rock is bodily raised, more or less, by the thickening of the roots spreading over the rock's surface? When such a case is brought to view, then the case will be fairly and specifically before the court of investigation.

"But why do not the limbs always remain near the ground? Answer.—They do until they die off, as the lower over-shadowed ones are pretty sure to do. Hemlock and Pine trees show this perfectly, for the knots remain to show where the branches were. When dead and gone at the surface, the succeeding layers of wood, covering all smoothly over, make 'clear stuff,' but it is clear delusion to believe that there have been no branches there; near the centre the knots or their vestiges are still preserved and plain to see on any section which divides the centre. Does our correspondent suppose that those Sugar Pines of the West, with trunks 100 feet high, before a vestige of a limb is seen outside, actually grew to that height without a limb?

"But, then, why does not the new external growth bring the (horizontal) limbs each year closer to the ground? Answer.—It does, by so much as the branch increases in diameter, and also when, long and horizontal, the lower limbs are weighed down. In consequence of this, I have had to lop some White Pine trees which overhang the road, and which, as they increased in weight and leverage, with the increase in length, began to get in the way of teams. In English park trees, where the lower limbs are carefully preserved, it is very common for them to lie on the ground. But at the trunk they will be found to be five or six feet from the ground; when young, of course, they were as high as that throughout, but have declined by their weight as they increased in length."

A German Sketch of American Gardening.

IN Herr Jaeger's "Gardening Art and Gardens," which was reviewed in this journal last week, a number of pages and several illustrations are devoted to landscape-gardening in the United States. The information given is generally correct, and though one would have been glad to see some other picture of an American home replace the "View of Blithewood," which is evidently reproduced from Downing's book, written many years ago, nothing better could have been chosen to illustrate the skill of American artists in dealing with the most fundamental and difficult problems of design than the large scale plans of the Central Park.

During the rule of the Dutch in New York, the author says, a few formal gardens in the characteristic Dutch style were laid out, but the growing supremacy of the English race soon gave landscape-gardening proper the upper hand. Parmentier is honorably mentioned as the first gardener of importance whose name has been preserved, but to Downing is rightly given the credit of being the first noteworthy American artist in this department. His death, however, is curiously placed in the year 1885, instead of in 1852. His book on "Landscape-Gardening" is described as "amply fulfilling its aim as a hand-book," and being "especially distinguished above others of its class by its portrayal of the characteristics of various species of trees and their proper employment in gardening art." Nothman and Thomas Lee are likewise mentioned as having worked at the same period; and one is glad to note that this foreign author, unlike many native Americans, recognizes the importance of the piazza in American rural architecture and sees its distinctly local significance. A long list of older parks and country-places is given, taken, of course, from Downing. But all these are as nothing, Herr Jaeger explains, in comparison with the great parks and cemeteries that owe their origin to recent years. To illustrate their character he describes the Central Park, in this city, and Spring Grove Cemetery, in Cincinnati. The choice is a wise one, for this cemetery was the parent of the others of its class, and the Central Park represents the successful treatment of the most difficult problem with which any modern artist has had to deal. After quoting a long description of the appearance of the park that had been printed some years before, he says: "The ridge of land which traverses the whole island of Manhattan becomes in the Central Park a rocky 'comb,' which cuts through the park, but does not divide it, for everywhere tunnels and bridges are placed in such a way as to bind the parts together above and below. The rocks in many places have been made larger and more picturesque by the removal of earth; splits and chasms have been turned into romantic glens; and all this seems as natural as though the hand of man had merely laid out the paths and concourses." Then the following words are quoted from the pen of a well-known German writer, Otto von Corvin, who visited the park not many years after it was laid out: "When I entered the park a prospect presented itself which, in the neighborhood of a large city, and especially of New York, I had not anticipated. Although unfinished and lacking large trees, this park is the most beautiful in the world, as it is the largest [?] and most peculiar. Truly, it does not possess those immense stretches of green, or great, shady avenues we see in the parks of London. Although beautiful meadows do not lack, yet one seems to find one's self in a charming district of the Harz mountains or the Thuringian forest. Everywhere rocks appear, and their naked sides are picturesquely clothed with intelligently-planted creepers." The remainder of this description need not be quoted, however, for it recites details with which almost all our readers must be familiar.

Spring Grove Cemetery Herr Jaeger calls the "most beautiful graveyard in the world." Its creator, as every one knows, was Adolf Strauch, a German by birth. He himself often declared that he had got his idea for a park-like cemetery from the description of Chinese graveyards in Humboldt's "Cosmos;" but Herr Jaeger says there was no need for him to go so far afield since he might have seen in Germany certain cemeteries portions of which, at least, were laid out in a park-like manner. "But in truth," he adds, "they are not even remotely to be compared with such a work of art as Spring Grove." Many other cemeteries and parks are noted with approval but the words used about one or two of them are worth quotation as showing that all does not look fair and laudable in American gardening to intelligent foreign eyes. "In the South Park in Chicago," the author says, "flower-bed artisticities reach the verge of lunacy, for with bright plants there have been formed figures in relief and portrait-heads, etc., as much as six feet in height. . . . And the park in Boston (by which is meant the Common and the Public Garden taken together), in spite of its size, must be called petty in arrangement, presenting a monstrous mixture of Franco-Italian and English gardening styles, and being tastelessly encumbered with flowers."

In conclusion, Herr Jaeger says that great interest is now universally felt in all the thickly settled districts of our country with regard to private grounds and gardens; and he notes with approval the promising fact that in laying out new towns and enlarging old ones, landscape-gardeners are more and more frequently called upon to give their help. The character of his book being popular and historical rather than technical, he does not lay so much stress upon the ability of our

foremost artists in planning great public parks—the most difficult of all the landscape-gardener's tasks—as does Monsieur André in his more practical hand-book called "*L'Art des Jardins*." But it is pleasant to see that with all the wealth of material from which he had to choose, dealing with times old and new, American artists and their work were esteemed worthy of so considerable a share of attention and praise.

Conifers Injured by Squirrels.

That squirrels have the habit of biting off the cones of coniferous trees in order to get at the seeds more easily, is well known, but why quantities of the twigs, tips and buds of these trees are sometimes found upon the ground in winter and spring seems not to have been generally understood. Complaints on this subject have often been made by people living near Boston, and attention has been particularly directed to the Norway Spruce. In some cases bushels of tips, from two to four inches long, could be gathered under two or three of these trees. High winds, disease, insects, birds, squirrels and other agencies have been suggested, but proof seemed to be wanting to substantiate any theory. That it did not result from strong winds during cold weather was proved by the fact that the trouble was local, as the ground under some Spruces would be thickly strewn with the tips, while other trees only a few rods away were quite free from evidence of injury. Neither, on careful examination, could any trace of disease, or the work of borers or other insects be found.

The injuries have been noticed in other parts of the country, and in the *Gardeners' Monthly* for 1885 there are several notes concerning it. The editor, p. 166, considers the "matter mysterious," and says that "mice or squirrels cannot do it, as the twigs are not cut by teeth, but broken, as examination by a lens clearly shows."

On page 227 Professor W. A. Buckhout gives several good reasons for supposing it was the work of squirrels, but he had not seen them do it, and, in addition to the Norway Spruce, he mentions similar injuries to *Pinus rigida*. The editor mentions specimens received from New Hampshire which "were broken off at a bud—disarticulated as it were—which a squirrel could not do," and he further thinks "that after the rodent has cut the branch, and drying commences, disarticulation of the side branches results."

At the end of a note (p. 276) from a correspondent at Lexington, Kentucky, who complains of similar injuries to Norway Spruces there, for which he can give no reason, the editor says: "On our grounds (Germantown, Pennsylvania) we have no squirrels, and yet the trees are so thickly strewn with branches—broken at the articulation, not cut by teeth—that the ground surface beneath the trees is covered."

Several years ago I noticed gray squirrels cutting off twigs of Norway Spruce in the winter or early spring, but not until very recently have I had what seems to be positive proof that they do all the mischief. After having carefully watched them at the work I think there is not the least doubt that besides cutting off the twigs at any place, they can also, and naturally do, "disarticulate" the branches at the point where the last season's growth began. In this vicinity a very large proportion of the twigs cut from the Spruces are severed at the "articulation," probably because the squirrels generally find it the most convenient place. As the squirrels reach forward and grasp the little side branchlets to draw them towards themselves, they find the branchlets bend most readily at, or close to, the base of the year's growth, and at the same place a small space is left clear of the sharp-pointed leaves, at once giving an opening and a weak point at which to sever it, which the squirrels do quickly and neatly with their sharp incisors. "Disarticulation of the side branches" would not naturally take place after drying until long after the leaves had fallen and the branches had begun to decay.

The object of the squirrels in cutting off the twigs is to enable them to get at the terminal and lateral buds, the heart of which they dexterously extract and eat while they have a comfortable foot-hold on a strong branch. For the same reasons they cut the nuts from trees and retire to a safe place before eating. Many buds are eaten without cutting off the twigs. Both the red and gray squirrels cut the twigs of Spruces, and I have seen the two species at work on the same trees at the same time.

They seem to prefer the Norway to either the native Black or White Spruces when growing side by side, probably because in the former the branches are more supple, and the leaves less sharp and rigid.

On calm days, when the squirrels are at work, most of the twigs which they cut off and drop may be caught and lodged

by their leaves among the branches of the trees, and being blown to the ground during strong winds, their appearance in large quantities after a storm is accounted for. On the flat, sprayed branches, on the upper part of a large tree, I found little heaps of the detached twigs. Although walnuts and hickories were not abundant, there was a good crop of acorns and other tree-seeds the past season, and it is difficult to say why the squirrels eat the spruce-buds, as their doing so does not appear to be from necessity.

If the attack should be made upon the same trees for a number of years it would naturally result in giving the branches a tufted and deformed appearance, if not proving a very serious or fatal injury.

Near the Arnold Arboretum there are some European Larches, the slender, pendulous twigs of which have been bitten off by squirrels in the spring, for several years at least, and the branches are covered with numerous knotty swellings and tufts, which are quite conspicuous, especially in winter.

I have found only one authority who has seen and recorded this habit in our squirrels. Dr. C. Hart Merriam, in his work on "The Vertebrates of the Adirondack Region," in the article on the red squirrel, p. 116, says: He eats the little buds that may be found scattered sparingly along the small branches of the Spruce, and, in order to obtain them easily, bites off the terminal twigs and drags them back where the limb is large enough to allow him to sit comfortably on his haunches while feeding. Under single trees, both in the great forest and on our own lawn, I have found enough twigs to fill a bushel basket. The injury thus done is sometimes very extensive."

In European journals there are frequent notices of injuries to Conifers caused by squirrels; but, in some instances at least, the attacks are of a different and more serious kind. A writer in the *Journal of Forestry* (London) for January, 1881, p. 578, says of them: "After a severe winter, during which a scarcity of seeds has been experienced, these animals betake themselves to the young woods, and do great damage by nipping buds from the extremities of the branches, thus causing the trees to become bushy and straggling in the top; they also in the early spring and summer months denude many Pine trees of their bark, commencing their attacks at two to five feet from the top, sometimes peeling all around and sometimes in patches; in the former case, the heavy winds will cause the trees to break; but, as regards the latter, the injury, if not severe, will in time heal over, although usually producing what is subsequently known as a flaw in timber. . . . In like manner squirrels attack deciduous trees, such as the Beech and Plane, thus frequently causing the tops to die. . . . In woods where there is a good mixture of Spruce Fir, their depredations will be found to be of the most serious nature."

By far the most serious charge that I have seen against the squirrels, in connection with their injuries to Conifers, occurs in the *Bulletin de la Société d'Acclimatation de France*, April, 1881, p. 253, where M. Ed. Rénard gives an account of the ravages caused by squirrels on the Pines in the forest of Rambouillet. Here the writer relates that previous to the year 1874 there were no squirrels known in the forest of Rambouillet; but about this time they were introduced, having escaped from a neighboring château.

At first their presence in the woods gave pleasure; then he says: "But one day, after a strong gust of wind, I saw on the ground, to my astonishment, a considerable quantity of the leaders (*flèches*) of Pines from two to three metres in height. I did not know to what to attribute this devastation, which I soon knew must be the work of the squirrels; they had gnawed entirely around the bark of the Conifers, and the dead tops of my trees were thrown down and strewn on the ground."

The destruction of the squirrels was ordered, and over 200 were killed in the year, and the injuries decreased. Later, however, a new invasion of squirrels from another forest destroyed some thousands of trees of *Pinus sylvestris*, by completely girdling the stems several metres from the ground, causing the trees to have a spreading form, and destroying their value for timber.

Acorns having been scarce the preceding year, he thinks that the squirrels, in the absence of other winter food, were obliged to eat the bark.

The trouble had increased to such an extent from year to year, the squirrels attacking fruit-trees as well as Conifers, that the forest administrators had established a reward of half a franc each for all squirrels killed.

I do not know that the squirrels have been found to peel the bark of Pines in this country, but it is not improbable that they would do so in times of scarcity of other food.

In the spring they sometimes bite through the bark of

Maples to drink the sweet sap which flows so freely at that time, and, after growth begins, they eat great quantities of the buds of some deciduous trees, especially of Maples, but without seeming to affect the trees very seriously, probably because there are plenty of the small accessory buds remaining to replace those destroyed and repair any injury done.

Arnold Arboretum.

J. G. Jack.

Agaves.

PERSONS familiar only with Agaves, or, as they are popularly, although improperly, called, Aloes and "Century Plants," grown in pots, can have a very slight idea of their massive strength and beauty when planted out permanently in a region whose climatic conditions are favorable to their full and perfect development. Our illustration upon page 115, from a photograph taken in an Algerian garden, shows how these plants look under such conditions. For producing certain effects in gardening, especially where plants are needed in immediate connection with buildings or other structures, in moderately warm or dry countries, like those which surround the Mediterranean, where, although natives of the Mexican plateau, some species of Agave are now perfectly naturalized, or like southern California, where some of the small species grow spontaneously, the Agave is immensely valuable. Even in countries where it is necessary to protect them from the cold in winter, and therefore to grow them in pots or tubs, these plants are better suited to decorate dry and sunny terraces, or the entrances to large buildings, than any others, as they can support heat and dust and continue to grow and improve for many years, or until the development of the flower-stem ends their existence; for these plants flower only once, and as this does not occur until they are fully grown, they early acquired the name of "Century Plants," because, confined in pots, the plants first introduced into Europe grew so slowly that they did not flower for many years. It is now known, however, that in a state of nature the largest species reach maturity at the end of fifteen or twenty years, or, perhaps, even in a shorter time; and their tall, branching flower-stems, often more than thirty feet high, are familiar and exciting objects to all travelers in northern Mexico.

New or Little Known Plants.

Fendlera rupicola.

FENDLERA RUPICOLA,* of which a figure appears on page 113, is a low shrub peculiar to the dry south-western portions of the United States, being found growing in the crevices of cliffs or among rocks from the valley of the Guadalupe, in western Texas, to the western borders of New Mexico and south-western Colorado. Although scarcely known in gardens yet, it promises to become so, as it possesses many qualities which will make it a most desirable addition to the number of small shrubs suitable for cultivation in the rock-garden or along the margins of small shrubberies.

Fendlera attains a height of from two to four feet. The branches are upright or somewhat pendulous, slightly angled or grooved, pale gray, and covered with small, entire, opposite leaves, which are revolute on the margins, prominently three-ribbed, and densely covered on the lower surface with pale tomentum. The bluish white flowers, with their conspicuous yellow stamens, are very showy, and are produced in the greatest profusion from the extremities of short lateral branches, which spring from the main stems of the plant.

Fendlera has been cultivated in the Arnold Arboretum for several years; it is perfectly hardy, flowering the middle of June and ripening its seed in September. It is growing in ordinary, good garden soil, and requires no special care or cultivation.

The genus Fendlera, of which but a single species is known, commemorates the services to botany of the late Augustus Fendler, a German naturalist, long a resident of the United States, and, after Wislizenus, the first botanist who visited New Mexico, where he made large and important collections of plants. It belongs to the Saxifrage

family and to the tribe of the Hydrangeas, which consists of sixteen genera of woody plants all natives of eastern Asia, the Pacific islands and North America. Among them are Hydrangea, Deutzia and Philadelphus, and several North American genera, which, like Fendlera, are monotypical, Jamesia of Colorado and Carpenteria of California being its closest allies.

C. S. S.

Foreign Correspondence.

London Letter.

PROFESSOR MACOWAN, director of the Botanic Gardens at Cape Town, has recently discovered wild plants of a very distinct and remarkable Scrophulariad, which is likely to prove a useful garden plant. It was first found by Ecklon in Tulbagh, about 100 miles to the north-west of Cape Town, and was described by Bentham in 1836 under the name of *Ixianthes retzioides*. Dr. Harvey figured it soon after in his "*Thesaurus Capensis*," and recommended it to the notice of English horticulturists. Till now, however, its introduction has not been possible, owing to the extreme scarcity of the plant in a wild state. Professor MacOwan, who has sent seeds of it to Kew, writes: "I beat over nearly every square yard of the mountain side wherever there was oozing water every time I went to Tulbagh, and last October dropped on to five large plants, almost trees for size, most splendidly in flower. The long floriferous branchlets were just one mass of sulphur-yellow bells, as close as they could well stick. I have since secured seeds, a portion of which I send to Kew; the rest goes to Vilmorin, Andrieux & Co., Paris." The plant is of shrubby habit, five feet high, with densely crowded leaves two and one-half inches long, one-quarter inch wide, toothed, dark green. The flowers are bell-shaped, one-half inch deep, with five spreading segments measuring one inch across and of a bright yellow color; they are produced in pairs or threes on short peduncles from the axils of the leaves. The plant grows in wet places. Many of the Cape Scrophulariads are remarkable for the beauty of their flowers, but, owing to their being semi-parasitic on the roots of other plants, they cannot be cultivated. Such plants are Cycnium, Buttonia, Gerardia, Harveya and Melasma, of which we have obtained seeds again and again for trial at Kew. At present we have young plants of Cycnium, Buttonia and Melasma, but they grow very slowly. We have also lately sown seeds of Harveya on soil containing a plant of *Barosma foetidissima*, which is said to be the host plant of this species.

The Cape flora is exceptionally rich in plants of great beauty and interest both for gardener and botanist. No country in the world has contributed so largely to English plant-houses, and although many of the plants which were cultivated here with so much delight fifty years ago are out of fashion now, they are certain to come into favor again. From 1775 to 1835 Cape plants were quite the rage; English gardens were filled with Ericas, Pelargoniums (the species), Proteas, and such like beautiful shrubs, while the Iris, Amaryllis and Lily families were represented in thousands. The survivors of this reign of the Cape flora are principally such bulbous plants as Nerine, Vallota, Clivia, Ixia, Lachenalia and Gladiolus. Freesia was lost entirely till about five years ago, when Professor Foster drew attention to it, whilst even Lachenalias and Neries have come into notice again only within the last ten years. The Ericas have almost gone, if we except a very few of the soft-wooded kinds. No one grows Portea except, perhaps, at Kew. Nor are the delightful species of Pelargonium, Oxalis, Watsonia, many Gladioli, Cyrtanthus and Crinum known in gardens, save in a very few. Mr. Endicott, of your country, is, I perceive, doing good work in growing and calling attention to some of these lost plants. In like manner a few specialists in England are striving to popularize many of the best of the least known Cape plants. Nor have all the good plants of the Cape been introduced yet. Witness the discovery of the glorious Poppy-flowered Sun-dew by Miss North when she went on a sketching visit to the Cape in 1885. This plant has flowers as large and bright-colored as those of the field Poppy. It is satisfactory to be able to add that there are living examples of it at Kew. There are many grand garden-plants at the Cape of which we know practically nothing.

In England, with our dull, wet, foggy winters, the cultivation of the more delicate Cape plants is surrounded by great difficulties. In America you have only the cold to overcome; light you have in abundance all through the winter. I imagine that Cape plants, if taken well in hand, would prove a far greater success with you than in England.

* FENDLERA RUPICOLA, Engelm. and Gray; Gray, *Pl. Wright.*, i. 77, t. 5; *Pl. Thurber.* 300.—Baillon, *Hist. Pl.*, iii. 349.

Among the newer stove plants the most attractive now are the following: *Ardisia mamillata*, introduced by Kew from Hong Kong three years ago, and now a favorite stove plant here. It is less than a foot in height, similar in habit to *A. crenulata*, but the leaves are softer, densely papillose, covered with silky hairs, and dark green. The berries are borne on the branches exactly as in *A. crenulata*, but they are of a bright scarlet color. Plants are easily obtained from seeds, and grow to pretty little specimens in about a year.

Begonia semperflorens hybrids:—Monsieur Lemoine has raised and distributed some very useful new winter-flowering Begonias, obtained by crossing *B. semperflorens* and *B. Lynchiana* (Roezlii). They grow quickly into bushy plants two feet high, with medium-sized leaves of the glossiest green, and large bunches of red, crimson or pink flowers. These are developed in January, and last in beauty for about two months. They are great improvements upon both parents, a statement which does not always apply to hybrids. The ever-green Begonias are at last getting the attention which has been so long refused them, and we have already some distinct and beautiful kinds, thanks to Monsieur Lemoine, the Messrs. Veitch and a few others. Even such old hybrids as *B. Knowsleyana*, *B. Wiltoniensis* and *B. Lindleyana* are of considerable value as autumn and winter-flowering plants.

Aphelandra chrysops, a stout-stemmed species with large, silver-banded leaves and handsome terminal spikes of canary-yellow flowers; *A. aurantiaca*, smaller in stature than the above, but of sturdy habit with shining gray-green leaves and large spikes of scarlet and yellow flowers; *Eranthemum albi-florum*, with orbicular leaves and branched spikes of pure white flowers; *E. cinnabarina*, a tall, single-stemmed species, characterized by large, oblong leaves and long, arching, branched racemes of purplish-crimson flowers; these are all in flower now and will remain in beauty for some weeks yet. Tropical Acanthads are deserving of a great deal more attention than they get. Most plant-stoves are dull and almost flowerless at this time of year, although there are hosts of such plants as those here mentioned, which are bright and attractive with flowers all through the winter. They are easily grown, requiring only ordinary attention at all times. Aphelandras are best when grown from seeds, which they usually ripen freely under cultivation.

In the conservatory the Himalayan Rhododendrons have begun to unfold their magnificent flower heads. Large specimens of *R. arboreum*, with the richest crimson blossoms, and of *R. Nilagericum* equally handsome, but pale pink in color

are the first to brighten the house; and they will be shortly followed by such splendid species as *R. argenteum*, *R. Nuttallii*, *R. Aucklandia*, *R. Edgeworthii* and many others. I can imagine a large, lightly-built, low-roofed conservatory, without any staging, but filled with beds of peat soil and planted with these Rhododendrons, Tree Ferns, Lilioms—such as *L. auratum* and *L. giganteum*. Such a house would require very little fire-heat and much less attention than when the plants are in pots. The charm of it would be largely due to the absence of pots and stages, of which we are a great deal too fond where green-houses are concerned. The popularity of the great winter-garden at Kew is owing to the absence of pots except on the shelves round the sides; and that

the plants prefer beds to pots is proved by the magnificent health of such things as Acacias, Polygalas, Bossiæas, Palms, Tree Ferns and Rhododendrons. No one can form any idea of the beauty of the *Habrothamnus* until he has seen them as at Kew. The enormous bushes, twelve feet high, crowded with long, arching branches which are literally weighed down by the large clusters of flowers they bear, make pot specimens of the same plants look ridiculous. They have been full of flowers since the beginning of December. *Senecio Ghiesbreghtii* is still aglow with its massive heads of yellow bloom. *Staphylea colchica* is attractive with its many racemes of white flowers, pure and graceful, and suggesting orange blossoms. This plant is grown in thousands by the London market-gardeners. A pretty plant, uncommon in color and of lasting qualities, is the Blue Marguerite, *Agathæa celestis*. It forms a compact, globose bush a foot high, with dark-green, spatulate leaves and long-stalked Marguerite-like flowers one inch across, the ray-florets pale violet, the disc pale yellow. It is scarcely ever out of flower, and is useful for cutting.

Fig. 98.—*Fendlera rupicola*.—See page 112.

ORCHIDS.—The best of these in flower now are *Paphinia grandis*, much the handsomest of the genus, its large flowers of the richest dark chestnut-brown, with streaks of white. The plant is small, often smaller than one of its flowers. Unfortunately, it does not appear to be easy to establish, as plants rarely flower after they have been in cultivation two years. *Calanthe vestita gigantea* has no equal among the *Vestita* section of the genus. It is truly gigantic in all its parts. It also blooms much later than the other kinds, and retains its large leaves healthy and green even till after the flowers are over. The spikes are nearly a yard long, arching, and the flowers are over two inches across, white with a red eye. *Oncidium splendidum* is a king among the *Oncidiums*. It is evidently a

good grower, very distinct in foliage, and the spikes are erect, over a yard high, branching and bearing large flowers, the lip of which is canary-yellow, large, the sepals and petals barred with red-brown. The individual flowers of *O. splendendum* are not unlike those of *O. tigrinum*, a resemblance which led to its being called a variety of this species; in pseudo-bulb, foliage and habit the two are widely different. *Cypripedium Curtisii* is a beautiful species, related to *C. superbiens*, and one of the most distinct of all the recently-introduced kinds. Messrs. Sander & Co. have a large batch of it, a few plants of which are in flower.

Kew, February, 1889.

Cultural Department.

Sparaxis and Ixia.

ACCORDING to Mr. Baker, of Kew, there are in south Africa about 800 species of plants of the Iris, Lily and Amaryllis families, whose underground portion is either a corm, a tuber or a bulb.

If we add to this number the bulbous and tuberous Oxalis, Pelargoniums, Othonnas, Crassulas, etc., we shall have a total of about 1,000 species, included under the popular name of "Cape Bulbs." Of these probably not one in twenty is cultivated either in this country or in England, though many showy hybrids of a few Ixias and Sparaxis are yearly offered for sale both there and here.

In horticulture as in other things, "the old order changeth, giving place to new." Cape Bulbs have enjoyed a period of popularity in the past, as the numerous plates of these beautiful flowers in the *Botanical Register*, the earlier volumes of the *Botanical Magazine* and other works will show. As a whole they have very much to recommend them. Nearly every one is of great horticultural interest for the grace, brilliancy or fragrance of its flowers. Hardly one is difficult to manage. Some are perfectly hardy; most of the others can be safely carried through a New England winter in a frame or in a raised bed, with a covering of leaves, and those which must blossom in the winter or not at all will do well in a sunny window.

The Ixia and Sparaxis, the former for the gracefulness of its tall spikes, and the latter for the extreme brilliancy of many of its forms, may claim a place in the very front rank of Cape Bulbs.

Sparaxis is a small genus, consisting of only three species, though there are several varieties of these found in a state of nature and a great many produced by the labors of gardeners. *S. bulbifera* has flowers of some shade of yellow, ranging from the lightest and faintest to very strong and bright ones, but always yellow. It is named from the elongated bulbs which it forms in the axils of its leaves, although the other species do the same with equal prolificacy. *S. grandiflora* is distinguished by its white and purple flowers. These two colors are always present, as far as I have observed. In some of its forms the purple is confined to the edges of the floral divisions; in others the whole flower is of a deep velvety purple except a white tip, or perhaps a light edge on the six segments. The third species, *S. tricolor*, is not outdone in brightness, in some of its forms, by any flower the whole earth can show. Its three colors are jet black, yellow of varying shades, and red of some very bright tint; scarlet or crimson, or some other as showy. These three colors in the best varieties form a whole more dazzling than any one not familiar with the flower could imagine.

I believe that the very numerous sorts offered by Dutch bulb-growers are varieties of these species, and not hybrids, for, though I have grown a very large number of them, I have never seen one in which the characteristic colors of two species met in the same flower. The stalk of the Sparaxis is from eight to ten inches high, and bears from four to seven flowers, each of which lasts several days. Its leaves are flat, long and somewhat blunt at the end, and grow more upright than those of the Tritoma, less so than those of the Ixia. The bulb is unusually white and clean in appearance, and is almost spherical. The plants sold as *Sparaxis pulcherrima* and *S. pendula* are not now included in the genus, but form the genus *Dierama*. I can say but little of them, and will say that little here. They are exceedingly beautiful, bearing long racemes of somewhat bell-shaped flowers of a lovely rosy hue, on gracefully bending, slender stalks four feet high. At least so we are told, and we must take it on trust.

I cannot make them flower, though I have had them for years under all kinds of treatment. The most skillful cultivator of bulbs in this part of the state has been equally unsuccessful. The plants appear to be like *Iris Robinsoniana*—most beauti-

ful things, whose beauty no one can cause to be developed. With covering *D. pulcherrima* will endure our winters; under glass it is evergreen.

The Ixias are very different from the Sparaxis in general appearance, their leaves being much longer, narrower and darker green, and usually somewhat twisted. During our shortest days, when the sun is only a few hours above the horizon and his elevation at noon is only about twenty-five degrees, the Ixias suffer more from deprivation of light than any other Cape Bulbs, except a few species of Gladiolus. For this reason better results will be obtained, I think, by planting these in February or March than by doing so in September or October. The flower-stalks of Ixias are slender and quite rigid and straight, and the flowers are clustered thickly at the top. The many kinds offered in Dutch catalogues appear to be hybrids, as they show peculiarities of two or more species in the same flower. These hybrids are, many of them, of exceeding beauty, and many are highly fragrant, having the delicious perfume of the Neapolitan Cyclamen.

The species, as far as I have cultivated them, are these:

1. *Ixia polystachya*; white-flowered, about twenty inches high, the stalk having from three to six lateral shoots, coming into flower at the same time as the central one.
2. *Ixia flexuosa*; twelve inches high, flower sometimes white, sometimes pink.
3. *Ixia hybrida* (*I. flexuosa* of Ker); white, with rose centre; highly fragrant.
4. *Ixia aristata*; white, pink or rose, according to variety, and frequently sold under fanciful names, as some others are.
5. *Ixia fragrans*; pink, if I have it true to name.
6. *Ixia patens*; generally deep crimson, a species sold by dealers under its true name and usually in its typical state.
7. *Ixia speciosa* (the *I. crateroides* of the catalogues); deep crimson, with lighter exterior.
8. *Ixia maculata* of Linnaeus (*I. conica* of Salisbury, and sold under both names); one of the most variable of plants; many varieties having centres of two colors, chestnut and blue, pink and blue, blue and crimson, etc., while the ground color is white, cream, lemon, buff, orange or light blue.
9. *Ixia columellaris*; also variable, but of soberer colors than *I. maculata*.
10. *Ixia monadelphica*, frequently sold as *I. columellaris*; pink, with crimson eye; yellow, with chestnut eye; purple, with blue eye, etc.
11. *Ixia paniculata*; a species I do not think worth growing; it has a very long-tubed flower of a brown paper color.
12. *Ixia viridiflora*; the most beautiful of all, having lovely sea-green flowers, with a purple centre.

There are six or seven others which I have never seen.

Canton, Mass.

W. E. Endicott.

Cultivating Wild Flowers.—With all the encouragement to skill offered by the system of premiums at our horticultural shows, specimens of extra good culture are seldom seen, except, perhaps, in the case of the Chrysanthemums. In the Old World visitors are sometimes surprised to see on exhibition some wild flower, taken in hand by a florist, who makes a wonderful specimen by care and good treatment. At a recent exhibition in Germany, one of the wild Orchids of that region was thus shown, and, according to the *Gartenflora*, a specimen was produced that far exceeded in beauty the rare Orchids of foreign lands, for which hundreds of dollars are sometimes given.

Improvement of the Pansy.—When, in the boyhood of the writer, some fifty years ago, the Pansy came to be some three-quarters of an inch in width, and the florists gave the varieties distinctive names, it was regarded as a wonderful achievement of modern skill. But an old work on horticulture in Britain, called "*Hortus Floridus*," has recently been brought to light, issued two hundred years ago, in which are pictures of Pansies just as large and fine. The query is, had the florists of these early times agents in their employ with exaggerated picture-books, or were the Pansies of those days as large and fine as those of our own time?

Maule's Quince.—*Pyrus Maulei* has flowered with us for several seasons past. English papers compare it with *Pyrus Japonica*, which the flower does to some extent resemble in form, though bright orange in color, and not red as in *Pyrus Japonica*. The flower also opens early, as it does in that species. But the foliage and habit are more like those of the *Pyracantha* (*Crataegus Pyracantha*) than those of the ordinary Japan Quinces. Like the *Pyracantha*, also, it has a disposition to be evergreen. It promises to be an excellent addition to our list of hardy shrubs.

Thomas Meehan.

Fig. 99.—Group of Agaves in an Algerian Garden.—See page 112.

Clematis paniculata—The question is often asked, "What is a good white Clematis to plant as a companion to *C. Jackmanni*?" To this may be replied *C. paniculata*. This Japanese species is of vigorous habit, floriferous, hardy, and, above

all, long-lived. Young plants with us last summer grew ten feet high and flowered from the ground to the ends of the shoots. In general appearance, *C. paniculata* somewhat resembles *C. flammula*, but the foliage is large and leathery, and the

flowers are produced in panicles often two feet in length, of a pleasing ivory-white color. They may be seen at their best about the second week in September, at which time the foliage is hidden by the flowers, which are followed by awned seeds with a reddish tint, and last until severe frosts set in. Although introduced in 1796, *C. paniculata* is by no means common in this country, owing to the difficulty of obtaining good seed, it being usually killed by frost before it is sufficiently matured to germinate.

Shortia galacifolia.—This interesting plant has proved perfectly hardy in New Jersey. When it has the protection of a cool house in winter it thrives better, however. The flowers are produced earlier, and last several weeks in good condition. Established plants flower freely. We have one in a four-inch pot with twenty-four buds, some of which are already expanded. Those who wish to cultivate this plant should, if possible, get established plants; collected ones are uncertain. *Shortia galacifolia* succeeds well in a soil composed of two parts peat and one of loam. It requires plenty of moisture at all times. We have also found that a half shady spot, such as a cool frame, is best suited to the plant in summer, as the sunlight is apt to scorch the young foliage.

Strong Vitality of Crocus Flowers.—In the latter part of November about fifty bulbs of a species of Crocus, probably *C. sativus* or *C. speciosus*, were received from a correspondent in Turkey. They came by mail, packed in dry cotton wool, and were, to all appearances, lifeless, but evidently belonging to the autumn-flowering section of the genus, as there were dried flowers of a purplish color attached to the bulbs. However, it was decided to plant them, and, shortly after this was done, signs of growth were visible in the production of leaves and the thickening of the leaf-sheath of the membrane. This thickening was thought to indicate the appearance of more blooms, when we were surprised to find that seed-pods and perfect seeds were formed, and this after the bulbs had traveled thousands of miles between the time of flowering and subsequent continuation of growth.

Passaic, N. J.

E. O. Orpet.

Sowing Acorns.—It is the popular belief that acorns and nuts must either be sown in the fall or kept in earth for spring sowing; but practice has shown that this is not essential. Indeed, walnuts very often fail entirely when sown in the fall. There is no objection to the preservation of such seeds in earth for sowing in spring, but anyone who has not done this may safely sow in April, if the seeds have not been allowed to become dry. A damp cellar, such as many nurserymen use for heeling in plants in winter will suit admirably. If the acorns and nuts have lost nothing in weight by drying since they were collected, they may be sown with assurance of success.

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

X.—A FEW OF THE NITROGENOUS COMPOUNDS FORMED WITHIN THE PLANT.

IN the previous papers of this series we have followed the course of inorganic materials into the plant, and we have investigated some of the products resulting from the chemical processes which go on in the assimilating and the elaborating cells. Thus far our attention has been confined to the cell-wall substance, the starches, the sugars, the acids, the fats, and the like, all of these being products which are devoid of nitrogen. The way is now open for a brief consideration of certain groups of substances, of which nitrogen is an essential constituent.

The element nitrogen enters the plant in some combination, as we have already seen, and its destination is the formation of what are known as albuminoidal matters, or proteids. The living matter in plants and animals alike, consists essentially of various proportions of these albuminoidal substances, in which, for the time, certain special activities are manifested.

When the living matter, with its associated albuminoidal substances, is subject to proximate analysis (that is, an analysis which stops just short of resolving it into its ultimate constituents), it is easy to discriminate between closely allied compounds which are almost the exact equivalents of the albuminoids found in the animal kingdom. In fact, they are commonly called vegetable albumin, vegetable casein, and vegetable fibrin, to distinguish them from their allies in the

animal kingdom. This nomenclature, although correct in its main features, is not sufficiently exact for the needs of modern science, and hence other terms, more precise and significant, have been bestowed upon most of them. For our purpose, however, it is sufficient to regard them as a whole, and to keep in mind the important facts regarding their bearing upon the work in the plant. First of all, then, it must be observed that the chemical changes which take place in the living matter of the plant, by which nitrogenous compounds are formed, are akin to what has been called dissociation. In a general way it may be said that the protoplasm itself contributes of its own substance to form these other products, but the processes of repair in a healthy cell keep pace with the destructive changes.

By what is recognized as an oxidizing process, or a sort of "fermentative" process (to use the term of one of the most recent and careful investigators of this subject), substances known as amides are formed from the albuminoids of the plant, and these may give rise to very complex combinations, some of which are immediately broken down, while others are maintained as distinct compounds in certain cells. A few of these compounds are occasionally broken down until their products appear as compound ammonias of a volatile character. Such are sometimes found in a few plants at the time of flowering.

In the form of these compound ammonias a little of the combined nitrogen of the plant may escape as a sort of excretion, but, aside from this, which is very special and limited, there is no true excretory process answering in the slightest degree to the elimination of urea in animals. From what we know of the very close similarity between animals and plants in their physiological relations, it is highly probable that some excretory process may yet be made out clearly. The behavior of a peculiar substance known as asparagin has led some investigators to look in this direction for a solution of the problem, but as yet there has been no conclusive evidence that this product plays such a part, or even assists, in such a way in the vegetable economy.

Among the more complex nitrogen compounds of the plant few possess greater interest from the point of view of useful applications than the so-called alkaloids. For the most part these occur in small amount, and, as a rule, are characteristic of certain plants. Thus alkaloids, of which we may take Quinina as the type, are characteristic of the Cinchonas; Morphina and its allies are found in the Poppies; Atropina occurs in Belladonna. In the plants closely allied to these there may be kindred but not identical alkaloids, so that it is at present impossible to assert beforehand, from the affinities of a plant, whether or not it possesses alkaloids of a certain character. In fact there are many indications that closely related alkaloids may occur in plants which belong to widely separated orders, a good example of this being afforded by the active alkaloid of Coffee, Tea and the like.

A practical point of some importance is to be here noted—namely, that, by judicious selection, the amount of an alkaloid characteristic of a given plant may be measurably increased. This is a consideration of much greater significance to cultivators in tropical and the warmer parts of sub-tropical countries than to residents of temperate climates, since, under those skies, the amount of the alkaloids is generally larger than in cooler regions.

A curious fact of no practical importance may be mentioned at this point—namely, that it is possible for one to kill an alkaloid-producing plant by the very alkaloid which it yields. For instance, by watering the soil with a solution of morphina, it is possible to destroy the Poppy.

Another interesting group of nitrogenous bodies found in plants comprises the unorganized ferments. These bodies have the extraordinary faculty of causing changes in other substances, without always, if indeed at all, undergoing change themselves. Thus an unorganized ferment, known as diastase, has the power of converting starch into soluble substances very readily utilized by the living matter of the plant. There are other ferments which are inert as regards starch, but act efficiently upon nitrogenous substances. The best cases of this class are met with in the so-called insectivorous plants and in the fruits of the Papaw, a tropical plant. In these and a few other plants active principles akin to the digestive ferments of the animal world are found in surprising amount. That which is characteristic of the insectivorous plants is related to if not identical with the ferment known as pepsin, while the Papaw fruit yields one more closely resembling those which can act in an alkaline fluid. There is good reason for the belief that these plants are not anomalous, except in the relatively large amount of the ferment which they

duce; on the whole, it is not unlikely that some similar substances are always active in the seeds of certain plants at a certain period of their germination. The fact that these ferments have an important office in the life of certain plants, and that others are found in almost all plants, leads to the question as to the possible use to vegetation of the alkaloids and other powerful nitrogenous principles which are found so widely diffused, and which appear to have no office in digestion or nutrition. It is usually said that these have the office of protecting the plant from invasion from unwelcome insects and other animals, and this is doubtless true, but it is not improbable that some of them may share with certain resins the power of resisting the attacks of more insidious enemies—namely, destructive fungi.

We have now passed in very brief review some of the more important substances which the plant forms in its laboratory. Looking at them all from the point we have now gained, we may say that they fall naturally into the following classes: (1) Those which are, or are allied to, the primary product of assimilative or constructive energy, depending on the reception of solar radiance; to this class belong the members of the sugar series; (2) Derivatives of the former class representing nearly or quite the same amount of stored energy, such as the cell-wall substance; (3) proteids, having nitrogen as an essential constituent, and forming the source of the living matter of the plant; (4) waste substances, both of the nitrogenous and the non-nitrogenous series, which are turned to account by the plant in protection, attraction, and so on.

The green cells of the plant, exposed to the light and air, are the seat of those activities which result in the construction of organic matter. Any other cells of the plant, provided the temperature is sufficient, may serve as the seat of any or all the many activities by which these primary organic products are converted into other matters. In short, to use a familiar expression, the energy of solar radiance winds up this marvellous machinery, which in its rapid or its more tardy running down, gives us all the phenomena of plant life. But it is to be remembered that, so long as the sun shines on an active plant which is properly supplied with the raw materials for its work, the machinery is being constantly wound up, and, as one may say, faster than in the economy of the plant, the supply of energy can ever be used. This excess is left for the use of other organisms, or it may accumulate, as in fact it has accumulated, in the stores of unused carbon of our living forests, and the forests of the past, our coal of to-day.

Cambridge, Mass.

George Lincoln Goodale.

The Forest.

The Forests and Woodlands of New Jersey.—IV.

THE largest Holly trees I have ever seen are at Wildwood, on Five-mile Beach, which lies along the Atlantic shore above Cape May. Many of them are more than a foot in diameter, with lofty and spreading tops, and in winter when these towering masses of dense evergreen foliage are decorated with an almost unimaginable profusion of bright scarlet berries, the effect is indescribably beautiful; and when, as sometimes happens here, the trees are wrapped for a few hours in a fleecy, feathery mantle of snow, the forest looks like a picture—a scene from an enchanted land. There is a fine, umbrageous forest here, almost immediately on the beach. It is nearer the ocean, indeed, than any other forest of equal beauty along our coast, so far as I have observed. Besides the Hollies, many of the Oak, Cedar, Sassafras and other trees are also very large. It is pleasant to note that the proprietors of the place have an appreciation of the charm and glory of fine forest trees, and that they intend to preserve many of them permanently. At Holly Beach there are also very fine trees.

In many of the towns of our country noble trees are often sacrificed to the notion, held by the street officers, that wide, wind-swept expanses of dust, bordered by straight walks from which all trees have been removed, are an indication of superior "enterprise" on the part of the inhabitants, and of energetic administration of the supervisor of roads. I have seen trees thus destroyed which had been the source of much greater good to the community about them than had ever been wrought by the man who murdered them. A curious feature or accompaniment of this vandalism, which may be observed almost everywhere, is the mockery of tree-planting along the same streets from which trees of great beauty and of historic interest, the product of centuries of growth, have been ruthlessly cut away. When the thoroughfares and roadsides of the town have been completely devastated, the officers proceed to

set out young trees along the streets. But the planting is usually performed in such fashion as to kill or permanently cripple most of them, and for a generation or two the inhabitants will see a miserable array of dwarfed and stunted bushes and spindling saplings where once stood the great trees which were the pride and glory of the village.

THE GREAT OAK OF SALEM.—There is a remarkable White Oak at Salem. It stands in the burying-ground of the Society of Friends. I cannot learn that any one knows its age exactly, but it is said to be at least two hundred years old. It is a wonderful tree for its size and symmetry, and for the great number and spread of its branches. It was measured in 1884, and was then eighty feet high; the trunk was eighteen feet four inches in girth, and the spread of the branches was 360 feet in circumference. The circle covered by them was 114 feet in diameter and its area 10,207 square feet. I am indebted to the courtesy of Mr. H. M. Rumsey for these measurements.

To see this tree is well worth a summer day's journey from Philadelphia to Salem. Any such tree is a credit to the town in which it stands. Its existence indicates a degree of civilization, an appreciation of the beauty and majesty of noble trees, which is by no means so general in our country as is desirable. In too many places such insensibility and vandalism prevail that no tree ever has a chance to attain to imposing proportions, the beauty of complete development, or the interest which attaches to great age. I am sorry to say that this fine tree has been seriously injured within the last few years by neglect of the wounds made by the removal of several large branches. The large cut surfaces are exposed to the weather and to the attacks of enemies of all kinds, without any protection whatever. They should have been covered at once with a thick coat of coal-tar or paint. While unshielded they invite the entrance of the spores of various fungi, or toad-stools, which will ultimately destroy the tree. Their mycelium is a perennial growth, and spreads through the sound wood until the entire tree is inoculated with a fatal disease. It is probable that in a few years this grand tree will begin to show symptoms of decay.

LARGE TREES IN CAPE MAY COUNTY.—There are some very large Oaks and other trees still standing in swamps, or on ground surrounded by swamps, in Cape May County—trees which were doubtless there when white men first visited the country; but there are, I believe, no considerable tracts of unbroken primeval forest in that region. Mr. Richard S. Leaming and Dr. Coleman F. Leaming told me of a White Oak which was nine feet across the stump, and forty feet to the first limb, and this limb was over two feet in diameter. At this height the tree was more than four feet through, and all below this was sound. A Methodist clergyman counted over 800 rings of growth. The same gentleman told me of a Tulip-tree ten feet in diameter, with a clear trunk forty feet or more in length. Both the Sweet and Sour Gums grow very large in that region. Mr. Richard Leaming is a ship-builder, and has had much experience with different kinds of timber. He says that Cape May County oak and gum timber is more durable than any other with which he is acquainted, except some kinds of wood from certain parts of Virginia.

THE OAKS OF MAY'S LANDING.—May's Landing, in Atlantic County, is remarkable among the towns of the state, and, indeed, among the towns of the whole country, for having been built—a large part of it, at least—in a very heavy Oak forest, without destroying the trees. Many of the house-lots or door-yards have never been cleared up. The great umbrageous White Oak trees stand close up to the very door-steps of the dwellings. The court-house and the churches are in the same way embosomed and embowered in a forest of wonderful beauty and interest. This characteristic of the town is so prominent and vital, that a visitor is soon led to inquire regarding its origin and the means of its perpetuation. The proprietors of the great Colwell forest domain, who formerly owned the land on which the town is built, and who still own much of it, have from the earliest times set the example of preserving and protecting the trees, and when selling lots in the town they have always impressed upon purchasers their desire that this policy should be permanently followed. The streets at some points have been moved to new lines, and turned this way and that, to avoid injury to the trees, and great Oaks three or four feet in diameter stand unharmed in the middle of the sidewalks, while generation after generation of the people of the old town walk reverently around them from youth to old age, till they lie down to sleep at last under the benediction of sheltering boughs and leaf-curtained canopies in the village cemetery.

PECULIAR HOLLY TREES.—From May's Landing the track of

an abandoned railroad leads the explorer into the heart of the woods. Young Pines are growing up between the rust-eaten rails, and the forest is again taking possession of the right of way. A mile or two from the town, at the edge of an old field, also abandoned, are some very remarkable and peculiar Holly trees. The trunks are densely "feathered" quite down to the ground, and the whole top of each tree is a solid mass of branches and foliage, wonderfully symmetrical in form, and nowhere penetrable by either eye or hand. I can hardly remember any trees so pictorial as these, except some Live Oaks in Louisiana, which will haunt me as long as I live. All about this region, as in many other places in the southern part of the state, the Mistletoe is an object of interest to visitors from lands where it does not grow, and some of it is gathered and sold for Christmas decorations. The fruit of the Persimmon should also be added to the list of forest-products which have a commercial value. It is always on sale in Philadelphia in its season, and perhaps in other cities.

Franklin Falls, N. H.

J. B. Harrison.

Correspondence.

Fruits for Cold Climates.

To the Editor of GARDEN AND FOREST :

Sir.—Under this title the position is taken by a correspondent in your issue of January 23d, that the Russian fruits have no prospective value in the Prairie States.

Such general statements are difficult to deal with in the narrow limits of a half column, but something should be said on the other side. Perhaps this can best be done by giving briefly the estimate of some well-known directors or officers of our Iowa Horticultural Societies, who have had much personal experience with the Russian fruits.

In the northern district of the state, containing forty-two counties of rolling prairie dotted with cities, villages and fine homes, only four varieties of the apple are now recommended for general cultivation, viz., Duchess, Whitney, Letofsky and Wealthy, and of this brief list Wealthy can only be grown profitably in the most favored portions. In this trying district, at the recent meeting of the Northern Iowa Society, Mr. J. B. Mitchell, of Howard County, exhibited the wood of about thirty varieties of the Russian Apples, as clean and white as that of Box Elder, while the best specimen of the wood of the Duchess he could find was colored. He also made an exhibit of Russian winter Apples, of good size and quality.

At the same meeting, Hon. R. P. Speer, Director of the Iowa Agricultural Experimental Station, stated, and has since published in Bulletin No. 3, that, "all of our American Apples, as well as the Apples from west Europe, have proved much too tender on ordinary prairie soils." After giving his experience on his home farm at Cedar Falls, Iowa, with Russian varieties from the Department in 1874, varieties from Mr. Tuttle in 1881, and varieties from the College in 1882, he says: "The winter of 1884-'85 was the coldest since 1855-'56. In April I found that nearly all the varieties from central Russia were hardy, while many kinds from western Russia proved tender. I also found the severe winter and unfavorable spring had killed more than 40,000 of my three-year-old trees of such varieties as Walbridge, Plumb's Cider, Fameuse, St. Lawrence, Wolf River, etc. My bearing orchard of 1,500 trees I also found contained no sound trees except of Whitney, Wealthy, and varieties which had come from Russia."

Then follows a list of Russian varieties "which have never shown any signs of blight, and which, on my grounds, seem to be as hardy as Duchess." This list contains fifty-eight varieties. Then follows a list of seven equally hardy sorts, which have shown traces of blight in a few cases where near blighting sorts. Still following are lists of sorts liable to blight, or not hardy on his own grounds, containing forty-three varieties of coast Russians or north Silesians.

Again, W. C. Haviland, of Fort Dodge, Iowa, has tried in orchard and nursery 120 varieties of Russian and north Silesian Apples, and at the recent State Horticultural meeting he exhibited the wood of sixty varieties as clean and white as that of Duchess, and in many cases much better.

Still again, John C. Ferris, of Franklin County, in north Iowa, has had for a number of years many varieties in orchard and nursery, and finds fully half of them as free from blight and as hardy as Duchess.

In addition we have over 200 experimenters in north Iowa with the central Russian fruits, who report a still larger per cent. of perfect varieties.

In the central and south districts of Iowa the need of hardier sorts is not so apparent on the loess and timber-ridge soils,

but the great prairie sections east of the Missouri divide must have varieties as hardy as Duchess if they prove long-lived and regularly productive.

But the final selections from the east European varieties will here be made from those imported from interior south Russia. Some of these, already fruited in south Iowa, have proved fine winter Apples, and the reports from trial-stations show the trees to be hardy up to the forty-third parallel. As an instance, Varonesh Rosy has proved as large, handsome and good as Rome Beauty has in the south district, and the fruit is found to keep as well as Grimes' Golden, yet its wood is as bright as that of Duchess when grown up to the forty-third parallel.

But your correspondent says that not one of the Russian Apples has been recommended for general cultivation by our Horticultural Societies of Iowa. Manifestly it would be hasty to attempt a selection as yet. Not a friend of the Russians in the West has urged it. It is yet promising experimental work, to be undertaken from the Atlantic to the Pacific, and in the Southern States.

As to unfruitfulness and low quality of Russian Apples, I can say that the fault of many varieties is to overbear when young. It is yet too early to decide that the sorts later in coming into bearing will not prove most valuable.

As to quality, we will grade them as Regel, Schröder, Fischer and other Russo-German pomologists have done. Those listed in Russia for dessert use are proving good in quality here, and those listed for cooking are prime for this use alone. This holds good for the 100 varieties fruited in Iowa the past year, so far as the Russian estimate is known.

As to the Russian Pears, Cherries and Plums, the story of experience is told in recent Bulletins of the Iowa Experiment Station as to their prospective usefulness.

Ames, Iowa.

J. L. Budd.

The Kentucky Coffee Tree for Street-planting.

To the Editor of GARDEN AND FOREST :

In your issue for February 13th you say that the Kentucky Coffee-tree "is an excellent tree for street-planting, possessing the merit for this purpose of not putting forth its leaves until late in the spring." Will you kindly explain why you think this characteristic a merit? It seems to me that trees that must often be the sole harbingers of returning summer which the dwellers in cities can enjoy should be of those species which put forth their leaves as early as possible. In the country, where a thousand minor forms of vegetation early delight the eye, the leafing time of the trees may be less regarded; but I, for one, rejoice most in those city trees which earliest cover themselves with green, and regard, for instance, the Willows in Madison Square with a peculiar degree of affection. A tree which puts forth its leaves very late hardly has a chance to play its part acceptably before the sun and dust of July destroy its freshness of aspect. In the unpaved streets of a village it may be desirable that the ground shall dry before the trees cast a dense shade. But does this argument apply in the paved street of a larger town?

New York City.

J. B. K.

[Perhaps not. One hardly associates street-planting with bricks and mortar, trees are so rarely planted in the thickly-settled parts of American cities; and in more rural regions, trees which come into leaf early keep the roads and walks under them wet and muddy late in the season. The heat of the sun, too, is not unpleasant when it first begins to make itself really felt, and there are people who object to being deprived of it by the early leaves of many kinds of trees.—Ed.]

Winter Care of Conifers.

To the Editor of GARDEN AND FOREST :

Sir.—It would seem fitting that a word of caution should come from GARDEN AND FOREST at this point in the season, following an open winter, as to the care of Coniferæ and plants with the evergreen habit. I am reminded of this by recalling a season not many years ago, when at this period, there being no snow upon the ground, there prevailed for several days an exceptionally low temperature. A severe unchecked frost followed, penetrating the ground four or five feet, and occasioning widespread disaster to plants, such as enter into the composition of many plantations in this neighborhood—choice varieties, not always easy to get or to raise successfully. It is very possible to have a recurrence of just such conditions for the first two weeks in March. The snow which comes to-day

is usually gone to-morrow, owing to the sun's position at this time of the year and to the influence of the sea air in this vicinity. The safeguard is simple enough: to cover valuable plants with any material likely to arrest frost—manure, straw, earth, evergreen cuttings, etc.

New York.

Jno. Y. Culyer.

The American Pomological Society.—I. Orange-Growing in Florida.

THE twenty-second biennial meeting of this Society, held a fortnight ago at Ocala, in the heart of the orange-producing section of Florida, and during the height of the orange season was naturally devoted largely to semi-tropical and tropical fruits. We present herewith extracts from a paper by Hon. G. E. Fairbanks, on the "Orange industry from a commercial standpoint," and in future numbers we hope to give the substance of several other papers read at the meeting and prepared, like this one, by members of the Florida Horticultural Society. Some of the more important features of the meeting will also be described.

It is hardly fifteen years since orange-growing gained any prominence in Florida, but this industry has already become the leading and by far the most important commercial industry of the state. Where but a few hundred small groves existed twenty years since there are now over ten thousand. Cotton, corn, sugar, rice, grazing, all require large areas. Orange-growing is the most compact and productive of all agricultural industries. An acre of land devoted to the culture of cotton will produce perhaps fifty dollars worth of cotton or twenty dollars worth of wheat, corn, or other grains. A well-established, mature orange grove can be relied upon to produce an orange crop worth \$300 to the acre, even at the low price of one dollar per box. One railway car will carry the product of twenty-five acres of cotton, but can only carry the product of a single acre of Oranges. A grove whose product is 10,000 boxes of Oranges will furnish freight for a train of thirty-three loaded cars, while a large cotton plantation producing 250 bales will furnish freight for only three or four cars. This illustrates the commercial advantage of orange-growing in building and sustaining railways. If we estimate the crop of Florida at present at 3,000,000 boxes, it requires 10,000 car-loads of 300 boxes to the car to move the crop, and calculating the average freight to all parts of the country at sixty-six cents per box the crop pays the railways \$2,000,000 on freight alone. The value of the box stuff used would be \$390,000; the nails \$30,000; the paper for wraps \$12,000, labor in gathering and packing \$600,000. Thus making an output of \$1,140,000 for simply preparing the fruit for market. If to this large sum we add the cost of cultivation, of fertilizers, of packing houses, teams, tram roads, and the tools and implements of labor, we can begin to realize the commercial value of this industry, even at this comparatively early stage of growth. When we realize that not more than one fiftieth of the Orange trees in Florida are bearing we are amazed at the possible and probable future development of an industry limited to this single state, and small areas in Louisiana and California.

In view of the vast area of groves still to come into bearing, and the natural increase of those now productive, the question naturally arises, What will be the future of the orange industry of Florida? Some, in a general way, say that we cannot overstock the market; but within ten years we may anticipate that the increased production of Florida and California will be very large, and if all the trees now planted in the United States were to come into bearing, there is no question but that the supply would exceed the demand. In facing this fact, our advantages and disadvantages for the culture of Citrus fruits may be briefly stated.

Our climate is adapted to the production of oranges in their greatest perfection, being neither too cold nor too warm, too dry nor too wet. Again, our orange-growing section lies within a thousand miles of the principal markets of the United States, and consequently transportation should be both rapid and cheap. On the other hand, our fruit matures or comes into market in the months of November and December, January and February, a period when naturally the demand is not so great as in the summer months, and when the transportation is at more risk on account of freezing weather. Again, we have the disadvantage of competition with inferior West India and Mediterranean fruit; and, in the third place, we have an inferior service by rail and steamers, with higher rates of transportation than for foreign fruit. And even for this brief period of our shipping season there is

always the risk of injury to the fruit by cold in December and January if it is allowed to remain on the trees. Labor, box stuff and commissions, are comparatively high, so that even at present prices of fruit more than half the money received in market is absorbed in expenses of placing and selling it.

It may be admitted at the outset, therefore, that lower prices are to be looked for. Nevertheless, orange-growing will never fail to yield a fair profit in Florida.

The increase of productive groves will not equal more than twenty-five per cent. of those set out, because a large percentage of groves have been planted in unsuitable localities, and will have to be abandoned. As the groves grow older there will be alternation of bearing and fruitless years, which will reduce the output one-half. The expense of caring for and working groves will be greatly reduced. The cost of preparing fruit for market will be lessened. Transportation will be made better and less expensive. System and co-operation will be introduced in the methods of marketing, so that a fairer average market price will be obtained. As the cost decreases the consumption of our fruit will increase. Even if eventually the net return to the shipper should be only fifty cents per box, allowing for a production of 250 boxes to the acre, the return would give a handsome per cent. upon the outlay.

To bring orange-growing to the best conditions of success fruit of the best varieties and of the greatest excellence as to quality must be produced. We cannot afford to send to market inferior fruit. All inferior groves, either in location or quality of soil, had best be abandoned, and only first-class groves maintained. The problem how to preserve our fruit and extend the period of supply safely over a longer period is yet to be solved. And meanwhile the highest success in orange-growing must be sought in the reduction of expenses and in improving the quality of our fruit.

Notes.

The United States government brought suit last year against the Sierra Lumber Company to recover damages of \$2,217,254.20 for cutting timber on public land in Tehama County, California. The trial has at last been decided, and the jury returned a verdict in favor of the government. The damages, however, were assessed at \$41,000 only.

The New York Central and Hudson River Railroad Company is to build at once four country stations from plans by Shipley, Rostan & Coolidge, the pupils and successors of H. H. Richardson. The stations will be of stone and of the general character and design of the rural stations built by Richardson and his pupils during the last ten years along the line of the Boston and Albany Railroad.

The *Ruellia macrantha* is getting quite common in Philadelphia as a window-plant. Certainly one more worthy it would be hard to find. Its large, trumpet-shaped, rosy flowers are produced for a month or two in succession. Another favorite window-plant is the old *Linum trigynum*, a member of the Flax family. Its yellow flowers, one to two inches in diameter, are well supported by its deep green leaves.

"Lime," states the *Garden* (London), "is said to be a good preserver of timber. Ships and barges used for the transport of lime last longer than others. . . . A platform of pine planks was used to mix lime on during three generations; then, being no longer required, was neglected, and at length hidden by grass that grew over it. Sixty years afterwards, on clearing the ground, it was discovered sound and well-preserved."

A farmer in Lockport, New York, was recently indicted by the grand jury for "neglecting to remove and destroy diseased Peach trees." The case will be an interesting one to horticulturists, as it will be the first one of the kind tried in this state, and will therefore test the validity of the law with regard to diseased fruit-trees. The trees in question were examined by a Commissioner appointed by the law and found to be affected with the yellows.

"There is no such thing," says the *Garden* (London), "as a blue Primula, although one might, from the descriptions in catalogues, suppose that the hybridist's highest hopes had been realized. What the florist, or whoever he may be, calls blue, and what is strictly that color, are two different things. The flowers that are called blue are invariably of a mauve shade, sometimes pale lilac, never self blue. That we are approaching closely to the long-wished-for shade we cannot doubt, and the hybridist, if he perseveres, will doubtless attain his object; but to call those Primulas blue that go under that name is misleading. When we do have a blue Primula we shall have a prize indeed, such as will justify high praise and commendation."

The Pennsylvania Horticultural Society has fixed the dates of its exhibitions for the current year. An exhibition of bulbous and other spring plants will be held on the 2d, 3d and 4th of April when prizes of \$100, \$75 and \$50 will be offered for the best collections of Orchids in bloom; and from the 11th to the 16th of November a Chrysanthemum show will be held, when prizes of \$100, \$85, \$65 and \$50 will be awarded for the best collections of twelve plants in twelve varieties.

The seeds of *Araucaria imbricata* are eaten in Chili as an after-dinner dainty, and with this custom is connected the origin of the oldest specimen of the tree in Europe. Towards the end of the last century, Menzies, the surgeon on Vancouver's ship, while dining with the Governor of Chili, preserved some of the *Araucaria* seeds which were offered him, and sowed them in pots on the voyage home. Five of them germinated, and one of them still stands near the green-houses at Kew.

In the collection of products from Lee County, Florida, now on exhibition in the Semi-tropical Exposition at Ocala are some remarkable Bamboos, grown near Fort Myers, which are large enough for fence-rails. This giant Grass survived the freeze of 1886, and it is probable that the cultivation of the Bamboo will be as profitable there as it has proved in southern California. As far north in Florida as Jacksonville a slender species, which reaches a height of twenty-five feet, survives the winter and is very useful as a decorative plant. No doubt it would serve more utilitarian purposes, and it has been suggested by Mr. A. H. Curtiss that if cut into proper lengths and woven together with two courses of wire, it would make a cheap, light and durable fence.

An excellent illustration of fruiting branches of the small Japanese Orange, known in this country as the Satsuma, from photographs taken in Japan, is published in a recent issue of the *Pacific Rural Press*. Of this plant Professor Georgeson recently wrote to *Orchard and Garden*: "The Japanese oranges are as different from our idea of an orange as they can well be, separating from the peel almost as easily as a grape, dividing into sections at the slightest pull, each section like a separate fruit, dissolving its piece into your mouth with a flavor of cherries, leaving no pulp behind, very good, excellently good they are. They, the latest of her fruits, add the crown of excellency to the already overflowing cornucopia of this 'Beautiful Land of the Sunrise.'" The Satsuma is now grown quite largely in Florida, where it is considered the hardiest of oranges, and during the last two or three years many thousands have been planted in California.

The Common Council of Philadelphia has authorized, without a dissenting vote, the Mayor of that city to negotiate for the purchase of Bartram's Garden to serve as a public park—the simplest method, on the whole, of putting into practical execution the scheme lately advocated in GARDEN AND FOREST. The plan, however, should be extended so that some stable corporation, like the Academy of Natural Sciences or the University of Pennsylvania, may have control of the management of the new park. The fact that the people of Philadelphia are securing a series of small parks is largely due to the public-spirited and tireless efforts of Mr. Thomas Meehan, the well-known horticulturist, who has been a member of the city government for several years, and who has recently been re-elected by a sweeping majority. Many generations of Philadelphians will have good reason to remember with gratitude his disinterested efforts for the improvement and happiness of his fellow men.

The *Gardeners' Chronicle* condenses from one of our consular reports an account of the isolated British settlement on Norfolk Island, in the south-western Pacific, about midway between the north cape of New Zealand and New Caledonia, and about 380 miles from each. The island is about five miles long by three broad, with a total area of 8,600 acres. It is just outside the tropics, the extremes of temperature are never reached, the climate is most equable, and the thermometer never ranges higher than 84° in the summer and never lower than 46° in winter. At one time the island was densely wooded with the native Pine (*Araucaria excelsa*) and other trees, but now it is covered with open, park-like downs, interspersed with this Pine. Originally used as a penal settlement, it was in 1856 made over to the descendants of the famous mutineers of the Bounty, who had increased and multiplied beyond the sustaining power of Pitcairn Island, and who were presented with Norfolk Island. The soil is exceedingly fertile, being composed of a dark chocolate loam, or decomposed basalt. There is a complete absence of frost, and almost every temperate and sub-tropical plant grows in luxuriance.

But three plants, or weeds, are so destructive to all other vegetation that a portion of every year is given by the whole community to their destruction; but in spite of this they are increasing. These are two *Solanums* and the *Cassia lavigata*. The whole island is parceled out into fifty-acre lots, held at a peppercorn rent; the original immigrants received fifty acres each, and for some years each married couple received the same grant; this was reduced to twenty-five acres. The native vegetation of the island is wholly peculiar. Besides the famous Norfolk Island Pine already mentioned, there is a Tree Fern (*Alsophila excelsa*) and a Palm (*Areca Baueri*); there are besides upwards of thirty different kinds of Ferns.

A correspondent writing to the New York *Tribune* from Ithaca, New York, gives the following recipe as the best for poisoning English sparrows: "Dissolve arseniate of soda in warm water at the rate of an ounce to a pint; pour this upon as much wheat as it will cover (in a vessel which can be closed so as to prevent evaporation), and allow it to soak for at least twenty-four hours. Dry the wheat so prepared, and it is ready for use." It should be distributed in winter in places where the sparrows congregate, but where domestic fowls will not be endangered, and a quick decrease in their numbers is certain to follow. This is a somewhat exacter form of the advice given by the United States Agricultural Department in its Commissioner's report for 1887; and to explain the necessity why it should be widely employed, the writer calculates the rapidity with which English sparrows multiply where they already exist, and spread further and further westward—covering the surface of the United States and Canada, he says, at the rate of 500,000 square miles yearly; and adds many instances of their powers of depredation. In cities, we all know, they do considerable damage, but how much is exemplified by the fact that "the sexton of St. John's Church, in Providence, Rhode Island, took 970 eggs and two cart-loads of nests at one time from the Ivy upon the church," and that "the luxuriant Ivy formerly covering portions of the Smithsonian building at Washington was thus totally destroyed." Every farmer, at least in the neighborhood of our eastern towns, is aware what enormous injury sparrows inflict upon ripening crops; and it seems indeed as though concerted action should be taken to prevent their becoming an intolerable pest throughout the whole country.

The great public parks in German cities are undoubtedly the most artistic, in scheme and execution, which have been laid out in recent years. It is a double surprise, therefore, to find, from time to time, in German horticultural journals, signs of bad taste exhibiting themselves in directions which have no parallel, we believe, in other countries. For example, one of the chief horticultural journals of Germany has recently devoted many pages to the praise of artificially constructed ruins, and has given illustrations to show how they may best be constructed. Of course, ruins which are essentially picturesque objects, and speak as strongly to sentiment as to the eye, are peculiarly beloved in the sentimental Fatherland; and artificial ruins are found there at almost every step—in the parks of wealthy land-owners, in the gardens of poets, on top of pretty hills that are laid out as public promenades, and in the depths of rocky ravines. Now they serve as studies or garden shelters, now as booths for the sale of refreshments, and again as outlooks affording a picturesque prospect. And, it must be confessed, they are usually placed in exactly those spots where, if they were only genuine, they would have the best possible effect. But the fact that they are not genuine so degrades them in the eye of sensible folk that they excite laughter or contempt rather than the poetic sentiment they are intended to serve. Most travelers believe, we fancy, that these artificial ruins are creations of the earlier years of our century, when sentimentalism ran riot in Germany, and expressed itself in a thousand other ludicrous ways. But it seems, from the evidence of the articles to which we refer, that the taste for them is not yet extinct; and it is either amusing or distressing, according to one's turn of mind, to read a serious discussion with regard to the best ways of placing them, of utilizing them for one practical purpose or another, and, especially, of making them "genuine." Truth, we are told, should always be considered in their formation—they should be well built, of dignified materials, and a strict regard should be paid to the dictates of style as revealed in the genuine ancient constructions. And all this effort after truth is to be expended in undertakings, the object of which is to embody a lie! It is almost needless to say that whatever may be the effort after truth in the matters of detail, it is the lie which makes itself most clearly felt in the result.

The Railroad in Horticulture.

THE service which the railroad is capable of performing in the development of horticultural taste and knowledge is considerable. Every inhabitant of a town visits the railroad-station, and if the town is in the neighborhood of a city, a considerable portion of the population passes through the station six days out of seven. The impression it makes, therefore, is powerful and lasting. Railroad-managers, or some of the more far-sighted among them, long ago perceived that a well-built and well-equipped station is the best advertisement that can be set up in a country town, and that the first impressions received by a stranger in arriving by rail have much to do in determining his choice of a home, and railroad-gardening has, therefore, come to be considered a necessary part of construction and maintenance among prosperous and progressing companies seeking to develop local passenger business. It must be confessed, however, that up to the present time railroad-gardening has failed, with few exceptions, to accomplish what the public has a right to expect of it from an artistic point of view, and that instead of using their opportunities for increasing the taste and knowledge of the communities they serve, railroad managers have generally been satisfied to reproduce all that was glaringly bad in the prevailing horticultural fashion of the time. This was, perhaps, inevitable, and it will be inevitable so long as men trained in other pursuits and engrossed in absorbing occupations feel that in these matters of taste and special knowledge they need not call for the advice of an expert of a higher class than the ordinary jobbing gardener. It is the old story—a man employs an architect to build his house, but thinks he needs no advice in laying out the park that surrounds it. The principles which underlie good railroad-gardening are simple. They relate—so far as such gardening has yet been attempted—to the improvement of the immediate surroundings of country stations, and to the shaping and turfing of the slopes rising or falling from the permanent way.

The essential features in the surroundings of a station are: convenient and abundant approaches, and some treatment of the ground not needed for the approaches. This treatment should be at once economical and permanent, and of a character simple enough to be successfully maintained by the station-master and his assistants, under the inspection and with the occasional advice of a higher officer charged with the management of the horticultural affairs of the corporation. The selection of a general system of treatment is the only difficult part of the undertaking, and it is here that railroad-managers have usually failed. Most railroad-gardens—and this is as true of Europe as of America—consist of a badly laid out and constructed approach, bordered with turf in which are cut as many large and often grotesquely-shaped beds as can be crowded in, filled during four months of the year with the most showy and ill-assorted plants and quite bare of all covering during the remaining eight months; of a few shrubs, mutilated almost past recognition by bad pruning, and a clump of Pampas grass to complete the decoration. Not infrequently this arrangement is varied by the introduction of the name of the station printed in bold characters with large white stones, or by pattern-beds of gay-colored sand or pebbles—mere “toys,” as Bacon wrote three centuries ago, “you may see as good sights many times in tarts.” Station-grounds thus arranged are not artistic, and therefore are bad from the point of view of the public. They are enormously expensive and difficult to maintain, and therefore are bad from the point of view of the railroad. It is evident that no railroad corporation, however prosperous, can go on year after year decorating station-grounds on a system which requires a large annual outlay. If railroad-gardening is ever to become a potent and permanent means of public education, it must be organized upon a more economical basis, and with more regard to the laws of good taste and of good business than has yet been shown in the United States or in Europe. This is a subject which has, however, occupied the attention of a few thoughtful men, and we feel confident that some progress has at last been made in railroad-gardening—a view which will perhaps be confirmed by an examination of the pictures of some of the suburban stations recently built by the Boston and Albany Railroad, which we begin to publish this week. The grounds surrounding these stations have been laid out with a view to convenience, neatness and simplicity. They contain no beds of brilliant flowers, and make no attempt at startling effects. They rely for their attractiveness upon convenient and well-kept roads, neat turf, a few good trees, and masses of well-selected and well-planted flowering shrubs among which herbaceous and bulbous plants are allowed to grow. The scheme is simple and, when thoroughly carried out in the beginning, is easy and inexpensive to maintain. And as true art, which consists in adapting any creation of this sort to its surroundings and to the requirements of everyday life, always impresses itself in the long run upon those who are brought in contact with its results, these simple station-yards are already exerting an influence which is shown, in the communities of which they are the centres, in a truer appreciation of what is most beautiful in gardening. The best scheme for treating railroad slopes and banks has not yet been worked out. The two extremes are the carefully graded and turfed bank, generally adopted in England when railroads were first built, and the rough, gullied slope, usually bare of vegetation or covered with an occasional growth of native shrubs which do not long escape the annual butchery of the track-gang. Some system intermediate between these two extremes is needed. The turfed slope, in spite of all the money that has been expended upon it, has not been successful even in England, where the climate is much better suited to the development of good turf than in any part of the United States. The grass slopes there are now generally in a bad condition, cut with gullies, filled with weeds, and really less satisfactory

than if Nature had been left to shape and cover them according to her own devices.

At least one company in this country has expended enormous sums of money in grading and turving its slopes, but the result, as might have been expected, is even less satisfactory than it has been in England—our hot sun and long droughts keep the turf brown through the greater part of the year, even when they do not kill it out entirely. What is needed is a covering which will be more permanent than turf, which will not require the constant cutting and attention that turf requires, and which can be secured without the excessive first expenditure for accurate grading and the deep soil that are needed to make a grass-covered slope presentable.

It has been suggested that a railroad slope covered with dwarf, hardy shrubs would be more secure and would look better than one covered with turf of the poor quality, which is all we can hope to secure in our climate in such positions. The value of this suggestion lies in the fact that such shrubs as might be used—wild Roses, dwarf Willows and Sumachs, Sweet-fern, Bayberry and several others—would, when once established, prevent the surface-soil from washing, would not grow tall enough to interfere with operating the road, and, if destroyed by fire, would grow again from the roots and soon cover the ground. There can, of course, be no doubt that a bank covered with any of these shrubs would present a more inviting and pleasant appearance to the eye of the traveler than a stretch of such turf as can be grown without great expense for annual renewals and for mowing, rolling and watering. The Boston and Albany Railroad Corporation has recently established nurseries near Boston, in which large quantities of native shrubs are now grown, with a view to testing the possibilities of covering with them the slopes in its suburban division. These experiments will be watched with much interest.

One of the important and interesting results of Mr. Pringle's botanical exploration of northern Mexico is his discovery of a vast forest of Oaks and Junipers covering the mountains of Chihuahua and extending north and south for a distance of nearly a hundred miles parallel with the lines of the Mexican Central Railroad, and in some places less than a hundred miles distant from it. When the Mexican Central Railroad was built, sawed-pine ties, cut from the mountain slopes of northern New Mexico and southern Colorado, were used; these were soon ruined by dry rot, and the company has now for some time been replacing them with *Arbor-vitæ* ties, cut in the swamps covered with this tree, which abound in the northern portion of the states bordering upon the great lakes. These ties cost the company \$1.12 delivered in their yard at Paso del Norte, and yet there is, Mr. Pringle believes, Oak and Juniper timber enough in this great forest-belt of northern Mexico to supply all the railroads of that country with ties for many years.

A plant with which to make a lawn that will remain green during the summer, without irrigation, in a dry region like central and southern California, has long been desired. Our advice has been asked upon this subject, and we have referred the question to M. Naudin, who directs, in southern France, the garden in which are now the largest collections of dry-country plants, and who has an unrivaled knowledge of such plants. His answer is as follows:

"We have at the Villa Thuret lawns of *Bromus erectus* (a European grass) which remains green without irrigation during the long droughts of the Provence summers. These lawns, however, are less beautiful than those of "Ray Grass," which will not flourish here.

"*Achillea Millefolium* is spoken of now for this purpose. It grows freely, even in the driest weather, and makes a handsome turf. It must be cut over, however, frequently,

to prevent it from throwing up flower-stems. This plant does not succeed in soil strongly impregnated with lime, but it grows freely in poor, gravelly, arid soil. It would succeed admirably, no doubt, in California. There is a native perennial plant here which covers the most barren gravel, and which, I believe, would make an excellent lawn in dry regions. It is the *Trifolium frugiferum*. The stems and branches are prostrate, and spread over the ground. This plant is very tough and hardy, and it produces freely heads of pale, rose-colored flowers, which resemble ripe strawberries—a resemblance which is the origin of the specific name. A lawn composed of this plant would not require cutting.

"It is possible that there exists in Algeria a grass or some other plant capable of resisting drought and great heat, and suitable for making turf, but heretofore no one there has thought of this matter. I will make inquiries of my African correspondents, and perhaps we shall find just the plant we need."

A correspondent of the *Southern Lumberman*, writing from Byram, Mississippi, calls attention to the value of the wood of the Tupelo Gum (*Nyssa uniflora*) for woodenware, especially for fruit and vegetable boxes. The wood is very light, nearly white in color, and its peculiar fibre prevents it from splitting. The supply is practically inexhaustible, and as this tree grows in swamps which cannot well be cleared and drained, it will not soon be destroyed. The wood has been valued locally for a long time for bowls and other articles of domestic use; and it now seems probable that it will soon become an article of considerable commercial importance, as it combines lightness and toughness in a greater degree than any American wood existing in such large quantities.

The changes in population which are likely to result from the exhaustion of the Pine supply of the forests about the head-waters of the Mississippi River and in the region of the Great Lakes will have a serious effect on the business of the railroad and steamboat lines of the north-west. They have hitherto been largely employed in carrying lumber and other supplies for the inhabitants of an extensive region which would have remained, to a great extent, unsettled and undeveloped had it not been for the stimulus and assistance which this great timber-supply has given to business and industry of all kinds.

Not only will the quantity of lumber to be transported soon be inconsiderable, but the occupations of the people of the country will be interfered with and crippled, and there will be a marked decline in the wealth of the region. The relation of these forests to the subsistence of multitudes of people who have never seen the woods themselves, is a conspicuous illustration of the importance of forestry subjects in their economic bearings.

Recent Botanical Discoveries in China.—I.

THE flora of the far east—of China and Japan—is so totally different from that of western Europe, so much richer, especially in ornamental shrubs and trees, that from the earliest intercourse with those countries Europeans have borrowed therefrom to embellish their gardens and green-houses. Yet, with few exceptions, the introduction of Chinese element dates within a century of the present time. So far as the British Islands are concerned, the plants of eastern Asia will flourish in the southern and western parts, at least, in about 10° or 12° higher latitude than in their native homes, and in eastern North America in probably about the same latitude as at home; but on this point my information is too meagre for me to write with authority. Here in England we were not altogether without evergreen shrubs and trees, though practically limited to the Holly, Yew, Juniper and Ivy, with the color-giving heather and furze, which cover and beautify so many miles of the least productive parts of the country. Now, the dwellers in towns, especially on our southern and western coasts, are more familiar with the varieties of *Enonymus Japonicus* and *Aucuba Japonica* than they are with native shrubs. Prominent among the

numerous other hardy plants of the Chino-Japanese region it is sufficient to name the incomparable *Wistaria Sinensis*, *Clematis patens*, *Ampelopsis Veitchii* and the China Aster; among more strictly green-house plants, though they thrive out-of-doors in the milder parts of the country, the Camellia, Chrysanthemum, Primula and Azalea.

But it is not my intention to dwell upon what we already possess; rather on that portion of the flora of eastern Asia which is still known to us only from dried specimens and the necessarily imperfect descriptions of travelers. Russians, French and English have recently contributed largely to the general fund of information, and it happens that each nationality has collected for the greater part in a different region or regions, the floras of which are so diverse that few of the novelties from these different sources are the same. Collectively their explorations have led to the discovery of an enormous number of new species, and no inconsiderable number of new general types. Considering the highly ornamental character of many of the Chinese denizens of our gardens, it was not to be expected that the later discoveries would surpass in beauty, grandeur, elegance or singularity what was previously known of the flora of the Celestial Empire. Nevertheless, as I shall presently show, the existence has been revealed of many herbs, shrubs and trees that would grace the gardens of our western countries.

Mr. Maximowicz is engaged on the Russian collections of Przewalski, Piasetzki, Potanin and others, but his numerous duties prevent him from making very rapid progress. M. Franchet has already published the collections made by the French Abbé David in northern China and eastern Mongolia and Tibet, and, in part, the exceedingly rich collections made by the Abbé Delavay, chiefly in Alpine regions, in the western province of Yunnan; while to the writer has fallen the task of the final elaboration of Forbes and Hemsley's "*Index Flora Sinensis*," which appears in the *Journal of the Linnean Society* of London. The last contains an enumeration of all the plants known to grow in China proper and the contiguous islands, with references to the publications in which they are described or figured, together with their synonymy, distribution in China and extensions beyond, with descriptions of new genera and species. Since the issue of the first part of the "Index" the materials in the herbaria of the British Museum and Kew have been largely augmented, the former by the acquisition of the herbarium of the late Dr. Hance, who spent nearly forty years in China and devoted his spare time, which was very little, to the elucidation of its botany; and the Kew establishment by numerous small collections, but more especially by very large collections made by Dr. A. Henry in the central province of Hupeh, and a considerable collection from the province of Szechuen, made by the Rev. E. Faber, a German missionary.

I propose passing in brief review such new species, or new genera, as are of interest to gardeners, not forgetting older ones of merit that have not yet been brought into cultivation, and interspersing notes relating thereto by the collectors themselves.

Clematis.—About thirty species of this genus are recorded from China in the "Index," and subsequent discoveries have added ten or a dozen more; some of them are quite new, others new to China. Among the latter a pink-flowered variety of *C. montana*, a species which is specially valuable on account of its hardiness and early flowering. The Chinese variety was collected on the mountains near Ichang, and was in flower in May, so that it possesses the merits of the typical Indian form, with a variation in color. *C. Henryi* ("*Icones Plantarum*," t. 1819) is a very distinct new climbing species, having simple, cordate-oblong three-nerved leaves and solitary axillary flowers, with thick, waxy-white sepals about an inch long, with a little pink in the middle on the upper surface. Flowering specimens were collected in Antelope Glen, Ichang, on the 5th of February; and Dr. Henry states that the flowers were seen peeping out of the heavy snow the same winter; therefore it must be a desirable plant for introduction. A very narrow-leaved variety of *C. recta*, having white flowers, succeeded by golden, feathery carpels, looks very pretty in the dried state. Of equal interest to the new species were wild specimens of *C. florida*, from the neighborhood of Ichang, where, however, it was only found in one spot. *C. Armandi* ("*Planta Davidiana*" ii., p. 2) is a tall, climbing shrub, with ternate leaves and ample terminal panicles of white, fragrant flowers about two inches in diameter.

Davidia involucrata is one of the most remarkable of the Abbé David's discoveries in the province of Moupin, Eastern Tibet. It is an elegant tree, between sixty and seventy feet high, with foliage singularly like that of a Lime-tree, and in

inflorescence and floral structure so peculiar that its place in the natural system cannot be determined with certainty in the absence of more complete material. The conspicuous part of the inflorescence consists of two oblong-cordate white bracts, six inches long, nearly opposite each other, and tapering at the tips. A little above these, and terminating the stalk on which they are borne is a flower, or cluster of flowers, consisting of a pistil and numerous stamens with red anthers. Its affinity is with the *Hamamelideæ*. The late M. Decaisne, in a letter to Sir Joseph Hooker in 1871, the year after the discovery of the tree, states that he was given to understand that it was in cultivation in the nursery of A. Leroy, at Angers; but, although Leroy may have had seed, it does not appear that he succeeded in raising plants. The Abbé David, in an introductory chapter to Franchet's "*Planta Davidiana*," states that it grew at an elevation between 6,000 and 7,000 feet, associated with a *Cerasus* bearing small red fruits, a gigantic *Corylus*, a *Quercus*, various *Laurineæ* and numerous species of *Ficus* of the most varied aspect. He mentions, too, that he collected good seed of several species of *Rhododendron* and three of *Magnolia*, which was lost in consequence of arriving in France during the war with Germany.

Magnolia.—Imperfect specimens were received at Paris of an arboreous species, between ninety and one hundred feet high, which bears very large white and purplish odoriferous flowers, similar to those of *M. Campbellii*, and produced in April and May; and Dr. Henry has sent specimens of two very fine species from the Patung district. They are both large trees, with huge deciduous leaves and large terminal solitary flowers, red in one species and white in the other.

Abutilon Sinense.—A very conspicuous shrub or small tree, with cordate leaves and showy yellow flowers, campanulate in shape, and from two to two and a half inches long. It inhabits mountain-woods to the northward of Nan-t'o, and attains a height of twenty feet. Should this prove hardy, it will well pay for introducing.

Decumaria Sinensis.—This is specially interesting on account of its being a member of a genus of which previously only one species was known—namely, *D. barbara*, a native of the Atlantic States of North America, from Florida to North Carolina, thus adding one more link in the chain of connections between the floras of these two widely-separated regions. Dr. Henry describes the Chinese species as a creeping shrub, hanging from the wall of the cliff in the Ichang Gorge, with beautiful clusters of fragrant white flowers. It bears a general resemblance to the American species, and is figured in the "*Icones Plantarum*," t. 1741.

Itea ilicifolia.—A distinct species with Holly-like (*Ilex Aquifolium*) leaves and long, narrow racemes of white flowers. Common about Ichang in rocky places on the tops and sides of cliffs. Judging from the dried specimens this is the most ornamental of the genus, which is restricted to eastern North America, the mountains of northern India and to China and Japan. Figured in the "*Icones Plantarum*," t. 1538.

Chimonanthus nitens.—A very well marked species of a genus previously supposed to be monotypic. From dried specimens it appears to be an evergreen, and even if not evergreen the white flowers are certainly produced with the thick shining leaves. A shrub five or six feet high, inhabiting the neighborhood of Ichang. Figured in the "*Icones Plantarum*," t. 1600.

Liriodendron.—We have imperfect specimens of a Tulip-tree from the Lushan Mountains, Kiukiang, from two different collectors. Whether they belong to a distinct species or to the North American species is uncertain. There is evidence of the early introduction into China of a considerable number of American useful plants, and there is always the possibility that the Tulip-tree may have been introduced. On the other hand, there appear to be differences. The Chinese Tulip-tree is described as of spreading habit, which is at variance with the upright habit of the North American tree as it grows in England; and the one flower seen is much smaller than any of the North American we have for comparison. The leaves, however, offer no distinctive character. Further information respecting the Chinese tree is awaited with great interest. It is noteworthy that no specimens of this tree have been sent in the very complete collections made by Dr. Henry.

Lonicera.—Upwards of thirty species of Honeysuckle have been detected in China, including seven or eight new ones in the later collections. Among the latter *Lonicera fuchsoides* is remarkably distinct and ornamental, reminding one much of some of the Andine species of *Fuchsia*, having ternate verticillate leaves and erect flowers. It was discovered by the Rev. E. Faber on Mount Omei, Szechuen, at an elevation of 5,000 feet. *L. Henryi*, from the Patung district, has terminal

clusters of small red flowers, and is most nearly allied to the Indian *L. glabrata*. *L. similis* is a slender twining shrub with elegantly formed lanceolate leaves of a pale color beneath, and slender flowers in pairs on axillary peduncles, shorter than the leaves. The name was given in allusion to the strong resemblance it exhibits in its foliage to an Indian variety of *L. macrocarpa*. *L. tragophyllum* is a handsome species allied to the European *L. Caprifolium* and the North American *L. sempervirens*, having even larger flowers, described as yellow. This also is from the Patung district.

Viburnum.—A genus of the same order as the Honeysuckles and almost as numerous represented in China. Seven are described as new, and two or three of them are very marked in character. *V. rhytidophyllum* has large, coarsely wrinkled leaves, densely felted beneath, and *V. Henryi* is a trailing shrub with foliage very much like that of some of the Lauro-cerasus section of *Prunus*. *V. propinquum* is nearly related to the common *V. Tinus*, though probably less attractive, as the flowers are smaller. Wild specimens of the old *V. macrocephalum* were sent by several different collectors from distant localities. In these only a few of the outer flowers are neuter.

Actinotinus Sinensis.—This is an arboreal *Viburnum*, with large palmately compound leaves, like a Horse-chestnut or Buckeye. It is figured in the "*Icones Plantarum*," t. 1740, and is without doubt one of the most striking novelties from the

The Railroad-Station at Auburndale, Massachusetts.

THE station at Auburndale, near Boston, on the line of the Boston and Albany Railroad, has a peculiar interest as being the first of the series erected by the late H. H. Richardson.

It is almost needless to explain that until Richardson began to build rural railroad-stations none had been erected in America which deserved much consideration as intelligent and pleasing works of art. Among our great city termini a few existed which were reasonably appropriate to their purpose in external appearance as well as admirably planned for the convenience of trainmen and passengers. But the best of our small country stations were plain, cheap structures, looking no more like stations than like buildings of some very different kind, while the average varied between grotesque and fragile attempts at picturesqueness of aspect and shabby make-shifts disgracing the very name of architecture. We had vulgar little stations that looked like exaggerated kiosks, and brick or wooden boxes which merely displayed the railroad company's desire to expend as little money as possible; but

Plan of Auburndale Station Grounds, Boston & Albany Railroad.

Patung district of Hupeh, though the flowers are not very showy. In floral structure this does not differ from the genus *Viburnum*, which is numerous in species spread all round the northern hemisphere and extending to the Andes in America and to Madagascar. In all these species the leaves are simple and undivided, therefore the Chinese plant was separated generically. Dr. Henry states that it inhabits the high mountains and is evergreen. Leaflets seven, petiolate, six to nine inches long, borne on a terete petiole six to ten inches long.

Ilex.—China is rich in Hollies, several new species having been sent since the part of the "Index" dealing with the genus was issued; but there is nothing among them to equal the beautiful varieties of *I. Aquifolium*. The new *I. Pernyi* ("*Icones Plantarum*," t. 1539) is similar to Fortune's fine introduction, *I. cornuta*, with comparatively small leaves, and Dr. Henry has sent a highly remarkable variety of *I. cornuta* with almost exactly square leaves, each angle terminating in a spine. *I. macrocarpa* ("*Icones Plantarum*," t. 1787) has an unusually large blackish fruit, but is not of a specially ornamental character.

Kew, February, 1889.

W. B. Hemsley.

"One should first seek out the natural character of the place to be changed into a park, in order to maintain this character and to draw out all its good points. This rule is but seldom observed."—Hirschfeld, 1777.

no rural stations that gave pleasure to the passing traveler's eye, accommodated him comfortably while he was waiting for a train, or showed that an architect worthy of the name had had a hand in their erection.

No problems, however, appealed more strongly to Richardson than those which were utilitarian in character; none delighted him more than those which had hitherto been neglected by art; and he was as eager to put his best thought into small problems as into large ones. Therefore, when the Boston and Albany Railroad Company asked him to design their station at Auburndale he showed for the first time what such a building ought to be. The plan, of course, in so small a station is very simple, there being but two waiting-rooms of almost equal size for men and women respectively. But the rooms are well proportioned and the ticket-office is well placed, projecting as a prettily designed bay upon the platform. The interior walls are wainscotted with brick, as being cheap, durable, pleasant to the eye, and easily kept clean. The woodwork is simple throughout, but, although no carving exists, it is carefully distributed and profiled and gives a look of refinement very different from the parsimonious nudity or the cheap elaborateness which the average country station

shows. Here, as well as in the architectural features proper, we feel that the hand of an artist has been at work.

Simplicity, dignity and solidity likewise characterize the exterior of the building, while its outlines and proportions are such that its true purpose could not be mistaken. A station is not a house to live in, but a house to wait in—a mere temporary shelter. The roof, therefore, not the walls, should dominate in its expression, and this prime fact Richardson never forgot, no matter what was the size of the station he was designing. The walls at Auburndale are low, and their windows are not conspicuously emphasized; but the roof is broad and massive, and the adjacent sheds are not mere adjuncts but integral parts of the building, their roofs being vitally united with its own. In a dwelling-house a more ornate chimney would have been appropriate as accenting the importance of the family fire-side, but nothing could be better on a railroad-station than Richardson's simple chimney. An interesting point is the design of the wooden posts which support the sheds. Here again there is no ornament. But the plain square-sectioned posts with their massive braces, affording three points of support to the beams, admirably express the nature of the material, and the slightly curved form of the braces prevents any look of stiffness or monotony in outline. The roofs of the sheds are open, showing the timbered construction. The walls of the station are of granite, trimmed with red sandstone, and the roofs throughout are slate, with terra-cotta ridges.

But a station like this would be shorn of half its comfort and beauty were it placed and surrounded as the American country station usually is. The railroad company was as wise in asking Mr. Frederick Law Olmsted to design its grounds as in asking Richardson to build it. Whatever the art, and however small the problem, only the best talent can produce the best result. If the accompanying plan is studied for a moment its excellence will make itself plain. The high-road passes obliquely by the station and from it, towards the right, diverges the approach in an easy curve, while near the porch underneath which passengers alight is a wide space for turning, and the little lawns are so disposed towards the left as to admit of the passage of numerous vehicles without danger of over-crowding. A path-way encircles the station, and the platform may thus be approached, without entering the building, either on foot or in a carriage. Under the superintendence of Mr. E. L. Richardson, who has charge of all the horticultural concerns of the Boston and Albany Railroad, these lawns have been covered with neat turf and adorned with hardy flowering shrubs, naturally disposed yet grouped in effective masses. The boundary fence to the right is hidden by shrubbery, and masses of it are so disposed around the walls of the building that, with their luxuriant covering of Japanese Ivy (*Ampelopsis Veitchii*), they almost seem part and parcel of Nature's handiwork. In summer this effect is the most charming that can be produced in a rural situation, while even in winter the delicate tracery of the naked vines and the bare masses of the shrubs preserve it to a considerable degree. No detail better shows Mr. Olmsted's good taste than the way in which, in laying out his path, he permitted planting close to the walls.

A single tree placed by the carriage-porch—which admits to the women's waiting-room—already groups agreeably with its roof, and in future years will be still more effective, throwing its shade over the spot where the idea of shelter is most conspicuously emphasized by the lines of the building itself. A sub-way runs under the tracks to a strip of lawn on the opposite side, which has its fence "planted out" with shrubs, thus affording the traveler a pleasant, verdurous prospect whichever way he may turn his eyes.

"A mountain range should be viewed in sections, and only once in its entirety; a city should be divided in like manner, and we should avoid getting the same view repeatedly. To break up a fine prospect effectively is, however, a much more difficult matter, than to expose it completely." *Pückler-Muskau*.

Foreign Correspondence.

London Letter.

SINCE my last letter we have had a coat of snow six inches thick, which remained with us two days and was accompanied by severe frost. Then came the south-west wind, and the snow disappeared as suddenly as it came. Before the snow the weather was genial, coaxing into bloom many out-door plants, amongst them many kinds of Crocus, Snowdrop, Snowflake, *Eranthis hyemalis*, the beautiful *Anemone blanda*, *Scilla bifolia* and several kinds of Muscari. Many of the dusky Hellebores were in full flower, and the deliciously fragrant Chimonanthus was gay with flowers. Planted on a warm border against a south wall this shrub never fails to bloom freely here. Its companion, *Jasminum nudiflorum*, with its long wands of bright yellow flowers, also was in full beauty before the snow and frost came. Even now again the branches are full of newly-opened flowers and buds. The flowers of *Nuttallia cerasiformis*, which was almost in full bloom, were destroyed by the cold. In England this shrub does not fruit, whereas in France and other continental countries its large, plum-like fruits are its chief attraction. Perhaps the most pleasing of the shrubs now in flower outside is the Japanese Witch-hazel, *Hamamelis arborea*. Your native species has little floral attraction, but the two species from Japan, *H. arborea* and *H. Japonica*, are beautiful flowering shrubs. *H. arborea* is probably only a large form of *H. Japonica*, but for garden purposes the two are quite distinct. At Kew, *H. arborea* is a pyramidal shrub six feet high, with numerous branches clothed with primrose-yellow flowers, one inch across, the calyx being of a deep claret color. In Japan this species grows to a height of twenty feet. It was introduced in 1862, is perfectly hardy, and is just the plant to be used for massing in positions where its bright yellow flowers would be seen from a distance. The Hellebores (*H. orientalis* or Lenten Rose) above referred to are frequently grown in pots for the conservatory. They are wanting in brightness of color, although some improvement in this respect has been made by breeders, especially in Holland and Germany, where Hellebores receive special attention. De Graaf, of Leiden, has raised many improved kinds, and he grows them in thousands. They are as hardy as the Christmas Rose, much easier to cultivate, and if only we can get brighter and clearer colors into them they will be of immense value as winter flowers. The best I have seen are Apotheker Bogren (rose-purple), Comm. Benary (white with crimson spots), Gertrude Jekyll (pure white), Peter Barr (purple) and Colchicus coccineus (rosy purple). At Kew, large clumps of these Lenten Roses are taken up from the ground late in the autumn, planted in pots and brought into the cool-houses to flower. When the flowers are over, the plants are returned to the borders, and they do not show any signs of having suffered from the treatment. Spring Crocuses are gaily in flower whenever the weather will let them push through the soil, and the sun woo them into expanding. I counted fourteen species in bloom to-day, *C. Imperati*, with its beautiful purple feathering on a buff ground, the color inside being bright rose-purple; *C. versicolor*, variable in its colors, but all the forms attractively marked; *C. Alatavicus*, *C. Korolkowii*, the earliest yellow, *C. chrysanthus*, with several other bright yellow, and one white-flowered species were amongst them.

The meeting of the Royal Horticultural Society was to some extent spoilt by the snow and cold, which prevented intending exhibitors from bringing their plants. There was, however, a varied and attractive display, rendered still more so by the unusual appearance of things outside. The most interesting exhibit was a collection of Narcissi grown in six-inch pots, some of them bearing as many as ten flowers. For the middle of February the display was unusually good, and the plants had not that drawn, weakened appearance which early, forced Daffodils generally have, the leaves of Mr. Barr's plants being short, sturdy and full green; many of the flowers were almost as good as the best of unforced ones. Amongst the yellows I noted, as first-class kinds for forcing, Spurius, Golden Spur, Obvallaris (Tenby Daffodil), Henry Irving, Santa Maria and Maximus. These were excellent in form, clear in color, and good in substance, in fact, perfect flowers. Many people spoil their Daffodils in forcing by placing them in a close house or frame. The secret of Mr. Barr's success is the use of bottom heat, with abundant top air and a low temperature. The pots are plunged over a bed of manure in a frame with a southern aspect, and the lights are removed in favorable weather, whilst even in the coldest weather plenty of ventilation is given. This treatment induces vigorous roof-action and keeps the leaves short and dark green.

The variegated form of *Yucca filamentosa* was shown in capital condition, by means of a dozen plants in eight-inch pots, the leaves being one foot long by two inches broad, bright green, with broad marginal bands of creamy white, the characteristic curly filaments being of a pale brown color. Such plants take a long time, at least six years, to grow from small suckers, and it is difficult to keep

strong language, such as few practical men will indorse. There can be no question that it is worse than waste of time to graft many plants which do as well, or even better on their own roots. Roses are a case in point, few of these plants being better when grafted than when raised from cuttings, whilst many of them are much worse. It is a fact that very few of the Pome and Drupe families existing in English gar-

Auburndale Station, Boston & Albany Railroad.—See page 124.

them in health. But when grown as those exhibited were they are exceedingly handsome. They color better and keep their health better also when grown in a warm frame or greenhouse than when kept cool. Out-of-doors this variegated form succumbs to the cold and wet of our winters.

A collection of variegated Kale attracted much attention, owing to the clearness and prettiness of the colors—creamy white, with very crisp margins, and the narrowest band of emerald green; others bright purple with green edges, others magenta and green, and so on. In cool conservatories these plants might fill the place in winter which Coleuses occupy in summer. Several collections of Cyclamens were shown, all of the plants being good, although not above the average attained by London growers of these plants. Messrs. Veitch sent a collection of flowers of the Javanese Rhododendrons, which seem to be perpetually in bloom with them. They also exhibited plants of *Cypripedium Lathamii*, a hybrid raised from *C. Spicerianum* and *C. villosum*. It is at least as good a plant as *C. Leeanum superbum*. Singularly enough the floral committee did not consider it worthy an award of any kind. Another hybrid called C. J. B. Haywood, the offspring of *C. Druryi* and *C. superbiens* was poor in color, in fact, one of those hybrids which ought to be destroyed as unworthy of their parents. When is selection to operate amongst the hybrid *Cypripediums*?

Some fine collections of Apples were exhibited by Messrs. Rivers, Bunyard and others. A collection of fruits of Oranges, Lemons, Shaddocks, etc., and a small bush covered with pale yellow fruits was exhibited under the name of Bijou Orange.

The value of grafting and budding in horticulture is being discussed in the *Garden* in such a manner as is likely to throw a good deal of light on a subject of vast importance, especially to fruit-growers. Some of the writers condemn grafting of all kinds whatsoever, one declaring that it is "jugglery," "a sham, very often a fraud, and nearly always a delusion." This is

dens are on their own roots. If all this proves to be wrong, we shall stand convicted of one of the biggest mistakes ever perpetrated in horticulture. That this cannot, however, be, I know from a very simple but conclusive bit of evidence no older than last October. One night toward the end of that month we had a severe frost. In a London nursery, where Peaches and Nectarines are grown in thousands, I saw many rows of low-budded, fan-shaped trees, every one of which was frost-bitten at the collar, just above the stock, whereas on the same ground not twenty yards away a bed of standard-grafted Peaches was unaffected. The difference between the temperature on the ground and six feet above is about five degrees, and the scion was unable to bear the temperature which the stock had safely weathered. To what extent is grafting practised in America? It would be easy to mention hundreds of failures attributable to grafting, more especially among Coniferæ and among many other trees and shrubs. In a great many cases it is by far the best plan to use stocks of the same kind as the scion. In a great many more it would be preferable to raise the plants direct from cuttings.

Kew, February 15th, 1889.

W. Watson.

"There is no part of improvement in which cautious operation is so necessary as in opening scenery. Injudicious planting may be remedied; but the evil resulting from injudicious removal can never be repaired, at least in the lifetime of the owner who has fallen into this common and destructive error. I was once consulted upon the improvement of a place on a large scale. The striking fault was the want of trees on the foreground connected with the house. I therefore marked several places for groups and single trees to supply this deficiency. But what was my astonishment when the owner told me he had cut down the trees that had occupied the very situation I had selected for planting."—From Gilpin's "*Practical Hints on Landscape Gardening*."

Cultural Department.

Forwarding Vegetable Plants.

YEARS ago we thought it essential to success in growing early cabbages that the seed should be sown in September and wintered over in cold-frames, or, south of Baltimore, planted out on the sides of elevated ridges. But this practice has been generally abandoned. We have found it more satisfactory to sow the seed in February, in boxes in a green-house or in a hot-bed; to transplant into other boxes as soon as the plants are large enough, and then to harden the plants in a cold-frame. Plants raised in this way are better than those from fall-sown seed, for they make a more rapid growth in spring, come in as early, and form a better crop, since they do not run to seed.

We use green-house boxes in preference to hot-beds for all kinds of plants, always taking care to get them into a cold-frame as soon as the character of the plant renders it safe to do so. This saves the trouble of preparing manure and making hot-beds, and handling, covering and airing through snow, slush and rain. The work can be comfortably attended to inside. Besides, by the use of shallow boxes not only is the irksome work of transplanting into a frame avoided, but the plants are kept in good shape for removal to the garden. A plant lifted from the box on the point of a trowel, and set with a lump of soil and manure on its roots gets a good start of one pulled from a frame.

Many amateur gardeners think when they make a hot-bed and sow tomato seed thickly therein that they are forwarding the plants for the garden. But a good, healthy plant started

purpose a well-prepared cold-frame is better, if not used too early. Here we sow our tomato seed in February, in green-house boxes, transplant into other boxes as soon as the plants are large enough to be handled, and then into frames for hardening by the middle of March. In the latitude of New York a month later than these dates will be the proper time. Plants thus transplanted are stout, stub-pointed and vigorous, if care is taken to expose them, after they go into the frames, to the open air whenever practicable. Such plants, set out here late in April, will give ripe fruit late in June or early in July. This practice involves more trouble, for which, however, the gain in earliness fully compensates. Egg plants and Peppers will not harden well in frames like Tomatoes, and the effort to make them do so will only result in stunted, unhealthy plants. We always pot Egg-plants and shift them, like any hot-house plant, until the weather is settled and the ground is warm—generally about the middle of May in this latitude. After this treatment, when the plants are put out, they are large and robust, and do not easily succumb to the Colorado beetle, which is fonder of them than of the Potato. A few early Cucumbers and early Musk-melons, treated in the same manner as the Egg-plants, will do well and give an early crop. Seeds of these very tender plants should not be sown even here before March, and a month later at the North. While the cold-frame is waiting for the tender plants some seed of early scarlet Turnip-radish may be sown in it. These, with care, will be out of the way by the time it is safe to trust the Tomato plants in the frames. Of course, during the fall and winter, the frames are kept at work with Lettuce and Cauliflower. The Lettuce being cut out, the Cauliflowers can be left without the glass when the time comes to sow Radishes in March, and with an extra

Auburndale Station, Boston & Albany Railroad.—See page 124.

in the open ground a month later will surpass in vigor, earliness and productiveness the tender and bleached plants raised in a hot-bed. If a hot-bed is to be used, the seed should be sown in a small bed; a week or so later a larger bed should be prepared, and into this the young seedlings should be transplanted as soon as large enough to be handled, though for this

frame the same sashes that grew the Lettuce and Cauliflower may be used for the Radishes and for hardening the Tomato plants. Few amateur gardeners understand the full capability of an ordinary cold-frame. A few sashes can be kept profitably at work on frames from November to June or later.

White Sports among Roses.

THESE peculiar developments or accidental growths, discovered from time to time among our Roses, are of a most interesting character, and they have either become more frequent of late years, or they have been more closely observed and cared for. In any case, the list of such variations has been much extended within recent years.

Botanical authorities have expressed the opinion that white variations, or albinos, as they are sometimes termed, may be expected among all colored flowers, and that, consequently, it is not surprising that they should be found among Roses. Up to the present time it is believed, however, that white sports have appeared only on the pink varieties, and have been most numerous in the Tea class. Some varieties appear to have a greater tendency in that direction than others. *Souvenir d'un Ami*, for instance, produced white sports, both in England and in the United States, at nearly the same time. As far as can be judged from descriptions the flowers of the two sports seem to be very similar, though there has probably not yet been a comparative trial of the respective merits of *The Queen*, the American sport, and *Souvenir de S. A. Prince*, the English variation.

Both the above-named sports have been much lauded, but it is rather premature to express a decided opinion on their merits, either for bedding-out or for forcing, though their origin is good, the parent having been a very popular variety for several years.

Another instance of a sport appearing in duplicate was that of *The Bride*, whose parent, Catherine Mermet, produced a white flower at nearly the same period in two different establishments, though one of these sports exhibited a tendency to a pink tinge in the centre of the flower.

So slight a difference as this, however, might easily be caused by a different soil or some peculiarity in treatment.

Another addition to the list of white sports, of comparatively recent introduction, is the *White Bon Silene*, the origin of which is clearly indicated by its name, the flowers being similar in size and shape to the type, but pearly white in color.

It seems somewhat strange, however, that after preserving its original characteristics for over forty years, the *Bon Silene* should, in 1883, produce a white sport.

In the hybrid perpetual class white sports have not been of so frequent occurrence, though the cause of this has not been explained unless it be that a majority of Roses of this class are of stronger growth and more vigorous constitution than the Teas, and therefore may not be so likely to produce sports of the character indicated. The absence of color may be due to some inherent weakness of the plant, on the same principle by which the white variegation of the leaves of plants has been accounted for.

The most notable instance of albino development among the hybrid perpetuals is that of the *White Baroness Rothschild*, which was introduced in 1882 by Paul. It is much like the type in growth and general appearance, and though a lovely Rose when in perfection, yet, like its parent, it does not flower very freely.

Orchid Notes.

Cattleya Percivaliana.—When some six years ago this grand *Cattleya* developed its handsome blossoms in our collection, there was much discussion as to whether or not it was an inferior variety of that Prince among *Cattleyas*, *C. Mossia*. After a season's growth, however, the plant proved to be entirely distinct, of most easy culture and worthy to rank among the foremost of this noble genus. It is a winter-flowering *Cattleya*, enriching our houses with its lovely blossoms when Orchid bloom is always acceptable. Four and five large flowers are produced on a single stem of a rich and charming rose color, the labellum being bold and very beautifully marked with deep, velvety purple, and finely fringed. For cutting and decorating purposes it will be found a valuable acquisition, remaining in bloom on the plant for four and five weeks. Varieties of this Orchid are many, and among the numerous plants now cultivated, several white forms have appeared which are still (like most white-flowered *Cattleyas*) extremely rare. During the summer months this species is in active growth, and an abundant supply of air and moisture will then be found necessary to insure good results, but the direct rays of the burning sun must be carefully avoided.

Dendrobium thyrsiflorum.—A group of this *Dendrobium* when in bloom is truly a magnificent sight, and when arranged with ferns and foliage plants its beauty is enhanced. It makes a splen-

did object for exhibition purposes, its lovely racemes of white and orange flowers are strikingly effective. Its culture is quite easy, producing blossoms in great profusion during April and May, which will remain in good condition three and four weeks if kept in a cool and dry atmosphere while growing. The plants should be so placed that abundance of light and air is available, and during bright weather occasional syringings overhead will prove very beneficial until growth is completed. It will then be necessary to remove them to a cooler situation so that the bulbs may mature thoroughly before they bloom. They should be left in these quarters until the flowering nodes at the apex of the bulbs show signs of swelling, when they may be returned to their former position to enable the handsomely racemes to develop. Pots or baskets will suit this species, with very little compost about the roots. During January and February the home of this *Dendrobium* is thoroughly searched by collectors, who ship large quantities to this country. Plants can thus be obtained at a low price. Rarely, however, are such masses received as are frequently developed under cultivation. Out of an importation of several thousand plants it is unusual to obtain a score of good-sized specimens. Large plants of this species still remain rare, therefore, and somewhat difficult to procure.

Principles of Physiological Botany as Applied to Horticulture and Forestry.

XI.—THE PHENOMENA OF GROWTH.

ALL growth in the vegetable kingdom depends on the multiplication of cells and the increase of these in size. It is hard to realize that the organs of the plant with their orderly arrangement and their beauty of form are dependent on the increase in number and size of the microscopic masses of living matter which we have examined in a previous paper of this series. In the cells of the plant the living matter exists as a comparatively shapeless mass of a soft and yielding substance, and yet this formless matter has given shape to the shell, if we may call it so, in which it is confined.

Moreover, these shells, or cell-walls, are of extremely diversified form and character. Hence it is still more difficult to understand in what way these formless masses can, in one case, give one shape, and in another, another shape to a cell-wall, always with such precision that the sum of these creations appears before us as a plant so definite in the unity of all its parts that we think of the whole as an individual and speak of it as such. Furthermore, each plant has its own shape, and the various species are recognized as such, even small deviations from the standard or type being detected by the observer. And yet all of these multiform structures spring from microscopic masses of a formless substance.

This statement, although correct in the main, may be somewhat misleading without further explanation. It is only at the earliest period of growth of new cells that this control over the shape of the imprisoning walls can be exercised. During this early period the living matter determines in all respects the architecture of its prison. Later, the hardening walls are no longer plastic, and, then, in the interior of the cavity, the living matter seems to lie helpless and shapeless except so far as it conforms to the shape of the firm walls around.

FORMATION OF NEW CELLS.—In the living matter of a young cell capable of multiplication there exists a roundish body, somewhat firmer in its consistence than the rest of the protoplasm. This body is known as the *nucleus*. When a cell is about to produce another, by the process termed multiplication (or, by a strange use of language, division), this nucleus undergoes certain changes in its internal structure. The word structure is used advisedly, for, although under high powers of ordinary compound microscopes, it may appear structureless, yet, with the very best modern lenses and with appliances for staining the nucleus, a tangled network can be plainly discerned, which sooner or later assumes definite lines resembling in no slight degree the lines of a map of the earth, with its meridians of longitude and its parallels of latitude. At a certain period in the development there is an accumulation of masses at the two poles, and a sort of an equator can be made out without much difficulty. These accumulations at the poles and the equator characterize the distinct separation of the nucleus into two parts, each of which becomes a new nucleus, each one in its turn to become the seat of similar activities and changes.

The nucleus is believed to have much to do with the distribution of nutritive matters in the forming cells, but exactly how it governs the arrangement of building material is as yet

unknown. It is enough to say that the division of the nucleus accompanies the multiplication of cells. Just here it is well to glance at the wonderful character of a process by which these nuclei give rise to new nuclei and their enclosing cells, and the latter in their turn give rise to others, and so on, the new ones assuming shapes unlike the earlier ones as the growth proceeds. The cells of the Maple produce in their multiplication the leaves, branches, flowers and fruit of the Maple, each new organ appearing at its proper time and place, while the similar cells of the Oak give us all the organs of the Oak. Yet between the early cells of the two, it would be hard to find any differences by which they might be distinguished. The cells of the one have inherited from their ancestry one set of characters, namely, those of the Maple, while those of the other have come down to us from an ancestry of Oaks.

FORMATION OF TISSUES.—The cells constitute tissues, or coherent clusters of cells more or less modified, and the coherent tissues make up, of course, the masses which we recognize as the organs of the plant. In their young state the cells which constitute these tissues may appear to be almost indistinguishable from each other in form and other characters, and the tissues may very closely resemble each other. As the tissues become older, the newly-formed cells increase in size, and the nature of the constituent walls may become modified. But these new cells of the tissues do not all change in the same way. Those of the interior of a stem in its youngest state are more or less compressed or hemmed in by the cells outside of them, and thus arise what are called *tensions*: the outer portions of a group pressing more or less on the parts within. Now, since all of these tissues are more or less yielding, it is plain that any force exerted on one side of a very young organ would change its tension, and there would be a resultant change of form. Such changes of form do take place, not only from external influences, but by internal forces and the resultant changes of form may go on with a good degree of rapidity. The various movements of plants are to be referred to this cause. The external influences exerted by the force of gravity, by light, by heat, by excess of moisture, or by shock, all result in changes of form of the tissues and the organs which they compose. Exactly what is the cause of the fluctuations in the internal forces is as yet unknown, although in many cases there is plainly a direct relation between changes in the osmotic force and the changes in form.

MOVEMENTS.—It may be said, in concluding this brief reference to the growth of tissues, that all young parts of all plants are capable of spontaneous movement. In a few cases, notably those of the twiners, like the Morning Glory and the Hop, the movement can continue even after the parts have grown somewhat older, and in many instances there are movements, attributable to differences in the tension of tissues, which are distinctly associated with the relations of leaves and the parts of flowers to light, moisture, and heat.*

RESPIRATION.—The chemical phenomena which accompany the growth of tissues can be passed over very lightly. There is, of course, an expenditure of building material and a slight consumption of oxidizable matter by which latter is procured the force requisite to put the former in its place. The consumption of this oxidizable matter (sugar or its equivalent) is practically a process of oxidation, and consequently there is a production and elimination of the two products—namely, carbon dioxide and water.

In all growth there is more or less heat evolved. This physical phenomenon can best be studied in such cases as the so-called Calla Lily, in the scroll of which, during the maturing of the flowers, there is an appreciable elevation of temperature.

This series of processes during the various phases of growth constitutes, when taken together with the oxidations necessary for other activities in the plant, what is called the *respiration*. Carbon dioxide is given off, but the amount exhaled from a plant even during its period of most rapid growth is very small indeed, and, so far as hygiene is concerned it may be disregarded in the air of our houses. There are, however, processes of oxidation which sometimes occur in the rich soil in which house-plants are grown which render it doubtful whether it is not better to exclude such flower-pots from the sick-room. Furthermore, when a plant is in full flower the amount of carbon dioxide given off is larger than at other times, and there are odors evolved by flowers which may prove annoying to the sick. But on the air of the rooms in which healthy people are living the respiration of plants cannot exert any deleterious influence.†

† Many interesting facts relating to this subject are presented in a popular manner by Dr. Andrus in his HOUSE PLANTS AS SANITARY AGENTS.

Correspondence.

The Drayton Garden.

To the Editor of GARDEN AND FOREST:

Sir.—Magnolia-on-the-Ashley is little more than a dozen miles from the city of Charleston, and it has been in the possession of the Drayton family since 1671. Many of the Live Oaks, which were great trees then, still shade the lawns and walks of this garden, and it is full two centuries since the lines of stately Magnolias which rival the Oaks in massiveness and dignity were planted. Early in the history of the place the grounds were laid out with a broad, Oak-bordered meadow in front of the mansion, with another spacious lawn on the river side, and the stream which here drops into the Ashley was expanded into a pair of quiet lakes by two massive dams. Then more Oaks and Magnolias were planted, with some flowering shrubs and herbs, and the paths were bordered with Box. But the minor details of the plan were neglected after a time, while the trees, whose roots found the best of nourishment in the phosphate beds which underlie this whole region, kept on making marvellous growth. In 1841, when the present proprietor, the Reverend J. G. Drayton, D.D.—then a young man with health, to all appearance, shattered beyond hope—returned to the home of his ancestors, he found the great trees, and besides them only some dimly outlined walks, a few specimens of Gardenia, Calycanthus, *Illicium anisatum* and some wild shrubs on the border. The young student began his gardening and the life in the open air, which offered the one slender chance for recovery, by planting two Rose bushes. He knew little about plants then and less about work, but since that day his own hands have done most of the planting which has made his garden famous the world over, in some of its features.

It was six or seven years before Dr. Drayton found he had a chance for life, and in 1848 he planted the first Camellias and Azaleas of his remarkable collection, in which they are now counted by the hundred. Of Camellias there are some 300 varieties, many of them seedlings of his own raising. The plants, too, are remarkably large, strong and floriferous. Many specimens are trees more than twenty-five feet high, with trunks thirty inches and more in circumference, and now carrying thousands of flowers. The Azaleas are quite as numerous, and equally remarkable for variety, vigor and size. There are probably 150 distinct kinds, with individual specimens from ten to fifteen feet high and fifteen to twenty feet in diameter. Of course there are other noteworthy trees and shrubs in the garden. So fine an example of *Thuya gigantea* can hardly be found on this side of the continent, and there is a *Cupressus funebris* worth a journey to see, with immense specimens of Box Tree, and Rhododendrons, Kalmias and flowering shrubs in abundance. But after all, to northern eyes, the Camellias and Azaleas are the glory of the garden in early spring. From this part of the coast region all, who can, escape in summer to the highlands of the interior. Dr. Drayton leaves for his summer home in North Carolina as early as the first of May, but the Azaleas are in bloom a month before, and the wealth of glowing color along the avenues and on the borders of the lawn, where these shrubs are massed, can hardly be imagined, while the Cherokee Roses are flinging out their white banners from the very tops of the forest trees on the lake shore and covering them all over with flowers, and the Magnolias fill the air with fragrance.

While the Azaleas are in flower there seems no room for anything else, but a month or six weeks earlier the Camellias appear to fill the garden. Last year they were at their best a fortnight before the great snowstorm fell upon New York, and certainly they never can be more beautiful than they are to-day, and have been for a week past. Numbers and measurements give no idea of the dazzling abundance of flowers among the bright green leaves on the long lines of Camellias that stretch away in every direction, flowers single and double, and showing every tint from snowy-white to almost crimson. Glimpses of the shining river are caught through vistas of flowers, and under the moss-draped branches of the Oaks. The bright colors are all heightened by the dark masses of Magnolia that rise behind them. On the lawn the turf is beginning to warm into a tender green, and sheep are nibbling in the meadow, already at their work of keeping it closely cropped. And all this just at the close of February. No wonder the place is so attractive to visitors from the cold North, and no wonder so many of them feel a debt of gratitude to Dr. Drayton for throwing open all this beauty to be enjoyed by strangers.

Charleston, S. C., March 2d.

S.

The American Pomological Society.—II.

The Meeting at Ocala, Florida.

THE late meeting of the American Pomological Society was held in Ocala in accordance with the invitation of the Florida Horticultural Society, and the northern visitors were impressed by the energy and intelligence shown by the members of this organization. It was natural that a large percentage of the papers should have been contributed by them and that they should have conducted most of the discussions. But the uniform excellence of the addresses was noteworthy. Nearly two hundred members of the local society were present, and their activity suggested the thought that the large percentage of the population engaged in fruit-culture helped to insure a more general familiarity with the methods which command success than can be found in regions where fruit-culture is subordinate to other branches of horticulture and agriculture. A large proportion of Florida Orange-growers came from a climate where this fruit does not flourish. The industry was new to them. There was no body of doctrine or experience to draw upon. The local society therefore, has been of signal advantage in furnishing a medium for the interchange of instruction and experience and the result is that, while there remains much to learn, the growing of semi-tropical fruits in Florida has already been placed on a foundation as secure as that of other branches of economical horticulture.

President Berckmans, in his opening address, said that the Pomological Society was founded fifty years ago, not only to unite the fruit-growers of the country in a brotherhood and furnish a means of social intercourse among them, but to be of practical utility in collecting and classifying the knowledge of different fruits gained in widely-separated localities. It had not been conducted in the interest of individuals, but was an impartial tribunal, setting its seal of approval on what had been proved good in practice and condemning what was unworthy; and since fruit-growing had become so important a factor in the production of national wealth the work of the Society could be truly characterized as patriotic. It had long been recognized in Europe as the most efficient organization of the kind in existence, and it was especially useful in this country where the fruit-grower owns the land he tills and where he can apply the mental force acquired in free schools to the conduct of a business which is under his own control and in which his planted orchards and other improvements will help to increase the value of property which he possesses in fee simple.

Mr. Berckmans then called attention to the Paris Exposition, and congratulated the Society that our government had established a Division of pomology in the Department of Agriculture, and that this Division was to be represented in the general exhibit made by the government at Paris. He invited attention to the progress made in utilizing surplus fruit, because this furnished a relief to the grower at times when over-production was threatened. He urged the importance of co-operating with the experiment stations with a view to making them more effective in general, and especially for the purpose of directing their efforts towards the testing of new varieties of fruit and devising means to make successful defence against plant diseases and destructive insects.

Mr. Berckmans concluded with a brief sketch of four members of the Society who had died during the year. These were Wm. Parry, of New Jersey, well known as an originator of small fruits, and more particularly identified with the introduction of the Kieffer pear; Richard Peters, of Atlanta, Georgia, a widely-known raiser of fine stock and fine fruit and the disseminator of many good varieties of native apples and peaches; A. J. Caywood, of Marlboro', New York, to whom we are indebted for several choice varieties of grapes and raspberries, and P. W. Reasoner, of Manatee, Florida, a young horticulturist of remarkable promise.

The attendance from the North was not so large as had been expected, but twenty-two states and the Dominion of Canada were represented, and among those who came and took an active part in the proceedings were such men as C. L. Watrous and G. B. Brackett, of Iowa; Geo. W. Campbell, of Iowa; Thomas Meehan, Jr., of Pennsylvania; F. L. Hexamer, of New York; E. Williams and J. R. Parry, of New Jersey; B. G. Smith, W. C. Strong and F. L. Temple, of Massachusetts.

The following are abstracts of some of the more important papers read at the meeting:

REPORT OF THE SUB-TROPICAL FRUIT COMMITTEE.

The committee on sub-tropical fruits which was created at the Boston meeting of the Society proved its value by presenting a report which gave a better account of the history and importance of this strictly southern industry than can be found elsewhere in the same compass. Unfortunately the report of the California member or the committee did not reach Ocala in time for the meeting, but the Gulf region, from Louisiana to Florida, was very thoroughly covered.

In Louisiana the Parish of Lower Plaquemines has the advantage of furnishing the earliest oranges. The entire crop is sold on the trees, and the oranges are often paid for while the trees are yet in bloom. The prospective crop of a hundred-acre Orange-grove was sold last winter for \$30,000 before a blossom or bud had appeared on the trees. In southern Alabama the hopes of Orange-growers were frozen out with the death of the trees in the cold January of 1886, but the Fig is here grown to perfection and yields enormously. No other strictly sub-tropical fruits are grown here, but, as in the northern region of Florida, fruits of Oriental origin like the Kelsey and Bhotan Blood Plums, the Peen-to and Honey peaches, the Le Conte and Keiffer pears, are receiving much attention. There is a reviving interest, too, in some old and almost extinct varieties of the Peach, while the cultivation of the Scuppernong Grape and of the Pecan is rapidly growing in commercial importance.

In the Florida Peninsula proper, and down to the 28th degree of latitude, the cultivation of the Citrus fruits is the absorbing industry. The trees here grow like weeds, attaining the largest size and most perfect development. Every known variety of Orange seems at home here, and many of the introduced kinds attain a sprightliness of flavor, combined with a juiciness and sweetness, which they never acquire in their original habitat. It is but reasonable to expect that in countries where these fruits have been cultivated for centuries, varieties of the finest texture and flavor may be looked for; and enterprising Floridians are collecting and experimenting with the best Oranges wherever they can be found. On the other hand, many persons hold that the best fruits can be had by selecting choice seedlings at home, which unite good quality with great productiveness. Many of the best-known groves in the Indian River region are from Florida seedlings, and even the famous Navel trees, on account of their unfruitfulness, have in some cases been budded with so-called native varieties.

The Lemon is more tender than the Orange, but the freezing weather, three years ago, did not cause irreparable loss in the southern counties, and largely increased areas are planted with this fruit every year.

Many persons consider it the most promising for cultivation of all the Orange family. Florida lemons were quite unsaleable a few years ago, but now, since more has been learnt of varieties and of proper methods of curing and harvesting, they lead the market in value.

The Pomelo, or Grape-fruit, has conquered a position for itself in the North, and must soon be as popular in the market as it always has been for home use. Its beauty and size and flavor must make it saleable, and its productiveness will make it profitable. It varies greatly, and new and improved varieties will certainly be produced.

The best varieties of the Lime have been so lately introduced that little is yet known of their commercial value. Besides these many minor fruits of this family have been introduced and are sparingly used in a domestic way, like the Citron, the Shaddock and the Kumquat, a diminutive Japan Orange of great value for preserving.

The Fig has already been mentioned, but it thrives best north of the Orange-belt. The Loquat, or Japan Medlar, is seen growing over all the State, and has proved profitable where planted for market. It is susceptible of great improvement, and the better varieties can be grafted on seedlings or on Quince roots, as is done in California. The Kaki, or Japan

Persimmon, is a comparatively recent introduction. Some of its varieties are so rich in color that they may be fairly termed gorgeous, and in flavor it bears as high a rank as it does in appearance. No doubt its introduction marks an era in the history of fruit-growing in the State, for its culture is no longer an experiment. Still, comparatively little is known as yet of its distinct varieties or their special uses. One of their most interesting fields of experiment now offered to horticulture is the hybridizing of the Kaki and the American Persimmon. In the Orange-belt the hardier varieties of the Guava, the Olive, the Date, the Carob, the Downy Myrtle, the Chinese Litchi and other fruits have been successfully grown, while south of this region the Custard-Apple, the Tamarind, the Tropical Almond (*Terminalia Catappa*), the Pineapple, the Hog Plum (*Spondia*), the Barbadoes Gooseberry (*Peireskea aculeata*), the Star Apple (*Chrysophyllum Cainito*), the Mango, together with the Banana and Coconut, are all in cultivation, and described with some detail in the report.

VARIETIES OF THE SWEET ORANGE.

Mr. E. H. Hart, whose Orange grove at Federal Point is famous for its extent as well as for the number of the tested varieties it contains, read a paper on the above subject. Mr. Hart, with much humor, explained how the original belief that there was but one kind of sweet Orange, all variations being accidental and temporary, had been swept away by the advent of new varieties and of the hundred seedlings, which were quite distinct to the educated eye and palate. The late P. W. Reasoner compiled a list of more than 150 varieties. All the worthy ones were not included in this catalogue, but it could have been reduced if some admitted as distinct varieties had been placed where they really belonged among the synonyms. It is not difficult to judge the quality of a variety, but it requires time to sift from the list those that prove shy bearers, those with fruit too delicate for transportation or those with other faults which detract from their profitability. Again, fashion is fickle, and the variety which sells well this year may not be in demand the next. Who would have thought a few years ago, when Mandarins and Tangerines were eagerly sought at fifteen dollars a box, that the time was not far away when they would melt down on the hands of the commission merchant for want of purchasers, or be left to hang on the trees to rot like sour oranges? The speaker went on to say that out of the infinite variety of apples known to pomologists, the standard market sorts could be counted on the ten fingers. Even on the amateur's list, no orange should be admitted without a rigorous examination. And the market varieties should be selected still more closely.

We have only space to add condensed descriptions of a few varieties of special merit. The Maltese Blood is a favorite variety of the Blood Orange. Its thin, tough, juice-preserving skin gives it a high rank as a shipping fruit, and its tendency to bear only on alternate seasons may be corrected by liberal cultivation and fertilizing. Several strains of this variety show slight differences, and one of the best for flavor, heavy-bearing and long-keeping is possibly a case of bud variation from the Jaffa, in which the red color has become fixed. The Jaffa, as well as the Long of Thomas River, gives evidence by peculiarities in the young foliage of remote connection with the Maltese Blood, and this explains, perhaps, the crimson pulp in the case above cited. Another type of Blood Oranges has the shape and characteristics of the ordinary round orange, with the addition of the tinted pulp. Some are sharply acid and others have an exquisite sprightliness, and many of the trees show a vigor and fruitfulness which, when elaborated by selection and judicious crossing, promise a race of which Florida may be proud. The Centennial, though ripe enough for use in October and November, possesses the exceptional advantage of preserving its juices unimpaired on the tree until May or June. Of very late varieties Hart's Tardiff takes the lead for quality and long-keeping, being in season from March till August, and growing sweeter all the while. To judge from market quotations the Navel family stands high in popular estimation, but a non-productive habit has caused growers to look upon it with suspicion. The unfruitfulness has been attributed to deficient pollen, but perhaps too profuse blooming, as in the Maltese Oval, may cause a shedding of the young fruit from temporary exhaustion. But when the vigor of a mature Navel tree has been sustained by liberal feeding or by budding on the stronger-growing Rough Lemon, there has been less cause for complaint. The Washington Navel now stands without a peer even in this royal family. It often surpasses the Pomelo in size, is finer-grained, solid to the very centre, and sweet and succulent as a Strawberry Pine. Of the Double Imperial Navel

lately procured from Mayor Rountree, of New Orleans, it is too early to speak. From the few specimens grown in Florida it seems of moderate size, very solid, fine grained and heavy, entirely seedless and of an exquisite vinous flavor. A thorny tree of vigorous growth and a somewhat different style of blooming from its relative, it seems like a new departure in the family, which may by its productiveness fulfill the promise of its abundant bloom. The apical mark is less prominent than in some other members of the family and often blind, but dissection always shows the orange within the orange. It is a true Navel, and only lacks the guarantee of fruitfulness to insure it a front rank among the choice oranges of Florida.

THE LEMON IN FLORIDA.

From an elaborate paper on this subject by H. S. Kedney, of Winter Park, we make space for a brief abstract only. Less is known of the Lemon and its cultivation than of the Orange, but although it demands more care and closer attention, the prevailing belief is that south of the region of danger from frost it will prove at last the more profitable fruit of the two. Fifteen years ago the finer varieties of lemon were introduced into Florida by General H. S. Sanford, to whom, and to Reverend Lyman Phelps, Lemon-growers owe a debt of gratitude for directing attention to the choicer kinds, and for setting the first example of a successful handling of this fruit. The Lemon should be budded on Orange stock, and as it needs more water than the Orange, high and dry locations should be shunned, and yet no water must be left standing about the roots. The trees should be planted much more closely than Oranges, since the dense shade preserves moisture and seems distasteful to the rust fungus. For obvious reasons heavy timber on the north and west of a grove will be found useful. Each Lemon-tree, if well cared for, should yield half a box of fruit the fifth year after setting, and in the tenth or twelfth year from six to eight boxes, which may be set down as a fair average yield. There are usually two crops a year, the first ripening in July and August, and the other in October and November. The Lemon-tree is much freer from diseases and insect pests than the Orange; it is rarely troubled with blight, "die-back," or scale. The rust-mite is its greatest enemy, and although a russet Lemon is quite as good as any other, it is unsalable—while a russet Orange is marketable.

Exhibitions.

The Recent Orchid Exhibition in this City.

THE Orchid Show recently organized at the Eden Musée by Messrs. Siebrecht & Wadley surpassed in interest either of its predecessors. As we remember them, neither was so rich in beautiful or curious plants, or so attractively arranged. The public appreciated its opportunity. Although the exhibition was open for a full week it was constantly crowded, and the number of catalogues sold proved that a genuine desire was felt to learn something about its contents. Of course at a show of this kind Orchids do not appear to the highest advantage. There are only two conditions under which they are seen at their best—either as isolated specimens or harmoniously massed, many individuals of similar kinds together. The very qualities which make Orchids attractive—their peculiar manners of growth and the vivid colors and eccentric forms of their flowers—give a confused, heterogeneous look to a general collection. The contrasts are so strong in such a collection that no one plant shows its true beauty, while the total effect is often unpleasing. Yet, anyone who made the effort to isolate one plant from another and study its peculiarities, had much to enjoy in this exhibition.

Messrs. Siebrecht & Wadley themselves contributed 176 Orchids, as well as numerous other rare or beautiful plants; Messrs. Pitcher & Manda sent seventy-nine varieties of Cypripediums and various other specimens; Mr. William S. Kimball, of Rochester—one of the chief amateur cultivators in the United States—contributed seventy-four specimens, and Mr. John Eyerman, of Easton, Pennsylvania, fifty-six, while from Mr. Man, of Weehawken, New Jersey, came fifty varieties of *Cattleya Trianae* alone. In this last collection was a white specimen that was labelled as "the largest in existence"—a splendid plant indeed, with seven flower-stalks and thirteen blossoms.

A large shelf filled with plants of *Primula obconica* may well have convinced all visitors that no "Chinese Primrose" is so beautiful as this. The fine specimens of *Strelitzia Reginae*—the "Bird of Paradise flower"—seemed, as is always the case when they are exhibited, to attract more attention than any of the Orchids. This is one of the showiest flowers in the world; and, whatever may be the case under other conditions, showiness

rather than beauty is what "takes" at a flower show. The thirteen varieties of Pitcher plants exhibited by Messrs. Siebrecht & Wadley, were likewise an attraction; but the most beautiful object in the room was a well-grown *Bougainvillea spectabilis*, trained on a large, fan-shaped screen, which it entirely covered with its masses of soft yet vivid crimson.

It is unfortunate that there is no good hall in New York for horticultural exhibitions. There is little choice except between the dark and gloomy hall of the Masonic Temple and the Eden Musée, which is well lighted but otherwise unfit for the purpose. It is not nearly large enough, and one is distressed to see beautiful plants crowded in among hideous mural decorations and equally hideous statues, and forming a mere adjunct to a collection of wax-works. The public has certainly shown that it takes a great interest in horticultural shows. Even the Metropolitan Museum has been crowded to suffocation when put to this service, and the smallest collection, well selected and attractively arranged, would be sure to be popular. Let us hope that a suitable horticultural hall will be provided when the Madison Square Gardens are reconstructed. But meanwhile the public owes a debt of gratitude to the enterprising firm of florists who have done so much, under difficulties, to show how the culture of Orchids has advanced in America.

Notes.

A novelty in the commercial world is the "Chamber of Commerce for Horticulture," which was recently established in Brussels. Its members will meet twice a month to transact business, after the manner of exchanges in other branches of industry.

The Tulip was introduced into Europe from Persia, passing by way of Constantinople. Johann Heinrich Hawart, of Augsburg, whose garden was famous in its day for the many rare exotics it contained, may first have brought it to Germany about the middle of the sixteenth century, and it appeared in England some fifty years later, during the reign of Queen Elizabeth.

An interesting plantation of fruit trees is about to be destroyed in the *Jardin des Plantes*, at Paris, in order that the space occupied by the menagerie may be extended. This is the collection of Pear trees which Decaisne studied when preparing his famous work, "*Le Jardin Fruitiier du Museum*." It contains about 550 varieties of Pears and forty-five varieties of Plums. Similar collections of Apple and Cherry trees formerly stood near by, but were destroyed in 1883.

In addition to the ordinary culinary uses of the Potato—which are much more numerous in France than in this country—there are many other services to which this esculent is put. In Germany spirits are made from it, and exported under the name of "Stettin brandy," while a large proportion even of the French cognac, which is fondly supposed to be the juice of the Grape, is in fact spirits of Potato. *Eau de Cologne* is likewise largely manufactured from Potatoes, while after the farina has been extracted from them, the pulp that remains is manufactured into picture-frames, boxes and toys, and the water expressed in the process is a valuable scouring fluid.

On the Castle Huntley estate, in England, a remarkable tree was destroyed by a severe gale which occurred on February 3d. This was an old Scotch Fir which, says the *Gardener's Chronicle*, was believed to be over 250 years of age and was "in some respects as remarkable a tree of the kind as could be found in the country. Its girth at the ground was twenty-four feet. At one foot up it girthed sixteen feet, and at five feet, fifteen feet. Above this the trunk swelled out until it had a girth of about thirty feet, and, although its limbs had been sadly broken and shattered by the storms of centuries, it had at the time of its fall a fairly good head. It was broken almost clean across about twelve inches from the ground, and the trunk internally was very much decayed to within an inch or two of the bark. The tree, had it been in sound condition, would, it was estimated, have yielded ten tons of timber.

The cottage at Fordham, which was once occupied by Edgar Allen Poe, has been offered by its owner, Mr. P. A. Karey, to the Park Department of this city with the request that it may be removed to some site in the Central Park or in one of the new parks above the Harlem River. The Central Park already contains as many buildings as it can well accommodate, and, even for the sake of historical associations, no other should be admitted within its precincts. But it is especially desirable to foster such associations in this country where commercial interests yearly destroy so many records of that

past which the lengthening perspective of time will make more interesting to our descendants than it seems to be to the average American of to-day. In one of the proposed new parks Poe's Cottage should certainly be placed on some site where the landscape-gardener can make it an agreeable and perhaps a useful feature in his design.

"A good deal of attention," says the *Gardener's Chronicle*, "has been given from time to time to the old Japanese lacquer-ware, some very fine examples of which are contained in the South Kensington Museum, and a very complete set, showing the whole process of its manufacture, is exhibited in the Kew Museum. At the time this collection was got together a full report was prepared to accompany it, in which the mode of extracting the lacquer from the *Rhus*-tree, and the entire process of lacquering, were described. Considering the very large quantity of lacquered goods that now come to this country from Japan in the shape of boxes, trays, flower-stands, vases, etc., it would seem to be of some importance that the trees which yield the varnish should be preserved, and we now learn from a report from Hakodate that, as it was considered that the Lacquer-tree (*Rhus vernicifera*) would not succeed in the North, the few trees first planted were not looked after; but last year 157 young trees, averaging from five to eleven inches in girth, were tapped, and the yield was fairly satisfactory. The amount of sap was less than the same number of trees of a similar size would have yielded further south; but the proportion of water and foreign matter was only one-fourth, while the sap of southern trees is said to be generally nearly half water. After refining, the lacquer was also found to give a high polish, and it is, therefore, intended to promote the growth of the tree as much as possible. The young trees planted last year amounted to 150,582.

Three fields of botanical investigation in northern Mexico still invite the zealous and hardy explorer, and promise abundant harvests of new species and of more detailed information than now exists, of the distribution of the plants of this important phyto-geographical region. These fields are: the high northern Cordilleras and their Sonoran slopes—a region some 200 miles south of Arizona, where a day's walk will take the traveler from lofty summits down into warm valleys, which open out towards the lowlands of Sonora, and in which grow the Palm and the Orange. The second region is that part of north-eastern Mexico occupied by the northern extension of the Sierra Madre, and extending southward from Monterey for nearly 150 miles. A few plants were gathered forty or fifty years ago in the extreme northern part of this region by Gregg, Berlandier, Thurber, Parry, and during the past few years by Palmer, Sargent and Pringle; but its flora is practically unknown, except along its margin, although since the opening of the railroad to Saltillo it lies at the very doors of the United States. A good trail, with numerous branches, now leads from Saltillo through the heart of the mountains southward to San Luis Potosi, along which numerous missionary stations have been established. It will not be difficult, therefore, to see a great deal of this region in a comparatively short time, and without danger. In these mountains will be found, probably, the southern limit of many North American trees, or new species of trees of North American forms. The third region is on the Pacific side of the continent—a hundred miles to the west and south of Guadalajara. Here in the wonderful "barrancas" through which the rivers of the high plateau rush down towards the sea, and along the entire western slope of the Cordilleras, from Calima to Sonora, will, perhaps, be found the best botanizing the North American continent can now offer to the searcher for novelties. It is to the examination of these three regions that Mr. C. G. Pringle, who has already done so much to increase the knowledge of the flora of north Mexico, expects to pass a large part of the present year. He will start again for Mexico as soon as he has completed the distribution of his plants collected last year in New Leon and Chihuahua.

Catalogues Received.

PAUL BUTZ & SON, Newcastle, Pa.;—Plants.—M. B. FAXON, 21 South Market Street, Boston, Mass.;—Vegetable and Flower Seeds.—H. W. HALES, Ridgewood, N. A Proposed Invasion of Central Park.

IT seems as though there would never be an end of the necessity to defend the Central Park against aggressions and mutilations of one sort or another. A bill has once more been introduced into the Legislature authorizing the city authorities to issue bonds to obtain \$300,000 for the erection of new buildings within the park for the menagerie which already exists there, and to extend its zoölogical collections. So often have similar bills been defeated, in deference to a genuine burst of popular sentiment expressed through newspapers and journals of every class, that we cannot feel serious fears that this time the result will be less fortunate. Nevertheless, it is incumbent upon us to say again that a scheme favoring the extension or even the permanent maintenance of a zoölogical collection anywhere within the borders of the Central Park is wholly pernicious and indefensible. It looks neither towards the best interests of the park nor towards those of the zoölogical collection itself. There is not a foot of the park which is not absolutely essential to its chief and only proper function as a breathing-space and pleasure-ground for the people, or a foot which can be sequestered without injuring that design which, as all critics, native and foreign, have agreed, is one of the very finest examples of landscape-gardening art that the world possesses. And, on the other hand, a good zoölogical garden ought itself to be a work of art—carefully planned for its special purpose and much more extensive in area than it could be within the Central Park. This, however, is not the only scheme which has recently been advocated for the invasion of the park. In the pages of the *Pharmaceutische Rundschau*—a respectable and usually well edited trade-journal published in German in this city—a long article has been published declaring that the proposed botanical garden, of which much has lately been heard, ought by all means to be laid out within the bounds of the Central Park. A botanical garden, rightly established and conducted, would injure the park quite as much as a zoölogical garden. As much even as a zoölogical garden it needs to be controlled by scientific men, free from the interference of politicians. It appeals, more dis-

tinctly than a zoölogical garden, not to idle curiosity, but to intelligent curiosity and the definite desire for knowledge, and therefore is even less appropriate in a great popular pleasure-ground. And, finally, the soil of the Central Park is unfit for the establishment of a great botanical collection. Every old New Yorker knows what this tract of land was before Messrs. Olmsted and Vaux took it in hand. One great reason why it is so exceptionally interesting among works of landscape-gardening lies in the fact that Nature had seemed to say, Here, whatever you do, you cannot make a beautiful park. And the same fact partially explains that necessity for cutting out its plantations which from time to time excites well-meaning, but mistaken, popular protests. All other considerations apart, then, would it not be the height of folly to establish a botanical garden in a place which has been made a beautiful park only under the greatest difficulties?

In the proposed new parks in the northern section of the city there is room and to spare for both a fine zoölogical and for a fine botanical garden. Let the legislature there set apart the necessary space for them. Let money be collected from private givers in such amounts as will show a genuine popular interest, and then let the legislature, if needful, assist from the public treasury; and, as we have already advised, let governing associations, free from political control, be incorporated similar to those which control the Metropolitan and the Natural History Museums. Thus, indeed, there would be a chance that we should have collections worthy of the name. Nor need it be objected that the new parks would be too far from the centres of population to be really useful. We must think of the future as well as of the present; and even to-day, as has been pointed out by those in charge of the scheme for a botanical garden, the borders of the Bronx are as accessible as was Fifty-ninth Street when the Central Park was planned. By the elevated railways they can be reached from the City Hall in less than an hour, while these railways and the Bridge bring Brooklyn and Jersey City much nearer than they were to the Central Park twenty years ago.

We shall hardly be accused of a lack of interest in the establishment of a botanical garden at least, or of a failure to appreciate the fact that if rightly established and maintained it will be a boon and benefit not only to this city, but to the American people at large. Nevertheless, we frankly say that we would rather never to see it established than see the Central Park—that great monument to American art and priceless pleasure-ground of the poor—curtailed and ruined for its sake or for the sake of any other scientific or political or money-making scheme. It is certain, too, that the whole public shares our feeling, and that there would be no surer way for a legislator to ruin himself in the eyes of the people than to make himself an instrument in the defacement of the Central Park.

We begin this week a series of articles on the art of gardening which will both interest and instruct our readers. Born in the earliest times, this art has been practiced wherever men have lived in settled communities. It has gone through many phases, each of which reflected the spirit and the tendencies of the passing age, and has differed in different countries in harmony with the character of national civilization. Its developments in Europe, like those of all the other arts, may be grouped under two main types, one of which, as Alexander Humboldt pointed out, illustrates the temperament and expresses the æsthetic ideals of the South, while the other stands in the same relation to the North; and perhaps the most interesting portion of the history to be laid before our readers will explain that intermingling of these two types in modern days which finds a parallel in the present condition of architecture, painting and sculpture.

A number of histories of the art of gardening have been published in other languages, and German literature, especially, offers several of considerable size, compiled with much industry, and covering the whole field. But so far

as we have been able to discover, no such work exists in our language. Innumerable theoretical and practical treatises on the art of gardening have been written in English, and in some of them a certain amount of historical information is given. But we believe there is no English work that deals historically with the whole subject, or looks at it from the most instructive point of view—as an individual and independent manifestation of the artistic instinct, yet one which has a vital kinship with all the others, and a vital relation to the general course of human development. Indeed, even the most learned and voluminous German historians have either neglected to emphasize the close tie which binds gardening to architecture, or, while professing to do so, have not followed the best historians of architecture with regard to the points in question. We believe that this fault has been avoided in the present series of articles. Of necessity the articles will be brief, but they will give all essential historical facts and conclusions, with sufficient description of individual works to make their significance clear.

It may be granted that the history of gardening is less rich and varied than those of some of the other arts. Nevertheless, it is far more varied and significant than most persons realize. It is only when attention is concentrated upon any subject that its full interest appears, and but little attention has in our country been given to this one. What does Emerson say? "Each work of genius is the tyrant of the hour and concentrates attention on itself. For the time, it is the only thing worth naming to do that—be it a sonnet, an opera, a landscape, a statue, an oration, the plan of a temple, of a campaign, or of a voyage of discovery. Presently we pass to some other object, which rounds itself into a whole as did the first; for example, a well-laid garden; and nothing seems worth doing but the laying-out of gardens."

Nor was there ever a time or place when the laying-out of gardens was of more vital concern than it is with us to-day. Here in America we are confronted with problems more numerous, more varied and more important than those which any other age or country has seen. There is no reason why the art of gardening should not be carried in America to a higher development than any of which European history tells. And the surest way to foster such a development is for artist and public to acquaint themselves with the creations of the past. In this art, as in architecture, the time for ignorant experiment has gone by. Only catholic knowledge and cultivated taste can serve as the starting points for progress.

Longleat.

LONGLEAT HOUSE, of which an illustration is given on page 139, is one of the most famous among the great Elizabethan homes of England. It stands some five miles from the town of Warminster, in Wiltshire, and its founder was Sir J. Thynne, who caused its erection between the years 1567 and 1579. It is now the seat of the Marquis of Bath, and is in perfect preservation. The architect is supposed to have been John of Padua, which is probably the fact, for the touch of an Italian hand would explain the greater simplicity in outline and massing that we note when Longleat is compared with other houses of its time and class, while classic feeling also speaks from many of the details of its treatment. But in building this English country-home the artist by no means imported his scheme ready-made from Italy. He wisely accommodated himself to local tastes and adopted many local architectural devices. For example, the windows are without conspicuous pediments, and are divided by the transoms and mullions which so long survived in England after that Gothic art had perished to which they owed their origin. Moreover, instead of the straight façades which we find in Italian Renaissance palaces, here each of the four great fronts is provided with bays, having those side windows so beloved in England because so essential to the full reve-

lation of the surrounding landscape. The front, most prominently shown in our picture, has three such bays, while the main or entrance front towards the left has four, with a stately doorway and flight of steps in the centre. The four great wings thus formed encircle a large interior court, in the centre of which, just back of the entrance, is a superb great staircase. The main wings are 220 feet in length, and the side wings 164. A second entrance leads into the gardens on the side-front opposite to that shown in the illustration.

The grounds around Longleat are of vast extent and great beauty. One of the entrance-gates is two and a half miles from the house, and from another a straight drive of a mile in length leads through one of the most stately avenues in England to the main doorway. The flower-gardens are divided from the deer-park by a charming sheet of water, and the park itself, some thirty miles in circumference, feeds more than a thousand deer. Gilpin, in his "Forest Scenery" (1791), speaks thus of the beautiful situation of Longleat: "A great house stands most nobly on an elevated knoll, from whence it may overlook the distant country, while the woods of the park screen the regularity of the intervening cultivation. Or it stands well on the side of a valley which winds along its front, and is adorned with woods, or a natural stream hiding and discovering itself among the trees at the bottom. Or it stands with dignity, as Longleat does, in the centre of demesnes which shelve gently down to it on every side."

The Art of Gardening.—An Historical Sketch.—I.

THE art of gardening means the art of arranging surfaces of land and water, with all the forms of vegetation they support and all such works of architecture or sculpture as may be thought desirable, according to some settled design or scheme. Its productions may vary in character between the most formal and the most natural-looking effects; and in size between the smallest bit of verdurous ground in a city street and the widest rural park. But they may always be distinguished by the fact that organized beauty has been sought in their creation. Horticulture aims at the development of beautiful individual plants. Economic gardening, like its sister craft of agriculture, so disposes the surface of the ground and the individual plants that cultivation can be most easily pursued. But when we speak of the art of gardening we imply a result in which, though individual plants are valued and usefulness is largely served, a beautiful general effect has been the main concern. Of course not all the results we see as the outcome of effort in this art are beautiful, but as much may be affirmed of any other art, and the aim, the intention, is the thing with which we must reckon in defining the field that an historical sketch should cover.

Gardening is thus a very complex art, serving (as I have said), not beauty alone but utility also, and demanding the assistance of architecture, of horticulture, botany and engineering. Yet it is a distinct and individual art, and its history shows many periods and phases, and is always expressive, to a most interesting degree, of the spiritual temper and the intellectual development of the peoples who have practiced it. But in tracing all the earlier stages of its story we must rely, to a far greater degree than with any other art, upon mere written and pictured testimony. Not only the huge monuments of the ancient architect, but the most fragile products of the potter, the glass-blower and the weaver, have come down to us from gray antiquity. But the gardens of the old world have wholly perished, and even those which were created only a few centuries ago have almost all been altered into something very unlike their first estate. A garden carries within itself the seeds of decay, and scarcely the most careful attention could preserve it forever. We can fancy, some old Roman garden, tended from age to age by skillful cultivators, renewing itself time after time, and reaching us in a flourishing condition. But even so, it would not be the same garden that the Roman artist had created. The main outlines of its scheme might be the same, but all its vegetation would have been often replaced, and could hardly have been replaced in entire accord with the first arrangement. And, of course, no approach to such care as this has ever been bestowed upon a garden. Being half the work of nature, gardens were even less likely to be cherished under difficulties than other works of art; and none decayed so quickly and entirely when once

the barbarian or mere neglect had laid a hand upon them.

The origin of art has been found by some in that desire to portray natural forms which led the cave-dweller to scratch the outline of a reindeer or a mammoth on a piece of bone; by others in that appreciation of the beauty of abstract lines and spots which the South Sea islander shows when he adorns his paddles and hatchets with incised patterns; and by at least one writer—Schiller—in the act of the savage woman who first bound a handful of wild-flowers into a garland or nosegay. But to find the origin of the art of gardening we cannot look back to savage times. Nor can we wisely conceive of it as practiced in the very earliest, most rudimentary periods of civilization. It must have followed and at first strictly depended upon the art of architecture. Not until men had built themselves solid dwellings and places of worship of some pretensions can gardens for the delighting of the eye have been designed. The fact may seem a strange one at first sight if we have been taught by the "romantic" school of thinkers, with Rousseau at their head, to picture a primitive civilization as one in which man lived "close to the bosom of nature" and loved her beauties far more than those which were due to his own efforts. Nevertheless, it is a fact in entire accord with all that we really know, and all that we can sensibly imagine, of a primitive society. In such a society nature must always have been regarded not as the friend, comforter and restorer of man, but as his enemy to be thwarted and subdued; and a different conception could not arise until man felt himself her master. What he first wanted was to get protection from the rigor of her elements, the attacks of her wild beasts, and the menaces of other men; and his first artistic efforts must have been to adorn his walls and roofs and to beautify his own person and the utensils and weapons he employed. The artistic impulse means the wish to make something individual—to put a fragment of the artist's self into the result; and it can have found an outlet in gardening only after men had grown well accustomed to living in settled habitations, and had lost their first intimate familiarity with nature in her wild estate.

Some authors have found the origin of gardens in the tree-worship of primitive ages. When fetishes were the gods, trees were even more universally adored than serpents, although, indeed—as the story of Eden is enough to prove—the two cults often went hand in hand; and when this stage had passed and abstract deities were worshipped, the earlier phase of development was perpetuated in the "sacred grove" which surrounded every temple in every ancient land. Other writers have imagined that the first gardens were merely homes for useful plants—edible vegetables, medicinal and incense-producing herbs. These the Nomad tribes carried about with them, and were forced to grow in protecting enclosures. Undoubtedly much in the development of gardening art was due to both these sources. But it is only when a desire for beauty of general effect makes itself clearly felt that art is born. And gardening, we may feel sure, had not reached this point until after architecture had made considerable strides.

Of course many early poets, and among them the poets of Judea, have described beautiful gardens as existing before structures of any kind. But, however early they may have lived, the mere fact that their words have come down to us implies a long-developed civilization; and the conditions and tastes they express are, I need hardly explain, those of their own period, not of the mythical period they profess to portray. When men were able to record themselves in perfected forms of speech they had long left the bosom of wild nature, had lost their first fear of natural forces and first familiarity with natural beauties, and were therefore in a position to appreciate the charms of the outer world and to long for spots in which they could enjoy them. We cannot believe that the "first man" lived in a garden, but it is entirely natural that when poets began to record their conception of primeval happiness they should have thus imagined. Bacon says that "when ages grow to civility and elegance, men come to build stately sooner than to garden finely, as if gardening were the greater perfection." And I may add that when men first came to work in art they must have begun to build before they began to garden, because a more rudimentary need was thus gratified, and a better outlet for the artistic impulse was thus afforded.

New York.

M. G. van Rensselaer.

The middle-grounds and distances are the first subject of study for the artist in landscape. The beauties and deformities, the pleasing and unpleasing objects, which the more distant parts of the site and the surrounding country exhibit, or are capable of exhibiting, to the house or other principal place of view—these are his unalterable data.

Planting and Rural Ornament, 1796.

Foreign Correspondence.

London Letter.

I HAVE lately been asked by a friend in America to inform him what species of Palms would probably thrive in the open air in the Southern States; and as this is a subject likely to interest many readers of GARDEN AND FOREST, I will reply through the medium of its pages.

At the outset I must state that, except at Kew, very few of the hardier kinds of Palms are cultivated in England, although recently some notice of the most ornamental of these has been taken by our horticultural journals. So far as I can ascertain, the same statement applies to such favored localities as the south of France, Italy, etc., where the conditions which favor the out-door cultivation of many extra-tropical, and even tropical, species of Palms are almost perfect. There are a few exceptions to this as in the garden of Mr. Hanbury, at Mentone, and in that of the late M. Dognin, at the Villa-Valetta, Cannes.

We are too apt to consider that all plants which are found in tropical countries must require stove-treatment. It took many years in the earlier stages of Orchid cultivation in England to convince gardeners that Orchids might come from the tropics of the old or new world and yet be what are termed "cool" subjects. I remember in my apprenticeship days a fairly large collection of these plants, which included *Odontoglossums*, *Cattleyas*, *Masdevallias* and *Dendrobiums*, every one of which were grown in a hot, moist stove; and it is not very many years since we were not allowed to carry an Orchid from one house to another without first enfolded it in cotton-wool. Ignorance of the conditions under which new introductions are found wild often cause one to make gross blunders in their cultivation. It is only three years since we received, for the first time, at Kew some handsome stems of one of the noblest of all tree Ferns, namely, *Alsophila crinita* of Ceylon—and not knowing more than that this species is a native of that island, we treated them as stove-plants. They grew rapidly, but the fronds died almost before maturing. Dr. Trimen, the Director of the Botanic Gardens at Ceylon, happened to visit Kew in time to save these plants for us. They grow only in the mountains, so that on removing the stems to our large temperate-house they soon recovered. Now they are magnificent specimens. Palms are not so delicate as tree Ferns, and many of them thrive in temperatures of considerable range. *Chamærops humilis* and *C. excelsa* (*Fortunei*) are examples of this, for they are perfectly healthy in a stove, quite as healthy in a green-house, and the latter species does very well out-of-doors in the neighborhood of London. The varying power of plants from warm climates to resist cold is often very remarkable. The *Kniphofias* and *Phygelius Capensis* occur to me just now as instances. Both are natives of the Cape, where they rarely, if ever, are frozen, yet in England they bear 20° of frost with impunity, whilst many plants which are their companions in a wild state succumb to the first frost here.

And now to the subject of Palms for temperate climates. In the Kew collection the following are perfectly happy in a house where the temperature is approximately the same as that in the open air all through the year, except that in severe weather it is never allowed to fall below 40°:

Jubæa spectabilis, the Chilean Wine Palm, a noble plant, with an enormous bottle-shaped stem and a massive head of large, dark green, pinnate foliage; *Chamærops humilis*, *C. excelsa* and *C. Martiana*, the two first well-known Fan Palms, with constitutions like nails, the last similar in leaf to *C. excelsa*; *Livistona* (*Corypha*) *australis*, a splendid Palm for a temperate climate, and also a first-rate tropical plant; *L. Chinensis* (*Latania Borbonica*); *Areca* (*Kentia*) *Baueri* and *A. sapida*, the former a truly noble Palm, with very strong, large, curved, pinnate leaves; *A. monostachya*, now called *Bacularia*, or the walking-stick Palm, a small Australian species, with stems one inch in diameter, five feet high, and a graceful head of irregularly pinnate foliage, and here rarely out of flower; *Washingtonia filifera* and *W. robusta*, both natives of southern California, and probably better known in America than here. These last grow rapidly in our coolest houses, preferring the border to pots, and their handsome leaves are greatly admired. *W. robusta* I have seen, in the famous collection formed by Herr Wendland at Hanover, with leaves six feet across, as stout as iron, with large brown teeth on the petiole, and the long, white filaments hanging from the blade-like silken threads. There is no Palm to surpass this for a temperate climate. In England it is scarcely known. All the *Braheas* are best here when grown in the cool-houses.

Two other Palms, generally known as *Braheas*, namely, *Erythea armata* and *E. edulis*, both natives of Mexico and both

grand plants. *E. armata* is cultivated in Belgium and other continental countries under the names of *Brahea Roezlii* and *B. calcarata*. It is not unlike a *Thrinax parviflora*, but the petioles are shorter and bear small marginal teeth, whilst the whole plant is of the most beautiful glaucous green—almost silvery. Here we call it the Silver Palm. It is scarcely, if at all, represented by large plants in English gardens. If any of your readers would kindly supply some definite information in regard to the climatic conditions and the character of mature specimens of this Palm, I, for one, would be greatly obliged. It is quite at home under cool treatment here. *Serenoa serrulata* is also a useful Palm for temperate climates. *Juania australis*, the Chonta Palm of Juan Fernandez, is developing nicely in a cold-house. We have only lately secured plants of this graceful and very interesting species, which had never before been in cultivation. It is very similar to *Glaziovya insignis*, or, to take a better known plant for comparison, *Cocos Weddelliana*. But the foliage is more robust and the stem stouter. We have not yet tried the *Glaziovya* under cool treatment, but I have been told it is quite healthy under such. We have a beautiful example of it in a warm-house at Kew. It is certainly one of the most graceful of all dwarf Palms. Its proper botanical position is in the genus *Cocos*. *Sabal Palmetto* is healthier in a temperate-house than in a stove, its erect-stalked, handsome foliage being most effective amongst other plants.

Phoenix dactylifera, *P. spinosa*, *P. reclinata* and *P. Canariensis*, the last named a very elegant Palm, almost as graceful as *P. rupicola*, which is the prince of the genus, flourish in a cool temperature. No Palm would be more likely to prove "as happy as a native" in your Southern States than *P. reclinata*, the dwarf of the two African Date Palms. It is a bright green, elegant-leaved plant, rarely exceeding ten feet in height of stem, and always tufted. In the south-east of Africa it is one of the most attractive plants to be met with; at Kew it is in perfect health in the cool-house. *P. Hanceana*, a sturdy, compact species, native of Hong Kong, grows freely in the temperate-house.

The newest and probably one of the hardiest of Fan Palms is *Nannorhops Ritchiana*, from Afghanistan, of which large quantities of seeds were distributed from Kew a year or two ago. Like many Palms, it grows very slowly in the infant stage, but we have already found that it does not like artificial heat, preferring the temperature of an unheated green-house. In habit and the character of its foliage it resembles the *Chamærops*, but when large it is almost invariably tufted. In California and other of your warmer states it is certain to prove quite at home. (Thus far the Palms grown under cool treatment at Kew.)

From a descriptive account recently published of the famous garden formed by the late M. Dognin at Cannes, I have obtained some valuable information in relation to the hardness of many plants which we usually keep in tropical houses. Thus, in addition to some of the Palms above mentioned, I find the following species were a perfect success in the open-air garden of M. Dognin, namely: *Cocos (Syagrus) campestris*, *C. australis*, *C. botryophora*, *C. flexuosa*, *C. Romanzoffiana* and *C. Yutai*. These are some of the very best of the genus: *Sabal Havanensis*, *S. umbraculifera*, *Thrinax Chuco*, *Ceroxylon niveum* and *Copernicia cerifera*.

The Villa-Valetta is one of the noblest gardens of sub-tropical plants in the Riviera; possibly in Europe. It is situated on the *Chemin de la Californie*, near the town of Cannes. The collection of plants, mostly exotics, is of the richest; succulent plants of all kinds, *Araucarias*, *Dammars* and similar *Conifers*; many species of *Bamboo*, *Tree-ferns*, *Cycads*, etc., are represented mostly by exceptionally fine examples, all arranged and grouped in an artistic manner, and all in capital health. There must be many situations in the south of your country where the conditions, as regards climate, are about the same as those of the Riviera. The possibilities in horticultural art in such places must be very great. With so many noble-leaved Palms and *Cycads*, elegant *Bamboos*, *Tree-ferns* and the hosts of other plants available, the making of magnificent gardens, of a kind totally different from what we are accustomed to in the north, ought not to be difficult.

Probably your nurserymen know as well as we do here, that in raising a stock of Palms, even of those which are hardiest, tropical treatment for seeds and young plants is much quicker and often safer than cool treatment. The only exception known to me is that of the *Nannorhops* already referred to. The same treatment answers for young *Bamboos*.

Orchids.—Following close on the heels of *Vanda Amesiana*, we have a second new introduction of Messrs. Low & Co.,

which is described as being related to the former, the flowers quite as large, and pure white, with a rosy-purple lip. It has subulate leaves, erect peduncles, a foot long, bearing from fifteen to twenty flowers. It has been named *V. Kimballiana* by Professor Reichenbach. A quantity of plants of it were sold by auction in London last week. Since the introduction of the gigantic-flowered *V. Sanderiana* no new additions have been made to this genus except these two recent arrivals. *Cypripedium politum* is the best of the hybrids now in flower. It is distinct in form, and the colors, though dark, are clear and attractive, the dorsal sepal being very prettily penciled. *Pleione humilis* is about two months later than the *Wallichiana* group. Several pans, a foot across, and crowded with large lilac and purple-brown flowers, have been an attraction at Kew nearly a fortnight, and they are still fresh. The strongest pseudo-bulbs bear two-flowered scapes. *Dendrobium Findleyanum* is one of the handsomest of the early-flowering kinds, its large flowers, three inches across, the rose-tipped white segments, and large, spreading, yellow-throated labellum, being exceptional at this time of year. It blossoms freely, too, and the shining, curiously-knotted pseudo-bulbs are interesting at all times. *Dendrobium nobile*, var. *nobilius*, is in bloom, and its glowing, purple, medium-sized flowers are delightful. Indeed, an average form of the type of this species has very few superiors. The best of the East Indian Orchids now flowering is *Phalænopsis Stuartiana*. It is as good as, if not better than, *P. Schilleriana* as a garden plant. W. Watson.

London.

New or Little Known Plants.

Helianthus mollis, var. *cordatus*.*

MR. FAXON has here figured a well marked and very showy variety of a species which in its ordinary state is by no means striking. As usually found, the stem of *Helianthus mollis* terminates in a short and stiff racemose-like inflorescence, the few coarse and rather short-rayed heads being almost sessile in the axils of the small upper leaves. Here we have what may be called, for a sunflower, a graceful inflorescence, the large heads borne upon long bracted peduncles, and the numerous orange-yellow rays forming a broad expanse of color which is shown to the best advantage. There is a marked difference, also, in the leaves, which are here broadly ovate, with a very short acumination, instead of ovate-lanceolate, and the heads are often closely surrounded by three or four broad bracts resembling the leaves. Otherwise, the forms are the same, and the variety is connected with the typical form by intermediate states.

The whole plant is some three to five feet high, very leafy and hoary, especially toward the top, with a villous or somewhat rough pubescence. It is perennial and hardy. The common form is found in dry, barren localities through the Western and Southern States, from Ohio to Iowa, and southward to western Georgia and Texas. This variety has been in cultivation at the Arnold Arboretum for three or four years, from seeds that were sent by Mr. N. T. Kidder, and were probably from New Mexico or Arizona.

Cultural Department.

Vineyard Notes and Studies.

THE many letters of inquiry which I receive about trellising and pruning Grape-vines lead me to fancy that something may be published yet on these topics which will be of interest, and may be of use to novices in grape culture. If grapes are to be grown for profit, it is evident that methods of culture should be planned as cheaply as possible. Two cents a pound for grapes does not leave much margin for extra cost in their production, and the prospect is now that grape-growers must reduce expenses to the lowest terms, or give up planting vines.

I prefer a trellis made of stakes, say four inches thick and four feet long, driven into the ground one foot and six inches. A single wire (No. 12) is stretched along on the top of the stakes, and is two and one-half feet from the surface of the ground.

* *HELIANTHUS MOLLIS*, LAM.; Gray, Syn. Flora, i. 276.—Var. *CORDATUS*, new var. Leaves broadly cordate, acute or short-acuminate; heads terminate on leafy branches or peduncles, often subtended by two to four leaf-like bracts.

Fig. 100.—*Helianthus mollis*, var. *cordatus*.—See page 136.

I would, usually, set the vines in rows, ten feet apart, eight feet distant from each other along the rows. The trellis need not be made until the third spring after the vines are planted. Before this time it is about as well to let them run on the ground. Thus three years' use of vine-stakes is dispensed with.

The stakes should be seasoned. I use White Cedar poles, sawed in lengths to suit. If, a few days before setting, they are given a foot bath of coal-oil their durability will be increased. Two feet of the bottom ends of the stakes may be dipped, and then set in a tub to drain for a few minutes. There

will then be but little waste of the liquid, and this preparation of the stakes will pay. It is of no use to dip them unless they are dry enough to absorb the oil. An impervious coat of paint would keep the sap in the wood, and thus hasten decay.

It is needless to set a stake to each vine. A stake every twelve feet is enough. Tie the vines to the wire. The canes will fasten of themselves. On this single wire may be carried as much fruit as the vines can mature. Twenty pounds is enough. I have had forty pounds, but then the fruit may fail to ripen.

The merits of this style of trellis are, first, cheapness; next, convenience. The vines are easily pruned and easily sprayed, which last operation will be necessary. The fruit is readily gathered, and the trellis is low enough to permit one to cross the vineyard in any direction. One need not creep under the rows or walk to the end of one to get on the other side of it. The grapes are near the ground, where they ripen better, and the vines trained low are less exposed to damage from winds.

Wire trellis is essential to the prosperity of the Grape-vine. It wants something which it can cling to and climb or run along, and it will treble its length of growth of cane if this congenial support be provided for it. The tendrils of the vine indicate that nature intends it to climb, just as plainly as the fins of a fish show that it is made to swim. We may notice how a Grape-vine will run when it gets into a tree-top, and can catch on to twigs and branches.

Another merit of the style of trellis described is that on it the vine may be preliminarily trained to stand alone by itself, if need be. I have many vines which, trained thus for years, can now stand like little trees. I keep them on the trellis for the sake of the advantage of the wire, but they are able to do without it.

Vineland, N. J.

A. W. Pearson.

Some Useful Decorative Plants.

ASPIDISTRAS.—Foremost among those plants to which special attention is invited are the most useful *Aspidistra elatior* and its variegated form. Admitting that they are old-fashioned and comparatively common, still they possess much beauty. The long, graceful, dark-green foliage of the type, or the leaves of the variegated variety, striped with creamy white, both present most pleasing effects, and for endurance under adverse circumstances, as in the dry heat of a dwelling-house or in a dark hall, they are unequalled. They may also be used to advantage in sub-tropical bedding during the summer. As to cultivation, it is most simple, as when potted in good loam, given an abundance of water, and a temperature of from fifty to sixty degrees, with a partial shade during the summer, no further attention is necessary. Propagation is effected by division of the rhizomes, which operation may be performed at any time of the year, but preferably in the spring, the divided portions making a new growth in a short time at that season.

COPROSMA BAURIANA VARIEGATA.—This charming garden form of *Coprosma Bauriana* originated in New Zealand, and makes a very ornamental shrub either for cool-house culture or for outdoor work in the summer, its glossy green leaves, with their broad marginal bands of yellow presenting so bright an appearance as to be specially noticeable. This is also an easy plant to grow after the young plants are once established, and with judicious pinching of the tips of the shoots will soon make a shapely shrub. The chief difficulty with some growers, however, has been found in rooting the cuttings, by which method the propagation of this variety is effected—the cuttings having a great tendency to damp off, unless carefully watered and ventilated. The best cuttings are small side shoots, such as those usually produced by an old plant that has been brought into a warm-house for a few weeks, and these shoots should be taken off with a small portion of the hard wood attached so as to form a heel for the cutting. Much care should also be taken to avoid any exposure of the cuttings to the full sunlight, as when wilted, even very slightly, they seldom recover sufficiently to produce roots.

EURYA LATIFOLIA VARIEGATA.—This charming plant is undoubtedly one of the best variegated plants for green-house cultivation, and it deserves to be more widely distributed than it has been. It grows freely in a Camellia-house, or in cool green-house temperature, and being naturally somewhat inclined to a pyramidal form, it soon becomes a highly ornamental specimen. Its foliage, somewhat similar in general outline to that of a Camellia, is beautifully marked with creamy-white, and in the young growth is frequently tinted with pink, and this, combined with a graceful habit, makes it a most attractive object. A moderately light, well-drained soil, containing a liberal

quantity of peat, is preferable for it, and in its growing season it enjoys plenty of water both overhead and at the root. It is propagated by cuttings, which should be made of about half-ripened wood, and placed on a slight bottom heat, in a close frame, with only air enough to prevent damping. At best the cuttings take a considerable time to root, but with proper care a fair percentage of plants can be secured. In all probability this plant would prove hardy in some of the Southern States—at least in those localities where Camellias are found to do well out-of-doors—and if so, it would prove a decided addition to the shrubs for open-air planting.

Notes from a Northern Fruit Garden.

FROM the fact that I not unfrequently see grapes growing and ripening in orchards and gardens where the vines are more or less in the shade, I am inclined to question the belief that grapes need all the sun they can get. If they need it anywhere, they do in northern Vermont and in Canada; yet I cannot discover that a moderate amount of shade retards ripening at all, except in the case of the Brighton, which, although a very early grape, does not even color here in dry, hot seasons when Delaware, Salem, Moore's Early and Eumelan ripen.

The practice of laying down Grape-vines and covering them for winter, is not universal; yet, with most varieties, in nearly all of New England this treatment pays. Growers find that even when the buds of uncovered vines all start well, the covered vines give a better crop, and ripen it earlier. If vines are planted against the south side of a light fence, laying them on the ground will be all the protection needed in a snowy country, as a deep drift will form in such a spot. Such a drift will not waste away for a long time where there is snow enough for pretty steady sleighing.

At the recent winter meeting of the Fruit Growers' Association at Montreal, which I had the pleasure of attending, it was the general testimony that the Wealthy apple, as grown about Montreal, or anywhere near the level of the St. Lawrence river, keeps no better than the Fameuse—that is, only up to the holidays. My Wealthys are sound and good now (February 15th), though Fameuse apples were gone soon after New Year, and this has been my experience in the dozen years that I have had the Wealthy in bearing. It keeps well until the vernal equinox; and the same is true of McIntosh Red, which, also, is complained of at Montreal as a poor keeper. My place is sixty or seventy miles south of Montreal, but it is nearly 1,000 feet higher. Still, I do not ascribe the better keeping of my apples entirely to the altitude of my land. The Wealthy matures with me, so far as I can see, as early as it does about Montreal—say about the middle of September. As soon as it is well colored it begins to drop, but growers do not seem to take the hint and gather it at once. If this is done, and the early part of the day if sunny chosen, the fruit if removed at once to a cool, dark cellar, will keep better than if it had been allowed to feel the many warm and even hot days of late September and early October. These are what hurry it on to over-ripeness and bring on early decay. It seems to me that this principle is applicable to all apples, as much so as to pears. As soon as the fruit will part readily from the tree it is ready to be gathered, and delay in this particular is at the expense, not only of keeping, but of quality. Wide alternations of temperature every day—at noon a burning sun, at night coolness even to frost—can have no other effect than to deteriorate quality and hasten decay.

Newport, Vt.

T. H. Hoskins.

Orchid Notes.

Cymbidium Lowianum is a very handsome variety of the well-known *C. giganteum*, which produces stout, arching racemes nearly four feet long and bears about a score of large greenish-yellow flowers. The lip is particularly attractive. It is of pale yellow, the front lobe being of a uniform deep maroon, with streaks of the same color in the throat. This variety, like the type, when well grown is a fine ornamental plant even though out of bloom, and it can be grown with the general collection of green-house plants. It is a very vigorous and strong-rooting kind. It should be grown in rich loam, with leaf-mould and sand. It requires abundance of water, and it should at no time be allowed to get very dry, as it is nearly always in active growth. The flowers will last in perfection nearly four months if kept in a cool-house, and when cut they will last longer than any other Orchid I know. It is a native of Burmah.

Calogyne flaccida.—This is a very attractive species, growing and producing its flowers very freely. It has oblong fur-

rowed bulbs, with two dark-green coriaceous leaves. The pendulous racemes spring from the base of the bulbs, bearing about a dozen creamy-white flowers, the lip being prettily blotched and streaked with yellow and crimson. This is an admirable plant for basket culture. It grows best in the cool-house, with abundance of water. It should never be dry.

Another species in flower now is *C. ocellata*, which somewhat resembles *C. flaccida* in general appearance. This species produces half-drooping racemes from the top of the matured bulbs, bearing nine to ten comparatively large pure white flowers, relieved by irregular blotches of yellow margined with reddish brown on the lip. This is a superior species, and will be found extremely useful for cutting and for window decoration, as it lasts a long time. It needs the same treatment as *C. flaccida*, and, I think, grows even more freely than that species. The variety *Maxima* differs from the type in

spreads very rapidly, and will cover the ground with a good permanent sod. It is very beautiful when in bloom, bearing spikes of small blue flowers about two to three inches long at the axils of the leaves.

I found this plant about fifteen years ago, growing wild in great abundance in the vicinity of Boston. Never having seen it in this section before, I called Dr. Gray's attention to it, and he stated that he had not before known of its growing on this side of the mountains of Vermont and New Hampshire. A few plants were then planted in the shade of some Pines, where they have flourished ever since.

This plant can be propagated very rapidly by making cuttings about three inches long and planting them in boxes of prepared soil two parts sand, and one of soil. They should then be placed in some cool spot where they will get a little light until spring, when a lot of nice plants will be ready to be set out.

Longleat.—See page 134.

having larger and more numerous flowers on a raceme. Both kinds emit a delightful Coconut fragrance. This Orchid was introduced more than sixty years since from northern India, and should be met with more commonly than it is.

Phajus grandifolius.—This is one of the oldest and best known of all tropical Orchids, having been introduced more than 100 years since under the name of *Bletia Tankervillei*. It may be found in almost every green-house, and, consequently, is more rationally treated than many of its rarer congeners. We grow a quantity for cutting. It is unsurpassed where very heavy work is required. It lasts a long time, and will open its buds in water. The stout spikes are about three feet high, rising above the dark-green foliage and bearing a score or so of large white and brown flowers. It is a luxuriant grower, delighting in a compost of rich loam manure, and plenty of sand. Care should be taken to retain the old foliage until the new growths are well advanced.

F. Goldring.

Kenwood, N. Y.

Veronica officinalis is one of our most valuable wild plants for planting in shady places where grass will not grow. It

One of the best features about this plant is the foliage, which is evergreen, keeping its color well all winter in the most exposed situation.

Somerville, Mass.

Plant Notes.

The Soap-tree of the Chinese.*

IN GARDEN AND FOREST for February 13th it was stated in the very interesting article on the Kentucky Coffee-tree that its Chinese congener, *Gymnocladus Chinensis*, "has not been introduced into the United States or Europe." This would, I believe, have been absolutely correct had it been written rather more than a year ago; at the present moment we have at Kew a number of plants about a foot high raised from seeds forwarded from Ichang by the indefatigable botanist and traveler, Dr. A. Henry. None of the plants have as yet developed characteristic leaves, but only simply pinnate ones with

* *GYMNOCLADUS CHINENSIS*, Baillon in Compt. Rend. Assoc. Franç. pour l'Avanc. Sc. 1874. p. 418, t. 4.

narrower, smaller leaflets, much more rounded at the tips than those of its American relative. Judging from the aspect of the young plants the species seems likely to prove a quicker grower than the Kentucky Coffee-tree. In the Kew Herbarium there is a good series of dried specimens of *G. Chinensis*. These exhibit a marked character in the pod, which is only half the size of that of *G. dioicus*, and the foliage, as is already stated, is very different from that of the American plant.

On one of the tickets attached to part of Dr. Henry's material is the following information: "The soft substance inside the pod is used for washing the face by Chinese women. The seeds themselves are strung together and made into a sort of 'chain-armor' undershirt for wearing next the skin in summer by coolies." To a sample of pods in the Museum No. 1 is affixed the following: "They are beaten with a mallet and used as soap. Sold at about sixteen to twenty a penny."

It seems desirable to put on record the exact date of the introduction to cultivation in Europe of a most interesting and, what may also prove, a valuable tree. I have, with this object, penned the foregoing lines. So far as I know they form the first record of the tree from the standpoint of the cultivator.

Royal Gardens, Kew, February, 1889.

George Nicholson.

BORONIA HETEROPHYLLA, figured and described in a recent issue of the *Révue Horticole*, is a newly cultivated species of a genus long known in gardens. It is a tall, glabrous shrub, with numerous slender branches; narrow, linear and sometimes pinnate leaves, and handsome and very fragrant red flowers, which are produced in the greatest profusion along the whole length of the stems. The *Boronias* are all natives of Australia, and excellent cool green-house plants. The present subject will probably prove a more vigorous grower than *B. megastigma*, the most commonly cultivated species, the flowers of which are not surpassed in delicacy and intensity of perfume, and it is pretty sure to become a popular addition to our winter-blooming green-house plants. *B. heterophylla* is said to have been introduced into European gardens by Miss Marion North, the celebrated traveler and flower-painter, whose collection of paintings, made from nature in nearly every part of the world, and presented by her to the English nation, is one of the most interesting features of Kew Gardens.

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

XII.—THE GROWTH OF ORGANS.

BY the multiplication of cells in the manner described in the last paper, all the different organs of the plant are built up and the several parts are joined together. The laying down of the partition walls in these microscopic cells is never a haphazard matter. Every plane and curve falls into its place in obedience to the law of inheritance, and thus the sum of shapes of the cells gives us the inheritance as a whole. Hence, for example, the cell-growth of the Maple gives us the Maple tree, differing in some essential particulars from every other Maple tree, even of the same variety, having slight differences, perhaps, in the distribution of roots and buds and branches, but still resembling its kin in all essential features, so closely, indeed, that its relationships are easily recognized. The laws of growth which underlie this remarkable uniformity of shape in plants which are descended from a common stock are not at all understood, though many of the facts bearing on the subject have been recorded. Some of these may be noted in connection with this portion of our subject; other facts relating to growth must be deferred to a later stage of our examination.

The order of study which will be found most convenient is, first, the mode of growth of the organs in their order of succession; second, the conditions of growth, and lastly, some of the physical phenomena which accompany growth.

GROWTH OF THE ROOT.—In the seeds of our common forest trees the root exists as a single conical cluster of cells at the end of a rudimentary stem. In the grasses and allied plants the origin is multiple and somewhat different, but this need not concern the present treatment of the subject.

GROWTH OF ROOTS IN LENGTH.—When the germ breaks through the seed-coats the root is generally the first thing to be seen, appearing at that period as a firm cone, which is seen to consist of two essentially unlike parts, an outer cap of flattened cells and a small group of minute cells in the hollow point of this cap. The root extends in length by the multiplication of the cells in this group. The renewal of the cap keeps pace with the extension of the growing point, and thus

the slender, thread-like form, protected at its extremity, insinuates itself through the crevices of the soil in which it could not be forcibly thrust. Practically only a very short portion of the root is at all capable of growth in length; in fact, it is generally said that only the protected tip can thus grow. As a matter of fact, however, some of the extension is due to the enlargement of the cells just behind the point of true cell-multiplication.

GROWTH OF ROOTS IN THICKNESS.—The roots of our common forest trees and shrubs thicken by the addition of new cells substantially in the same manner as that which is characteristic of stems, to be described presently.

GROWTH OF ROOTS BY BRANCHING.—The arrangement of roots is so much disguised by the distortions arising from the pressure of the soil that there seems to be no sort of regularity in their branching. But if roots are grown in water, especially water containing a sufficient supply of nutrient material, their arrangement is seen to be one of a good degree of symmetry. Each new root-branch starts naturally from a group of cells lying very near what one may call the shaft of the root. If, as happens when roots are closely pruned, the new root-branches are very numerous, there is no regularity at all in their distribution. Every root-branch, whether it arises from a pruned or an unpruned root, is provided at its slender tip with a root-cap precisely like that which belongs to the earliest roots, and the growth is after the same fashion. But there are a few differences in the directions taken by the main and the lateral roots, some passing downwards in a far more oblique course than the others.

Under favorable circumstances roots can start from any part of a stem, but they are more abundant at the joints than at any other places. All these roots striking out from the stem and branches obey nearly the same laws of growth which we have already noticed in those which appear underground. Thus, in striking cuttings, the roots which appear at the cut end of a shoot are in all substantial features like those which form in the natural way, as lateral branches in normal roots.

THE GROWTH OF STEMS IN LENGTH.—The promise of the main stem of an ordinary forest tree is contained in the rudimentary bud in the seed. This is, like all buds, a shortened stem, in miniature, with most of its parts only dimly foreshadowed. When a bud unfolds, the future joints of the stem or branch are barely outlined, but as the development proceeds, these joints become well defined and the distance between them increases. In definite growth the end of the developing stem is terminated by a newly-formed bud, and at the close of the annual period of growth this new bud stands ready to unfold when occasion offers. Under ordinary conditions in our climate, the buds do not expand until the beginning of the spring period of growth, but if the leaves of a tree are swept off in summer by insects, it sometimes happens that there will be two growths from buds in a single year. In the case of plants which have what is called indefinite growth, there is no true terminal bud, but the stem or branch continues growing until it is stopped by frost; the growth in the following year begins in the uninjured parts.

It is difficult to realize that all the upward and lateral growth of our trees is from buds, and that when a given bud has ceased growing for the season, it has stopped its growth in length once for all, and all further extension of the stem and branches must be from the development of the newly-formed buds.

In case of injury to a terminal bud, some of the lateral buds appear as if stimulated to accelerated growth, and one or more of the off-shoots assumes the place of leader, and continues the upward development.

The branching is, of course, dependent on the arrangement and the development of the lateral buds. Each bud is normally in the upper angle formed by a leaf with the stem, but there are certain exceptions to this. The normal buds govern the shape of the plant.

Seldom do all the buds of a plant develop. Those which remain inactive are soon covered up by the growth of the tree as it thickens, but under certain circumstances some of the buried buds may start into activity.

GROWTH OF STEMS IN THICKNESS.—Confining our examination, as before, to our common forest trees and shrubs, it is to be noted that the stem, even in a very young state, can be easily distinguished into bark, wood and pith, together with thin plates of cellular tissue which fill the spaces between the wedges of wood. Just outside of the wood and under the bark is found a layer of cells (or more than a single layer), which possess the power of growth to form an inner part of the bark and an outer layer of wood, while at the same time it can keep itself in repair. This development of

the film of growth is usually continuous in a given season, but it may be interrupted, in which case it is possible to have two rings added to the wood in a single year, whereas, as everyone knows, there is usually only one new ring for each year's growth.

This film of growing tissue under the bark is often termed the cambium layer. At the earliest period of its growth it is charged with sweet nutritive matters fitted to serve as building material. If this cambium layer is injured locally, irregularities in development result.

Branches and roots thicken in much the same way as the main stem.

In closing this short statement of the manner in which a stem grows, it is well to note the manner in which a twig can be grafted or a bud can be implanted on a foreign stock. The success of the transfer depends upon the fitness of the cambium layer of the one to grow conjointly with the cambium layer of the other. If the union is not perfect, or if the two parts, scion and stock, are not the same structurally, complete union cannot take place.

Cambridge, Mass.

George Lincoln Goodale.

Correspondence.

Squirrels and Conifers.

To the Editor of GARDEN AND FOREST:

Sir.—It is a sign of good common sense to say "I don't know" when it is not easy to know, but it is far from creditable to say "I don't know" when the means of knowing cannot be far away. I am never asked why the branchlets have fallen so thickly under Norway Spruce trees in winter without a sense of shame as I say, "I don't know." Whoever can tell me shall have my best thanks. I was about to draw a check for these thanks to a large amount in favor of Mr. Jack (see GARDEN AND FOREST, March 6th), but after reading I feel still compelled to answer, "I don't know." When he claims to have positive proof that squirrels do "all the mischief," he may speak from his own experience. No doubt he has gathered up branches cut off by squirrels. But he must be content with saying that they did cut his trees. They don't cut my trees. There are no squirrels where the seven trees twenty-four years old are now standing in my sight. The many hundreds of branchlets there could not be cut by an enemy not present. But if it be suggested that squirrels may be there at an odd time without my knowing it, I reply that the branches themselves show that they have not been cut at all. I enclose you a few gathered at random. You see the cut "done quickly and neatly with their sharp incisors" is a myth, so far as these branches are concerned. The cut is as ragged as the most fashionably edged piece of note paper could be. And as for their doing the work in order "to get at the buds," they could not reach down to the ends of the slender branches at the points where they are broken if they tried. And, more than this, not a bud, as you see, has been disturbed. In the many hundreds of branchlets that lie under my trees, not one bud has been disturbed, so far as I can find. I know that squirrels do cut branches to get at the seeds more freely. No one can tell an old seed collector, especially a collector of Pine seeds, anything new about this. Quite familiar with the gnawing of a pine branch by a squirrel, I can bravely say, the squirrel is not in this trouble at all. I am speaking of my trees, not Mr. Jack's.

I feel so mortified over this ridiculous puzzle that I examined the shoots again under a good glass to-day. It was evident there was no bending of the branch to break it. It could have been broken only by a force operating in the direction of the branch, a longitudinal power, it might be termed. Going to the tree and breaking a branch by pulling the twig in contrary directions, I found the fracture of precisely the same character, and so I deduce this truth that it must have been something pulling the twigs downwards that broke them. What can that force have been?

I have my own thoughts, but as yet they are but thoughts. To-day I confine myself to actual facts. I would ask you to say whether the twigs I send you do not confirm all that I say so far.

Germantown Nurseries, Philadelphia.

Thomas Meehan.

[The specimens sent by Mr. Meehan evidently have not been cut off by squirrels. It is to be hoped that he will investigate this matter further.—ED.]

To the Editor of GARDEN AND FOREST:

Sir.—To supplement the interesting paper of Mr. J. G. Jack in your first March number on the disarticulation of Spruce twigs, allow me to say that while, no doubt, squirrels are to be

blamed for much of the damage done in this manner, other causes are at work to which the damage is sometimes traceable, and this is especially true of deciduous trees.

It is well known, for instance, that Oaks and Poplars and some other species (*Taxodium*) are subject to a spontaneous disarticulation of their short shoots, very similar to the process by which the leaves are severed from their insertion at the base.

Another cause for the dropping of twigs in the Pine tribe is the work of a beetle larva (*Hylesinus*), which, hollowing the marrow of the twig, weakens it and promotes its breakage at the first severe wind.

I have also some notes of observations which credit hailstorms with part of this damage. Thus Forest-master Alers reports his observation made on June 19th, 1886, in a forty-year-old growth of Spruce: The tender shoots of the year, which had then a length of from one to four inches, were cut off by the hail always at the articulation. This happened before the eyes of the observer, and the freshly-broken twigs were lying on the white hail so thickly that he could not make a step without treading on them, while there had been none before.

In connection with this subject it will be of interest to note the observation of foresters, that after a large loss of the young twigs a rich seed year follows, which may be explained on the principle which induces fruit-growers to remove the young twigs for the purpose of stimulating fruit production.

I would offer two other possible causes for the damage. The one has suggested itself to me by observing that in the grounds of the Department of Agriculture, where squirrels do not abound, after severe cold, with high wind from the northwest, a large quantity of broken Spruce twigs without leaves was found, mostly on the north-west side. This may be explained by the rubbing of the tender, partly-frozen twigs against each other and against the stronger twigs, which latter also show loss of foliage due to the rubbing. This winter, which was free from icy blasts, no such broken twigs are observed, although the rubbing off of needles is quite frequently observable. The other cause may be referred to the neighborhood of a tree like the Birch, which in a high wind is apt to whip off the tender twigs.

Washington, March 9th.

B. E. Fernow.

New Hampshire Forests.

To the Editor of GARDEN AND FOREST:

Sir.—In an article copied, in your issue of February 20th, from a Manchester, New Hampshire, paper, referring to the sale of state lands in 1867, injustice, doubtless unintentional, is done the late Gen. Walter Harriman in this sentence: "Most of the timber lands in Pittsburg, etc., were sold for twenty cents an acre during Gov. Harriman's administration." This sale of the public lands was authorized by a joint resolution of the Legislature, the proceeds being set apart by the next Legislature as a perpetual school fund.

Gen. Harriman's love of trees and of all plant-life was intense; his protests against, not only unnecessary tree-trimming, but also against the ruthless clearing of shrub growth on our road-sides, were constant and characteristically vigorous. He favored forest preservation and the protection of our rural hedge-rows and lanes from the unsympathetic treatment of the modern road surveyor; and none deplored more than he that destruction of the forests of his native state, which, as Mr. J. B. Harrison well remarks, is producing a "blight and a curse upon this sanctuary of beauty and peace."

Boston, Mass.

J. R. Leeson.

The American Pomological Society.—III.

The Meeting at Ocala.

FURTHER abstracts of papers read at this meeting by members of the Florida Horticultural Society are presented below, and we may add in some future number articles on the Pineapple, the Fig and the Peaches and Grapes which have proved valuable on the Florida Peninsula. Many important papers by northern members were not read owing to the absence of the writers, but they will appear in the published proceedings.

The most important action of the Society in reference to semi-tropical fruits was the appointment of a committee to frame a "scale of points" for judging oranges—so that fruit from all portions of the country can be tested by a uniform standard. Of new varieties of fruits, very few

were added to the approved lists. The Lucretia Dewberry and the Early Harvest Blackberry were recommended for the southern states.

The Wilder medals were all awarded to Florida exhibitors at the Exposition in Ocala. The Lake County Shippers' Union, Marion County, Sumpter County, Lee County, Rev. Lyman Phelps, E. C. Hart and D. W. Adams each received a silver medal, while Citrus County, Polk County, Volusia County, O. P. Rooks and E. S. Hubbard each received a bronze medal. The county exhibits thus honored were collections of fruits and other products growing in each. The taste displayed in the arrangement of these exhibits, as well as the variety and value of material showed, plainly justified the unusual course of bestowing a prize upon a county instead of upon an individual exhibitor.

METHODS OF ORANGE CULTURE.

An essay on this subject, by the Honorable C. F. A. Bielby, gave complete instructions for growing oranges, beginning with the clearing of the land. This is an important matter, for vast tracts capable of yielding the best of oranges are still covered with forest growth, and Mr. Bielby described the approved methods for clearing each variety of land, namely: (1) The gray hummock, so-called, with its heavy timber of Live Oak, Hickory and Bay; (2) the black hummock or low level of dark mould covered with an almost impenetrable growth of hardwood and undershrubs; (3) the high Pine-land, a rolling country often from thirty to sixty feet above water, covered with stately Pines; (4) the medium Pine-land, level and from four to six feet above water, with trees as large but hardly as tall; (5) the flatwoods or low Pine-lands. On all these soils, which can again be divided according to the various subsoils, whether of sand, limestone, clay or coquina, the Orange will thrive, and as the grove-owner on each variety of soil is suited with his own, this proves that the advantages and disadvantages of each are quite evenly divided. To chop, pile and burn the growth on gray hummock, to grub the roots and burn again would cost from \$75 to \$100 per acre, while the burning would work a ruin to the soil from which it would not recover. To clear away the underbrush, pile it in windrows twenty-five feet apart together with the trees less than three inches in diameter; to cut the standing timber and lay it along the wind-rows; to grub a strip eight feet wide between the rows; to work this with the plow, and set the trees in well-dug holes, four feet in diameter and fifteen feet apart will cost \$35 an acre. If the timber is left standing between the windrows and deadened, and if four-foot holes are dug fifteen feet apart, as before, the cost of clearing and planting will be \$20 an acre, and although the dying branches will begin to fall the second year, and some of the Oaks themselves will soon follow, little damage will be done in this way, and the shade will be a help to the young Orange-trees.

The black hummock is usually wet, and needs surface drainage. All the undergrowth, with the smaller trees and some of the large timber, should be cut, and all can be burned with little injury to the soil. Much of the timber should be left standing to be thinned out as the Orange-trees occupy the ground. The trees should be set on mounds, or better on ridges twenty-five feet apart and running parallel with the drainage. To clear this land costs \$165 an acre, and although the water is at the very surface, the Orange-tree flourishes on this deep soil producing bright, thin-skinned and heavy fruit. In the Pine-lands the cheapest way is to deaden the timber by girdling. The flatlands have been considered of little value, and even now in fairly accessible localities they can be bought for from one to five dollars an acre and the clearing will cost but five dollars more. On these low, wet Pine-lands Mr. Bielby once found a tree of enormous size from which 8,000 oranges had been taken in a single crop. None of the soil in these Pine-lands can be called good, but since moisture is the most important factor in orange-growing, an open sub-soil under little hills and valleys is the worst, while level Pine-lands with a clay subsoil is the most promising. Upon these Pine-lands, as knowledge of fertilizers and of methods of cultivation has grown, the greatest advance in Orange-culture has been made within the past few years.

In the northern part of the state varieties which ripen in October and November are to be preferred, so that the danger of freezing may be avoided. From Lake George down to latitude 28° 30' December is a safe market month, while south of this, as in the Indian River country, where fruit hangs on the tree sound and sweet till March and April, the latest and finest

fruit can be grown with safety and profit. Orange-trees should be set high, with their crown-roots showing well above the ground. The supply of moisture determines the method of cultivation. Where soil is light and dry the harrow should be used every ten days from February to November to keep the weeds from using the water which the trees need, and to conserve the supply of moisture in the ground by checking evaporation at the surface. For soils of darker color and finer texture, with underlying clay or yellow sand, the better method is to keep the soil stirred about the roots as far as the trees throw partial shade, and allow some growth of Crab-grass or the like on the remainder of the grove, not to be turned under while green, but to die down in autumn on the surface. In the black hummock and flatwoods the hoe should be used alone, but the flatwoods may be harrowed in dry years. The effort should be to preserve the moisture where there is just enough, and to use up the surplus where there is too much. With abundant moisture, the question of fertilizers is not so difficult, but it is always a serious one. On the alluvial hummock over marl, groves that have been bearing fifteen years without any fertilizers show no deterioration in brightness, sweetness, fineness of texture or weight of the crop, and for such soils the evil days seem yet far in the future. The gray hummock soil over clay and limestone will make trees five or six years old, but to trespass further upon the native fertility of the soil is to invite catastrophe. After this period groves on the gray hummock, and on the Pine-lands from the outset, fertilizers should be used. Caution in the use of nitrogenous material should always be exercised, but potash in the form of pure sulphate is invariably good, while phosphoric acid in ground bone, and lime in gypsum, are usually profitable applications. The above is but the skeleton of a part of Mr. Bielby's admirable paper, which included a discussion of the diseases and insect pests to which the Orange is subject. It was written in so clear a style and out of such fullness of experience and knowledge that all who heard it will watch with interest for the appearance of that Manual of Orange-culture which Mr. Bielby ought to prepare.

THE KAKI, OR JAPAN PERSIMMON.

After many unsuccessful attempts to introduce this fruit in the higher latitudes of the United States, Mr. P. J. Beckmans and the late A. J. Bidwell succeeded in establishing it in Georgia and Florida. Mr. B. F. Livingston, whose paper treated of this fruit, stated that no fruit tree in Florida grows as thriftily and vigorously and with so little manure and cultivation as the Kaki, especially when grafted or budded on the wild native Persimmon. This stock, however, is best grown from seed, as the old-field root-sprouts are barren and predisposed to attacks from a beetle, whose larvæ cut into the heart of the tree, and down through the pith into the large roots. Mr. Livingston's trees, grafted in February, 1888, on one-year-old seedlings, now average six feet high, exceptional specimens being eight feet high and two inches in diameter above the stalk. Trees should not be allowed to bear when too young, for they are very precocious, and February grafts sometimes set fruit in nursery rows the next summer. With no other fertilizer than swamp muck, specimens of the fruit weighing more than a pound have been produced, and the trees do well on all the kinds of Florida soil, from wet bottom land to high and dry soils. The fruit differs remarkably in size, color, flavor, texture and adaptability to varied uses. There is much confusion of nomenclature, but they can be grouped into families, each one having certain common characteristics, which were described by Mr. Livingston. His concluding advice was to select only well-established and identified varieties, as promiscuous planting would be sure to include many indifferent and almost worthless kinds.

Periodical Literature.

From a recent issue of the *Scientific American* we reproduce the following interesting information in regard to the manufacture of "Wood Cloth":

Mitscherlich has applied the bisulphite process for reducing wood to the production of a fibre from wood which can be spun.

Thin boards or laths free from knots, but of any desired width, are cut into strips in the direction parallel with the grain, and are then boiled in a boiler containing a solution of sulphurous acid or bisulphite. This boiling effects disintegration without requiring that the strips of boards shall be reduced to very small pieces. After boiling the wood, it is dried in the open air or in specially constructed drying rooms. By thus drying the product, the fibre, which is originally very

weak, and tends to break at the slightest strain, becomes comparatively strong, and does not resume its very breakable condition on the addition of water. The operations are carried out as follows:

The damp masses on the frame are transferred to a traveling endless cloth, which leads them to a pair of rollers, which may be plain or provided with corrugations in the direction of their length, the ribs of the one roller being made to gear into the recesses of the other one, whereby they effect a simultaneous strong bending and squeezing of the masses. The cutting of the material in passing through the corrugated rollers is avoided by causing the endless cloth to pass over the lower roller and by placing a canvas covering around the upper roller. The pressed masses fall from these rollers on to a second endless cloth, which conveys them to a second pair of rollers, from which they are conveyed to a third pair, and so on, they being preferably pressed in this way six times. By continued treatment of the wood the fibres become at length so pliable and isolated from each other that they can be employed directly for coarse filaments. For obtaining a perfect isolation of the fibres, however, without material deterioration, these operations alone are not suitable, and their special purpose is to loosen the fibres in the transverse direction, so that in the following operation a thin, long fibre may be obtained. For this purpose the boiled and pressed masses are completely dried. After drying they are combed in the direction parallel with the fibres by means of devices provided with pins or teeth, in a manner similar to the operations for combing flax, cotton, etc., but with the difference that the pins or teeth of the apparatus must be made very strong. The separation of the extractable matter from the fibre produced by boiling the gums and soluble organic matter can be effected at any time. It is, however, preferably effected after the fibre has been spun into threads, etc.

Recent Publications.

Field and Hedgerow, by Richard Jefferies. Longmans, Green & Co., 1889.

Under this attractive title Mrs. Jefferies has collected, since her husband's death, twenty-nine of his latest essays, originally published in a number of different periodicals. The longest is the "English Deer-Park," about which a word was said in this journal when it was printed in the *Century Magazine* last autumn. Many of the others are bits of description, commentary or analysis, only three or four pages in length. But all have the distinctive stamp of Jefferies' mind and style strongly set upon them, and all were worth republication. The variety in ostensible subject-matter is also great. These are some of the titles: "Nature and Books," "The July Grass," "The Country Sunday," "Swallow-Time," "Buckhurst Park," "Some April Insects," "The Makers of Summer," "My Old Village," "My Chaffinch," and "Locality and Nature." Nevertheless, they may all be divided into two classes—those which chiefly exhibit the writer's keen love for the minutest facts of Nature, and those which chiefly reveal his equally keen interest in the minutest traits of rural man. Perhaps in future times the greatest value of the book may seem to lie in its record of the odd superstitions and methods of expression of the English rustic in this our time, and in the picture which, taken as a whole, it presents of his material and spiritual condition. But to us, interesting though it is in this respect, those pages which deal with birds and flowers and the countless aspects of the wide out-door world are the most attractive. Minuteness of observation and delicacy of analysis could no further go, and color facts, especially, are dwelt upon in a way which one would expect only from a landscape-painter with the most sensitive retina and the most extended experience. Jefferies himself would certainly have resented such a comparison, for his feeling about artists seems to be that they are men spoiled by the "conventionalities" of their craft for the clear observation and intelligent appreciation of the beauty which the world presents. Nevertheless, such powers of observation and appreciation as his are characteristically those which go to make up the artistic temperament; and despite the success he gained as a writer, one who knows what the study and practise of art really mean, must believe that he would have compassed a still higher success had he taken to painting instead of writing. What he wished most of all—he tells us himself over and over again—was to open the unseeing eyes of the average man to the loveliness of Nature, to define with the nicest exactitude her ever-varying charms of color and form, and especially to bring forth the spirit which underlies her colors and forms, and speaks through them to the human soul. And, as he likewise tells us in this volume, in the chap-

ter called "Nature and Books," he finds language wholly unequal to the task, and decides that though millions of books have been written about Nature, the books which will really interpret her are still all to be indited. The truth is that such books cannot be indited. Language can never do the work that Jefferies wished to do. And though art cannot do all that he felt desirable in the way of the definite presentment of tiny, intangible details, it can interpret the spirit of nature to the spirit of man far more effectually than syllables of prose or verse. What is even Wordsworth's work in this direction to Corot's? With the sounds of Nature poetry, of course, can deal more or less successfully, while painting cannot deal at all.

"The moan of doves in immemorial elms,
The murmur of innumerable bees."

Such emotions as these words excite lines and colors cannot excite. But sight finds still more and richer food in Nature than sound; and had Jefferies been a painter he would surely have been better satisfied with his own lot as well as a more important factor in the delighting of the world. Then he would not have cried in despair, "The flower has not given us its message yet. . . . I want the inner meaning and the understanding of the wild-flowers. . . . Why are they? What end? What purpose?" Approaching such questions, as Jefferies did, from the intellectual point of view, no answer is possible; but approaching them from the artistic point of view the answer reveals itself to the painter as he paints, and the observer as he gazes. The end of Nature's beauty is the delighting of man, and it delights man fully only when he has read something of himself into her forms and colors. Unconsciously Jefferies felt this, trying, as he did, to read man into Nature with the help of words; but words were not the proper tools for his purpose.

Nevertheless, all that they could do, without the magic of rhyme and rhythm, he accomplished; and there is no eye but will see more beauty in Nature, and see it more clearly, and appreciate it more intensely, after reading such passages as the one which attempts to analyze the color of the May Dandelion, or comments on the "Winds of Heaven," or in "Locality and Nature" describes a river-bank on Exmoor. The way, too, in which human and natural factors are constantly mixed together, no matter what may be the title of the page, is in refreshing contrast to the writing of many lovers of Nature, who seem to believe that because they love Nature they must either ignore or protest against the presence and the works of man.

Recent Plant Portraits.

Botanical Magazine, February.

STRELITZIA NICOLAI, *t.* 7038; a splendid arborescent species, long cultivated in European gardens, and, until 1858, when it flowered at St. Petersburg, confounded with another south African species, *S. Augusta*. The geographical range of the latter, and the exact locality where the former species grows spontaneously are still unknown.

STYRAX OBASSIA, *t.* 7039; "one of the most attractive of the many hardy shrubs introduced within late years from Japan, where it is a native of the southern mountains of Kiusiu and Sikok. Siebold, who discovered it in Japan, attributes to it no other property but its scent of Hyacinth." The hardiness of this very ornamental shrub, or small tree, in our northern states has not been entirely established yet.

IRIS MEDA, *t.* 7040; "this is a well-marked new Iris, which was discovered in Persia, in the year 1882, by the Austrian traveler, Polac, and introduced by him to Vienna. Its nearest alliance is with the south European *Iris Chamæiris*, of which the flower in the type is yellow, and of which there are two fine violet varieties." The perianth-tube of the flower of this new plant which has been produced in England in the gardens of Professor Michael Foster, whose collection and knowledge of Irises are unrivaled, is greenish yellow, copiously varied from top to bottom with brown; the outer segments are brown in the centre, with a dense yellow band. The flower is curious, rather than handsome in its markings; and its interest would seem to be rather botanical than horticultural.

OPUNTIA RAFINESQUII, *t.* 7041; a well-known and widely-distributed North American plant.

DENDROBIUM GRACILICAULE, *t.* 7042; an inconspicuous species of no horticultural value; a native of Queensland, of New South Wales, and of Lord Howe's Island.

ODONTOGLOSSUM CARISPUM, var. *RUCKERIANUM SUPERBUM*; *Revue Horticole*, February 1; M. André suggests that this fine plant, which is a native of the mountains to the north of Bogota, may be a natural hybrid between *O. crispum* and *O. Andersonianum*.

Notes.

Our associate, Professor A. S. Packard, sails for Europe this week, and will pass the summer in Germany and Italy.

The eighty-sixth annual exhibition of the Imperial and Royal Horticultural Society of Vienna will be held this year from the 25th to the 29th of April, inclusive.

One hundred and twenty different varieties of Willows are successfully grown, it is said, by Mr. S. J. A. Salter, F.R.S., in his private grounds near Basingstoke, England.

Professor Oscar Drude, Director of the Royal Botanical Garden in Dresden, Germany, has just published an atlas showing the geographical distribution of plants. The maps measure sixteen by fourteen inches, and the work can be bought for about \$4.

It is reported from Berne, Switzerland, that recent snow-storms of exceptional severity have done much damage in that neighborhood, not only ruining many picturesque old bridges and houses but destroying thousands of the splendid Fir trees which clothe the mountain sides.

A year ago the Dutch horticultural journal *Sempervirens* asked for reports upon *Stachys tubifera* for European cultivation as an article of food. Twenty-one reports were submitted, among which seventeen were favorable, recommending the plant as a valuable addition to the list of table vegetables. Good sandy soil, not too dry, is said to be the best for it, as the tubers then become beautifully white, while in heavier soil they assume a brownish color.

Chrysanthemums are largely cultivated in Dalmatia to supply chemists with the substance from which the well-known "Dalmatian insect powder" is made. The island of Lesina is the chief seat of cultivation, and the flower most generally grown is *C. cinerariaefolium* Trev. It is said that no other local crop pays so well, the product of a single acre of ground bringing a gross receipt of \$500 to \$1,500; and the government yearly distributes plants at very low rates in order that the industry may be still further developed.

Mr. Abbot Kinney's retirement from the California Forestry Commission is to be deeply regretted. He has devoted much time and study to the question of forest preservation in California, and his services to the state in this way have been great. His term of office has expired, and the Governor has appointed in his place Mr. F. J. Moffitt, a member of the State Senate. The other members of the Board, as it is now constituted, are John D. Spreckels and W. S. Moore. Mr. Kinney was Chairman of the Board, and its success in the past has been due to his energy and zeal.

Professor Rothrock contributes to the last issue of our valuable contemporary, *Forest Leaves*, an interesting article upon "Tree Growth as Determined by Location," which is graphically illustrated by the portraits of two White Oaks—the first grown in a forest and closely surrounded by other trees and the second developed in the full enjoyment of abundant light and space. The second tree is one of the most magnificent specimens of its kind which can be seen. It stands on the banks of Mantua Creek, in central New Jersey. This tree is not tall, but it has a spread of branches of one hundred and three feet, and a trunk diameter of six feet three inches.

Eastern Roumelia is the real source of the world's supply of Attar-of-Roses, many provinces sharing in its production, but the richest regions being those which lie around the famous Shipka Pass and the district of Maglis further east. The name Shipka itself means "Wild Rose." Here a famous White Rose is grown which has always been considered a peculiar species. But specimens collected on the spot by a person sent for the purpose by Dr. Dieck, Director of the National Arboretum near Merseburg, Germany, were recently submitted to Monsieur Crépin, the well-known authority on Roses, and he pronounced them "simply the typical form of the familiar *R. alba* of our gardens."

According to a writer in the *Gardeners' Chronicle*, singular survivals may still be found in England of ancient methods of "allotment gardening." In Somersetshire, for example, he says, "there are two large pieces of common land called East and West Dolemoors, which are divided into single acres, each bearing a peculiar and different mark cut in the turf; one of these is a horn; others are, four oxen and a mare, two oxen and a mare, a poleaxe, a cross, a dung-fork, an oven, a duck's nest, a hand-reel, and a hare's tail. About midsummer of every year these lots are 'raffled,' and each particular portion is taken over by one individual for the ensuing year. Archaeological research affords several examples of this singular phase of allotment gardening."

Monsieur André dedicates, in a recent issue of the *Revue Horticole*, a new genus of *Bromeliaceæ* to Mr. J. G. Baker, the English botanist, who has long studied this difficult family. *Bakeria tillandsioides* flowered this year in the garden of M. Devansaye, who cultivates one of the largest collections of these plants in Europe, and who had received it from Brazil without a name. In habit it resembles a *Tillandsia*, but it produced a long, slender, flexible scape, with branches covered with numerous, small, violet-colored flowers. Judged by the colored plate published in the *Revue*, *Bakeria*, with its graceful inflorescence, springing from a rosette of narrow, silvery leaves, will make a charming addition to the number of ornamental plants of its family, which are more appreciated in Europe than in this country.

Dr. R. A. Philippi, writing from Chili to the *Gartenflora*, speaks of a singular sight which met his eye on the way from Traiguen to Angol. "One sees great fields several acres in extent thickly covered with Oats, among which no other plant of any other kind appears, except, perhaps, some species of *Oenothera*. But the crop has not been sown by men, but is a spontaneous growth of *Avena hirsuta* from southern Europe, called 'Tiatina' by the Chilians. . . . In certain parts of Valdivia *Hypochaeris radicata* has become a public pest; it stands so thickly that the rosettes formed by its leaves entirely cover the ground and permit no other plant to grow. Where it appears, however, it kills out two other pests—*Rumex Acetosella* and *Brunella vulgaris*—and in its turn is suppressed by *Trifolium repens* which is spreading more and more widely year by year. As European man drives out the native American man, so European plants drive out those indigenous to the soil."

Dr. Masters, in the issue of the *Gardeners' Chronicle* for February 9th, shows that *Abies subalpina* of Engelm., a Fir of the interior Rocky Mountain region, is really the same as the tree of which a fragment gathered forty years ago in Oregon, is preserved in the herbarium at Kew, and to which Sir William Hooker applied the name *A. lasiocarpa*. If this view is correct, and the specimen, judged by the illustrations which accompany Dr. Masters' article seem to substantiate it, one of the most troublesome cases of synonymy among American trees is cleared up. Less clear is Dr. Masters' reference of Murray's *A. bifolia* to *A. subalpina*. We have never examined Murray's specimen, which is here figured by Dr. Masters. It is hardly worth while, therefore, to express any opinion in regard to it, and we only suggest that the size and shape of the cone, and the shape of the scale in Murray's specimen bear a strong resemblance to some of the intermediate forms which seem to connect *Abies grandis* and *A. concolor*, and which abound in southern Oregon.

A correspondent of the *Revue Horticole*, M. Desbois, of Orleans, sends to that journal the following interesting note on the effect of sulphate of iron upon the rigidity of the stems of plants. "The La France Rose, although beautiful, is often produced on the summit of a stem too feeble to support it. The way to obviate this is to water the plant when the bud is partly grown with a solution of sulphate of iron. The stems become, when treated in this way, sufficiently rigid to support the expanded flowers, which gain depth and beauty of color. I have used sulphate of iron in a large number of similar cases, and always with excellent results; and I have never known a plant injured by it, or found that too large a dose could be administered. The solution should be made stronger for plants growing in heavy soil than when the soil is light. During the last season a dozen Fuchsias treated with sulphate of iron flowered freely in spite of the unfavorable weather; the flowers were exceptionally brilliant in color, and the shoots were unusually vigorous. I saved by the same means a Marechal Niel Rose-bush which had been seriously injured by cold, but which entirely recovered, and is now more vigorous than ever." It is to be regretted that M. Desbois does not give the strength of the solution which he uses with such excellent results.

The Improvement of Villages.

A LADY interested in the development and improvement of her town, and recently appointed one of the managers of a newly organized Village Improvement Society, writes to ask in what way she can best exert her influence to further the aims which the founders of the Society had in mind when it was created; or, in other words, what she and her associate Directors can do to improve the sanitary condition and the appearance of the town. It is situated in New England not far from one of the smaller cities, and it has long been famous for its rural beauty. The township is large, and contains a number of villages. A part of the population, living at one extremity of the town, is almost exclusively devoted to manufacturing, while other parts are occupied by the expensive villas of many summer residents. The population is unusually heterogeneous. The increase of the manufacturing population and the influx of persons seeking summer homes have had the inevitable result; and the improvements of recent years, to use a familiar, but not always a very appropriate, expression, have destroyed a great deal of the rural and sylvan charm which once made this town beautiful, and desirable as a place of residence. The inhabitants, naturally, are now anxious to do something to restore the lost beauty, or, at least, to preserve that which remains, and to adopt some general scheme of improvement suited to the changed conditions of the town and to the changed requirements of its inhabitants. It is not, of course, practicable, or within our sphere, to give a specific plan of improvement for any particular town or property; and all that is expected of us in this particular case is some general statement calculated to provoke discussion and the consideration of the general principles which seem to underlie the whole question of rural town-improvement.

The object of the founders of Village Improvement Societies is clearly to improve the sanitary condition of towns and their general appearance, and in this way to improve the well-being of the inhabitants, and then to elevate their intelligence, stimulate their love of Nature and develop

their artistic feelings. The first requisite for the accomplishment of this purpose is to secure for the people of the town an abundant supply of pure water and a good system of sewerage-removal for the villages and for the isolated dwellings. These are the principal requisites for insuring the health of a community. This being accomplished, the preservation of natural scenery and rural beauty, the improvement of roads, the planting of shade trees, the decoration of public squares, the beautifying of school-grounds and the surroundings of railway-stations, the removal of obnoxious and unauthorized advertisements, the practice of thrift and neatness, should all in turn occupy the attention of the officers of the Improvement Society.

No one will deny that these things are necessary and important, or that a town in which such matters are carefully looked after is a much better place to live in than the ordinary American village. But how can these improvements be brought about? How is an independent body of industrious, public-spirited and intelligent individuals to make themselves felt in the administration of the affairs of a large town? It is evident that they must rely upon some method of more general application than those adopted by societies of this character in small country towns, in which a few men and women are permitted to plant trees at their own expense, and to see that no injury comes to them after they are planted. For this is what the Village Improvement Societies meant in their early days in many small New England villages.

The executive committee of a society, however large its membership, could hardly operate with any prospect of success in a thickly populated town covering many square miles of territory by any direct personal process; and it seems to us that its only chance of success lies in its ability to impress its ideas upon the community through the education of public sentiment. A society working independently—that is, undertaking to improve a town, or any part of it, at their own expense—would find themselves at once in conflict with the local town officials, and this conflict of authority would necessarily injure their efficiency and usefulness. The sphere of such a society to be really useful must be educational, and must depend on the increased intelligence of the community for obtaining from the town officers and from the citizens themselves the improvements good taste and the highest interests of the town demand. The directors of a society will find more than enough to occupy their time if they approach the subject from this direction, and they will find, too, that progress based on popular intelligence will be more permanent and more satisfactory than if it is the result of isolated individual effort.

The first duty of the officers of the society to which we have referred is to raise from their public-spirited fellow-citizens a good round sum of money, for education and reform cost money; having secured this, let them begin an educational crusade against popular ignorance and indifference to everything connected with public health, convenience and taste. Let them combat this ignorance and this indifference in every way in their power—by the diffusion of sound advice through the press and by special publications, through the lips of clergymen and school-teachers, by popular lectures, and by all the other methods which, once set in motion, have never yet failed to quicken the pulse and stimulate the intelligence of the American people.

This is the way, and the only way, in which an individual or an association of individuals in one of our communities can make its influence felt in a lasting manner. And this is the advice we offer to our correspondent. Make yourself and your co-workers educators in the first place, and then censors; and when anything is done in your town which is calculated to injure it or the welfare of its inhabitants, let the fact be known in such a way that there can be no mistake about it. Your influence will increase and spread, and gradually but surely you will ac-

comply what you desire, and make your town a credit to its inhabitants and a delight to the stranger within your gates.

Pruning Shrubs.

OUR climate is so favorable to the growth of hardy deciduous shrubs that these should play an important part in every American garden, especially in the Northern and Eastern States. A small garden can be made very attractive with a proper selection of shrubs alone from opening spring, when the earliest of them are in bloom, until they glow with the rich colors of their autumn foliage, and even later still, for many of them are covered with bright fruit far into the winter. When properly planted in deep, rich soil they demand comparatively little care, although a mulching with coarse litter is a help to many varieties, and an occasional light dressing of decomposed manure, or of bone-dust and ashes will often prove beneficial.

But how shall they be pruned? As a rule, the knife should be used with caution—not to “trim them into shape,” as the phrase goes, but to encourage their development into the best typical form. Severe pruning tends to enfeeble either shrub or tree, and the removal of large branches usually interferes with the natural and, therefore, most graceful outlines of either. So far as any general rule can be laid down, it may be said that shrubs will be the most vigorous and in their best form the year through, when no pruning is attempted beyond the thinning out of the weaker and overshadowed branches in order to afford the stronger ones a better opportunity for growth. Shrubs have a beauty in winter as well as when they are in full foliage or flower. In the leafless season a mass of shrubbery is enveloped with a haze of delicate color which comes from the melting together of the different tints of the bark of the small branches; and this color, together with grace of form, that in shrubs which is quite as distinct in winter as in summer, can be destroyed by careless cutting. The shearing of shrubs into formal shapes, such as cones and spheres, or cutting off all the tops at the same level, means, of course, the destruction both of the health and beauty of the plant.

But when shrubs are used for special purposes they require special treatment. If abundant bloom is the object chiefly aimed at, the time and manner of pruning should be chosen with this end in view. Shrubs which bloom early in the spring, like Thunberg's *Spiræa*, for example, form their flower-buds on the growth of the previous year. If this growth is cut back in autumn or in early spring, the flower-buds, too, are cut away and the bloom of the year is destroyed. With such shrubs the proper course is to wait till the flowering season is over and then prune away a considerable portion of last year's wood. This will encourage new shoots, which will start at once and begin to make flowering branches for next spring. On the other hand, shrubs which flower late in the season, like the Rose of Sharon, some of the *Tamasisks* and the Great Panicked *Hydrangea*, make their flower-buds on the wood that forms during the growing season of the same year. These late-flowering shrubs should be pruned now, before the new growth starts. If the *Hydrangea* just mentioned is cut back so as to leave but one or two eyes on each branch of last year's growth, these will put out vigorous shoots, each of which will bear at the extremity a large panicle of flowers next fall.

These directions may be summarized as follows:

For general purposes, shrubs should never be cut back so far as to impair their vigor, nor be pruned so as to destroy their natural outlines.

Shrubs which bloom early, on wood of the previous year, should not be pruned in autumn or in early spring when it is desired to secure abundant flowers, but immediately after the blooming season.

Shrubs which bloom late, on wood of the current year, should be pruned after the leaves fall in autumn, or in early spring before they start.

THERE is no insurmountable difficulty in protecting the forests upon the national domain or those in the Adirondack region of this state, if the Congress of the United States and the Legislature of New York will give to this subject the serious consideration which its importance requires. But popular legislative bodies only reflect popular demands, and if we are to have forest-preservation in this country it will be because the people of the United States, instructed in the material requirements of their country, insist upon it. The Executive Committee of the Horticultural Society, of Newton, Massachusetts; in recently passing a resolution, which we gladly publish, expressive of intelligent concern for the preservation of the forests and of sympathy with all efforts directed to that end, set an example which might well be followed by other bodies of men, whether they are tillers of the soil or not, who are interested in the future of the United States. If every organized society in the country will pass resolutions upon this subject, if every newspaper will publish and endorse them, and if every man and woman will use his or her influence in bringing the subject of forest-preservation to members of Congress, personally and by petition, sooner or later the country will be saved from those special and particular evils which the extermination of the western forests will bring upon it:

Resolved: That the Newton Horticultural Society desire to express, through the medium of the public press, their entire satisfaction in the efforts that are now being made to awaken the people to the great importance of preserving the forests throughout our country. In New England, and especially in northern New Hampshire, as well as in other regions, the forests are fast disappearing before the axe of the logger.

Not only are certain districts thus robbed of their chief attraction to lovers of natural scenery, but the value of the streams, which take their rise among them, for manufacturing purposes, is seriously impaired, not only by the droughts but by the inundations thereby produced. Our countrymen, generally, must be educated up to a knowledge of the important truths which so vitally concern them, and we therefore cordially welcome every effort, however humble, to bring about so desirable an end.

Especially do we recognize the value of the weekly diffusion of knowledge on forestry in all its relations to the interest of the people, made by GARDEN AND FOREST. Could its articles on this subject be more widely diffused and brought to the notice of the capitalist, the farmer, the contractor, the builder, in fact, every one, the result would be most satisfactory.

It would be unwise to sit down and close our eyes against matters which so intimately concern ourselves as well as coming generations; we, therefore, as members of a society designed to foster and promote a love for the beautiful and useful in Nature, would entreat our fellow citizens and countrymen to give new and persistent attention to all that concerns the preservation of the forests.

The Garden (London) recently republished in full the admirable “Hints About Lawns” which Mr. J. C. Olmsted wrote for GARDEN AND FOREST; and an accompanying editorial note read as follows: “If landscape-gardening were as true and clear as the above sketch, that art would not now be the horror it is to sensitive men.” In justice to Mr. Olmsted, to his famous father and to other American landscape-gardeners, it should be explained to our English contemporaries that their art, as practiced here, is by no means a horror even to the most sensitive eyes. Horror is excited only when the land-owner himself tries to do an artist's work, or when he mistakes for an artist some one who has no better title to the name than lies in the fact that he can grow plants successfully.

Some idea of the wonderful growth of trees in the fertile soil of California—a growth which seems almost fabulous to persons living in less favored regions—will be gathered from the following statement printed in a recent issue of the *Pacific Rural Press*. The trees are in Antelope Valley, in Colusa County, and have not been irrigated. A Fig-tree, planted in 1874, has a top thirty feet high by thirty feet

through, with a trunk five feet seven inches in circumference at the smallest part, which is two feet from the ground. A California Walnut (*Juglans Californica*), planted in 1882, is twenty-five feet high, with a head twenty-five feet through, and a trunk diameter of twelve inches. An English Walnut, planted in 1884, is sixteen feet high, with a trunk six and one-half inches in diameter.

The Art of Gardening.—An Historical Sketch. II. —Egypt.

IF we wish distinct proof in support of the belief that man's love for art developed before his love for nature and that he practiced architecture in advance of gardening, we may find it in the fact that all the early gardens of which we have any accurate knowledge were formally, architecturally arranged. Egyptian gardens are portrayed in many paintings and bas-reliefs, succinct and conventional, of course, in treatment, but easily deciphered and clear in the witness they give to the rigid formality of the Egyptian style. Although the civilization portrayed in these pictures is the earliest of which history, as distinguished from mere legend, speaks, it was already highly developed and must have existed for many ages. And when we remember the physical character of the land, with its burning sun and level plains, devoid of all that picturesqueness of surface and that richness in large vegetable forms which other countries exhibit, we can easily believe that gardening art was widely practiced on the banks of the Nile. Temples were surrounded with gardens; the rich Egyptian lived in country houses encircled by larger ornamental demesnes, and gardens existed in which the architectural factors were of accessory, not primary, importance. But whatever the size of the enclosure, it must have been formally disposed. Such was the case in all ancient lands, but there were especial reasons why it should have been the case in Egypt.

Local taste, as every relic we possess declares, ran emphatically in the direction of symmetry in all forms of art. And we can understand why if we glance at the physical aspect of the land. It is, so to say, Nature's most formal, symmetrical creation, with its single wide river, its vast level plains, and those bordering mountains which are but perpendicular walls of rock. Picturesqueness is nowhere suggested—Nature did not teach the Egyptian what its charms might be, nor reveal to him the beauty of variety. Although a multitude of minor plants grew, of course, in his fertile soil, trees were present in but few varieties, and everywhere order, balance, sobriety, and a persistent, if splendid, monotony of outline met his eye. Even to-day, with all our preference for landscape-gardening properly so-called, we feel that a large measure of formality would be prescribed in Egypt by the dictates of Nature herself. Here one does not desire an outlook into the distance so much as to seclude one's self from its sameness behind barriers which allow the imagination to believe that variety may lie beyond them. Here the chief essentials are coolness and shade. But no brooks exist; to simulate natural ponds would be too gross and palpable a deception—the formal basin is really the most natural expedient. As all vegetation must be irrigated, and as in its larger forms it is supplied in no great variety, both convenience and beauty are best served by a symmetrical disposition of the plants. And, in general, only a garden with a distinct element of architectural stability and grandeur would seem in harmony with the outer world. If we feel this to-day, how much more must the Egyptian have felt it to whom experience had revealed no other kind of beauty? As he naturally evolved the most solid and most symmetrical kind of architecture that the world has seen, so, too, he naturally created only formal, architectural gardens.

The common type of temple-garden is, of course, the one most frequently shown in Egyptian picture-records. It was not so much a place into which men could escape from the imprisonment of walls and roofs as an adjunct to the beauty of the building—a stately court-yard surrounded by high barriers and planted with rows of trees which seem often to have grown in pots. Avenues of trees must likewise have formed the approach to the temples, obelisks, sphinxes and other sculptured monuments mingling with their more pliant forms. Thus, for example, we may picture the great sphinx-avenue which leads for more than a mile between the temples of Luxor and Karnak, now a waste sandy stretch lined by headless figures, but once verduous under foot and shaded by tall Palms or Sycamores.

Other pictures show us gardens of more importance lying around palace or temple, with wide parterres, long rows of

umbrageous trees, groups of Palms and great basins and canals flowing with water; and one picture at least on the wall of a Theban tomb, shows a villa-garden in which architectural elements by no means preponderate. It is a great square walled enclosure, lying close to a river—the Nile, of course, as there was no other—from the banks of which steps lead up to the only entrance, a noble gate. On the opposite side of the garden, near what we may call its back wall, stands the villa. To right and left of the entrance are great longitudinal basins of water, while two others, of a square shape, lie further back. The side walls are lined with trees, between each pair of which a vine is trained against the wall, and outside the front wall, close to the river, runs a row of trees evidently of exceptional size. The centre of the garden is occupied by a vineyard, divided by paths into seven sections, which is encircled by its own wall and fills perhaps a third of the whole area. And all the remaining portions are sub-divided into regular sections, amid which kiosks and shelters are arranged, filled with various kinds of plants in masses. Several different species of trees are indicated, and among them we may divine the Sycamore and the Date Palm, while in other spots we see great groups of rush-like foliage, and the basins hold aquatic plants. This, indeed, must have been a spot where man could refresh himself in seclusion and peace; yet nothing could well be more formal, more architectural in design.

A picture which was discovered by Champollion and is now in the Louvre, shows a garden surrounded by a wooden wall, and again lying by the river between which and the wall stands a row of trees cut into spherical forms. In the centre of the enclosure is a great arbor of vines, encircled by a double row of Palm-trees, while in other parts square pools and symmetrical parterres of flowers are indicated, and an open kiosk of four rooms covered with vines. In other pictures we see trees clipped into columnar shapes, and in all we realize the natural desire of everyone who built a garden to place it close to Father Nile.

The chief shade-tree of the Egyptians was the Sycamore—of course the true Sycamore, *Ficus sycamorus*, and not one of the very different trees which in modern Europe and in America are called by this name. The Date Palm must have been equally conspicuous, valued for its fruit as well as for its beauty, and harmonizing well in its graceful yet stately lines with the architectural forms about it. The Doum Palm (*Hyphane Thebaica*), the Acacia, the Carob-tree (*Cratonia siliqua*) the Almond, the Pomegranate, the Myrtle and the Laurel were also familiar trees; the Vine was everywhere present; and a wall-picture of the eighteenth dynasty shows us an apartment in which ornamental foliage-plants are growing in pots.

It is probable that lawns and parterres of grass were unknown in Egyptian gardens—in no hot southern land can they ever have been perfected. But their place was supplied by flat parterres of flowering plants, which, it is in harmony with all we know of Egyptian taste to believe, formed carpet-like patterns of vivid colors. Of course such patterns were entirely appropriate when the design of a garden was formal; the Egyptian feeling for color was so well developed that we must fancy them peculiarly beautiful in the grouping of their tints; and never can they have had so admirable an effect as here, where the architectural forms they encircled were painted in conspicuous designs with bright blue and red and green.

New York.

M. G. van Rensselaer.

The Cedar of Lebanon.

THE Cedars of Mount Lebanon are, perhaps, the most renowned and the best known natural monuments in the world. Religion, poetry and history have all united to make them famous. Distinguished travelers and men of science have visited them, and their story has been told over and over again. There are, however, grave doubts, at least, whether the Cedar so often mentioned in the Bible was the tree now called the Cedar of Lebanon; and the forests which Solomon cut to rebuild the Temple were, perhaps, composed of Junipers or of some other tree with more durable wood than that of the Cedar. There is no doubt, however, that the Cedars of Lebanon in more modern times have been objects of veneration. Belon, the author of the first work upon Conifers ever written, visited Syria in 1550, ascended Mount Lebanon, and visited the Monastery of the Virgin Mary, situated in a valley below the grove of these trees where the festival of the Transfiguration was held. For this solemnity the Marmites—a Christian sect inhabiting Mount Lebanon—with many pilgrims, repaired to the grove. The night before was celebrated in dancing and feasting by the light of fires built with branches cut from the

Cedars. The following day the Patriarch celebrated high mass upon an altar erected under one of the largest of the trees, which, we are told, were planted by the hand of King Solomon himself, at least this is the story related to the faithful; and "that the Patriarch officiated pontifically on this solemn occasion; that his followers were particularly mindful of the Blessed Virgin on this day, because the Scriptures compare her to the Cedars of Lebanon; and that the same Holy Father threatens with ecclesiastical censure those who presume to hurt or diminish the Cedars now remaining,"—an injunction which does not seem to have been very strictly obeyed, for the number of very old trees in this famous grove has been steadily diminishing ever since. Belon found twenty-eight of them standing at the time of his visit. Thévenat a century later found twenty-three. Only sixteen large trees were seen by Maundrell in his journey from Aleppo to Jerusalem, made in 1696, although he found many small trees growing near them. The number of the large trees continued to gradually diminish, if the reports of travelers are to be believed, from this time, although the grove being protected more or less successfully from fire and from sheep and goats, the young trees increased. In the middle of the last century there were twelve of the old trees remaining, and between four and five hundred smaller ones of all sizes. Dr. Pariset, who visited Mount Lebanon in 1829, found the grove in substantially the same condition as when Dr. Pococke had seen it eighty years earlier.

But the most experienced observer who has ever seen the Cedars on Mount Lebanon is Sir Joseph Hooker, who visited Syria in the autumn of 1860, for the purpose of examining the grove, in regard to which little was known scientifically up to that time. A very interesting account of this visit was published in the *Natural History Review* in January, 1862, with the author's views upon the specific rank and the origin of the different species or forms of the genus. The elevation of Mount Lebanon was found to be 10,200 feet, and that of the valley, where the trees are growing, 6,200 feet. "The number of trees," to quote from this article, "is about 400, and they are disposed in nine groups, corresponding with as many hummocks of the range of moraines; they are of various sizes, from about eighteen inches to upwards of forty feet in girth; but the most remarkable and significant fact connected with their size, and consequently with the age of the grove, is that there is no tree of less than eighteen inches girth, and that we found no young trees, bushes or even seedlings, of a second year's growth. . . . The position of the oldest trees (of the 400) afforded some interesting data, relative to the ages of the different parts of the grove, and the direction in which it had lately spread. There were only fifteen trees above fifteen feet in girth, and these all occurred in two of the nine clumps, which contained 180 trees. Only ten others exceeded twelve feet in girth, and these were found in immediately adjoining clumps, one on one side and one on the other of the above mentioned. There were five clumps containing 156 trees, none of which was above twelve feet in girth, and these were all to the westward (or down-valley) side of the others. On this side, therefore, the latest addition to the grove has taken place."

One of the old Cedars of Mount Lebanon appears upon page 149. The illustration is made from a photograph taken upon the spot and communicated to us by Mr. Francis Skinner, of Boston. It was supposed, until comparatively recent times, that all the Cedars left upon the earth were in this famous grove, but now they are known to occur upon different chains of the Taurus, where, with *Abies Cilicica* and *Juniperus foetidissima*, they form extensive forests; while as late as 1865 Mr. Jesup, an American missionary, discovered five large groves in the Lebanon itself, three east of 'Ain Zahaltah, in the southern Lebanon, one of which was said to contain 10,000 trees. Other groves were also discovered at this time, so that upon the Lebanon alone the Cedar is known in ten distinct localities. The same tree, or one hardly to be distinguished from it by any of the characters which botanists consider valuable, *Cedrus Atlantica* occupies the mountain ranges of Constantine, the western province of Algeria, bordering upon Tunis, and abounds on the eastern Atlas ranges. They characterize the upper mountain zone between 5,200 and 7,200 feet, and approach to within twenty miles of the sea. Cedars, too, were found upon the mountains of Cyprus after the recent English occupation of the island, which only differ from those of the Lebanon in the shortness of their leaves, and which serve to form an important link between those of Asia Minor and of the Atlas. West of the Lebanon, at a distance of 1,400 miles, or nearly the same distance as that which separates the Atlas from the Lebanon, occur the great Afghanistan forests of

Cedrus Deodara, which extend eastward along the Himalaya almost continuously to Nepal, occupying various elevations between 4,000 and 12,000 feet, and in Afghanistan outnumbering all other Conifers in the number of individuals. The Deodar, or "Tree of God" of the Hindoos, is one of the most valuable timber-trees of the Himalaya.

Sir Joseph Hooker states in the paper from which we have already quoted that "the African Cedar differs from that of Lebanon in having a perfectly erect, rigid leader, and straight, stiff ends to the branches, all of which in the Lebanon plant droop more or less. In the African the cone is generally smaller, the leaves shorter and more glaucous, and the scales and seeds triangular in form (instead of quadrangular). There are two forms of Cedar in Algeria as in Taurus, and characterized by the same differences in each country—viz., a greener long-leaved, and a more silvery short-leaved variety. The *C. Deodara* has a much more pendulous leader and ends to its branches, and longer leaves of a more glaucous hue than *C. Libani*, though not such silvery leaves as the *C. Atlantica*. The cones are as large as those of *C. Libani*, but the scales and seeds are the same form as those of *C. Atlantica*, and hence markedly different from those of *C. Libani*. . . . It should be added that there are no other distinctions whatever between them—of bark, wood, leaves, male-cones, anthers or the structure of them—nor in their mode of germination or duration, the girth they attain, or their hardness."

The conclusion reached by Sir Joseph is that the three Cedars are well marked forms, generally distinct, but occasionally approaching or passing into one another, and all derived from one common parent.

The Cedars are related botanically to the Larches and to the Firs. Their stiff, awl-shaped leaves are produced like those of the Larch, from very short lateral branches, but unlike those of the Larch, they are persistent. The cones are upright, with deciduous scales like those of the Firs, but they are much larger, and are composed of broad and rounded, closely imbricated scales, and do not mature until the end of the second or sometimes the third season.

The Cedar of Lebanon was planted early in British gardens. The exact date of its introduction seems uncertain, although it is probable that it was about 1680, and that the famous trees of the Chelsea Botanic Garden were really the first. A good deal of conflicting testimony, however, has been produced at different times upon this subject.

Bernard de Jussieu carried from London in 1734 the first specimen planted in France; unless, as has been suggested lately, Belon really brought the Cedar to France from Syria at the time of his visit in the middle of the sixteenth century. Jussieu's tree is growing where he planted it in the *Jardin des Plantes*, and is still healthy and vigorous.

No foreign tree perhaps has ever been more generally planted in England during the last two centuries, and thousands of noble, wide-branching old specimens, scattered from one end of the kingdom to the other, are among the most impressive objects in many stately parks and pleasure grounds.

Our illustration upon page 151 will serve to show the Cedar of Lebanon as it appears in England. It is a view of one of the most famous country places, Wilton House, near Salisbury, long the home of the Pembrokes, where lived the lady whom all the world knows through old Ben Jonson's epitaph as "Sidney's sister, Pembroke's mother." Here it was that this lady's brother, Sir Philip Sidney, wrote the "Arcadia," and although he died a century before the first Cedar was planted in England, Wilton House in those days must have possessed many of the features which has since made it famous. "The shading woods, . . . the rocks, woods, hills, caves, dells, meads and brooks" which answered the poet's sigh for his absent "Stella."

Here in the United States the Cedar of Lebanon is not often seen. It is not hardy in New England, where, perhaps, more attention has been paid to the cultivation of exotic trees than in other parts of the country; and although a few good specimens may be seen in the neighborhood of this city and of Philadelphia, where the tree seems to be hardy enough when once established, the number is not large, and it does not seem to have been a favorite with planters. It is not known who first planted the Cedar in the United States. Mr. Downing, in his "Landscape Gardening," published in 1849, speaks of a specimen in the grounds of Mr. T. Ash, at Throggs Neck, in Westchester County, in this State, as the finest in the Union, being at that time fifty feet high. It would be interesting to know if this plant still survives. The specimen planted at Woodlawn, near Princeton, New Jersey, by the late Judge Field in 1842, and now the property of Professor Marquand, was thirty-six feet high in 1859, and is now fifty-four feet high,

Fig. 101.—A Cedar of Mount Lebanon.—See page 147.

with a trunk girth, one foot above the ground, of seven feet two inches, and a spread of branches of thirty-three feet—certainly not a very remarkable growth in forty-six years. There is a fine Cedar on the grounds of the old Prince Nursery, in Flushing, now some sixty-five feet high, with a trunk which measures, five feet from the ground, eight feet and two and a

half inches, but the fact that this tree is so rarely seen in the Middle States still needs explanation.

The best accounts of the Cedar of Lebanon are found in the paper by Sir Joseph Hooker already referred to, and in the historical and cultural essay published by Monsieur Loiseleur-Deslongchamps in 1837, entitled "*Histoire du Cèdre du Liban*."

Foreign Correspondence.

London Letter.

WE are getting tired of double flowers, not long since the acme of perfection with horticulturists. The first tendency to doubleness in a flower was hailed with delight, and the monstrosity was coddled and encouraged till a perfect double flower was obtained. Thus came the double Dahlias, the Hollyhocks, and hosts of other things besides. The double Dahlias were discarded for the single-flowered kinds not very long ago, and most people asked how it came to pass that such monsters as the big Dahlia were tolerated. The revolution now is against the double Camellias, which very few people admire. No lady will wear them; they are worthless for bouquets. In fact, they have had their day. But the single-flowered Camellias are in favor, and are likely to become very popular. The blossoms of *C. reticulata* are too large to be worn by any one save a calman at a wedding, but they are grand flowers, nevertheless. The bicolored flowers of *C. Doncklaari* are also handsome. These are, however, large-flowered species. But we have now a race of Camellias, recently introduced from Japan, and being rapidly propagated by the nurserymen here, which are remarkable for their compact habit, small leaves, and small single or semi-double flowers of the most elegant form, and varying in color from white to deep crimson. Probably they are the result of crossing the small-flowered *C. Sasanqua* with the larger-flowered race, but, whatever their origin, they are certain to become popular garden-plants. I do not pretend to any knowledge of the horticultural methods of the Japanese save what I have seen in a few plants imported direct from Japan, but these show a lamentable want of neatness and true horticultural skill. These grafted Camellias are a case in point; nothing could be more primitive, nothing uglier than the manner in which they are grafted. No English horticulturist would tolerate such work. The Japanese distort, starve and mutilate their plants to get them into some ridiculous and unnatural shape; they cannot allow their plants to grow their own way. This may be art, but it is an abomination all the same. Judging of Japanese art in the garden from the papers lately published in GARDEN AND FOREST, I will say that we want none of that kind of garden-makers in England at any rate.

None save a Philistine would venture to find fault with double Roses; at the same time the single-flowered kinds are creeping into favor in many gardens in England. The Rose Conference and Exhibition to be held at Chiswick in July next is expected to bring to the front a great many Roses which at present are known only to a few specialists. This, of course, applies chiefly to species, for which a special appeal is made in the schedule. Many of these are of great beauty and as easy to manage as the Dog Rose, but they are rare in English gardens. Your Cherokee Rose flowered here for the first time, I believe, last year; and now many growers are wanting it. The handsome, large-flowered *R. involucrata*, said to be the most tropical of all Roses, was not in cultivation until it was introduced from India to Kew last year, where it flowered out-of-doors in autumn. The flowers are white, and very fragrant. Probably this species will prove hardy in the south of England. Seeds of the new *R. gigantea* have also been received at Kew, and the pretty little *R. minutifolia*, figured in GARDEN AND FOREST last year, is represented by young plants raised from seeds supplied by an Italian nurseryman. The seeds distributed by Vilmorin & Co. at a franc each all failed. The remarkable Afghan species, *R. simplicifolia*, is in vigorous health here, but it does not flower; on the other hand, the hybrid, *R. Hardyi*, raised from the last-named and *R. laxa*, flowers frequently. It is one of the most beautiful of all single Roses; it has large yellow petals, cup-like in arrangement, with a blotch of crimson in the base, suggestive of the Gum Cistus flowers. *R. simplicifolia* would probably do better with you than in England, as it does not like our damp, dull winters. Does any one know of the existence of the single *R. anemonifolia*? We have the double red and double white, as introduced by Fortune, but the single-flowered form is not known here. As it is Japanese, some of your readers who introduce plants direct from Japan may know something about it. The single-flowered Banksian is almost as rare. The white and the yellow double-flowered varieties of this grand Rose are plentiful enough, but we did not know of the existence in gardens of the single-flowered form until it was found last year in the garden of Mr. Hanbury at Mentone. Our knowledge of Roses will no doubt be greatly improved by this forthcoming conference.

The death of Mr. J. T. Peacock, of Hammersmith, has robbed English horticulture of one of the most remarkable

of its patrons. Many years ago Mr. Peacock was famed for his rich collection of succulent plants, a collection which in point of number of species was surpassed only by that at Kew. He paid very high prices for large specimens of *Echinocactus*, *Cereus*, etc., and whenever any of these arrived or flowered he threw his garden open to visitors. These large plants always perished in a short time after their arrival in England. Mr. Peacock's collection of succulents grew so large that he could afford to loan great numbers of them to the Crystal Palace, the Royal Horticultural Society and other large public gardens. Latterly he turned his attention to Orchids, and before his death he possessed one of the richest collections in the neighborhood of London. The whole collection of Orchids and succulents is to be sold by auction. It is remarkable that so many large private collections of Orchids are distributed by the auctioneer annually. Last year, within about three months, no less than six large collections of Orchids were sold by auction in London. This year already five large collections have been placed in the auctioneers' hands. Orchids are costly playthings, no doubt, and although some amateurs have occasion to regret ever having had anything to do with them, others are lucky and get most of their outlay back. There must be an enormous number of new growers to make a demand for all these plants; besides these, the importations which are ever on the increase. The last big arrival was three thousand fine plants of the new *Cypripedium Rothschildianum*, which were sold here on Thursday last. Those who bought and paid dearly for the few sold last year will have occasion to regret their purchases now. There is a good deal of lottery in the Orchid trade; much more than in any other branch of horticulture. There is a marked increase in the number of growers in France, Germany and Belgium, and I am told that in America Orchids are almost as popular as in England.

The directions given in GARDEN AND FOREST, on February 13th, for the management of green-house plants makes us here envious of the weather which enables you to syringe green-house plants twice a day in winter, and makes it necessary for you to use shading. Here we do not get sun enough for Ferns, even, and no one would think of using shading in February, or even in March, for any plant save filmy Ferns. The losses caused by the bad light, fogs and changeable weather here are often heart-breaking. English horticulturists would be glad to get some of that sunlight in February which is over-abundant with you. For early forcing your bright sunlight in winter must give you an immense advantage. For the last fortnight the weather here has been dull and snowy, with a cold north-east wind blowing, and scarcely any sunshine. Plants outside have been nipped by frost, or they have crept back into their winter shells. In-door plants are suffering from fire-heat and want of light. In the country matters are not quite so bad, and I speak only of what is experienced by horticulturists in the neighborhood of London.

Cultural Department.

Asparagus for the Home Garden.

IN boyhood I was accustomed every spring to wander along "high-water mark" on the shore of the Chesapeake and gather the brittle stems of the wild Asparagus, which grows there in the greatest abundance. No knife was needed, for the stems snapped off at the lowest point where they were tender. All that was gathered was therefore eatable. This wild Asparagus was never as large as the highly-fed stems from the market gardens, but one who has become accustomed to its use will always take it in preference to the cultivated sorts. My early experience with this savory plant intensified my distaste of the first market asparagus I ate, which was white, and worthless as an article of food. Argenteuil Asparagus is celebrated as unsurpassed, and some authorities assert that Asparagus, to be good, must be bleached, but if the canned French Asparagus is a fair sample of the bleached product, it is only sophisticated palates which prefer the stringy white stalks to the tender green stems which have developed above ground.

To make an asparagus bed for home use there is no need to buy roots, which in many cases will come to you in a mouldy and worthless condition. Asparagus is a wonderfully hardy plant and will stand any amount of rough treatment, but nothing so quickly moulds in damp packing as the roots do, and many nurserymen will pack them with wet moss and in this way insure their destruction. In making an asparagus bed, remember that it is to last many years. It will therefore pay to prepare the soil very thoroughly. If your garden is of heavy clay it will pay you to use an abundant dressing of sand. If the

spot is wet thorough drainage is essential. Trenching twenty inches deep, with a thick coat of manure worked in, will pay. Get as good a strain of seed as you can, although I have grown as fine Asparagus from seed gathered from the wild plants as I have from any of the colossal sorts, and any "variety" you may get will be full of other varieties. Asparagus, being a diceous plant, is hard to keep in strict strains. On one corner of the plot selected for your bed, or near by, prepare a small bed and sow the seed as early in spring as possible. As soon as the young plants are large enough to handle, say two or three inches high, and about the size of very fine knitting-needles, lay off your plot in rows two feet apart and dibble the plants in six inches apart. Keep them well cultivated all summer, and in the fall give a coat of rough manure all over. The next

Primroses.

The true Primrose is very rare in this country. The flowers generally grown and offered for sale in the flower-stores as Primroses are hybrids probably between the common Primrose (*Primula vulgaris*) and the Cowslip (*P. officinalis*), and possibly (*P. elatior*) the Oxlip; but the varieties and hybrids are so intercrossed that it is hard to trace their real origin. The flowers are borne on short pedicels springing from a common peduncle, and the whole may be termed an umbellate scape. In the true Primrose the scapes are uniflorous, all springing from the root-stock or crown, the individual flowers being much larger and of better form than in the hybrids.

The hybrid Primroses, as well as Polyanthus, are easily

The Cedars at Wilton House.—See page 147

spring you can cut a little asparagus, and the roots being near the surface it will be very early. The next fall and spring thin out the plants in the row, leaving only every fourth one to grow. The second spring give the bed a dressing of Kainit (German potash salts) before growth begins, at about the rate of a ton an acre. Then, when the young growth appears, cut your tender green asparagus off at the surface of the ground, and pity the deluded people who consider the white woody underground portion of the stem eatable.

The subsequent culture will be a heavy fall dressing of manure and a dressing of Kainit once in three or four years. A one-year-old Asparagus plant raised in this way is larger by far than the two-year roots sold by nurserymen. I once planted a large bed in this way, and the following spring marketed good Asparagus from it, which could not have been done from two-year-old roots buried several inches under ground.

Crozet, Va.

W. F. Massey.

raised from seed sown in a cool green-house in March or in frames in April. When large enough to be handled they are transplanted into boxes and kept in a shady place until they are large enough to plant into nursery-beds. We plant them in beds surrounded by stout boarding or planking, which are known as "cradles," over which we can lay lattice-work, or other light shading, during the hottest weather. In color the flowers vary from almost white, through yellow to nearly crimson. In some of the varieties a short, common peduncle, with long pedicels, gives the plant the appearance of the common Primrose. These hybrids are largely grown for spring bedding, especially in England. Owing to the practice of transplanting in spring for immediate effect they are not so satisfactory here as we could wish. Root-action is disturbed, and vitality consequently reduced, so that the first few bright days in May causes them to wilt so much that they begin to look "seedy" before they really arrive at their best. Much

better results are obtained by letting them bloom where planted from seedling-boxes, especially if they are so arranged as to have the protection of a few sashes from the middle of March onwards.

The true Primrose does not mature seed very freely, but it is easily increased by division. It is not easy to keep it, however, during the hottest months. A cool soil and shade during the brightest part of the day are necessary to success.

When fall comes we plant our Primroses along with the Violets, and get abundance of bloom during the winter. Primroses make up very nicely in bouquets of twenty-five to thirty flowers, with a few of their own leaves.

Alpine Ariculas can be grown from seed and treated in the same way as recommended for the hybrids. They can be used for bedding in the same way. They do not ripen seed, but continue blooming, though sparingly, throughout the summer.

Wellesley, Mass.

T. D. Hatfield.

Orchid Notes.

Dendrobium Farmerii is a lovely Orchid, especially adapted for basket-culture, belonging to the evergreen section of the genus, with quadrangular stems, about a foot high, producing near the top pendulous racemes or bunches of straw-colored flowers, delicately tinged with pink, and having a rich golden lip. It is a native of the Khasya Hills, and is easily grown, requiring a warm house during active growth, after which it may be placed in a cool-house and kept fairly dry. There are two rare and choice varieties of this species—one with golden-yellow flowers, while in the other they are pure white.

Dendrobium splendidissimum is the best of a series of hybrids resulting from the crossing of *D. nobile* and *D. aureum*. It is a grand Orchid, combining the best qualities of both parents, and retaining the Primrose fragrance of *D. aureum*. The flowers are nearly four inches across, white, suffused with rosy-purple, the lip having a large blotch of deep purple, surrounded with a zone of creamy-white. This plant should have a long rest in a cool-house in order to flower properly.

Dendrobium primulinum is a fragrant Orchid, deciduous, producing pendulous bulbs about one foot long, from the sides of which come solitary, pale mauve flowers, with large spreading lips, which are white, tipped with rose. The variety *Giganteum* has much longer and very slender stems. The flowers are much larger, with a very much developed lip, often two inches across, pure white, and veined with purple. It was introduced in 1857 from Nepal. It requires the same treatment as *D. primulinum*, and should be grown in a basket or on a block.

Phalanopsis Veitchii.—This rare species, now in flower with us, is presumed to be a natural hybrid between *P. rosea* and *P. Schilleriana*. The habit of the plant is like that of *P. Schilleriana*, but is not nearly so robust. The scape is that of *P. rosea*, and bears about a dozen pretty pinkish flowers, which in shape and markings strongly indicate the parentage. The two plants we have are, I believe, the only ones that have yet been found. The pale variety, *Brachyodon*, is much more attractive than the type. In it the flowers are somewhat larger, and the plant more robust. This variety is represented by a unique specimen.

P. Stuartiana is a somewhat recent addition to this lovely genus, and proves to be a great acquisition. It is now pretty plentiful, very easily grown and an abundant bloomer. It may best be described by calling it a white *P. Schilleriana*, though in many respects it is abundantly distinct from it. There is a great variation in the foliage. In some plants the leaves are deep green, with only the faintest marbling, while others can scarcely be distinguished from *P. Schilleriana*. The flowers are usually cream-colored or pure white, the inferior halves of the lateral sepals yellowish, copiously spotted with dark cinnamon. Sometimes the whole flower is speckled with purple, as in *P. punctatissima*. The flowers are very closely set on the raceme, which is usually much branched, even on small plants. This species is interesting for its propensity to form root-buds, which quickly develop into flowering plants. It requires the usual *Phalanopsis* treatment, and now is a good time to overhaul the plants and remove the old decayed moss and roots, replacing them with new compost of fibrous peat and clean sphagnum. Baskets or cylinders of wood or clay will be found most suitable for this class of plants.

Odontoglossum niveum is a slender, low-growing Orchid, with ovoid, compressed bulbs, and linear, lanceolate leaves about one foot long. The slender racemes bear about a dozen very pretty flowers, about three inches across, white, waxy, copiously spotted with reddish-purple. The narrow segments are reflexed at the points, and the lip is beautifully

ornamented with a golden crest. This species was introduced nearly half a century since from Pamplona, where it was found at an elevation of 6,000 to 8,000 feet, and until recently was very rare. A fine plant is in bloom with us, and grows freely with the other *Odontoglossums*.
F. Goldring.

Kenwood, N. Y.

Galanthus Elwesii.—Last fall we planted several hundred bulbs of this pretty Snowdrop in a cold-frame. As the result, probably, of the abnormal mildness of the winter season, the first week in February found all of them in full bloom, and they are still in good condition, although the soil is frozen solid. The sashes serve to keep off snow and rain, enabling them to maintain their snow-white purity. *G. Elwesii* is quite distinct from *G. nivalis* and its varieties, the petals being distended and narrowed at the base, the inner perianth-segments smaller, and constricted above their middle. Planted with *Chionodoxa Luciliae*, this Snowdrop makes a pleasing sight in the early spring months. Both are perfectly hardy.

Ornamental Grasses.—The *Eulalias*, especially *E. Japonica* and its varieties, *Zebrina* and *Variegata*, are well known as ornamental plants, and deservedly so. The *Eulalia gracillima univittata*, however, is not as widely known as it should be. It is dwarfer than those named above, and is of a graceful habit, its distinctive feature being a pure white mid-rib running through each leaf. Last year this plant fully established its value and reliability as a decorative plant.

Scirpus Tabermontani zebrina, or Porcupine-grass, as it is sometimes called, is well worth growing, too. Being of doubtful hardiness, for assured safety it should be wintered in a cool green-house. When first introduced into cultivation it was grown as a warm green-house plant, but has since proved nearly hardy. Any little trouble taken with it will be amply rewarded by its tufts of leaves, two to three feet long, resembling bunches of porcupine-quills, except in color, which in the grass is green and white in alternate bands. The younger leaves are suffused with rose. Another species, equally pretty, is *S. Holoschanus variegatus*, a grass with leaves banded in the same way. This is quite hardy, and grows a foot high. These grasses do best in soils that are moist and rich.

Astilbe Japonica aureo reticulata.—This is a more valuable plant, if possible, than the species, being quite as useful for flowers, while the leaves are veined with rich yellow. The leaf-stalks, too, are noticeable for their crimson hue, giving the plant a distinct and attractive appearance when grown as a pot-plant. This variety is of strong constitution, and promises to become popular.

Passaic, N. J.

Plant Notes.

Berberis Lycium.*

WHEN this Barberry comes to be better known—and a figure which has been prepared for the *Botanical Magazine* will do much, when published, to further a knowledge of and create an interest in the plant—it will surely become a favorite. Hitherto, I believe, there has been no figure of *B. Lycium* published, and I do not find any record of the plant being cultivated. It has been growing at Kew for several years under the name of *B. elegans*, and this name occurs in the lists of several continental botanical gardens. No one hitherto appears, however, to have identified the species under its garden name with the wild type, which occurs in sunny places and elevations from 3,000 to 9,000 feet above sea-level in the western Himalaya, from Garwhal to Hazara. In the Kew collection are individuals which are undoubtedly referable to *B. Lycium*, and, indeed, identical with it, *i. e.*, they cannot be separated even as varieties from a nurseryman's standpoint—*B. glaucescens*, *B. arihuacensis*, *B. aristata* (under the latter name widely different plants—belonging, perhaps, to three distinct species—are cultivated in English gardens).

B. Lycium, as far as Kew experience allows me to judge, seems as hardy as our native *B. vulgaris* or the North American *B. Canadensis*, and produces its wealth of golden racemes after all the allies of *B. vulgaris* and the very numerous forms of that species have passed out of flower. On the other hand, however, it appears not to blossom in a young state, but cedes to none in beauty and floriferousness when once the bush has reached the flowering stage.

It forms an erect bush about a couple of yards in height, with whitish bark and subsessile, subpersistent, lanceolate or narrow, obovate leaves, of a light greyish-green above and very glaucous beneath. As a rule the leaves are entire, but

* *BERBERIS LYCIUM*, Royle, *Botany of the Himalayan Mountains*, 64; *Transactions of the Linnean Society of London*, xvii., 94.

on strong, vigorous shoots they are not infrequently furnished with two or three spiny teeth. The drooping raceme is longer than the leaves, is either simple or compound, and is often corymbose; the berries are elongated in form, violet in color, and are furnished with a conspicuous style and capitate stigma.

In the districts where it is found wild, Royle says *B. Lycium* is largely used in the manufacture of *rusot*. The following lines respecting *rusot* are copied from Royle: "The wood and bark of the Himalayan species of Barberry are not only used simply in India, but an extract is prepared from them which is to be found in every bazaar, and described in all the works on materia medica. This is prepared by digesting in water sliced pieces of the root, stem and branches of any of the species of Barberry in an iron vessel, boiling for some time, straining and then evaporating to a proper consistence. This extract is much employed in Indian medicine, and everywhere known by the name of *rusot*." *George Nicholson.*
Royal Gardens, Kew.

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

XIII.—SOME OF THE CONDITIONS WHICH FAVOR RAPID GROWTH—CERTAIN PHYSICAL PHENOMENA OF GROWTH.

THE MEASUREMENT OF GROWTH is by no means so easy a matter as would appear at first to a casual observer. In the case of strong shoots, which increase in length very rapidly, it is, of course, sufficient merely to make measurements with any accurate scale, at proper intervals. For instance, shoots of Bamboo can grow at the rate of six inches to one foot in twenty-four hours, and such rapid growth can be very readily measured. But when we are dealing with plants which grow slowly, or when we desire to note the amount of growth during short periods of time, it is necessary to make use of apparatus by which all growth can be registered, and the exact times of growth known. In general, such pieces of apparatus consist of a drum made to revolve regularly, by means of clock-work, and bearing smoked paper, which can be marked by an index connected with the growing part of the plant under observation. When such an apparatus is properly adjusted it can run along for many days, making an accurate record of all the varying rates of growth, and the times of these variations can, of course, be easily compared with the rates. It has been urged that, in the case of such experiments, the plants are withdrawn from their natural conditions and subjected to special conditions in the laboratory which may disturb in many ways their natural activities; and hence, it is said, it is not right to conclude from these experiments that the growth registered by the apparatus is the same which the plant would have made in the open air or in its natural home. Such objections are not well founded. Nevertheless, they must, in some instances, be taken into account, and, further, it must be remembered, in examining the general conclusions drawn from the results of experiments of this character, that different plants, under precisely the same conditions, may behave very differently. In fact, there are a good many peculiarities or idiosyncrasies of plants which are as yet wholly unaccounted for. But the general statements which now follow are based on an examination of a large number of plants, and doubtless apply, with very few exceptions, to all of the common plants which fall within the province of the horticulturist and the forester.

RELATIONS OF GROWTH TO TEMPERATURE.—There appears to be a certain degree of temperature which is suited to the most rapid growth of every plant. Growth can take place at temperatures far above this, and can continue at temperatures far below it, but at the optimum the multiplication and the enlargement of cells proceeds most rapidly and uninterruptedly. The degrees which have been made out for some of our common plants are given in the following table:

	Minimum.	Maximum.	Optimum.
Wheat,	41° F.	108° F.	84° F.
Cress,	34° F.	98° F.	80° F.
Red Clover, . .	42° F.	82° F.	70° F.
Indian Corn, . .	48° F.	115° F.	90° F.

These figures are fair averages of those given by observers. RELATIONS OF GROWTH TO LIGHT.—In general it must be admitted that cell-growth is retarded by light. At first this seems very strange when we reflect that it is through the agency of light that the green parts of plants construct all their building materials. The putting of these materials in place is, however, quite a different matter. It can go on in the light, but it proceeds, as a rule, faster in the dark. A moment's consideration will show that all growth of ordinary roots takes place in the dark, and the thickening layers of stems are com-

pletely shielded from the light; moreover, the unfolding of buds at the covered growing points of stems and branches is another case in point. To the cultivator of plants the fact is familiar that in a dim light the seedlings are apt to be "drawn," whereas in bright light they are more "stocky," and are better able to resist attacks of disease. The growth is less rapid in the latter than in the former case. Hence we must bear in mind the fact that rapid growth is not by any means necessarily that rate which is best for the plant under cultivation.

RELATIONS OF GROWTH TO THE MINERAL MATTERS IN THE SOIL.—This subject is one of surpassing importance, since it underlies all success in cultivation. The experiments in this field of observation have been conducted not only in special soils prepared for the purpose, but also by a method capable of yielding even more satisfactory and exact results—namely, by what is known as "water-culture." When seedlings have thrust out one or two strong roots, and a few leaves, they are placed above the surface of the solution which is to be employed in the experiment, and the roots are permitted to dip into the liquid. For instance, one plant will be grown with pure water, another with water containing one of the salts of potash, another with another salt of the same base, and so on. It is plain that such observations can be indefinitely extended to all classes of substances.

From the myriads of results which have been obtained by this mode of experimenting, the following general conclusions appear at the present time to be justified:

Growth and the preparation of materials for growth are checked when the substances mentioned below are absent, or are present in too small amount—combinations of potassium, magnesium, calcium, nitrogen, iron, phosphorus. These, together with sulphur in very small amount, and for some plants, sodium and chlorine, may be regarded as absolutely indispensable. Acting on the hints afforded by water-culture, it is possible to provide for a certain species of plant the precise amount of the substances best adapted to the needs of its growth. In practice, however, there are several serious difficulties which stand in the way of transferring these results from the laboratory to the garden or the forest. The most perplexing hindrance is that as soon as a solution of these mineral matters comes in contact with the soil it is liable to undergo changes in composition. Some kinds of soil, notably clayey soils, have the extraordinary power of withdrawing from solutions certain of the matters held in solution, and in this mechanical adhesion, as it is called, the abstracted substances are liable to be acted on by the air which is entangled in the soil. Although the plants may get at these matters after a time, and perhaps in the very best form in which they can use them, we are not sure that what we place on the soil is what the plants are going to get. For exact information in regard to this most important matter the reader may consult some authoritative work like that which is mentioned at the end of this paper.*

PHYSICAL PHENOMENA OF GROWTH.—The pressure which is exerted by a growing part is in some cases, capable of measurement. The results of such measurements are surprising. Only a few examples can be cited here; other cases may be found in the treatises referred to in earlier papers of this series.

Darwin found that the tiny underground stemlet of a germinating bean was able to move a weight of rather more than three pounds, and in another instance about eight pounds.

In the case of the fruit of a squash placed in a frame-work connected with a lever, a force of more than two tons was exerted by the multiplying and enlarging cells.

When trees grow on ledges the increase in the thickness of the large roots at their very base will frequently raise the whole trunk for a distance of an inch or more, the firm ledge under it affording an unyielding support, against which the pressure of the cells of the thickening roots comes. This fact should be borne in mind in the examination of those cases of supposed growth in height of old thick stems which may have served as gate-posts. By the raising of the end of the gate above its former level the old stem, which we know is incapable of growth in length, may appear to have grown, whereas it was simply being lifted by the roots underneath.†

Cases in which growing roots have torn asunder stone foundations, into the crevices of which they have insinuated themselves, are doubtless familiar to all the readers of this paper. The force exerted in all these instances has been exercised solely by the innumerable delicate, thin-walled cells, which increase in number and in size in the orderly manner we have attempted to describe.

Cambridge, Mass. *George Lincoln Goodale.*

Correspondence.

To the Editor of GARDEN AND FOREST :

I have about two acres which I want to put into a grove of Nut-trees, such as Chesnut, Hickory, etc., and would like to know the best size to get the trees and the right distance apart to plant them. Of course, I shall thin them out to some extent as they grow up, but do not want to do this until those taken out will be of some service.

New York.

C. D. Miller.

[It is more economical to plant the nuts of Hickories, Walnuts and Chestnuts where the trees are to grow than to transplant seedlings. The nuts should be procured in the autumn and kept over winter in moist sand, as if they are allowed to become dry they lose their power of germination. They should be planted as soon as the frost is out of the ground in the spring. If the ground is hilly or filled with rocks the nuts must be planted, two to six feet apart, wherever sufficient soil can be found for them, by making a hole with a stick from a half to one inch deep, dropping in the seed, and then closing the hole by pressing the foot upon it. This, too, is the best method for planting where the ground is so impoverished that it will not produce a heavy crop of grass or weeds. But when the ground is rich and level it should be ploughed and marked out as though it were intended for a crop of corn; the nuts should be planted four feet apart, and the soil should be cultivated to destroy the weeds until the seedlings are large enough to shade the surface, after which no further cultivation will be needed.]

Seedling Chestnut plants, one to two feet high, can easily be transplanted and can be procured from nurseries. So can seedling Black Walnuts, although little is gained by planting seedlings rather than seeds of trees which, like the Black Walnut, the Hickories and the Oaks, make strong tap-roots. Seedling Hickories are not kept in any large quantity in American nurseries.—Ed.]

To the Editor of GARDEN AND FOREST :

Sir.—In the notice of the Double-flowered Horse-chestnut, by George Nicholson, of Kew, published in No. 51 of GARDEN AND FOREST, I find it stated that the flowers became double by the changing of the stamens into petals.

In a double-flowered Horse-chestnut which I examined last summer, the discoid base of the flower was converted into a pillar, from which arose four distinct flowers in succession, each furnished with its complement of stamens and petals. There was, at the same time, a spiral movement which had disposed the petals of the different flowers in such a manner as to produce a many-petaled rosette, but each flower of the series retained its own stamens unchanged.

I intend, hereafter, to endeavor to observe whether plants belonging to the *Discifloræ* differ in their method of doubling from plants belonging to the *Calycifloræ*.

Media, Penn.

G. A. Lewis.

To the Editor of GARDEN AND FOREST :

Sir.—Your remarks upon the vandalism of cutting down and peddling out the remains of the old historic Oak at Woodbridge, Connecticut, remind me of an incident of my own experience which has never been recorded, but is worthy of mention as an illustration of a degree of barbarism which it seems incredible can still exist.

During the late civil war there was, at one time, a great demand for "Pasture Oaks"—as the White Oaks growing singly in open fields were called—the timber of which commanded a high price at the Navy Yards.

Near where I then lived in Massachusetts was a farm which had been in the family of the man who then occupied it, for more than 200 years, the house in which he lived being more than 150 years old. It stood, perhaps, ten rods back from the high-way, and on each side of the entrance to the lane which led up to the house was a magnificent White Oak, which must have witnessed the course of life from infancy to the grave of many generations of the ancestry of the man who then owned and tilled the farm. I passed them almost daily, and they were to me a constant source of admiration, both on account of their intrinsic grandeur, and the reflections excited by the thought of the stories they could tell.

You can better imagine than I can describe my sensations when, on approaching the place one day, I saw one of them prostrate, and the owner with his assistant busy in cutting down the other, and the only reply he made to the exclamation that rose involuntarily to my lips was that he "guessed there would never be much more timber in 'em, and he never again could get so good a price for it."

Minneapolis, February 20th.

H. W. S. C.

To the Editor of GARDEN AND FOREST :

Sir.—It having come to my knowledge that a florist of this place, David Cliffe, was suffering from poison supposed to have been caused by some plant, I was led by what has appeared in GARDEN AND FOREST to suspect that perhaps *Primula obconica* might be that plant. I wrote him of my suspicion and this is what he replies :

"I am positive that *Primula obconica* is poisonous to some persons. As you know, I was under treatment for poison which I received from Poinsettia, through cuts in my hand. Feeling much better, I busied myself potting my Primulas. In the evening I was completely blind from my face being swollen. It remained in this condition for a day. Since this my foreman, after packing up some of the plants, had his hands and arms poisoned. Last week a customer who had taken some of the plants refused to take any more, saying some who had handled them were poisoned by them."

It is hard to believe this of any *Primula*; and probably the cases in which it poisons are very few, as there is no doubt that hundreds handle it with no ill effects, just as is the case with many other plants. Personally, I am compelled to avoid any contact with the common Poison Ivy; and even the seeds of the Oregon Maple (*Acer macrophyllum*) and of the *Ostrya Virginica*, both of which are covered with minute hairs, and excite an itching and inflammation of my hands, while many others who have handled them are not at all affected. The *Primula obconica* is such a beautiful and useful plant that it will be much regretted if it should be proved to be really poisonous to many persons.

Germantown, Phila.

Joseph Meehan.

To the Editor of GARDEN AND FOREST :

Sir.—Permit me to express my satisfaction with your editorial article on the "Soil and National Development," in your issue of February 13th. It is true, as you say, that all wealth is drawn from the earth itself, and it is equally true that the rocks and minerals, and especially the soil which is produced from them, are useful to man just in proportion to his knowledge of them and their properties. It will be fortunate for our people if you can arrest their attention, and show them in what ways the soil is being ruined in large regions of our country, and by what methods its fertility may be preserved as an inheritance for future generations.

The richness of the virgin soil is made up of the savings of past generations of plants, very much as the riches of a nation are made up of the small savings of past generations of men. If we continue to return to the soil a fair equivalent, in energy and mineral, for that which we remove in the crop, the soil will grow richer; but if we continue to remove the crop without such equivalent, if we steadily plunder and rob the soil, it will finally be reduced to the state of barrenness and savagery from which it has been raised by the vegetation of past ages.

Mahoning, Ohio.

J. W. Pike.

Recent Publications.

Die Landschaftsgaertnerei; ein Handbuch fuer Gaerter, Architekten und Freunde der Gaertner-kunst. Von E. Petzold, Leipzig, Haessel.

The first edition of this work on landscape-gardening was published in 1862, and won high praise in Germany despite the fact that the author was said to have followed the English artist Repton with too confiding a faith. After twenty-five years of study and experience, during many of which Herr Petzold has held the position of Park and Garden Director to Prince Frederick of the Netherlands, he now reissues his book in an augmented and much-improved form. The subject is discussed in the thorough German way, and among the most interesting chapters may be named those which treat of "The Colors of Trees and Shrubs with reference to Foliage, Flowers and Fruit," "The Characteristics of Tree-forms as affecting the Lines of Landscapes," and "The Arrangement and Care of Cemeteries." Form, color and linear and atmospheric perspective, are discussed with reference to the landscape-gardener's problems; all the elements which enter into

his work are separately examined; the characteristics of the old and new styles in gardening are explained; and, in short, nothing theoretical or practical is omitted which could serve to make a useful hand-book for artists and amateurs. Some of the illustrations are from designs by Friedrich Pr  ller, a landscape painter and professor at the Art Academy of Dresden.

The Rose Garden. By William Paul, F.L.S., etc., London: Kent & Co. Ninth edition.

The fact that this book has within a comparatively few years passed through nine editions establishes its value among the many manuals of its kind which have appeared in England. Of course its second division, which gives careful directions for the cultivation of many kinds of Roses, is less useful in this country than in England. But in the first division is contained an essay on the history and poetry of the Rose, which is delightful reading; the origin of many favorable varieties is explained in an interesting way; and an appendix contains two valuable articles on the botany and the entomology of the Rose. A full bibliography of works on the Rose published during the past ninety years adds to the merits of a very attractive work.

Periodical Literature.

Now that a project is on foot, under the auspices of the Torrey Botanical Club, to establish a botanical garden in this city, it is interesting to recall the fact that such a garden long ago existed here.

An article recently published in the *American Druggist* quotes as follows from the *American Medical and Philosophical Register* of July, 1811:

"This institution, the first of the kind established in the United States, is situated about three and a half miles from this city, on the middle road between Bloomingdale and Kingsbridge. The ground, consisting of about twenty acres, was originally purchased of the corporation in this city, in 1801, by Dr. David Hosack, the founder of the establishment. The view from the most elevated part is variegated and extensive, and the soil itself of that diversified nature as to be particularly adapted to the cultivation of a great variety of vegetable productions.

"Immediately after the purchase, the proprietor, at a very considerable expense, had the grounds cleared and put in a state of cultivation, arranged in a manner the best adapted to the different kinds of vegetables, and planted agreeably to the most approved style of ornamental gardening. A conservatory for the preservation of the more hardy green-house plants was also built.

"As the primary object of attention in this establishment was to collect and cultivate the native plants of this country, especially such as possess medicinal properties, or are otherwise useful, among others, such gardeners as were practically acquainted with our indigenous productions were employed to procure them, and by the distinguished liberality of several scientific gentlemen in this country there were in cultivation at the commencement of 1805 nearly 1,500 species of American plants, besides a considerable number of rare and valuable exotics.

"In the year 1806 very important additions were made to the collection of plants, from various parts of Europe, as well as from the East and West Indies. A second building for their preservation was also erected, and the foundation of a third laid, which was completed in the following year. In the autumn of the same year, 1806, a catalogue of the plants, both native and exotic, which had been already collected, and which amounted to nearly 2,000, was published. Since that time the botanic garden has been greatly improved. The buildings, which are erected on the most recent plan adopted in institutions of this kind, consist of three large and well-constructed houses, exhibiting a front of 180 feet. The greater part of the ground is brought in a state of the highest cultivation, and divided into various compartments, calculated for the instruction of the student of botany and medicine, and made subservient to agriculture and the arts. The whole establishment is surrounded by a belt of forest trees and shrubs, and these are again inclosed by a stone wall two and a half feet in thickness and seven feet high."

In the year 1810 the legislature purchased the garden from its owner and put it in the care of the Regents of the University, who in their turn confided it to the College of Physicians and Surgeons of New York. It was not many years, however, before the ground it occupied became so valuable that the garden was "rooted up." Many of the plants were sent to the Bloomingdale Insane Asylum. In 1835 the twenty acres were

valued at \$100,000. Their value to-day it would be almost impossible to compute. In 1876, adds the *American Druggist*, a scheme for a botanical garden was started in this city, certain persons asking the legislature for a charter which would permit them to establish it in the neighborhood of the Natural History Museum. But as their action was prompted simply by a desire to prevent the Park menagerie from being removed to this locality, no more was heard of the garden when it was decided that the menagerie should remain at the Arsenal. The project of to-day has been born under very different conditions, and we may hope it will have a very different outcome.

The February number of the *English Illustrated Magazine* contains an interesting article, by Mr. H. Barton Baker, on "Cognac," the town and castle, not far from Angoul  me, which, from a medi  val stronghold, were transformed years ago into a manufactory of brandy. The castle still stands almost intact, but is used as a warehouse for brandy-casks, and the quaint streets of the city everywhere reveal the presence of the dominant industry. Even the house-fronts, formerly of pure white stone, have assumed a piebald look in consequence of the fumes from the warehouses. The account of the processes of making and keeping the spirit which the author gives are most entertaining. "But," he says, "brandy is rapidly becoming a thing of the past, thanks to the ravages of the phylloxera. Only eleven years ago the Cognac district had about 60,000 acres planted with vines; of these nearly 8,000 have been utterly destroyed, and over 20,000 seriously injured; since then three-fourths of the area have been desolated and the remainder much affected, and the opinion of the leading merchants is that the chances are that in another generation the true *eau-de-vie* will be a liquor *introuvable*. Some attempt is being made at replanting the vineyards, though, in most cases, the pest reappears upon the young shoots, and here and there experiments are being made with American vines, which are said to be phylloxera proof, but the prospects of Cognac can scarcely be said to be improving to any great extent."

This state of things has brought about a painful decrease in the activity of the town, especially as regards the immense establishment organized in an ancient convent which is owned by the Messrs. Hennessy. "But while an utter stagnation of business prevails among the large houses, some of the smaller ones are driving a brisk trade—not, however, with the production of the grape. From Holland and Germany large consignments of spirit obtained from grain, potatoes, beet, or any refuse from which alcohol can be distilled, are sent into Cognac. This new fiery liquor is doctored, watered, flavored, colored, put into bottles or casks, branded 'cognac,' and is received as such all over the world. This is the stuff the English publican vends, sometimes pouring it out of old bottles bearing a well-known label to deceive his customers. In fine, it is this decoction that is generally drunk in this country and Germany and in all parts of France as well, especially in the Parisian caf  s, under the name of cognac. Those who drink pure brandy nowadays have to pay very dearly for the article."

The best brandy now costs at least twenty-five English shillings a bottle, and is said to be almost all consumed in the United States.

According to the *Pharmaceutical Record*, the source of the opium supply of the United States is central Asia Minor. Here the Opium Poppy (*Papaver somniferum*) is "easily cultivated on the plains or lower ranges of hills, a good rich soil being necessary, and considerable labor expended in caring for the plant during the season of growth. Seed is planted during the months of November to March, inclusive, in order to protect against possible accidents by storm, and also to secure a succession of ripening plants. When the plant has flowered the leaves that fall are collected (used as wrapping and packing in part), and when the capsule has attained its growth, the collectors begin their work in the afternoons by incising the capsules with an instrument formed like three knife-blades, which are separated from each other by a film of cotton twine and all bound as one; the operator takes the capsule in the left hand and with the right rapidly passes the blades around it in a spiral upward. In the morning the exuded milky juice, which, by exposure to light and air, has become of a brownish-red color, is scraped off, and the collected juice placed on a poppy leaf to partially dry in the sun. The opium as it dries is made into suitable balls and wrapped with poppy leaves, and packed in dried leaves to prevent the adhesion of the lumps into a mass. Beyond this simple process there appears to be no further manipulation of the drug, except where dishonesty is practiced, as the addition of various adulterants.

Notes.

Two new parts of Baillon's indispensable "*Dictionnaire de Botanique*," being Fascicles xxii. and xxiii., have reached us. The work is now brought down to "Leth."

Miss Emily L. Gregory's studies upon the "Development of Cork Wings on Certain Trees" is now reprinted in pamphlet form from the pages of the *Botanical Gazette*.

Last winter a Philadelphia gardener placed a frame over a spring in which Water-cress grew. The warmth of the water prevented freezing, and he had Water-cress all the winter.

Mr. Frederick Janson Hanbury, F.L.S., proposes to publish, by subscription, an illustrated monograph of British Hieracia. It will be issued in quarterly parts at six shillings for the colored, and at four shillings for the uncolored edition; and five years, it is estimated, will be required to complete the publication. Mr. Hanbury's address is 69, The Common, Upper Clapton, London.

Sixteen plans were recently presented in competition for the commission to lay out a new public park in Utrecht, Holland; but although two were rewarded with second prizes none was thought worthy of the first prize. Had as many plans been prepared for a work of this description in America it is certain that the most careful and exacting judges in the world would have been amply satisfied with some of them.

The Philadelphia Select Council, on March 7th, passed an ordinance appropriating Bartram's Garden and two other pieces of ground for park purposes, and providing for their purchase. Some other small parks have been given to the city, and additional ground will probably be bought by the city to increase the number and area of its open spaces. The movement for this object is most judicious and important.

The National Horticultural Society of France offers a prize of 2,500 francs, to be paid at the end of the present year, for the best practical work upon vegetable and fruit gardening and floriculture published since April 6th, 1886. It is offered in the name of the late Dr. Joubert de l'Hiberderie, who left the sum of 60,000 francs to the Society for the purpose of establishing this prize. Presumably the work must be written in French.

The Monograph of North American *Umbelliferae*, upon which Messrs. Coulter & Rose have been constantly engaged for a number of years and which has appeared in the *Botanical Gazette*, is now issued separately in a handsome pamphlet of 144 pages with ten plates of 159 figures of cross-sections of the seed of the different genera, of which there are fifty-two indigenous to the continent north of Mexico with 217 indigenous species.

The annual banquet of the Philadelphia Florists' Club, was held last Thursday evening, and the guests from Boston, New York and other cities had renewed occasion to observe that the florists of Philadelphia excel in hospitality and good-fellowship, as they do in intelligence, taste and skill. A unique feature of the occasion was the toasting of several of the newer Roses, and the responses by the growers who had been specially interested in the dissemination of these varieties were instructive as well as entertaining.

Dr. C. C. Parry has recently printed in the proceedings of the Davenport Academy of Natural Sciences an account of the genus *Ceanothus*, with an enumerated list, and notes and descriptions of several Pacific coast species, based upon his forty years' observation of these plants in their native habitats. Dr. Parry distinguishes for the first time the following: *C. intricatus*, known only on the summit of Mt. Tamalpais, near San Francisco; *C. Andersoni*, from the Santa Cruz Mountains, *C. Californicus* and *C. divergens* from Napa Valley. With the two species of eastern America, thirty-three species are included in this, the latest revision of this difficult genus.

Professor Eaton, who lectured recently on Oaks at New Haven, said that the largest and most famous Oak that had been known in the State of Connecticut was the Charter-oak, on the Stewart estate in Hartford. "Two hundred and one years ago it was a large and ancient tree. The historical connections which have made it famous are well known. On August 20th, 1856, a great storm swept over this part of New England, and the aged tree was blown down. It was then 700 or 800 years old. The event caused much excitement. A dirge was played by the army band, and the bells were tolled at sunset. It was thirty-three feet in circumference and thirty-seven men could stand in its cavity at one time." This Oak was a White Oak (*Quercus alba*), while the tree recently cut down by vandal hands at Woodbridge, Connecticut, was a Black Oak (*Q. tinctoria*).

The *Cercle Floral*, of Antwerp, proposes to hold next year an exhibition illustrative of "Botany in its Geographical, Commer-

cial and Industrial Aspects"—that is to say, not only the floras of different countries will be illustrated, but also, as fully as possible, the various products derived from them. Of course, collections with a similar aim have already been formed in various places, notably at Kew. But in this temporary exhibition it is proposed to bring the living and the manufactured products more closely together than is possible in permanent museums. The results of the skill of the hybridizer will also be systematically shown. Great botanical collectors will be honored by having as many as possible of the plants which they severally introduced grouped together and appropriately labeled. Those plants will also be gathered together which are most useful from an artistic point of view, as furnishing decorators and artisans with graceful suggestions. A congress will be held for the discussion of the various questions which such an exhibition will naturally bring up, and if the wide-reaching programme is carried out with any degree of success, Antwerp ought to be very attractive to students and lovers of plants during the summer of 1890.

It is usual, says the *Illustrirte Garten Zeitung*, of Vienna, to believe that the prices paid for Tulips in Holland during the celebrated "Tulip mania" have never since been equaled. The fact that they have been rivaled in recent times has not excited much attention because no single class of plants has been so conspicuously preferred as was the Tulip in its day. For example, a sum equaling \$2,250 was paid by a nurseryman in Erfurt, Germany, for the original plant of *Magnolia Lenné*; in 1876, Mr. Francis Parkman, the historian, sold a hybrid Lily (*Lilium Parkmanni*) which had been produced on his estate near Boston to an English nurseryman for \$1,200; and about a year ago Monsieur Lemoine, of Nancy, France, gave \$200 for a bulb with two or three bulblets of the first semi-double *Gadiolus*. The prices given in this country for the Bennett and the Puritan Roses at the time of their introduction, and more recently for the Mrs. Alpheus Hardy Chrysanthemum, are familiar to all, but in these instances, of course, a large amount of stock was sold, while the sums paid by old Dutch amateurs were for single bulbs. Orchids bring higher prices to-day than any other plants. The Messrs. Veitch paid \$1,800 for a *Cypripedium Stonei platytanum*, a plant more curious than beautiful, which consisted of but a single flower-stalk, at the base of which were three young shoots about one and a half inches in length; the same firm, on another occasion, gave \$1,400 for two plants of *Cattleya Trianae* var. *Leeana*, and a list of similar prices might be greatly extended.

A correspondent of an English journal, replying to a query whether there is such a thing as a plant that moves spontaneously, replies that *Desmodium gyrans* must be the plant referred to. It belongs to the Pea family and is a native of the East Indies, "where it rejoices in the name of Burram Chandali. It is a somewhat slender plant, seldom exceeding two feet in height; the leaves are not large, but trifoliate, the two leaflets at the base being much the smallest, and these comprise that portion of the plant which appears to be continually on the move, but the movement is very irregular, although rapid. The texture of the plant is somewhat thin, the color of the leaves being a bluish green, and the constitution appears somewhat delicate. I believe it to be a biennial, but have found it difficult to keep the plant alive during the winter months. Seeds can be obtained from the principal seedsmen. . . . The plants become characteristic as soon as the first leaves next the seed-leaves are formed, and the eccentric moving powers are developed. It does not like cutting, and the best plan to produce a bushy plant is from time to time to pinch out the extreme point of the shoot. It enjoys strong heat and a moist atmosphere. It is one of the most extraordinary plants in the vegetable world, but it does not possess any beauty." In Nicholson's *Dictionary of Gardening* 'Moving-plant' and 'Telegraph-plant' are given as the popular names of this *Desmodium*, and it is said that the leaflets move up and down "either steadily or by jerks, the movements being most marked during bright sunshine."

Catalogues Received.

Can the Nation Defend its Forests?

THE *Daily Commercial Bulletin* of this city says it is incumbent upon Congress to protect the forests on the national domain, but adds that the plan we have proposed for their defense ignores limitations upon federal authority that must be maintained. The *Bulletin* does not say what these limitations are, but it appears to think it would be wrong for the nation to use adequate means for the protection of its own property. We are not aware of the existence of any limitations which forbid the nation to guard its forests from spoliation and destruction, and if the people of the country can be brought intelligently to consider the magnitude of the interests involved, they will, no doubt, find a way, or make one, to protect the forests on the public lands in the Pacific and Central States. There was much solemn argument in this country in 1860 and 1861 to the effect that the nation could not preserve or defend its own property; that there were insurmountable limitations in the way. But since 1865 intelligent men have mostly been of the opinion that the American people can defend their own national property—if they want to. There is nothing whatever to prevent the people of the nation from providing effective means for the preservation of the forests on the public lands, except the lack of popular interest, intelligence and foresight regarding the relation of these forests to the welfare and civilization of the country.

But the timber thieves, of high and low degree, who have grown rich by plundering these forests, the mining and railroad corporations and private individuals who for many years have been appropriating the public property to their own use and aggrandizement, are all earnestly opposed to the exercise of the power which the people of the country unquestionably possess—the power to defend the nation's forests from systematic and exterminating pillage. They would think it very improper, perhaps unconstitutional, to employ the army for this purpose, although its officers have been educated at the expense of the nation, and the whole force is maintained for the purpose of having a body of trained and competent men always ready

for the service of the country; and the defense of national property is one of the principal objects for which the national army exists.

Is it not absurd to insist that although the nation owns these forests, and can dispose of them as it chooses, it cannot provide for the sale of the trees when they need cutting, but must allow mature and valuable timber to go to waste, or be stolen, because it would never do for the "Government" to sell lumber? The Government is already, and always has been, an extensive lumber dealer. It buys lumber in large quantities, while it permits enormous thefts of valuable timber from its own forests. The Government sells land, and old iron, and a great many other things. What kind of catastrophe would result if competent officers should be empowered to sell timber from the public lands, under regulations embodying some knowledge of forestry? The timber of the public forests is constantly sold with the land on which it grows. Of course, if the nation chooses to do so it can sell the timber, while it retains possession of the land and protects it so that a new forest-growth will in time be produced. To do this would be a very simple and commonplace business transaction.

There is not much force in the argument that because the nation does not employ the machinery of the "Government" to do something which is entirely unnecessary, that is, to manage mines and ranches, therefore it cannot, or must not, employ it to protect its property in the forests on the public lands. If the relation of certain mines and ranches on the public lands to the welfare and civilization of the country were the same as that of the mountain forests in California and Colorado, the nation could assume their management, and it would be entirely proper that it should do so. It could even employ its own soldiers to guard and defend its mines and ranches from plunder and destruction if this became necessary.

No well-considered objection to the plan for the care of the nation's forests, which was proposed in this journal a few weeks ago, has been brought forward. The unanswerable argument and sufficient reason for the adoption of that plan is the fact that it presents the only means available for the permanent conservation of forests which are the indispensable guards and regulators of the flow of the rivers which have their sources in them, and that upon these rivers a great area of country must forever depend for the water without which agriculture, and even inhabitan-
tancy, will be impossible.

These are the essential and intimately related facts in the case: A great region, now nearly uninhabitable on account of extreme desiccation, could be made highly fertile and capable of supporting a dense population, by means of irrigation. The water required for this purpose can be obtained only from the rivers which rise in the forest-covered mountain-lands which are still public property. If the forests are destroyed the water will not be available or controllable for irrigation. The forests are being rapidly destroyed, and under existing methods of government control their speedy extinction is certain. They belong to the nation, and could be protected by employing the national army for their defense, until a system for their permanent conservation could be devised and put in operation.

Tree-planting.

TREES are generally planted in this latitude during the month of April or in early May, although certain advantages may be gained by autumn planting. It is best, as a rule, to secure the trees in October, while nurserymen have time to fill orders properly, even if the planting is delayed until the following spring. As soon as the trees are secured all bruised roots should be carefully cut away with a sharp knife, and if the trees are carefully heeled in, the wounds will have time to form a callus and small rootlets will be made before freezing weather. These feeding roots will help to keep the tree supplied with moisture as it is dried out by the winter winds, and they will be ready

for immediate work when the tree is planted in its permanent position. The ground should also be prepared the previous season, broken up and deeply trenched by hand, if practicable, with the surface-soil left on the top. Next to trenching, the best practice is to dig holes for the trees in autumn. If the trees are to grow to large size, a hole three feet deep and twenty feet across is none too large. The soil should at once be returned to the holes with the surface-soil on the top, unless it is thin and gravelly, when good peat or mould should be thoroughly mixed with it. By planting-time the prepared soil will have firmly settled and small holes can be dug in the centre of the large ones. These should be considerably wider than the spread of the roots. One man should then hold the tree in an erect position while another spreads out the roots in their natural position, when finely pulverized soil should be dropped upon them, and, by a gentle movement of the tree, every cavity about the roots should be filled. It is essential that the soil be brought into close contact with the roots, and when the hole is nearly filled the earth should be trodden down, working from the outside of the hole toward the trunk of the tree. After this, the remaining loam should be thrown in and rammed down solid. No water should be poured about the newly-planted tree, but tall trees should be securely staked to prevent swaying and loosening the roots.

Trees will often survive when planted with less attention to details than is here recommended, but careless tree-planting is wasteful and disappointing. To be reasonably certain of having healthy, vigorous and long-lived trees, the work must be done thoroughly and intelligently. The rules here given are not new, but thousands of trees are lost every year by neglecting them, and they can hardly be repeated too often. We add a few other general directions which every novice should heed. Make a careful study of your ground, and decide exactly where each tree is to be planted before you send your order to the nurseryman. Never buy your trees first and then hunt for a place to put them. Never let the roots of trees, and especially of Conifers, become dry for an instant. It is good practice to dip the roots in thin mud as soon as they are unpacked, and then to keep them covered until the tree is planted. Dry weather and a moist soil are better conditions for transplanting than rainy weather and a water-soaked soil. It is generally a waste of time and money to transplant large trees. A tree with good roots and two or three feet high will soon overtake one that is transplanted when twenty feet high, or more, and will make a more beautiful specimen.

Special cases demand special treatment. Maples, Elms and Lindens, for example, have shallow roots, and larger trees of such species than of the more deeply-rooting kinds can be successfully transplanted. Trees with tap-roots, like Oaks and Hickories, should be planted when very small. Larches should be planted very early, because they are among the first trees to start into growth. It is safest to transplant Tulip-trees and Magnolias just after the buds have started, otherwise their fleshy roots are liable to decay while dormant. As a rule, Conifers can be transplanted later than deciduous trees, because they begin growth later. Better plant one tree well than a hundred without deliberation and care. Even a well-selected and properly planted tree will prove a disappointment if it is neglected.

A considerable share of public attention here has been directed of late to the trees in Central Park, through the efforts of a public-spirited, but in this instance imperfectly instructed, body of citizens, who have formed an organization to look after the interests of the upper part of the city. An expert representing this association has recently made a report concerning the cutting down of the trees in the park, and as this report has been circulated, and as the statements which it contains are calculated to bring discredit on the park officials among persons who are not familiar with the circumstances, it is proper to state that if they have

erred at all in cutting it is in the direction of omission and not of commission. Many of the statements made by the expert of the West Side Association have no foundation in fact. In some cases he has failed to discriminate between the necessary pruning of trees and shrubs and their destruction; and he has made no distinction between the cutting out of dead trees and the cutting down of living ones.

The condition of things in Central Park, so far as the trees are concerned, is this: More trees were properly planted when the park was made than could grow eventually in the space allowed to them. It was intended, of course, that all these superfluous trees should be removed as necessity dictated. But this thinning, which the poor nature of the soil over much of the park made all the more necessary, was neglected for years, and the trees were allowed to grow up huddled together, without sufficient room, light or nourishment. Some native trees died from this cause, as well as many foreign trees which are now known to be unsuited to this climate, and which were planted in large numbers; and dead and dying trees even were allowed to remain to the detriment of more promising neighbors.

Two or three years ago the Superintendent found that a general system of cutting would have to be inaugurated all over the park, or that in a comparatively short time there would be few trees left. He sought and obtained the advice of experts, and proceeded with great caution to the task which public ignorance in such matters, and public clamor have made disagreeable and difficult. The cutting, up to this time has been confined principally to the removal of dead Conifers, particularly Norway Spruces, which are scattered all over the park, and to a few glaring cases of overcrowding about which there could be no possible question as to the propriety of removal. The number of trees which have been cut is large, perhaps, in the aggregate, but no proper impression has been made upon the plantations, and the work has been allowed to languish, probably because the fear of public outcry was too strong for the Commissioners. There are hundreds of good people who cannot be made to understand that an intelligent lover of trees will feel impelled to cut away an offending one whenever its removal will add to the beauty, the health and the longevity of half a dozen others. At the present time dead trees, or trees so nearly dead that a few years more will finish them, are allowed to disfigure the park, and a half-dead, misshapen Spruce, fast pushing really fine and vigorous deciduous trees out of shape is a common sight. Few parts of the park are not disfigured or injured by sickly, misshapen, or diseased trees, and it is the duty of the Commissioners to cause such trees to be removed. What they need is the support and encouragement of the public and the wild assertions which have been made in this city during the past month about destroying the trees in the park will, if they have any effect, retard well-advised and well-considered plans for its improvement.

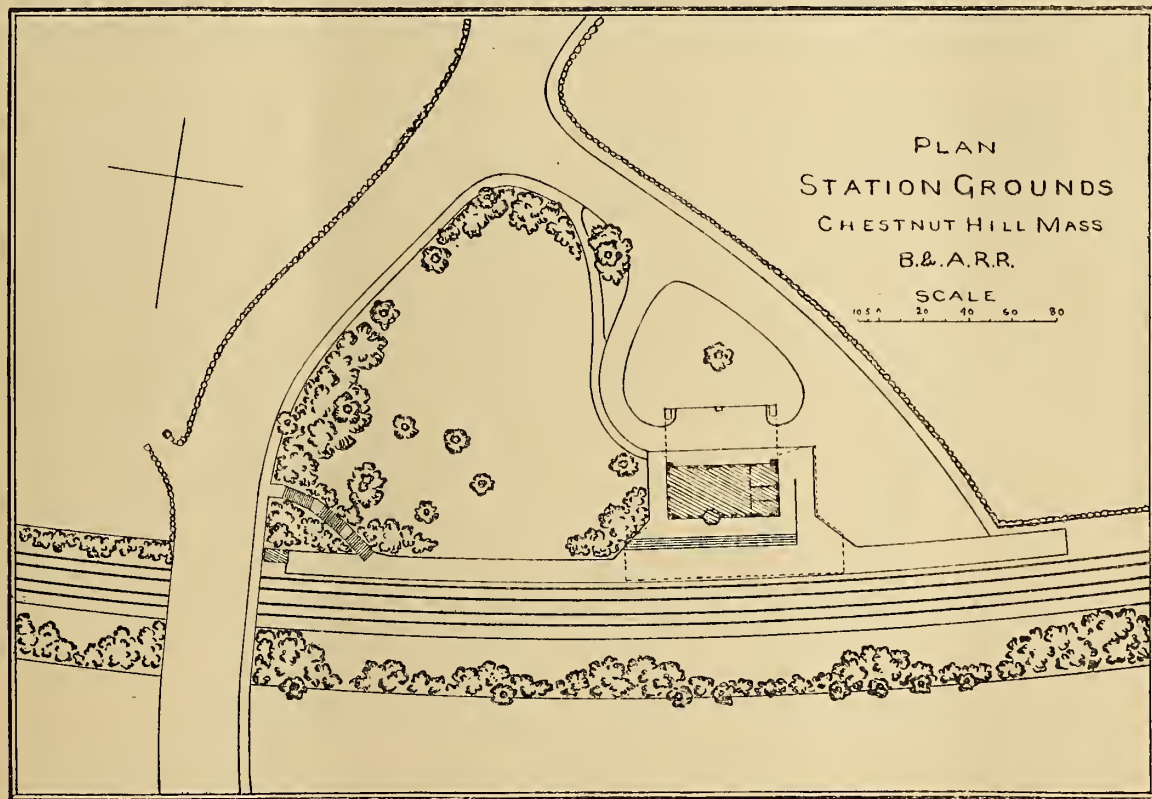

The most important and valuable piece of work performed up to this time by the Board of Forest Commissioners of this state is the preparation of a bill (Senate Bill number 354) which will, if the Commissioners succeed in securing its passage, prevent railroad corporations from obtaining a location over the state-lands now held in the forest-preserve, or which may at any time in the future be joined to it. This is a matter of public importance deserving the careful attention of the members of the Legislature, and the support of all persons interested in the development and prosperity of this state.

The most immediate danger which now threatens the north woods comes from the railroads. A number of projects to extend lines already operated in the wilderness and to build new ones are now on foot; and their promoters are pushing them vigorously. The preservation of any portion of the Adirondack forests is due to their re-

moteness and inaccessibility to railroad communication, for it must be remembered that they are composed largely of hard woods, which cannot be made to float down the streams to the mills. The Pine and Spruce has been cut, or is rapidly disappearing, but the removal of these trees does not destroy the forest, unless fire, fed by the *débris* from the evergreens, is allowed to follow in the track of the lumberman. As long as the hard-wood trees which form probably nine-tenths of the Adirondack forest are not cut and are not allowed to burn up they will continue to perform those services which make these forests valuable to the people of the state. But if railroads penetrate the wilderness, every stick of hard wood which these forests contain will, in a surprisingly short space of time, be brought to market; while the danger of fire will increase in proportion as they are built. Fires will spread from the railroad locations far into the forest, and, as the region becomes more accessible, the number of fires set by hunters, campers and log-cutters will necessarily increase.

ing the White Pine shown in our picture, page 163, a clump of old White Willows, a branch of which is seen near the Pine, and a symmetrical American Beech that stands in the centre of the lawn opposite the carriage entrance. Another American Beech, the leafless form of which shows at the extreme left of the picture, stands in the grounds of a neighboring residence, which, of course, the landscape-gardener took care not to conceal from view. In other directions, as may be seen from the plan below, masses of foliage border the grounds. On the other side of the track, as at Auburndale, is a narrow strip of grass, edged with trees and hardy flowering-shrubs, and everywhere these masses are neither stiffly arranged nor scattered without purpose, but carefully grouped so as to secure variety in unity, interest, grace and harmony.

The extreme size and solidity of the arches which form the porch of the station have been criticized as inappropriate in so small a building. But we may recall what was lately said of Auburndale—a station is essentially a

Plan of the Chestnut Hill Station Grounds—Boston and Albany Railroad.

The creation of railroad lines over private property cannot be prevented, but the state is able to protect its own property, and it is not wise to maintain an administration to protect these forests, and then to give to private corporations the right to destroy them.

The Railroad-station at Chestnut Hill.

THE station at Chestnut Hill, near Boston, like the one at Auburndale, which we recently described, was built by the late H. H. Richardson for the Boston and Albany Railroad Company, and the grounds were laid out by Mr. Frederick Law Olmsted, and are cared for by Mr. E. L. Richardson.

This is perhaps the prettiest and most picturesque of all the great architect's rural stations, nor are its grounds equaled in beauty by any others. The road descends somewhat steeply towards the entrance of the grounds, and then more steeply after they are entered, while the building itself stands a little higher than the tracks, and is connected with them by a flight of steps extending across its whole length. Several fine trees ornament the grounds, includ-

shelter, not a dwelling-place, and its roof is therefore of far more importance in giving it the right expression than its walls. These arches sustaining only a roof, would indeed be inappropriate in a house, but they can be permitted in a station even by the most exacting of purists, if he remembers the true purpose of the design. Nothing could be more beautiful than their vigorous, simple curve, and nothing could be more hospitable and protecting than the air they give the building. Nor is it a misleading air, for the comfort supplied by this great porch in wintry weather can hardly be exaggerated. In judging of these stations, it may be remarked, the same standards cannot be applied that would be justly applied in many other parts of the country. They are small because freight-traffic need not be accommodated; yet their approaches must be capacious and their porches must afford protection to considerable numbers of people at once, as the local passenger-traffic at certain hours of the day is very large. They are suburban stations, and everyone knows what that means in the neighborhood of a busy American city. And for the same reason it was appropriate to build them in a more costly manner than might have been wise in a really rural stopping-place. In this station, again, Richardson used granite

for the walls, Longmeadow sandstone for the trimmings, and slate for the roof. The treatment is as simple yet artistic, inside and outside the building, as we found it at Auburndale, but the waiting-rooms are wainscotted in wood instead of brick. In this case the conformation of the ground made it better to carry the pathway close to the walls rather than allow a space for planting between. Otherwise the path would have had to ascend the slope and descend it again at an inconveniently steep angle. But this conformation of the ground hides the path from many points of view and allows the walls to look as though they sprang directly from the plantations—an effect that will be increased at the spot shown in the picture by additional shrubberies which are to be set out this spring.

The business standpoint is not the highest from which to advocate the furtherance and development of good art. Yet it is a standpoint which few persons can wholly ignore, and least of all a railroad company, the directors of which are the custodians of its stockholders' interests. It is worth while, therefore, to ask, Could there be a better advertisement for a suburban neighborhood than a station and grounds like these? They imply refinement, good taste and a regard for the amenities of life in the local community. They predict that the company which has provided them will care for its patrons' comfort in other directions too. And they promise that those moments of detention which are a daily factor in the business man's existence will not mean that purgatory of impatience, disgust, and even physical distress which in most places they have meant for so many years to thousands of long-suffering Americans. It is not too much to say that these stations of the Boston and Albany Railroad, taking buildings and grounds together, are the best of their class in the world; and the company which was wise enough to build them has found them a good business investment.

New or Little Known Plants.

Calochortus Obispoensis.*

THE Mariposaes, or "butterflies," of California well merit this name given to them by the Spanish settlers. Scattered here and there over the hillsides, with their wing-like petals of very diverse hues and patterns broadly expanded, they appear in truth like so many butterflies hovering in the sunlight over the low weeds and bushes among which they grow. One of the most bizarre of the many species and varieties is the *Calochortus Obispoensis*, which was discovered by Mr. J. G. Lemmon, the well-known adventurous and successful collector of California, in 1886, on dry, stony hills eastward of San Luis Obispo. Its general habit and character are shown by our illustration, page 161—the deep-seated, fibrous-coated bulb, which is very dark-colored; the sparingly branched stem a foot or two high, as usual in the genus, with narrow convolute leaves and conspicuous flower. Of their coloring, however, no idea can be given in the figure. The sepals themselves are unusually strongly colored on the inner surface with orange and purplish brown upon a greenish-yellow ground. The petals are remarkable in not having the ordinary broad, fan-like form, but are shorter than the sepals and not much dilated, terminating quite abruptly and often cleft at the summit. The ground color is lemon-yellow, deepening to orange toward the base, and becoming brownish-red at the apex, the effect of which is heightened by a dense covering of long delicate hairs of the same or somewhat darker hues. Near the base is the usual roundish pit or nectary, which is margined by a dense fringe of long orange-colored hairs converging together over it. The erect filaments and anthers are of different shades of orange, the upper part of the filament being often tinged with purple. The whole combination is very peculiar and striking.

Foreign Correspondence.

London Letter.

LAST summer in England was a bad one for most plants. Our indoor collection of Nymphæas made few new tubers through lack of proper summer weather, and these few are small. We keep them moist all winter, as we keep Caladiums, Arisæmas, and indeed all deciduous or tuberous Aroids. They winter better when kept moist. Thousands of such plants as Caladiums are annually sacrificed to dry treatment. The tuberous Begonias keep best in dry sand or cocoa-nut fibre. To know what requires a dry rest and what must have moisture at all times is of great importance. For instance, one finds the greatest difficulty in making young men understand that whilst Hippeastrums and some Crinum must be kept absolutely dry all winter, Vallotas, Nerines, Brunsvigias and other Crinums must be kept moist. The watering-pot is the greatest friend the bulb-dealer has.

Poppies are now great favorites as garden flowers, but it is not many years since all such plants were rooted up from the garden as noxious weeds. A few here and there, and these invariably the exotic species, might be seen, but they were not popular. In the fields in autumn the great blaze of scarlet Poppy is a picture scarcely to be excelled anywhere. Some great traveler, Wallace I believe it was, has stated that not in any part of the tropical world had he ever beheld anything half so glorious as an English field of scarlet Poppy or a wood carpeted with Blue-bells. We have taken a leaf out of the book of the Chinese and Japanese gardener so far as regards our native Poppy (*P. Rhæas*) and we have as the result of a very few years' cultivation and selection a most beautiful strain of what in itself is a grand Poppy. By "we" I mean the secretary of the Royal Horticultural Society, the Rev. W. Wilks, whose Shirley Poppies are now in great demand, on account of their clear and rich tints. Nine years ago Mr. Wilks noticed in his garden a common field Poppy with a white-edged flower. From seeds saved from this plant he obtained varieties with more white in the flower, and others of a uniform pale color. By careful selection he succeeded in fixing the most distinct and attractive shades, and the Shirley Poppies are now available for every garden. The colors range from pure white through pink to glowing scarlet, minus the blotch of black at the bottom of the petals, a conspicuous character in the type. Some are red with white edges, others white with red edges. Singularly enough I brought seeds from South Africa two years ago which were said to be gathered from wild plants, and these produced flowers of *P. Rhæas* with bilobed petals, which were white with red edges. It is surprising that a plant which appears to have been unaltered in a wild state, during thousands of years, should have broken away from its color characters so readily under good cultivation and selection as has *P. Rhæas* in the hands of Mr. Wilks.

Hippeastrums are fast developing their flowers, about a week's clear weather being all that is needed to bring the majority of the kinds into full blow. Messrs. Veitch and Mr. B. S. Williams are the most famous workers at the improvement of these plants as garden flowers. Dean Herbert, greatest of bulb-mongers, raised many hybrids and seedlings, and Mr. James Douglas has been very successful in obtaining improved forms. The prices paid for good kinds of Hippeastrum are almost as high as the best Orchids fetch. Veitch and De Graaf, of Leiden, have been most successful in breeding large-flowered, clear-colored, well-shaped varieties, whilst Williams has paid more attention to form and color with medium size. Some of the latter are charming plants, without any coarseness, and perfect in color. I note one, a new seedling, named J. R. Pitcher, raised from a deep red-flowered kind, crossed with Mrs. Lee. The flower is medium in size, a perfect trumpet in shape, and the color deep crimson, with darker veins, the throat being almost maroon. Hippeastrums have become very popular here. The only defect in these highly-bred kinds is in their supposed weak constitutions; although the raisers have no difficulty in keeping the best of their productions from year to year. Coburgias are also in bloom now. These and the Stenomessons are of the choicest and most interesting of garden Amaryllids, but they are rarely met with. They are all Andean, and require the same treatment as the Hippeastrums, which they resemble in leaf and scape, but the flowers are long, tubular, drooping, with the limb about one and a half inches across. *C. luteo-viridis*, with flowers lemon-yellow shot with green, and *C. incarnata*, with rosy red, green-tipped flowers, are both in flower at Kew.

Growers of fruit trees, such as Apples and Pears, are paying particular attention to the selection of the most suitable stock for grafting the different kinds upon. Valuable statistics on

Fig. 101.—*Calochortus Obispoensis*.—See page 160.

this question were collected and published by the Royal Horticultural Society in their Reports of the Apple and Pear Conferences held at Chiswick several years ago. Exhibitors were required to state with each kind of fruit shown the nature of the soil upon which it had been grown and the kind of stock used. The general opinion was greatly in favor of the Paradise and Quince stocks. Mr. G. Bunyard, of Kent, a most successful grower of fruit and fruit-trees for market, has

recently discussed this question, and as his opinions on a subject interesting to your readers may be valuable, I quote them: "Now, I maintain that it stands to reason and common sense, that surface roots must receive the benefit of the rains, sun and air more than the anchor roots, which are, by reason of their position, more removed from such benign influence; and the teaching of fact in this case follows out the leading of logic, and we find by experience that Pears grafted upon the

Quince stock and Apples upon the Paradise can, do, and will produce handsome, clean, well-colored and full-flavored fruit, even in adverse summers, whilst in more propitious seasons the quality is super-excellent, and still proves our theory." The wild Pear stock, with its strong roots and few fibres, and the Crab-Apple stock, equally coarse-rooted, are used for trees intended for orchards, but they will not bear comparison with those recommended in the production of large crops and fine fruit in a short time.

'That those who plant Pears grow fruit for their heirs,
Is a maxim our grandfathers knew;
But folks have learnt since, if you graft on the Quince,
The fruit will develop for you.'

A few days' sunshine would transform our Orchid-houses into paradises, but we must wait till April for the great flush. *Cypripedium Elliottianum* is now in bloom, and proves even better than my description of it a few weeks ago; *Odontoglossum Edwardii* bears its tall, branched spikes of purplish flowers, the nearest approach to true blue in an *Odontoglossum*; *Angracum citratum*, with the most charming little wreath-like spikes of creamy-white flowers; *Arides Vandarum*, truly a "thin" Orchid, although its pure white, curiously formed, large flowers are both interesting and pretty; *Dendrobium Ainsworthii* and its second, *D. Leechianum*, the handsomest of all hybrid *Dendrobiums*, and taking rank with the best of the genus; *Calogyne cristata Lemoniana*, and the pure white form, a pearl of snowy whiteness, and the new *Phalanopsis gloriosa*. These are the pick of what are in bloom now. I have recently seen some magnificent examples of *Dendrobium* which had all their old pseudo-bulbs cut away last spring and were apparently a great deal stronger for it. Pruning appears to be good for most of the strong growing *Dendrobiums*; at any rate I have seen it practiced on about a dozen kinds, which made stronger growth the season after. The rare and beautiful *D. Phalanopsis* apparently prunes itself, the pseudo-bulbs dying at the base the year after flowering. By fastening these to rafts of Sphagnum they are induced to develop offsets, and thus out of what looks like an evil, good may come.

Orchard Notes.

Hints on Grafting.—Any good whittler can make a scion live. But making a scion live is the smaller part of grafting when one operates on large trees. To secure a new top of good shape and proportions, which shall be easy of access, is a difficult matter. If one attempts to get the head very low, in order to make it convenient, he usually grafts too large limbs and sacrifices too many important branches. If, on the other hand, he aims to graft small limbs he generally makes a top which will be almost inaccessible—a series of what are called "mules' tails," long, naked branches with a bush on the end of each. That grafting is best which modifies the original shape of the tree the least. Stand at a distance from the tree and form an accurate idea of the shape the new top should assume. Then cut the main "stubs" at about the same distance from the body of the tree, using small limbs—say one inch in diameter—and many of them. Then fill in the top with "stubs" along the sides of the main limbs, in such positions that the symmetry of the head will be maintained and supports for the picker's feet will be secured. Use a great number of scions. Part of them may need to be cut out, perhaps one in nearly every "stub," as the new top becomes thick, but if the thinning is properly done good results will follow.

Shall we Whitewash Fruit-trees?—There are several reasons given for the practice. One man would whitewash to stop up the pores in the bark, that disease may not enter. But really the bark on the trunks of trees has no pores. Another whitewashes to protect the trunks from the hot sun—a wholly imaginary benefit. But the greater number whitewash without any reason. Something must be done to the trees, and whitewash is as cheap, handy and conspicuous as anything. Others whitewash to kill insects, and in this there is apparently some reason. But there are better washes for this purpose. The soap or caustic soda washes, with a slight addition of carbolic acid, are better. And if it is desired to soften up the bark on young and slow-growing trees—and this is often the chief benefit of a wash—whitewashes are of little avail.

Peach Yellows.—Yellows and yellowness should not be confounded. Yellows is a disease; yellowness is a condition. Yellowness may be due to poor soil, poor culture, borers, hard winters. It is amenable to treatment. Yellows is wholly different. It is communicable and does not submit to treatment. It has no relation whatever to soil-exhaustion or

methods of culture. I have lost a whole orchard upon new ground. I have seen orchards set upon virgin soil die with yellows. One who has had wide experience with the disease cannot hold to the soil-exhaustion notion, if he is an honest observer. Prompt and radical removal of diseased trees will keep the disease in check. No other course has been successful. This has. No consideration should allow of dallying. It is time to stop quarreling about the cause of yellows, and check the evil by vigorous concert of action. The investigation of the yellows is one of the things which Peach-growers should demand of experiment stations.

Protection for Young Trees.—This is often needed, particularly on the surface of the soil, and for several reasons: To prevent soil from freezing too deeply; to prevent heaving; to prevent too great drying of the surface by winter winds; to keep trees from swaying in soft weather and forming funnels about the base which collect water. A mound of earth about the tree is good. Some mulch, in which mice will not nest, is good. Snow is excellent when it can be held. To hold it, dump a load of manure in a pile on the windward side of the tree, three or four feet from it. Snow will drift over the pile and persist about the tree.

Longevity of Trees.—Complaint is made that Apple and Peach-trees are shorter lived than formerly. It is probably true. It would be strange if it were not. High culture forces and develops a tree prematurely, as compared with natural growth, and stimulates production. This is, no doubt, in some measure at the expense of long life. But there is no occasion for lamenting the fact. Short life and much fruit is better than long life with the same amount of fruit. When trees begin to decline, cut them down. Younger ones are more profitable. A Peach-tree is seldom profitable after twelve years old, and a Plum-tree after fifteen or twenty.

Vineyard Notes and Studies.

BY the third spring after planting the vine will have growth enough to need the trellis. Remove all canes but the best one; prune this to three feet long and tie it to the wire. It may make what growth it will during the summer. Some vine-dressers, thinking that nature may be helped by art, practice "summer-pruning." It is needless and noxious. If one will try summer-pruning for a few years, and also leave a row of vines untouched, he will need no argument to convince him that to summer-prune a Grape vine is to do worse than waste time. Late next autumn the pruner may begin to shape the vine for growth on the trellis. Taking two of the branches grown from the main stem, as near as may be at the height of the wire, shorten them to six buds each. These branches will be made fast to the wire, and the vine when pruned will resemble a capital T. A few spurs, with one bud each, may be left near the crotch to grow renewal canes for next year. On the arms of the T not more than six buds should be left, because not more than six buds will grow. The vine always tends to push toward its extremities. If nine buds be left on a branch, the six nearest its end will start and the three next the trunk will probably remain dormant. In training the vine one must take care that it does not get beyond control. We often see vines with a long stretch of bare and unfruitful cane, a common result of stupidity in pruning. It is easy to keep the vine within bounds, maintaining growth of new wood and fruitfulness near its trunk. In pruning the vine for another year the canes which were made fast to the wire may be cut out and new canes from the spurs left near its middle may be laid on the wire. This is the "renewal system" of pruning, and suitable for varieties of the *Labrusca* family.

A Grape vine thus pruned will seem to have small chance left to bear fruit, but it must be remembered that each bud will form three or four clusters of Grapes, which should weigh about a pound each. Supposing twelve buds be left on the arms, and, say, six buds on spurs about the main stem; these eighteen buds may be counted on to set fifty-four clusters of fruit; too many for the vine, in vineyard culture, to carry.

The renewal system of pruning will not suit vines of the *Riparia* class. These must be pruned on the "spur system," and must be allowed to gradually extend themselves. The Clinton, the Oporto, the Ironclad will fruit best when pruned to spurs. The main arm may be gradually prolonged to one hundred feet in length. For some years I have had the fruit from a *Riparia* vine which stretches several arms more than a hundred feet each in length, and which yields yearly several hundred pounds of fruit. The *Riparia* vines should be pruned in autumn. If cut in February the vines will bleed, and the buds upon the spurs will not grow.

Anything more than general hints on the principles of vine-pruning is useless. To learn to do this well one must do it for some years, and notice results of his work. If he have the gift of observation and the capacity to learn from it he can prune vines intelligently. If he does not learn thus he never will. It is rare to find a good hand at vine-pruning. A poor one is worse than none.

The results of judicious pruning and training, on such a trellis as described (page 136), will be that in a few years the vine (of the *Labrusca* Grape, at least) will be fitted to stand alone, needing no trellis support. Thus, a considerable expense per acre is saved, and, with Grapes at ten dollars a ton, there will be less loss in their production.

When planting the more tender Lilies, it is advisable to prepare a bed and arrange each kind according to its height, and in fall, when they have died down, place a frame over the bed, fill with dry leaves and cover with shutters. In this way all the tender kinds, including those from California and *L. longiflorum*, *L. Harrisii*, *L. giganteum*, *L. Brownii* and choice varieties of *L. auratum*, may be wintered with safety.

Plants that need division (and many kinds thrive better when periodically lifted), such as the tall Phlox, Day Lilies, *Iris Kämpferi* and *I. Germanica*, should be taken up and divided with a sharp knife. The soil should be enriched before replanting, for such plants are gross feeders. Delphiniums, to succeed well, need a moist soil. If the soil is sandy, and liable

Chestnut Hill Station, Boston and Albany Railroad.—See page 159.

For the *Riparia* vines a trellis is necessary, or they may climb over trees. They demand room to spread themselves, and then will produce liberally. The flowers of the *Riparia* vines have reflexed stamens, and seem to be benefited by pollenization from other sorts, although I cannot understand why.

Vineland, N. J.

A. W. Pearson.

The Flower Garden.

THE month of April should be a busy time among hardy, herbaceous plants. All dead foliage should be removed and a light top-dressing of well-decayed manure or leaf-mould applied and lightly forked in; care should be taken, however, not to fork where bulbs are planted. Any additions to the hardy plant-border should be made as soon as possible, and this is especially advisable in the case of all kinds of Lilies, for if these are not planted, early root-growth commences, and the prospect of good flowers the first season is not promising.

to dry out in summer, even heavier soil, as clay, should be added. With this treatment even the best double kinds will thrive and be perennial. Choice Alpines, such as *Androsaces*, *Gentiana excisa*, *G. verna*, *G. aculis*, *Dianthus glacialis*, *D. neglectus* and *Arabis Androsace*, should be examined. They will probably be lifted by the action of frost. When such is the case, make them firm, and place a little fresh soil on the surface, and if pieces of porous stone be placed round the plants they will not be liable to injury from heavy rains or dry spells. Hellebores are becoming popular, owing to their season of flowering. These are deep-rooting and need to be planted where they will be sheltered from direct sunshine. We find them succeed best when planted in this way, and when the ground is dug deep and lightened with plenty of leaf-mould. Any bare, dry places should be planted with *Pyrethrum Tschischewii*. This will form a nice carpet even on a dry bank; and for shady places, such as under trees, where grass will not succeed, *Vinca minor* and its varieties may be used, and when planted a foot apart a good covering will be the result the first

season. Such perennials as may have been raised from seed, should, when large enough to handle, be pricked out in pots, and when well rooted be planted in their permanent positions. Seedlings of many kinds when treated in this way flower well the first year.

Passaic, N. J.

E. O. Orpet.

Orchid Notes.

Lælia bella.—This is the most magnificent hybrid yet produced, combining the excellent qualities of *Cattleya labiata vera* and *Lælia purpurata*, both of these being the best representatives of their respective genera. In richness of color it is far superior to both. The habit and general appearance of the plant greatly resembles *C. labiata*, but the bulbs are more slender and the leaves longer and narrower. The flowers are about nine inches across, and of a uniform rosy purple. The large handsome lip is a rich amethyst purple, deepening to a much darker shade towards the front, while the orange throat is beautifully penciled with crimson. They exhale a delightful primrose fragrance. This very rare hybrid first flowered with the raisers, Messrs. Veitch & Sons, in 1884, and I believe only two plants are as yet in this country.

In strong contrast to the foregoing is the pretty dwarf-growing *L. Lindleyana*, a plant seldom seen, and which is probably somewhat rare in its native habitat in southern Brazil. The slender bulbs usually have two very thick, leathery and narrow leaves, light green and dotted with purple. The short peduncle bears 3-4 flowers about four inches across, with narrow, pure white segments, blotched and spotted with rosy purple, the front lobe of the lip being of the same color. This plant does well in an intermediate temperature, and thrives best in a basket with very little soil about the roots, enjoying abundance of water during the growing season.

Another *Lælia* from the same region as the preceding, and now in full bloom is *L. harpophylla*. This Orchid was, until the last few years, very rare, but large importations have now rendered it within the reach of all. It is a very showy plant, producing from the apex of its slender stems clusters of some half dozen orange-scarlet flowers. These are about two inches across, with narrow segments. The long, narrow, front lobe of the lip is recurved, edged with white, and has a very crisp margin. This Orchid will be found very useful for cutting purposes, and a few plants of it with its rare and showy color assist greatly in brightening the more sober tints of its congeners. It requires about the same treatment as *L. Lindleyana*, except that it is more suitable for pot culture, and should be constantly syringed, as it is somewhat subject to the attacks of yellow thrips.

Lælia Pitcheriana is another garden hybrid, now prettily in bloom. It is the result of crossing *Lælia Perrinii* with *Cattleya crispa*. The character of its growth is intermediate between these two, but the flowers are very much like those of the *Cattleya*. They are of wavy outline, white, flushed with rose, and the lip is white with a large purplish blotch on the anterior lobe. The variety *Alba* (also in flower) is devoid of this blotch on the lip. This plant grows freely with us among the general collection. It is still very rare, although it was first flowered in 1868.

Angracum cryptodon.—This rare plant resembles in habit and foliage *A. Sanderianum*, producing a loose raceme about one foot long, bearing about a score of flowers. The narrow sepals are of cinnamon color, terminating in a spur of the same color about three inches long, the broader petals and ovoid lip being pure white. This peculiar combination of color renders the Orchid very interesting as well as attractive. It is a native of Madagascar, and like other species from that country luxuriates in strong heat, with a maximum of moisture, and it may be grown in a basket filled with charcoal and moss.

Cochlioda (*Odontoglossum*) *rosea* is an attractive little Peruvian Orchid, with drooping racemes, which bear a score of rosy, carmine flowers about one inch across, the top of the column being white. It grows in dense masses, and bears abundant flowers, which last a long time. The cool-house suits it best, with a liberal supply of water at all seasons.

Kenwood, N. Y.

F. Goldring.

Propagating the Weeping Sophora.—It is well known to nurserymen and landscape-gardeners that no adequate supply of good, clean specimens of this beautiful and useful weeping tree has yet been accessible, and the sole reason for its scarcity has been the difficulty of getting straight and smooth stems of sufficient height upon which to graft the drooping variety. No trouble whatever is met in grafting or in getting a strong growth of the top, when once a stem tall enough to use is se-

cured. We have learned, by accident, as many such useful things are learned, to produce tall, clean, unbranched stems, of six to nine feet, in one season, at little expense, by the following method: The *Sophora*, like most Japanese plants, loves a moist atmosphere, and will grow extremely fast in a close, moist place. In spring, after the green-houses are emptied, plant dormant *Sophoras*, about three-fourths of an inch in diameter, in the earth-bottom of the house, which should be made fairly rich. Cut them back to the crown and set them one foot apart each way, and by December 1st they will be out of the top of the house, and as smooth as willows. Then lift and keep them protected in a cellar or frame, or heel them deep in a well-drained place till spring, when they can be planted in nursery rows and grafted at the same time, with most gratifying results.

Plant Notes.

Cytisus capitatus.—This charming little compact-habited bush, with its dull green, hairy, trifoliate leaves and terminal corymbs of yellow flowers, has attracted the notice of some continental nurserymen who have worked it on tall stems and exported it to England under the name of *Cytisus nigricans nana*. *C. nigricans* is a taller-growing plant, with long, erect racemes. *C. capitatus* is found wild in some of the mountain districts of southern France, Switzerland and in central and eastern Europe. It flowers in England from July onwards, and, according to Loudon, was first introduced to cultivation in 1774.

Genista virgata.—One of the most beautiful of all the showy leguminous shrubs in the Kew Arboretum is, without doubt, the subject of this note. Although a native of Madeira, it seems with us quite as hardy as our native Broom (*Cytisus scoparius*). In spite of its merit the species is far from common; it has small leaves and slender branchlets, every one of which is terminated in July with an upright, golden raceme. There are numerous old specimens at Kew from six to eight or ten feet high and as much through, and these must have successfully passed through many winters which left their mark on not a few of our indigenous trees and shrubs. In some gardens *G. virgata* is cultivated under the name of *G. elata*, which really represents a widely different plant, and is nothing more than a vigorous form of the European *G. tinctoria*, a pretty perennial with a woody base.

Principles of Physiological Botany as Applied to Horticulture and Forestry.

XIV.—REPRODUCTION IN THE HIGHER PLANTS.

BY means of the multiplication of cells and their increase in size, all growth takes place in the vegetable kingdom. This process of growth can take place, under certain conditions, in parts which have been completely separated from the plant, for instance, as cuttings, tubers and many other underground structures. Moreover, as is well known, it is possible to transfer certain separated parts to other plants with which they unite, after which, both the stock and scion, continue to grow as one. That which is common to the growth of such separated parts, whether they are placed in the ground, as in the case of cuttings, or grafted or budded on some other plant, is this: all the individual peculiarities of the parent plant from which the fragment was derived, are perpetuated with little or no change. In other words, all these fragments have carried their ancestral peculiarities with them, and, as the cells of which their buds are composed multiply and increase in size, they obey all the traditions of their parentage. Hence, in general, propagation by means of buds is a sure way to continue the cultivation of a special variety, and for this reason we perpetuate our choice varieties of fruits preferably by grafting or budding. We recognize the fact that with the planting of the seed we are very likely to obtain some deviation from the straight line in which the desirable variety has come down to us.

It must not be thought, however, that there can be no variation in propagation by buds. It occasionally, though rarely, happens that a bud or a shoot will manifest a capricious divergence from the ancestral traits; and, what is harder still to understand, in some cases the scion may be affected by the stock on which it is grafted. In still others, however, it may affect the stock. But these cases are exceptional in the highest degree, and do not invalidate to any extent the general statement that the bud is relied upon to keep the variety true, while it is to the seed that we look for variation.

It is necessary that we should now glance at the structure and the office of the flower; that mechanism by which in the plants which are called the *higher*, seeds are produced.

THE FLOWER, for instance, in the case of flax, consists essentially of a branch with leaves arranged in definite order, but all so changed in their character that they are readily distinguished from ordinary foliage leaves. With the exception of the outer circle of floral organs (which are frequently much like green leaves), the parts of the flower are of very delicate texture and possess some color unlike that of the outer row. Within the highly-colored crown, or corolla, of the flower, we come to the male organs of the blossom, known as *stamens*, which consist of slender threads, each bearing at its summit a minute sac filled with the fine grains of *pollen* or fertilizing dust, by which the *ovules* (delicate roundish bodies in the central organ of the flower) are to be impregnated. The central organ, termed the *pistil*, bears the ovules in a closed case, known as the *ovary*, which is surmounted by a thread-like prolongation at the summit of which is the *stigma*, a receptive sticky surface to which the pollen clings.

The pollen, or male element of flowering plants, consists of microscopic grains which vary considerably in size, shape and sculpturing of the surface. The forms and markings in a few instances are so characteristic that they may be employed for distinguishing large groups of plants, but in general the grains are merely round or ovoid, and have no very distinguishing features. Pollen grains are either simple or compound, the latter sort found in comparatively few species. One of the most interesting forms of clustering of grains is found in the milk-weeds and in the Orchid family, some of their clusters being provided with minute stalks and sticky discs, by which they can be carried by insects from one flower to another.

A vast amount of pollen shed by some of our forest trees and shrubs is scattered far and wide by the wind, borne, one may say, at random, with only the merest chance of any of it falling on the female flowers of the same species. And yet, as matter of fact, it is waste with good results; for out of the prodigality successful fertilization is secured. It is a familiar fact that the amount of pollen collecting on the shores of our northern lakes is so great as to attract attention from the sulphur-yellow color which it imparts to the water. With the pollen grains which collect on the shores there are generally commingled the spores of some of our lower plants, notably those of Lycopodium, or Christmas evergreen. These spores are enveloped in a delicate film of resinous matter, which makes them water-proof for a long time, and causes them to burn with a flash when they are brought into contact with flame. In this way they can be distinguished from the pollen with which they are mixed.

At the opening of a flower, the pollen, borne in some way, either by the wind or by insects, reaches the sticky stigma, to which it adheres. After a variable time, there protrudes from the pollen-grain a microscopic tube, containing protoplasm or living matter. This tube descends through the style to the cavity of the ovary, where it comes into contact with the ovule. For every ovule, there is supposed to be required, at least in nearly all cases, one pollen tube. The ovule possesses an intricate structure which, in its simplest form, may be said to be a sort of minute vegetable egg (in fact, the word *ovule* means this very thing), containing in one part a cell somewhat larger than those surrounding it. This larger cell contains, as do the other smaller ones, protoplasm or living matter, but the protoplasm in this larger cell presents certain peculiarities of form which need not be further described. It is sufficient to say that one part of this protoplasm becomes affected in a remarkable manner by the protoplasm in the pollen tube, and, as a result of this action, the former begins to divide and subdivide, the other cells of the ovule undergoing changes, but of a less remarkable character. The dividing contents of the large cell of the ovule become sooner or later distinguishable as forming the embryo or germ, and associated with this is a certain adequate amount of food, all being enclosed in the hardening ovular coats, which become the integuments of the seed.

Unless the ovular protoplasm is acted upon by the contents of the pollen tube, the globular body withers away and comes to nothing. Contact of these two diverse elements is requisite to the formation of the germ within the seed. There are a few anomalous cases known as those of *parthenogenesis*, in which germs appear to be produced without the action of pollen, but these are so very exceptional that they may be disregarded in the present treatment of the matter.

After the seed begins to ripen, concomitant changes take place in the ovary, the whole ripening into the fruit. The fruit may be defined as the ripened ovary; the seed may be called

the ripened ovule. In the ripening of the fruit there is generally more or less change in the neighboring parts, and these modified parts may become conjoined to make what is popularly called the fruit. For instance, the Strawberry consists of a thickened pulpy stalk, which has acquired sweetness and a delicious flavor. Upon this rounded or conical fruit-stalk are borne numerous ripened ovaries, which seem so much like seeds that until one cuts them open he is unwilling to believe that each is a fruit-case holding a seed.

Ripened seeds and fruits bear some curious relations to each other. For instance, it is rare to find any ovary containing more than a couple of seeds, which is incapable of opening and discharging some of its seeds. On the other hand, fruits which have only one or two seeds are very apt to remain closed even when they are "dead ripe." The bearings of these relations on the manner of dissemination can be easily thought out by any observant person who will note the different sorts of fruits and the numerous contrivances which they possess for distributing their seeds. In connection with this it should be said that one-seeded fruits are often furnished with some means for dissemination, such as by wings, plumes, hairs, hooks, claws and the like.

If one were to examine the flowers of our common forest trees in the hope of finding such flowers as we have described in the case of the flax, he would be disappointed. A few have showy blossoms, like the Magnolia, Tulip-tree, and Catalpa, and, among shrubs, Rhododendron, Azalea, and so on, but these are exceptions. Most of our trees have flowers which are very much reduced in numerous particulars, but all of them agree in this: that they contain either the male organs, the pollen-bearing stamens, or else the female organs, the pistils with their ovules, or in very many cases, both of these in the same flower. But the flowers of trees at the North are, as a rule, brought down to very narrow limits as regards color and complexity. Nevertheless, since they possess the essential elements of the flower, they can produce seeds with germs, and hence carry on that form of reproduction by which variation is introduced into the line of succession.

In conclusion, it may be said that a seed is an embryo plant, supplied with a sufficient store of food and provided with a protecting case. It has also been given some means by which it may be carried to some distance from the parent plant, thus lessening competition.

George Lincoln Goodale.

The Forest.

Forestry in California.

THE following extract is taken from the last report of the California State Board of Forestry. The report was prepared, we believe, by Mr. Abbot Kinney, of whose efficient services the state has recently been deprived:

The debris of the hydraulic mines in this state is infinitesimal and harmless in its damages compared to what must occur if the high Sierras are unduly denuded of their forest covering. In such case the rains must flow off more rapidly and the snows melt more suddenly than at present. Thus the perennial value of the streams for irrigation must diminish, and sudden and destructive floods are certain to occur. The histories of such countries as Palestine, Persia, Greece, North Africa, Spain and the south of France demonstrate the results of unwise forest extinction, especially upon the mountains. That California will prove no exception to the rule is shown by the instances of the diminution of springs and streams, and by the formation of torrents in this state due to forest destruction, collected and presented with time, place and witnesses in our last report. Now that these mountain water-sheds in forests so important to the irrigators, farmers and consequently to all persons in the state have generally passed into private hands, there seems but one way left to deal with the question. This way is by education of the people, to demonstrate that a wasteful and unscientific destruction of forests upon certain critical points of important water-sheds, while temporarily beneficial in a gain of a few thousand dollars to some individuals, threatens the loss of millions of dollars of property to others. Thus the carelessness or improvidence in the mountains of one man may destroy the property and means of livelihood of thousands of his fellow citizens in the valleys below. This point established, legislation in the line of the forestry laws of other experienced and civilized countries can be had. We will then have a reasonable regulation of lumbering methods, upon important water-sheds of the state, with a view of preserving the integrity of our springs and streams for the pro-

ductive interests of the state. No doubt a cause of action would lay against any one who by such use of his own forest property did damage to his neighbors, either by diminishing their water-supply or by so suddenly augmenting it in the form of torrents as to destroy their property. Such remedy will be the state's last resort, and can only be relied on after great damage has been done. Wise measures should prevent such serious injuries to the people. The active attention of the Board has been given not only to the preservation of our forests, but also to the planting of trees for economic and ornamental purposes. Our native trees have been too much neglected, but with the exception of the Monterey Pine they are generally of slow growth, especially in dry situations. The foreign trees introduced have disadvantages in most cases, and that extraordinary grower, the Blue Gum, of Tasmania, is not capable of supporting the frosts of many of our interior points, nor the excessive drought of others. It happens that the very places where trees would be of the greatest advantage are those where the trees usually relied on for planting will not succeed or do but poorly. The Board has endeavored to remedy this condition by the introduction of other trees suited to the more difficult climates of the state. After extensive correspondence, the Board felt justified in recommending several trees as being better able to resist excessive drought and to grow with reasonable rapidity than any we had hitherto tried. The trees recommended were the Locust, Catalpa, *Eucalyptus viminalis* or Manna Gum, the *Eucalyptus leucoxylon* or Blue Gum of South Australia, and the *Eucalyptus corynocalyx* or Sugar Gum. Taking all things into consideration, the last is probably the best. Our recommendations were largely based on the experiments of the forest department of South Australia, under the able direction of Mr. J. Edine Brown. His department has planted a number of stations with trees in the dry interior of Australia, where the climatic conditions bear a close resemblance to those in the drier portion of our state. While in these extreme stations the Blue Gum of Tasmania (*E. globulus*) did not do well, the other trees named flourished beyond expectation. These trees and even their seeds were not to be had in this state. The Board, therefore, imported seeds from Australia, and distributed them free throughout the state. Many successful plantations are the result. No tree has been found to grow more rapidly in situations suited to it than the common Blue Gum. Experiments by a member of the Board show, however, that there are other trees not very inferior in this respect, while much more valuable in other qualities. Two trees planted from the pot, six inches high, in the middle of August, a year ago, at Santa Monica, nineteen months from the seeds and fourteen months from the transplanting, are now respectively fourteen feet six and a half inches and fourteen feet six and three-quarters inches in height. One of these trees is a *Eucalyptus corynocalyx* (Sugar Gum) and the tallest a *Eucalyptus viminalis* (Manna Gum). A tree of the *E. gomphocephala* (Tooart Gum) of the same planting is fourteen feet one inch high. It must be said, however, that the soil and climate of Santa Monica are especially favorable to almost all forest trees.

Periodical Literature.

Professor L. Wittmack, of the Landwirthschaftliche Hochschule at Berlin, has recently contributed to the *Berichte der deutschen botanischen Gesellschaft* an important paper on "Die Heimath der Bohnen und der Kurbisse" (The Home of the Bean and the Pumpkin). He says that as early as the year 1879 he expressed the opinion that the Garden Bean of Europe (*Phaseolus vulgaris*) was not of Old World origin, but came from the New World, the remains from the ancient Peruvian mummies brought from the necropolis at Ancon by Drs. Reiss and Stübel, entrusted to him for identification, having led him to that belief. Later, in the meeting of naturalists at Danzig, and before the Agriculturists' Club at Berlin, he had spoken more positively. He had at the same time endeavored to point out that what the ancients had called *Phaseolus*, *Faseolus*, etc., was in all probability a sort of *Dolichos*, and Professor Körnicke had, in consequence, further shown that it was *Dolichos Sinensis*, or a variety of the same, *D. melanophthalmos*. Professor Wittmack further observed that the word *frizol* or *frisol*, from which the Spanish *frijol*, the German *fisolen*, etc., had come, was an American word, and, according to Reiss, was of West Indian origin; unfortunately, it had an accidental resemblance to the Greek and Latin *phaseolus* in sound.

Alphonse De Candolle had shown that *Phaseolus vulgaris* had no Sanskrit name, and therefore its origin must be in western Asia, but there it had never been found. It is, there-

fore, almost incomprehensible that the idea of its American origin should not have been conceived, particularly when, out of the sixty different sorts of *Phaseolus* there are twenty-eight native to Brazil alone, mostly of the large varieties. Had the old writers who relate the story of the Spanish conquest been studied, the opinions would have been different. Acosta mentions two kinds of Beans, Garcilasso de la Vega speaks of three or four kinds. Oviedo (1525-38) alludes to them in San Domingo, the other islands, and still more on the continent; in the province of Nagranda (Nicaragua) he has seen hundreds of bushels gathered, and in another place he observes that they are indigenous. Cabeza de Vaca found *frisoles* in Florida in 1820, and, in 1835, in the northern limits of his journey in New Mexico and Sonora. He mentions them repeatedly, mostly in connection with Pumpkins. Pedro de Cieza de Leon describes them as cultivated in Popaya (Colombia).

Alphonse De Candolle, in his classic work "*L'origine des plantes cultivées*," after citing the observation of Professor Wittmack, says: 1. *Phaseolus vulgaris* has not long been cultivated in India, south-western Asia and Egypt. 2. It is not certain whether it was known in Europe before the discovery of America. 3. At this epoch the number of varieties in European gardens suddenly increased, and all authors began to mention it. 4. The majority of the varieties of the genus exist in South America. 5. Seeds apparently belonging to this kind have been found in Peruvian graves of uncertain age (meaning whether before or after the conquest), but mingled with many plants, all of American origin. At the end of his book he places *Phaseolus vulgaris*, to be sure, among the three plants whose nativity is either wholly unknown or uncertain. The two others are *Cucurbita moschata* and *C. ficifolia*, Bouche (*C. melanosperma*, Al. Br.).

In the meantime two high authorities have likewise pronounced for the American origin of the Garden Bean—Asa Gray and Hammond Trumbull. According to them, Columbus found, three weeks after his arrival in the New World, near Nuevitas, in Cuba, fields of *faxones* and *fabas*, very different from those of Spain, and two days later, on the north coast of Cuba, again land "well cultivated with *fexoes* and *habas*, very different from ours." Faxones or fexoes are, as the editor of the journal, Navarrete, notes, the same as "frejoles" or "judias," the Spanish name for *Phaseolus vulgaris*.

De Soto found in 1539, on his landing in Florida near Tampa Bay, fields of Maize, Beans, and Pumpkins in great quantities, and the same elsewhere. Jacques Cartier found Maize and Beans among the Indians at the mouth of the St. Lawrence in 1608. Lescarbot speaks of various kinds of Beans among the Indians of Maine, Virginia, and Florida, planted between the hills of Maize; Lawson, in his voyage to Carolina, 1700-1708, says that the Kidney Beans were here before the English came, very abundant in the Maize-fields. The "Bushel Beans," a wild kind, very flat, white and with a purple spotting, were trained on poles. Asa Gray and Trumbull here say in parenthesis (*Phaseolus multiflorus*?), but Professor Wittmack thinks *P. lunatus* must have been meant. Lawson mentions further: Miraculous Pulse, so-called on account of the long pod and the great yield, very pleasant in taste; and further, Bonavies, Calavancies, Nanticoches, and an abundance of other kinds with pods, too numerous to mention, which we found the Indians possessed when we first settled America.

The Beans in the Northern States were named Indian Beans, in contrast to the Sow Beans introduced by the English, which were called Garden Beans.

In no Egyptian sarcophagus and in no pile-structure of Europe have Garden Beans been found, says Professor Wittmack; whereas the Sow Beans have been, though only recently, and very few in the Egyptian graves, since they were regarded as impure. He also points to Sow Beans in the collections of Schliemann and Virchow at Hissarlik (Troya), and by Schliemann at Herakleia.

"On the other hand, I have now had the good fortune to find prehistoric seeds of *Phaseolus vulgaris* from North American graves. At the International Congress of Americanists held in Berlin from October 2d to 5th, Professor Edward S. Morse, of Salem, and Mr. Sylvester Baxter, both delegates of the Hemenway Expedition, showed a portion of the collections made by that archæological undertaking, which was instituted by a lady of scientific enthusiasm, Mrs. Hemenway, for exploration in the south-west of North America (Arizona). Among the specimens were some examples of Maize from Los Muertos on the Rio Salado, in loose, charred kernels, together with a thin cob exactly resembling the prehistoric Maize from the mounds in Ohio. But who can depict my astonishment when, with the permission of Dr. Uhle, of the Museum für Völkerkunde, I examined the little box of Maize somewhat more

closely and found therein indubitable Garden Beans, besides some fragments of a pod somewhat resembling in shape a string of pearls? The latter, which is distinguished by strong, forked, netted veins upon the surface, I would regard as *Prosopis glandulosa* (*Algarobia glandulosa*), the so-called Mesquite. It is six to seven millimeters broad, two to three thick, and agrees very well with the figure of the same in the annual report of the Commissioner of Agriculture for the year 1870, Washington, p. 410, plate XXI., although no veins are shown on the latter, which is only superficially drawn. The Mesquite is to-day an important article of food for the Indians in the desert. The fruit is eaten like St. John's Bread; also ground and mixed with water, eaten as porridge or (unbaked) bread. The seeds of the Garden Beans that I found are all small, much smaller than those from the Peruvian graves, which compare with our larger and largest kinds. The smallest from Arizona are only 6.7 millimeters long, 3.8 wide, 2.9 thick; the largest 8.9 millimeters long, 4.8 broad, 3.2 thick. Many Beans are split in consequence of the charring.

Among these halves is a very large one 10.3 mm. long, 6.3 broad and 2.7 thick. We have yet to-day many Pearl Beans as small as this. The prehistoric Beans would also appear somewhat larger if the hull of most of them were not lacking. When hulled, a modern Bush Bean, "round, pale yellow wax," in form corresponding to the last-mentioned half Bean, has a length of 10.4 mm., breadth of 6.0 and thickness of 4.0, and a "white Pearl Bean" from the collection of Von Marten, unhulled, is only 7.5 mm. long, 4.7 broad and 3.4 thick. This latter corresponds most nearly to the prehistoric example; and, accordingly the Bean from Arizona is to be regarded as a Pearl Bean, *Phaseolus vulgaris saccharatus*, Von Martens (the Garden Beans, No. 97), which belongs to division VI., Ellipticus, the Egg Beans. Prehistoric Beans, so far as I know, have not until now been encountered in America. The present discovery is, therefore, of universal interest, and it confirms the American nativity of the Garden Bean. That it is in reality the latter with which we have to do in this case, is shown by the agreement in the position and shape of the root germ as well as the plumula. In certain of the split Beans are to be seen very plainly both of these characteristic primordial leaves."

In regard to the Pumpkins, Professor Wittmack first calls attention to the fact that Naudin, in his monograph on the subject, holds all three of the cultivated kinds, *Cucurbita maxima*, *C. Pepo* and *C. moschata*, to be of Old World origin, and in his *Nouvelle recherches*, 1856, he says that *C. Pepo* was perhaps known to the Greeks and Romans, but the introduction of the other two in European gardens does not appear to go back over two centuries. De Candolle remarks that the historical data do not disprove, neither do they support, the American nativity of *C. Pepo*, and at the end of his work he classifies it as American. *C. maxima* he regards as native to the Old World, but allows that it has been found by Barter only "apparently wild" on the banks of the Niger in Guinea. Professor Wittmack was personally assured by Professor Schweinfurth, however, that this observation amounted to nothing, for Pumpkins were now always found wherever there were negroes, who now cultivate them extensively. Professor Wittmack had found seeds of *C. maxima* of normal size, and of *C. moschata*, in the Peruvian collections from Ancon; it therefore seems that America must be the home of these, and when De Candolle is disposed to regard *C. Pepo* as American, his designation is perhaps better to be applied to the very similar *C. moschata*. Nothing of the Pumpkin kind has been found among the ancient Old World collections, and there is no recognizable description of them before the discovery of America; they are first encountered in the sixteenth century. Gray and Trumbull have shown that there were Pumpkins in the land of the Hurons before the arrival of the Europeans. Professor Wittmack has examined their references, often in the original where they only had an English translation. This was essential, since the Spanish word *calabazas* was not always to be translated by the English Pumpkin; it seems as if the Bottleneck Squash, *Lagenaria*, were often meant. But when, for instance, De Soto, in 1539, declares at Apalacha, in western Florida, the *calabacas* of Uzachil to be better and juicier than those of Spain, he cannot have meant *Lagenaria*. Professor Wittmack regards the researches of Gray and Trumbull on this subject as very convincing; but since they do not discuss the species, he hopes that the seeds may be found among North American remains, in order to determine the latter. Nothing is known of the nativity of *C. ficifolia*, better known as *C. melanosperma*; De Candolle is of the opinion that it is American, since it is perennial, and all known Cucurbitaceous perennials come from Mexico and California.

Exhibitions.

Flower Show in Boston.

THE spring exhibition of the Massachusetts Horticultural Society is expected to bring together a display of bulbous plants, Indian Azaleas and other green-house and stove plants, and is considered one of the most important held by the Society during the year. In spite of the unusually favorable season, however, the exhibition in Boston last week was less interesting than many of those held in previous years. Many prominent Massachusetts gardens were not represented, and few novelties or remarkable plants were shown. Indian Azaleas did not form a conspicuous feature, although half a dozen compact little plants, shown by Dr. Charles Weld of Brookline, were well done. Larger plants were sent from the garden of Mr. N. T. Kidder, of Milton, but the flowers were not fully open, and lacked size and substance. The Orchids were few in number and not remarkable, and the bulbous plants, with the exception of Hyacinths, were below the average in quality. Of Hyacinths, however, the display was magnificent, Mr. Kidder staging as fine spikes of bloom as have ever been seen in Boston. From the same garden came a collection of Cinerarias in well-selected varieties and beautifully grown.

There was nothing in the exhibition, however, from a cultural point of view, to compare with the forty-eight cut Roses—Mervielle de Lyon, Baroness Rothschild and Her Majesty—shown by Miss Simpkins, of Yarmouth. Such flowers of Her Majesty have not been seen in Boston before. The Tea Roses, shown by Mr. Thomas Mead, of Dorchester, were wonderfully well grown, too. A great mass of *Primula obconica*, shaded with numerous small plants of *Cocos Weddelliana*, was contributed by Mr. Benjamin Grey, and showed the decorative value of these plants when used in this way. A collection of hardy spring-flowering plants, in pots and in flower (not very well flowered or arranged), were sent from the Cambridge Botanic Garden. This collection, judging by the number of people who constantly gathered about it, was the most attractive feature of the exhibition. Mention must be made of a fine seedling Rhododendron raised by Mr. James Comley, gardener to Mrs. F. B. Hayes, of Lexington. It is said to be a hybrid between *R. maximum* and some garden variety of *R. Catawbiense*, although the foliage shows no trace of the blood of the former species. The truss is large, compact and well-shaped, and the flowers are large, white, or faintly tinged with pink, and handsomely marked on the upper division of the corolla with pink spots. The plant is seven years old, and is now flowering for the first time. It has shown itself perfectly hardy, and if it proves to be a free bloomer and possessed of a good constitution and habit, it will make a valuable addition to the list of desirable hardy Rhododendrons, among which there is none with light-colored flowers now known here quite equal to it, if it is fair to judge by the single trees exhibited.

Mr. F. L. Temple, of the Shady Hill Nurseries, exhibited two plants of the Japanese Umbrella Pine (*Sciadophytis*) imported from Japan; each eight or ten feet high, and perfectly furnished to the ground—interesting in themselves, as unusually fine specimens, and as showing how plants of this size can be imported successfully from Japan. R. & J. Farquhar & Co. showed Pansies of a good strain, and there was the excellent display of seasonable vegetables which is always seen at a Boston exhibition.

Notes.

The great summer horticultural exhibition at the Crystal Palace, near London, will open this year on the 11th of May.

The death is announced in England of the Rev. J. G. Wood, a very popular writer on natural history subjects. Most of his works have addressed themselves to students of animal life only, but his "Garden Friends and Foes" has a special interest for horticulturists.

At a recent meeting of the Horticultural Society of Paris a red-berried Mistletoe (*Viscum cruciatum*) was exhibited by Monsieur H. Luiseau. It is a native of Portugal, where it usually grows on the branches of the Olive-tree. Its leaves are cuneiform in shape and smaller than those of the common Mistletoe (*Viscum album*), and its berries are a bright crimson-red.

An English correspondent writes: There is little of interest in bloom out-of-doors, but in frames and cool-houses the European Cyclamens, Crocuses, Hepaticas, *Iris Persica*, *I. reticulata*, *Bongardia Rauwolfii*, with numerous kinds of Narcissus, are now in full blow. The Snowdrops, with their numerous names, but all looking alike at a distance of ten yards, are at their best, and so is the beautiful Snowflake.

The *Revue Horticole* calls attention to the merits of the new dwarf Polyantha Rose, Mademoiselle Blanche Rebatil, already figured in the *Journal des Roses*. The value of this introduction, which was raised by M. Alexandre Bernaix, near Lyons, in 1885, is the dark color of the flowers, something unknown before in this class, and a character which the raisers of new varieties will not be slow to take advantage of in improving this charming class of dwarf Roses.

English journals say that a fence about five feet high and of considerable extent which encircles the grounds of a new house erected for Baron Knopp at Forest Hill in the environs of London, is built entirely of "Jarrah timber," and "attracts considerable attention from the passers-by" as the "varied and delicate shades of the wood" are conspicuously ornamental. Jarrah timber is the wood of *Eucalyptus robusta*, var. *rostrata*, a native of western Australia.

M. Crépin has succeeded in obtaining from India a few seeds of the new climbing white-flowered *Rosa gigantea*, which, it is believed, is destined to become a valuable addition to our single Roses. The flowers are dazzling white and of enormous size. It is a native of Upper Burmah, a region where frosts are unknown, so that in the Northern States *Rosa gigantea* must be treated as a green-house climber; but in the Southern States it will doubtless prove perfectly hardy.

Some idea of the new class of demands made upon the American forests will be gained from the fact that a firm of wood-workers in one of the smaller towns of southern Illinois has recently received an order from St. Louis for forty million wooden butter-dishes. Its product last year was thirty-three million butter-dishes, besides immense numbers of fruit-boxes, sugar-buckets, etc. The principal wood used for this purpose in the Mississippi Valley States is Liquidambar or Sweet Gum (*Liquidambar Stryraciflua*).

M. Cornu, Professor of Culture at the *Jardin des Plantes*, exhibited on the 28th of February, before the National Society of Horticulture of France, branches of *Prunus Davidiana*, *Pyrus baccata*, *Forsythia suspensa*, *Deutzia gracilis* and other shrubs, in full flower fully two months earlier than these plants bloom at Paris naturally. These early flowers were obtained by inserting branches, cut from plants growing in the open ground, in moist sand in a green-house where the temperature was maintained between 50° and 60°.

At Ribston Hall, Wethersby, a severe gale recently destroyed the beautiful *Abies Pinsapo*, which was one of the earliest specimens planted in England. It was thought to be about forty-five years old, was over forty-four feet in height, and at one foot from the ground girthed nearly twelve feet. Ribston Hall is the estate which gave us a well-known Apple, the Ribston Pippin. The seed of the original specimen is said to have come from Rouen in 1787, and this parent tree stood until a few years ago, while a sucker which sprang from its roots is still in existence.

The demand for Sycamore lumber, as the wood of *Platanus occidentalis* is called, is increasing very rapidly wherever tobacco is packed. This wood, which does not split readily, is now almost exclusively used in the United States for tobacco-boxes, and immense quantities are shipped to Richmond, St. Louis and other tobacco-packing centres. One mill on the Embarras River, in southern Illinois, has within a few months received orders for eleven million feet of this lumber; and

mills through that part of the country are busy sawing up the great Sycamores, which once were the crowning feature of the country of the Illinois.

Mr. E. S. Goff reports, in *Agricultural Science*, some investigations upon the distribution of starch in the Potato tuber. The study was undertaken partly to ascertain whether any clue to a rational method of cutting Potatoes for seed could be discovered in this way. The test showed that the part richest in starch lies within the cambium-layer and adjacent to it, and that the portion lying nearest the so-called seed-end is richer in starch than that of the opposite end. Experiments have shown that cuttings from the seed-end yielded more than cuttings from the stem-end, but the greater vigor of the eyes at the seed-end as compared with those at the opposite end can hardly be accounted for by the slightly greater amount of starch in that part of the tuber. The only conclusion as to the method of cutting for seed seems to be that it is probably better to cut the tuber longitudinally, since transverse cutting would unequally divide the nutriment of the young plant.

A correspondent of a French botanical journal recently gave several recipes for preserving the color and form of dried flowers. One method is to immerse the stem of the fresh specimen in a solution of thirty-one parts by weight of alum, four of nitre and 186 of water for two or three days, until the liquid is thoroughly absorbed, and then to press in the ordinary way, except that dry sand is sifted over the specimen and the packet submitted to the action of gentle heat for twenty-four hours. Another method is to make a varnish composed of twenty parts of powdered copal and 500 parts of ether, powdered glass or sand being used to make the copal dissolve more readily. Into this solution the plants are carefully dipped; then they are allowed to dry for ten minutes, and the same process is repeated four or five times in succession. Plants may also be plunged in a boiling solution of one part of salicylic acid and 600 of alcohol, and then dried in bibulous paper. But this act should be very rapidly done, violet flowers especially being decolorized by more than an instantaneous immersion. Red flowers which have changed to a purplish tint in drying may have their color restored by laying them on a piece of paper moistened with dilute nitric acid (one part to ten or twelve parts of water), and then submitting them to moderate pressure for a few seconds. But this solution should never be allowed to touch the green leaves, as they would be decolorized by it.

An article on Danny Park, Sussex, the residence of Mr. W. H. Campion, which was recently published in the *Garden* (London), includes an illustration of a most remarkable tree. It is a specimen of our Cottonwood (*Populus monilifera*), and stands near the house, isolated on one side of a wide lawn. "It is probably," says the *Garden*, "one of the quaintest forms of tree-growth" that exists in England. There is no record to show when it was planted, but it must be at least a century old, for "the stem at two feet from the ground girths thirteen feet, the first branch starting about nine feet up the stem, while most of the others are found about two feet higher up," and the greatest spread of the branches being 150 feet. But the most remarkable thing about the tree is not its size, but the curious form it has assumed. Not only do all the lower branches droop so that they lie upon the ground, "but some of them have rooted, and the new roots, infusing fresh vigor into the branches, have caused rival leaders to shoot up, some of which have now attained a height almost equal to that of the parent tree. If these upstarts put out branches like the parent there will be some day a forest of stems, like those of the Banyan tree, which spreads and covers acres. But the Banyan supports its head upon straight stems, which are like a great array of pillars upholding some mighty dome, the ground being left free and scarcely obstructed. The Poplar does otherwise. Its branches form a confused labyrinth of stems, crossing and recrossing one another, entirely impeding the progress of anyone who would walk beneath its shade. . . . If, instead of winding in and out, the branches had all grown out straight from the stem, much more ground would have been covered, for the longest branch, though confusedly interwoven with the others, is forty-five yards in length, that being only five yards less than the greatest diameter of the branch spread. The tree also makes a large mass of distinct and noble-looking leafage, for the broad ovate leaves are nearly all about the size of one's hand." The picture shows the tree in winter, when its singular development of course appears most clearly. It is protected by a railing, but a winding path leads to the central space near the trunk, which in summer must be a thickly over-shadowed bower of considerable size.

The Boundaries of the New Parks.

THE attempt to secure a legislative enactment authorizing the Park Commissioners to sell such portions of the new park lands in the annexed district of this city as they might deem proper aroused such strenuous opposition that it seems to have been practically abandoned. The promoters of this scheme, however, have conceived another which is a trifle less audacious. They have revised the maps of the new parks to suit their purposes, and now ask the legislature to sanction these changes and to empower the Park Board to sell such lands outside of the new boundaries as the city has already acquired.

In examining the merits of this proposition it should be remembered that really we have no new parks. A park is an organized work; it is the expression of some design. The city possesses only certain pieces of ground which are to be used as the foundation of parks in the future. The boundaries of these lands were not fitted to any design whatever, but were laid down by a board of worthy citizens in accordance with their notions about the adjustment of conflicting interests and a vague idea that the city needed about so many acres. No doubt the particular shape of the territory was a matter of minor consequence to them, and they would probably mock at an expert who should assert that ten acres lying somewhere adjacent to the limits of their park land might be worth ten times as much as any other ten acres next to the boundary line, but on the inside. Of course no cursory examination by the best landscape-gardener in the world would enable him to say where the boundaries should be. No one could tell this unless he had the essentials of a design outlined in his mind, and a design implies serious study. No study by any competent expert has here been made. The boundaries have been determined altogether without relation to any plan, and of course, if any good plan is adopted they will need to be adjusted to suit it.

Here was the fundamental mistake. No one would attempt to construct a park without a design, and certainly the counsel of the designer could never be of greater value than in the selection of a site. When a site is chosen in a

general way, it will be evident to a competent artist that it is adapted to some leading motive. In working out this motive, the prominent features of the scheme will enable its author to decide where the park should begin and end. In studying the plan of one of the new parks the maker will be certain to come to a point where a piece of land outside the given boundaries will be found essential to the consistency and unity of the design, and if this land cannot be secured, another motive must be adopted. Here runs a ridge, for example, and on its crest a road must be laid. It is plain that certain unsightly or incongruous city structures will grow up in full view from this pleasure drive, and they can be only shut out of sight by tree-plantations upon lands outside the present boundaries. After the land for Central Park had been purchased it was plain that more space was needed at Fifth and Eighth Avenues on Fifty-ninth Street to secure some dignity of approach and entrance. To complete the design in the artists' minds blocks were added also at the northern end of the park, and these additions were made at enormous expense. For similar reasons, and because the designers showed that the value of the Prospect Park site would be many times multiplied by the change, its boundaries were swung entirely out of their original position. The same thing will happen in the case of the new parks, unless the designing is entrusted to some journeyman, who will have no trouble to fit his kind of park into any given space. The journeyman's work does not grow out of an idea, but is run into a mould.

But because these boundaries will probably need modifying, it does not follow that their revision should be entrusted to a ward politician, or to his lawyer, or to a firm of brokers in neighboring real estate. To invite counsel from artists of this sort would be worse than the original folly of asking none. It is plain that the boundaries of the park lands should be left as they are until advice is had from some one competent to fit them to a consistent design, and competent to give intelligible and coherent reasons for the changes if any are required. A work of this magnitude demands creative talent of the highest order, and it should be entrusted to no other than a recognized master in his art. The completion of the parks is not a matter of immediate concern, although the city is sweeping towards them with ever-increasing speed, and the selection of a designer should not be long delayed. But until that selection, and the best possible selection, is made there can be no excuse for meddling with the park lands or their boundaries. Let them alone.

There has always been in this country an enormous waste of wood at the saw-mills in sawdust, slabs and other parts of logs too small or of too poor quality for use as lumber. The value of this refuse, could a market have been found for it, would easily have amounted during many years to millions of dollars every year. Its disposition has always been a serious labor and expense to manufacturers. For many years the sawdust was poured from the mills directly into the streams. But this practice assumed such vast proportions in some parts of the country that the streams became entirely choked up and so injured that both the general Government and some of the States were obliged to pass laws to protect rivers from this debasement. The burning up of all the waste from a large mill, amounting perhaps to seventy-five or a hundred cords a day, is difficult and expensive; it necessitates the use of an expensive furnace and a large force of men and teams; but the greater demand for wood-pulp and the improved methods of preparing it recently introduced are gradually turning what was once pure waste into a valuable product. The use of soda, applied in the wood "digester" simultaneously from above and from below, is changing methods of pulp manufacture; and the time perhaps is not remote when the great fires which burn day and night for months at a time, wherever lumber is manufactured on a large scale, will go out, never to be relighted.

A recent number of the *Saturday Review* devotes a page to "Forestry." No special familiarity with the subject is displayed by the writer, and the article contains nothing new and little worth quoting except these sentences:

"In a lifetime a man may find out a tree or two, grand and handsome in their maturity, which flourish on his land. But he plants many, exceedingly pretty and promising when young, which, as they advance in years, show that they languish in a foreign country, and present miserable contrasts to the splendid parent trees from which the traveler has brought the seed. In ornamental planting, except where a mass of thick covert is required for the picturesque, a tree should have plenty of room to display its proportions and full growth."

This can hardly be called forestry, but it is sound doctrine, and it can hardly be repeated too often for the benefit of those who are tempted to plant foreign trees, or to plant any trees without giving them ample space to spread out into strong and characteristic growth.

We have received the following notice from the Corresponding Secretary of the American Forestry Congress:

"The next meeting of the American Forestry Congress will be held in Philadelphia, on the 16th, 17th and 18th of October, 1889. Papers to be read at the meeting should be sent to the Corresponding Secretary before October 1st. I shall be glad to receive, from any source, short and vital papers on any of the practical aspects of forestry, and of tree-culture and preservation in this country. It is desirable to avoid long historical dissertations, and reviews of the general subject of forestry, as they benumb the faculties of the hearers, and lead to no valuable result. We wish to show that we have passed beyond this stage of the forestry movement. Some of the subjects to be discussed, and the arrangements of the local committees, will be announced hereafter. If the press of the country will kindly publish this notice I shall be grateful for their courtesy and cooperation. Every facility will be afforded for reporting the proceedings.

Franklin Falls, N. H.

J. B. Harrison.

Gardening in Florida.

ONE who visits Florida for the first time is impressed most of all with the fact that the land is so largely wild and unsubdued. Outside of a few old settlements, pioneers are everywhere attacking the original forest, and the inhabitants are brought into as close contact with primeval nature as are those on our western frontier. Life in Florida, however, is not pioneer life as known in the West. Hotels, with every modern urban appointment, are to be found in the most untamed sections of the state, and evidences of luxury are seen in clearings where the stumps are still standing. But well-kept gardens are not noticed among other marks of refinement. This does not imply a lack of taste or of inclination to the art, for elaborate gardens cannot reasonably be looked for in a country comparatively new. The whole aspect of nature must be softened and mellowed by years of human control before fair gardens are developed naturally and harmoniously out of their surroundings.

It is not to be inferred from this that Florida has no ornamental planting to show. On the contrary, examples are seen everywhere, and they are full of promise. Great numbers of the shrubs and vines that are the ornaments of northern green-houses are here in full flower in February and March, to the constant surprise of tourists from colder latitudes. The great vine of *Bignonia venusta*, with its mass of orange-colored flowers, which covers the side of a house in St. Augustine, and the sheet of snowy bloom from a plant of *Solanum jasminoides*, stretching across the front of the piazza of the Putnam House in Palatka, will not be forgotten by anyone who has seen them. Specimens of Laurestinus, Chinese Hibiscus, Oleander, Allemanda, Poinsettia, Fragrant Olive, Rhinospermum and other flowering shrubs, trees and vines, which are seen everywhere, together with stately Bamboos and such collections of Palms as have been gathered by Mr. E. S. Hart at Federal Point, all prove that in years to come central and southern Florida will have gardens wherein will be displayed whatever is beautiful and luxuriant in the semi-tropical vegetation of the world.

Our purpose, however, is not so much to speak of the future of gardening in Florida as to call attention to some of the possibilities of genuine landscape work with the abundant indigenous growth of the state itself. The grandeur of mountain

scenery is lacking, but the dense forests on rolling lands, the numerous lakes and rivers, the abundant broad-leaved evergreen trees, the Palmettos, which are characterized by a grace and stateliness rarely equaled, furnish material which can be combined in pictures of infinite variety and interest.

The home of Mr. A. H. Curtiss, at Talleyrand, on the bank of the St. John's River, a few miles from Jacksonville, well illustrates what can be accomplished by a careful study of the natural features of the region in the way of bringing out the beauty that was waiting to be revealed. About the house are disposed many rare and beautiful plants, but they add little to the general effect produced by the broader treatment of the grounds. Back from the river bank, which is covered with low trees and shrubs, among which Honeysuckle and Smilax clamber, with yellow Jessamine rioting over all, is an open space, and beyond this is the Orange-grove, which forms a feature of the grounds of every home in Florida—and a grove of healthy Orange-trees, with glossy foliage and golden fruit, is a spectacle of which the eye never tires. Behind this is a heavy forest of Live Oak, Water Oak, Hickory, Magnolia and Red Bay. The rich undergrowth of small trees and shrubs—Holly, *Andromeda feruginea*, Sweet-leaf, Vacciniums and a score of other shrubs, with inter-twining vines and a more modest growth of Scrub Palmetto, Partridge-Berry, Ferns and other lowly plants upon the forest-floor are all allowed to remain and encouraged to grow. Winding roads are cut through the woods, opening here and there, to give glimpses of the Orange-grove framed in with moss-draped branches of the Oaks, or of the broad river with the thickly-wooded banks beyond, or of some striking object like a great Magnolia, which is remarkable for its size and for that dignified expression that only comes to these trees with great age.

There is little more to be said; for it would be impossible, even if it were not outside of our present purpose, to give any adequate idea of the beauty of these distant pictures, or any satisfying description of the fine native trees in the forest or standing in loose groups about it. The lesson to be enforced is that whether in the low levels of the South, or on the rocky coast of New England, or in a glen among the Alleghanies, the aim should not be to transform home-grounds into something foreign or fanciful, but to unfold and enhance the native and peculiar beauty of the spot; to develop its own beauty rather than to decorate it with imported ornament. This is not an easy achievement, it is true. It implies an artist's sense, and it means an ability to treat nature with respect, if not with reverence. Surely one who agreeably leads you to a point where you unconsciously pause before a well-composed picture from which all incongruities are shut out by a frame of foliage, is accomplishing what the landscape-gardener aims at in his best constructive efforts. Many who attempt this kind of work in Florida or elsewhere will fail of very high attainment; but they will not be in such danger of displaying impertinence and pretentiousness as will those who endeavor to obliterate from their land everything that is distinctive, and rid it of everything common, so that they can trick it out in exotic finery of their own choosing.

The Art of Gardening.—An Historical Sketch.—III. Egypt and Mesopotamia.

AFTER the isolation in which the Egyptians lived during the earlier centuries of their civilization had been broken through—after their kings entered upon that long series of foreign conquests which the monuments so lavishly celebrate—exotic plants were cultivated as well as those native to the valley of the Nile. The Rose, for example, was not a native of Egypt, nor can we guess at the date of its introduction, yet in later years it was very largely exported to Rome. The sacred Lotus itself was probably an exotic; and on certain bas-reliefs we see large trees in pots which are being transported by water, thus illustrating the statement that the triumphant armies of Egypt brought home from other lands such plants as struck their fancy, and placed them as trophies in front of palace or temple.

Flowers and ornamental plants were used in profusion, not only to enliven the Egyptian garden, but to perfume and adorn the apartment. The Rose was doubtless a prime favorite, but no plants were so beloved as the Lotus (see page 172) and the Papyrus. These grew in masses in the Nile, and were cultivated in every canal and basin. And the degree to which they were employed in sacred ceremonials is proved by the direct influence they had upon architectural development. We are all familiar with those Egyptian capitals which simulate an open Lotus-flower or a closed bud, and with the reeded shafts which show so strong a likeness to bundles of Papyrus

stems. But neither of these forms is found in the earliest monuments, nor would they readily occur to an architect under ordinary conditions. Their existence is best explained by the belief that the plain shafts and rectangular capitals originally employed were decorated for festivals with sheaths of reeds and wreaths of blossoms, and that the charming effects thus produced were afterwards translated into stone.* Thus gardening paid back to architecture a portion of the debt it owed for its own development. It is hardly needful to refer to the frequency with which Lotus blossoms appear in Egyptian picture records, held in the hands of priest and king during the performance of the most sacred rites. There is abundant testimony—graven, painted and written—to prove that flowers, and especially the Lotus, were thought essential to every act which the Egyptian performed in life, and followed him even into the grave. Only a few months ago withered garlands of Roses were unearthed from certain tombs in Lower Egypt—tombs which date, indeed, from perhaps the third century after Christ, but nevertheless embody the traditional customs of a far earlier time.

When we pass from the gardens of Egypt to those of Babylonia and Assyria, historical evidence is not so rich, but still convinces us that formal arrangements prevailed. There was as much reason here as we found in Egypt why picturesque and varied effects should not have been desired, and why gardening should have been the handmaid of architecture. Here again was an immense, flat, featureless country, peopled by a race of mighty builders.

Nothing that existed in all antiquity was more famous than the "hanging gardens" of Babylon. They are as well-known by name as the Pyramids of Egypt, and, like the pyramids, were counted among the Seven Wonders of the World. Yet not a trace of them remains on the site of Babylon, unless it be in certain foundation walls which have been assumed to belong to them; and from the historian's page we can scarcely gather much accurate knowledge. They were designed in harmony with the design of the Chaldean temple—in the form of a great square, artificial mound, the several stages of which, rising one above the other, rapidly decreased in size, leaving wide terraces on all four sides. Strabo thus describes them: "The shape . . . is a square, and each side of it measures four plethra. It consists of vaulted terraces raised one above another, and resting upon cube-shaped pillars. These are hollow and filled with earth to allow trees of the largest size to be planted. The pillars, the vaults and the terraces are constructed of baked brick and asphalt. The ascent to each story is by stairs." Modern artists, relying on this passage, have often pictured the terraces as flanked by rows of great stone columns, and their fantasies have been reproduced even in serious histories of gardening, whose authors, while diligently consulting all records which deal professedly with this art, do not seem to have thought it needful to study architectural evidence with regard to architectural facts. Columns were not used in Babylonia, where no building stone existed,† and were rarely employed even in Assyria, as, though stone could readily here be obtained, the Assyrians clung to the precedents of Babylonia whence their civilization had been derived. "Many stately rooms of all kinds," says Diodorus, whom other writers confirm, were constructed along the sides of the terraces; but we must believe that their arched roofs were supported by solid piers, not columns. Or, as the picture-reliefs show a frequent use of slender shafts, constructed of metal or of wood sheathed with metal, to support the walls or porticos of small pavilions or kiosks, the apartments may have been flanked by projecting pavilions thus sustained. The surface of each terrace was covered with a coat of bitumen to prevent the percolation of water into its mass of sun-dried brick; and upon this was laid a stratum of earth thick enough to nourish flowers, shrubs, and even large trees, among which the Cypress and the Palm were doubtless most conspicuous. Strabo says that at the sides of the stairs were "water engines by means of which, persons, appointed expressly for the purpose, are continually employed in raising water from the Euphrates into the garden; for the river . . . flows through the middle of the city and the garden is on the side of the river." And Diodorus says that one of the apartments "had in it certain engines whereby it drew plenty of water out of the river through certain conduits and conveyances from the platform of the garden, and nobody without was the wiser or knew what was done." Nevertheless, we cannot fancy any extensive hydraulic machinery. No trace of preparation for such machinery—no tanks, canals or conduits—have been found in the great artificial mounds which supported the palaces of

Assyrian kings. The most recent historians believe that their enormous water-supply must have been carried up from the adjacent Tigris by endless files of human beings; and thus, too, the hanging gardens of Babylon must have been watered; or, at the most, such simple hand machines and wheels as are still used on the banks of the Nile may have served to pass the buckets up from one terrace to another. Direct architectural evidence apart, it seems unlikely that large tanks and conduits could have been constructed in a land where unburnt brick was the main building material and stone was used merely to face the lower portions of interior walls.

The walls of the terraces were twenty-two feet in thickness, and tradition has given them an enormous area. But if we accept even the widest measurements of ancient writers (who were more prone to exaggeration than to understatement) we can compute them to have covered a space not much exceeding three acres; and even if this denotes the size, not of the lowest but of the uppermost terrace, it does not mean a very large garden, according to modern ideas. Yet when we consider the wholly artificial and very singular method of their construction, and the surprise a traveler must have felt to find a garden of any size flourishing under such difficult conditions, we can easily see how the hanging gardens won their exceptional fame.

The history of Mesopotamia falls into three great periods—those of the early Chaldean or Babylonian dominion, of the Assyrian or Ninevite empire, and of the second Chaldean empire, when Babylon more than renewed its ancient power and splendor. The hanging gardens of Babylon were associated in all classic times with the name of the fabled Semiramis, and their origin was sometimes carried as far back as the year B. C. 2000, into the period of the first Chaldean empire. But even Diodorus saw the folly of this idea and attributed them to the second period of Babylon's glory. A plausible supposition is that they were built by Nebuchadnezzar, the mightiest monarch of this second period, who left his capital the most splendid city in the world, to console his wife, a Median princess, for the loss she suffered when she left the mountains of her native land for the level plains of Mesopotamia. But, in truth, nothing is known of their origin or its date. They were still flourishing in the time of Alexander, but perished, we can imagine, when ruin overtook the town, even more quickly than its other vast monuments, constructed like themselves of thick cores of crude brick, only slightly protected from drenching rains and scorching suns by a facing of kiln-dried brick or of stone.

Foreign Correspondence.

London Letter.

THE meeting of the Royal Horticultural Society on March 12th was of exceptional interest, because of Mr. J. Gilbert Baker's lecture on the Saxifragæ. That the addresses by specialists, which form part of the Society's programme for the year, are likely to promote the welfare of the Society, as well as of horticulture itself, was plainly indicated by the number of fellows and visitors who assembled to hear Mr. Baker's lecture. Saxifragæ do not appeal with much force to the popular gardening spirit, although both Mr. Baker and his scientific view of the genus and Mr. George Paul in his instructive practical paper on the cultivated Saxifragæ made it abundantly clear that the genus is eminently worthy of general cultivation. The geographical distribution of the 180 species recognized by botanists, the diversity of character in habit, foliage and flower, the beauty of the flowers of many of the species, and the comparatively few hybrids known, were the principal points dealt with by Mr. Baker. About ninety species are in cultivation, the best of which belong to the section *Kabschia* of Engler, and of which *S. Burseriana*, *S. media*, *S. marginata*, *S. casia* and *S. Tombeanensis* are examples. In the group called *Porphyron* we have the pretty *S. oppositifolia*, *S. retusa* and *S. Pyrenaica*. These are all cushion-like in habit and bear numerous large Primula-like flowers. *S. pyramidalis* and *S. longifolia* are the best of another group, which is characterized by rosettes of longish foliage and tall, graceful, pyramidal racemes of beautiful white flowers. *S. pyramidalis* is one of the most beautiful of all plants for the rockery, and even when grown in pots for the green-house it has few rivals. Mr. Paul's paper was devoted chiefly to showing how easily Saxifragæ, as a rule, may be cultivated in an ordinary garden. Both these papers, as well as two others by specialists on the cultivation of Saxifragæ, will be published in full in the resuscitated journal of the Society, the first number of which was

* See Perrot and Chipiez, *History of Ancient Egyptian Art*.

† See Perrot and Chipiez, *History of Art in Chaldæa and Assyria*.

issued on Tuesday last. The revival of the Journal is a most commendable step, and cannot fail to do the Society good.

There was a fair number of interesting plants exhibited as well as some excellent groups of cut flowers, the Daffodils being the great attraction. A superb strain of Persian Cyclamens was sent by the St. George's Nursery Company, Hanwell, the flowers being remarkable for their large size and their purity and wide range of color. Market growers in the neighborhood of London are wonderfully successful with Cyclamens, and in the last ten years the improvement made in the form, size and color of the flowers has been considerable. *Clivia* (*Imantophyllum*) *miniata*, var. Lady Wolverton had the honor of receiving the first certificate awarded by the Society for a seedling *Clivia*. It is by far the handsomest *Clivia* I have ever seen, not forgetting the many fine varieties shown at the great Ghent Exhibition in April last. It bore three enormous heads of large, full, well-formed flowers, the segments overlapping and spreading so as to form a perfect limb, such as florists delight to see. The color was bright orange-scarlet, yellow in the throat. In Belgium and in France the *Clivias*, and particularly *C. miniata*, have been favorite garden plants for many years. The latter species was introduced from Natal by Backhouse, of York, in 1854. In 1877 Van Houtte distributed a hybrid raised from *C. miniata* and *C. nobilis*, which was named *C. cistanthiflora*. It blooms at Kew every spring, but it is not much better than the last-named parent as a garden plant. All the best *Clivias* are seedling forms of *C. miniata*. They are fast coming into favor in England on account of the time they flower (February to April), the length of time the flowers last and the bright colors of some of the forms. Amongst the best are Ambroise Verschaffelt, Marie Reimers, Van Houtte, Baroness Schröder, Sovenir de F. Vervæne, Madame Lemoir, Joseph Spæe and Madame Donner. They grow and flower best when treated as intermediate plants.

Other plants were Amaryllis, John Ruskin, a new Veitchian seedling with broad, rounded petals, the flower very large and crimson in color; *Iris Rosenbachiana* of the Persica group, dwarf, with mauve standards and stigmas, the falls orange and purple, said to be quite hardy, having been tested by Barr & Sons, Covent Garden, who exhibited several plants in flower; *Primula petiolaris*, a pretty little Alpine species, with a tuft of Auricula-like leaves and a cluster of short stalked, large, pale violet flowers—a new introduction, and, if easily cultivated, likely to become popular with all who admire Alpine plants. *Mutisia clematidis*, a most delightful climbing composite, with the leaves of a Vetch and large pendant flowers, in which the thick-spreading scarlet ray florets are like those of a single Dahlia, the disc florets being almost entirely hidden in the long urceolate involucre. To botanists this last was much the most interesting, *Mutisia* being the only genus of *Compositæ* in which the leaves bear tendrils. Horticulturists know the difficulties of successfully growing *Mutisias* in England. *M. decurrens* is one of the most beautiful of all hardy plants; so, too, is *M. ilicifolia* and *M. grandiflora*. Probably you know more about these plants than we do. In a few gardens one or other of those named are a success for a time, but they perish suddenly, just when one begins to feel that he has established them. If *Mutisias* are in American gardens, all lovers of hardy plants in England would be thankful for information concerning them.

Cypripedium Rothschildianum was exhibited in flower. It is a magnificent plant. The dorsal sepal two by two and a half inches, buff-colored, with deep crimson lines, the lower sepals smaller, but similar in color; the petals are six inches long, and half an inch broad at the base, from which they are gradually narrowed to a deflexed point, their color being buff, with crimson longitudinal lines and basal spots; the pouch is like that of *C. Stonei*, but vinous purple in color; and the curved, beak-like rostellum is most remarkable. The plant is as robust in growth as *C. Stonei*, and the scape is erect, stout, a foot long, with two flowers.

By its side was a plant, also in flower, called *C. Elliottianum*, but I have good grounds for suspecting that some mistake has been made in regard to the plants introduced and sold under this name. There can be no mistake about the type plant which was described by Professor Reichenbach and figured by Mr. Moon, a thoroughly trustworthy artist, who has drawn hundreds of *Cypripediums*, and who told me that *C. Elliottianum* was, in his opinion, the most beautiful of all. The type had white sepals with dark red lines, drooping petals, white, with purple stripes and freckles, and a brown-red pouch. But the plant shown under this name was simply a diminutive pale-colored form of *C. Rothschildianum*. The probability is that two distinct species have been collected and sold under one name. A splendid example of *Dendrobium nobile*, var.

Wallichianum, was exhibited as a proof of the wisdom of pruning, so far as regards the cultivation of this species and its nearest allies. The specimen was four feet in diameter, and bore about eighty flowering pseudo-bulbs, each over two feet in height and bearing numerous fascicles of flowers. There must have been at least a thousand fully-opened blooms upon it. All the pseudo-bulbs, save those in flower, had been removed, and the grower stated that these will be cut away as soon as the new growths push new roots. A hybrid *Cymbidium* from the Messrs. Veitch combined the characters of its parents, *C. eburneum* and *C. Lowianum*, but was inferior to both; the sepals and petals are pale buff, the lip creamy white, with a rone of dull crimson and a white margin.

Dendrobium Schneiderianum, a Veitchian hybrid obtained from *D. aureum* and *D. Findlayanum*, was shown in flower. It is dwarf in habit, the flowers are in fascicles of about three, and are somewhat nodding; they measure nearly three inches across, and are ivory-white, with pink tips to the sepals and petals, the lip having a yellow throat and a blotch of purple in front.

The last of the Chrysanthemums appeared under the name of Mrs. J. N. Gerard, and was labelled as of American origin. The flowers were of the flat Japanese type, six inches across, lilac-purple, with pale tips, and chiefly remarkable for their lateness.

Kew, March 16th.

W. Watson.

The Oriental Nelumbium Naturalized in America.

IN the early days of my enthusiasm for aquatic plants I read an item in a foreign horticultural journal stating that *Nelumbium speciosum* had been successfully grown in the open air and had withstood the winter unharmed in the "Jardin des Plantes" at Paris. In January, 1876, while in that city, I made a search to ascertain the truth of the statement, and found an artificial basin five or six feet in diameter in which were standing the dead flower-stalks and decaying foliage of the *Nelumbium*. There was one inch of ice upon the water of the pool at the time, and it was but natural to infer that the plant would prove hardy where lower temperatures prevail in winter than at Paris. During the next few years I cultivated the *Nelumbium* successfully in my garden here and proved its hardiness when its tubers are not exposed to actual freezing. I found that a temperature causing the formation of ten inches or more of ice on the water above the dormant tubers was no obstacle to successful cultivation. Having seen large ponds filled with masses of our native species (*N. luteum*) a desire arose to see how this foreign floral treasure would behave under like conditions.

Two miles from my present home is an artificial pond, a secluded corner of which was selected for the experiment. Many years ago this spot was rich meadow-land, where farmers were accustomed to cut hay. The soil is a dark, greasy clay, and, since the formation of the pond, has been made richer still in vegetable matter by the deposit of sediment in time of freshets by the wash from adjoining hills. *Nuphar advena* was the principal aquatic plant growing there. By the courtesy of the farmer who owns the property the experiment was made, and about nine years ago a single plant of *N. speciosum* was placed in the centre of the little cove where the water is from one to two feet deep. It soon became established and began to spread in all directions, blooming profusely each year. One summer it was nearly destroyed by cattle from an adjoining pasture. They found the foliage a sweet morsel, waded in, and ate it all down.

In a year or two the plants recovered and went on making their marvelous growth, and during the past summer and autumn they showed a solid mass of magnificent foliage and bloom, covering three-quarters of an acre. Last August, at the height of the blooming period, about 500 of the beautifully-shaded pink flowers were open at once. In their last stages of expansion they measure from ten to thirteen inches in diameter. They stand from three to six feet above the water, and in some instances, flower-stalks pulled from their base in the mud, measure eight feet in length. Multitudes of leaves are found twenty-four to thirty inches across, and one season I found a leaf which measured thirty-six inches in diameter. The tallest man is hidden from view when walking through the mass of foliage. Not content with remaining in the water, an occasional plant will creep a few feet out into the thicket of Alders and wild Roses on the bank, apparently satisfied with a moist soil without water on the surface. When the frosts of October arrived a few buds were caught still unexpanded.

Such a tropical aspect does this plant here present that one would scarcely be surprised to see Palms and Bamboos growing upon the shores of the pond. Could similar pictures be reproduced in the parks of our large cities they could not fail to attract the admiring attention of thousands of people.

I believe that the day is not far distant when this so-called "Sacred Lotus" and its beautiful varieties will be as universally cultivated and as popular in America as they now are in some eastern countries. I may here mention one of its habits which would seem to furnish an example of "vegetable intelligence." During the summer the slender rhizomatic stems spread horizontally in every direction, but at only a moderate depth in the soil. Upon the approach of autumn the growing points of these rhizomes descend to a much greater depth (sometimes eighteen inches), and there the tubers are formed which lie dormant until late in spring, when an increase of temperature induces a new growth. This new growth immediately reascends to the normal level, and the process of horizontal growth is repeated. Is this not a design to preserve the tubers from freezing and the depredations of animals? The accompanying illustration was made from a photograph taken in August, 1888, and does not show the entire plantation.

Bordentown, N. J.

E. D. Sturtevant.

and no other plant has played so prominent a part in the ceremonies of royal life, in the rites of religion, or in the development of art.

Many kinds of Water-lilies were familiar to the ancient Egyptians, and the name Lotus seems to have been given to them all. Among them were *Nymphæas* analogous to our common white and yellow Water lilies, and also a species with blue flowers (*N. carulea* or *stellata*), and another which was either red or white with red-streaked sepals (*N. Lotus*). But the true Egyptian Lotus, the "Sacred Lotus" of the whole East, is the plant with rosy flowers which Linnaeus called *Nymphæa nelumbo*, but modern botanists have placed in another genus and called *Nelumbium speciosum*. This no longer grows wild in the Nile, and, perhaps, was not a native of Egypt. It appears in very early pictures produced at a time when Egypt was

The Sacred Lotus in New Jersey.

[We have more than once alluded to the great service rendered to American horticulture by Mr. Sturtevant in popularizing the cultivation of the finest aquatic plants in this country. A still greater service is his demonstration of the fact that the beautiful "Sacred Lotus" can be naturalized here. Its hardiness having been demonstrated, there is now no reason why this Lotus cannot be made to cover shallow ponds from Cape Cod through all the coast-region of the middle and southern states; or why this beautiful plant may not become as conspicuous a feature in American life and art as it is in those of Japan, where, although doubtless introduced from continental Asia, it is as widely spread as any indigenous plant. If the Bordentown experiment proves to be the precursor of many thousand more, as it is sincerely to be hoped that it may, Mr. Sturtevant's name will deserve to live among those of men who have made valuable contributions to American civilization.

As far back as written history or the picture-records of ancient peoples reach, the "Sacred Lotus" may be found;

practically shut off from the rest of the world; and if it was, indeed, an exotic, must have been introduced in those primitive days when this part of the world was being peopled, or re-peopled, by tribal immigrations from the East. But there is nothing improbable in such a supposition. Tree-worship was one of the very earliest forms of religion, and where trees were adored certain flowers may well have been held sacred and have been transported from place to place, together with such herbs and roots as had proved themselves possessed of healing properties. The Lotus seems to have been revered in India as well as in Egypt from the dawn of history; and it is not impossible that it traveled from the former country—where we know it is indigenous—to the banks of the Nile at a time so remote that even Egyptians of the earliest historic dynasties may have believed in its local origin.

The difference in habit between this plant and the *Nymphæas* will readily be appreciated from our illustration. "It is at least one-third larger," says an observer who has

studied it in Egypt,* "than our common Water-lily, from which it differs also in the behavior of the leaves and of the stems which bear the flowers. These do not float on the surface of the water, but rise above it to a height of from twelve to fifteen inches. The flower, which stands higher than the leaves, is borne upon a stalk which, instead of being soft and pliant like that of the Water-lily, has the firmness and consistency of wood. It has an agreeable smell like that of Anise. In the bas-reliefs the Egyptians are often seen holding it to their nostrils. The fruit, which is shaped like the rose of a watering-pot, contains seeds as large as the stone of an Olive. These seeds, which were eaten green or dried, were called 'Egyptian Beans' by the Greek and Latin writers because they were consumed in such vast quantities in the Nile valley. . . . Even the root was not wasted; according to the old historians it had a sweet and agreeable taste."

Herodotus compares the seeds of the Nymphæas to those of the Poppy. They, too, were eaten, being pounded in a mortar and made into a kind of bread. But neither of these plants should be confounded with the Lotus which formed the food of the so-called *Lotophagi*, in Ethiopia, and has been so widely celebrated for its Lethe-like effects by ancient and modern poets. This was the "Lotus-tree," which Pliny says some persons identified with the Celtis, but which modern commentators believe to have been the *Rhamnus Lotus* of Linnæus, the *Zizyphus Lotus* or more recent botanists.†

The extensive thickets which the Lotus formed along the banks of the Nile are frequently pictured on Egyptian monuments, with men in boats hunting aquatic birds and animals among their crowded stems; and ancient writers tell us that popular festivals were held among these green and rosy water-groves. Constantly when sacred ceremonies are portrayed, Lotus-flowers are held in the hand of the chief figures. They were the symbols of generation, life, resurrection and immortality, and therefore consecrated to Osiris. The four genii of the future world are sometimes depicted standing upon them, and they likewise form a seat for the infant Horus, while historians tell us that they were appropriately presented to the guests at funerals.

In Assyrian and Persian sculptures the Lotus is almost as conspicuous, alternating with the Pine-cone as an accompaniment of the most solemn rites. In India, again, we find the same thing—constantly the Lotus occurs, and its sacred character is always apparent. Hindu legends say that Brahma came forth from its blossom, and Sri and other gods are sculptured sitting upon an open flower and holding buds in their hands. Buddha is likewise thus portrayed, and, according to some accounts, first appeared floating on this mystic flower.‡

Perhaps it was the spread of Buddhism which carried the Lotus to China and Japan. But from whatever place it came and at whatever time, it soon grew to be as familiar and beloved as it had been at home. At every step in Japan one finds great tanks filled with the Lotus, and in many religious ceremonials it has its function, while the peculiar grace of its habit and its beauty of form and color in leaf and bud and flower and fruit, added to its religious significance, have made it chief among the artist's models. Countless works of Japanese art are based, palpably or remotely, upon the Lotus, from the delicate lines of the surface-decoration applied to some tiny object or the pattern on a woven stuff, to the great bronze vase in which

the living plants are grown. Our illustration on page 175 shows such a vase or tank, which was brought to New York a few years ago by the late Mr. Edward Greey.* Nothing could be more beautiful than its outline, faithfully copied from nature, yet admirably adapted to the chosen purpose; nor could a more splendid piece of decoration be imagined for a public park or the terrace near some stately mansion than such a vase filled—as we now know it could be filled—with the "Sacred Lotus" of the East.

But it is not alone in Japan that the Lotus has conspicuously entered into decorative and instructional art. Its portrayal as a sacred emblem was not the only manner of using it in Egypt. On page 170 will be found a reference to the vital part it played in the development of Egyptian architecture, while in all the decorative work of this country it is the dominant and sometimes almost the only motive employed. The leaf, the bud, the flower and the fruit-pod, all were conventionalized in the most artistic way, and woven into the most graceful and harmonious patterns. The same is true to a lesser degree of Assyria, Persia, India, Phœnicia and Cyprus. Lotus motives are of common occurrence on the Cypriote vases in the Metropolitan Museum. Doubtless the sacred character of the plant had much to do with its universal adoption in art; but must not the artistic instinct have been keen among peoples who first chose so exceptionally beautiful a plant as a sacred emblem, and then adapted it so admirably to the painter's the sculptor's and the architect's use?

The subject of architectural development is too wide and complicated to be here examined. But we may at least briefly say that some writers believe that Lotus-forms, starting from Egypt, vitally influenced in later ages the course of Assyrian and even of Greek architecture. They believe, for example, that the so-called palmettes, rosettes and anthemions of the Greeks were derived not from the Palm-tree but from the Lotus, and that even in the Ionic capital we may see a conventionalized reproduction of its downward curling sepals or petals, with its clustering stamens or petals in the centre.†—Ed.]

Cultural Department.

Why Seeds Fail to Grow

THIS question is a vital one, and pertinent to this time, when all farmers and gardeners are preparing their soil for planting seeds. We all know that a large proportion of the seeds sown fail to make plants, and for this there are many reasons. In the first place, many seeds sold and sown have lost vitality because of age. It is not an uncommon practice for seedsmen to sell from a given stock until it is used up. No matter how old a dealer's seeds may be, they are liable to become mingled with the new. This is particularly true of what are known as commission, or "box seeds." Many seedsmen endeavor to build up a large business by selling cheap seeds, instead of giving customers seeds perfectly fresh, and of choice selection, so as to remove one cause of failure.

Again, through climatic influences, or some other condition of growth, many seeds are abortive, or have a low vitality, from imperfect development. For instance, nearly all the Sweet Corn grown the last year germinates badly. On an average it will not test more than two-thirds the usual percentage of sound seed. The same is true of many other seeds. These are simply misfortunes, for which neither seedsmen nor planter is in fault.

But, after all, the main cause of failure is the planter himself. He fails to comprehend the needs of newly-sown seeds. His success should be in proportion to the care he has given to the preparation of his ground. But the very fineness to which he reduces its particles adds a new danger to the seed, unless soil and seeds are closely compacted together. Neglect to firm the soil about seeds is the main cause of failure to germinate. Peter Henderson's paper on "The Use of the Feet in

* Perrot and Chipiez, *History of Art in Ancient Egypt*, vol. ii., p. 124.

† "It is about the same size," says Pliny, "as the Pear-tree. . . . The fruit is about the size of a Bean. . . . It has branches thickly set with leaves like the Myrtle. . . . In the country where this tree is indigenous the fruit of it is so remarkably sweet and luscious that it has even given its name to a whole territory and to a nation who, by their singular hospitality, have even seduced strangers who have come among them to lose all remembrance of their native country. . . . A wine is also extracted from this fruit very similar to honied wine. . . . Such is the tree that is so-called in Africa, the same name being given to a certain herb," which was probably Melilotus, a leguminous plant, "and to a stalk that grows in Egypt belonging to the marsh plants." This stalk, of course, is the true Lotus.

* This picture was prepared for Mr. Greey's pamphlet on *Japanese Bronzes*, and shortly before his death he kindly consented to its reproduction in GARDEN AND FOREST.

† See W. H. Goodyear, "The Lotus in Ancient Art," *American Architect and Building News*, February 9th, 1889, et seq. These articles are extremely interesting from the point of view of art; but the author has not clearly seen the general difference between the Nelumbium and the Nymphæas. Nor can there be any doubt that the Nelumbium was the true "Sacred Lotus" of Egypt. The witness of all Oriental nations would suffice to prove the fact.

Sowing and Planting" has been of great value to the planter. By following his instructions, loss of seeds, loss of time, loss of crop, and loss of patience can be avoided. The reasons why firming the soil around the seed when planted are so important, can be easily understood. There is stored up in every perfect seed a latent germ, the development of which is conditional upon the presence of proper proportions of warmth,

puts forth furnishes the young plant with food ; it simply holds the plant in position until the true or feeding roots are formed. The seed itself contains sufficient food for the infant plant, until its true leaves and roots are formed.

The feeding rootlets of any plant are delicate fibres, and their furniture of root-hairs is never seen by the casual observer. Now, when the rootlets are formed, if the soil is not

A Japanese Lotus Vase.

air and moisture. When any seed is put into the ground, and loosely covered with light, dry soil, it is exposed to drying winds which carry away the moisture, while the same circulation of air prevents the persistent warmth which is needed to promote the chemical action needed for germination and growth. It often happens that seeds germinate without making growth afterward. When growth commences it is in two opposite directions, upwards into the atmosphere, and downwards into the earth, the two sources from which plant-food is supplied. It is a mistake to suppose the first root the seed

pressed firmly around the main root, the feeders have nothing to hold to or live upon, but dry up and perish in the open spaces between the loose-lying particles of soil. When the earth is closely packed the young rootlets at once find moisture, which contains food, and find support, as well, in the thin crevices through which they feel their way. In thinning out plants where they have come up too thickly in the seed-beds, the feet should always be used in pressing the soil firmly around the plants left.

Deep planting is another cause of the seed's failure to ger-

minate or to grow after having started. The importance of more care in this direction cannot be overstated. Observation and experiment made in planting various seeds at different depths show some wonderful results. Take, for instance, Sweet Corn, and in planting several rows, cover from one-half inch in depth to five inches. The first will germinate without a loss of five per cent., while the last will not grow five per cent., and an almost exact ratio will hold between the increased depth and the percentage of failure; at the same time, the vitality of the plants will vary in the same proportion as the germinating properties. The cause for this difference is, that at the season of Corn-planting sufficient warmth is not found much below the surface. Again, Corn planted at a depth of three or more inches will not make as rapid or healthy growth as when covered only half an inch or one inch, because it makes two sets of roots—surface and underground roots—the one being quite as important as the other. The surface roots form at the first joint, just above the kernel, when it is covered to the depth of three inches; this joint is below the surface, and the plant ceases growth until a new or unnatural joint is formed at the surface of the ground, from which these roots proceed. When Corn is planted in mellow ground the hoe should never be used in covering, the feet being the best implement that can be employed for the purpose. When the Corn is dropped, with the foot scrape sufficient earth over it to cover to the depth of half an inch, then step on the hill in such a manner that it will get the whole weight of the body, and the work will be well done. The same rule will apply to the planting of many other seeds. The diameter of a seed is generally the proper depth for its covering when planted.

Mechanical assistance in planting will often help the germination of seeds, and consequently the growth of plants. If seeds of squash and the like are put in the earth endwise and germ down, they will sprout much sooner and with more certainty. It is true, also, of Lima Beans, that when planted edgewise and eye down they come up more quickly and surely.

Pertinent to this time and subject is a word on transplanting, as it shows the importance of firming the soil around the roots of young plants. Last year in GARDEN AND FOREST, I gave a few hints on transplanting, taking the ground that the proper time for this work is in pleasant weather rather than a rainy day. I stated then that plants, when removed from the seed-bed into the position they are to occupy, should be puddled in, and that the earth should then be pressed around the roots, after which loose dry earth should be scattered around the plant to prevent evaporation. I never put out plants in any other way, and never lose one; while plants set in a rainy day often fail, unless the rain is very heavy after transplanting, so that by its own force the earth is thoroughly packed around the roots. If plants are taken up when the soil is quite dry it drops from the roots without injury; on the contrary, if wet and heavy it carries away, in parting, many of the fine roots with it, and from this injury the plant is slow to recover.

But a few days since a gardener from Long Island thanked me for the article of last year, saying that he followed the instructions to the letter, put out the plants on a pleasant day without discomfort, and did not lose a single plant, and had the largest and finest crop of cabbage and cauliflowers ever known in that section. His neighbors, who waited for a rain, had only half a crop.

In cases of failure in germination the blame is usually charged upon the seedsman. He is sometimes guilty, but I am convinced that fully ninety per cent. of the failures result from improper methods of sowing and planting.

Garden City, N. Y.

C. L. Allen.

Palms.

A LITTLE extra care given to this class of plants at this time of the year will be well repaid by a more vigorous growth and greatly increased beauty during the remainder of the season. Cleanliness is absolutely essential to their welfare at all times, but especially now, when careful washing with a sponge will effectually rid the plants of the various insect pests, such as scale in variety, and mealy-bug, so often found upon them. Thrips and red-spider, though capable of doing much injury to the foliage, are not often found in quantity when the plants are syringed regularly and thoroughly. By giving this work proper attention now, much labor will be saved later in the season and finer plants secured. There is a difference of opinion as to the best wash to use. Many growers consider "Fir-tree Oil" the most efficacious, but although this is undoubtedly good, it will be found more expensive and also more likely to injure the tender young foliage than a solution of whale-oil soap. The kerosene emulsion has also been

tested for this purpose, but needs careful preparation, and its use is also attended with some danger when the mixture is allowed to remain on the foliage for any great length of time. A similar objection holds against the use of a carbolic acid solution, although it has proved most effective in some cases. If not already re-potted, this work should be attended to at once, since active root-growth has commenced, and if the plants are allowed to become very much pot-bound the foliage will soon lose color and become more or less stunted.

Clean pots should always be used, and they should be well-drained with potsherds, cinders, charcoal or some similar substance, because a majority of Palms luxuriate in an abundance of water at the root as well as overhead during the growing season. If any plant should be found with unhealthy roots, the old soil should be shaken out or washed off the roots, and the plant should then be re-potted in as small a pot as possible, care being taken to work the new soil firmly in among the roots. Where a rapid growth is desired, it will be found best to make the compost rather light, by the admixture of about one part of peat to two of loam, and some good sharp sand, with the addition of one-sixth of the mass of short, well-rotted stable manure. If the space at hand is somewhat limited, it may be advisable to merely top-dress some of the larger plants, or to shift into a heavier soil than the above mixture, so that the plant will be kept in healthy condition without being encouraged to rapid growth. It will also be found necessary to give a light shading on the Palm-house quite early in the season; at least on the side exposed to the afternoon sun, otherwise the foliage of some of the more tender varieties may suffer, but it is well to avoid over-shading, particularly where some of the plants are used for house decoration, as the leaves become too delicate for this purpose, and consequently are soon disfigured.

As to general treatment, it may be added that Palms should never be allowed to become very dry, and during the growing season should be watered very freely, many of the stronger-growing sorts being benefitted by a good watering with liquid manure occasionally. This treatment, combined with a moist atmosphere, plenty of fresh air, and a temperature of sixty to sixty-five degrees at night, includes the most essential points of culture for those in general use, but is not intended to apply to all species without any qualification, as some of the delicate sorts require a special treatment.

W. H. Taplin.

Orchard Notes.

North and South Slopes.—There is a wide difference of opinion as to the best aspect for fruit. Some contend for northern slopes, some for southern, and both are right. The decision turns upon locality and varieties of fruit. Near large bodies of water late spring frosts seldom do damage. Spring comes on more gradually, evenly, and plants do not start so early. In such localities southern slopes are usually preferable. But away from such bodies of water spring temperatures are commonly more fluctuating, and plants start relatively earlier. Here northern slopes are usually best, as blossoming is retarded. This is particularly the case with early blooming varieties. I often hear people remark that in certain years the only peaches they had were on trees standing on the north side of a building. The reason is that these trees had blossomed late and had escaped late frosts. In many localities late frosts are more to be dreaded than severe winters, and the only successful practice comes from close study of one's individual conditions.

Atmospheric Drainage.—Cultivators usually overlook the fact that with many crops atmospheric drainage is fully as important as drainage of the earth. Cold air is heavier than warm air, and settles in the hollows. The chief reason why hills and slopes are better for fruit is because the cold air drains off. Hedge-like wind-breaks and natural barriers often obstruct atmospheric drainage, and late spring frosts and early fall frosts are the result. I have known a hollow to be drained of cold air, by a channel cut through a bank, with remarkable results.

Grafting Cherries.—A current horticultural journal says that Cherry-trees are very difficult to graft. I have never found them so. The buds swell early, and the grafting must be done very early, otherwise there is no difficulty. Cherry-tops can be changed as readily as Apple-tops. I often hear it remarked that stone fruits cannot be grafted, but the remark has no foundation. Did not Thomas Andrew Knight give us the practice of root-grafting as the result of experiments upon stone fruits?

Too Few Varieties.—It is good counsel that advises growers to set but few varieties, but the advice and practice may be carried too far. The number and kind of varieties must depend upon conditions, largely conditions of market. It is not good practice to set a variety simply because every one else does. Markets often demand a variety of products. Tastes change. Many apple-growers in western New York would have been glad of something besides Baldwins last fall. Plan a succession. Plan for various available markets, and a variety of ways of disposing of the crop. This usually demands more than one or two varieties. *L. H. Bailey.*

Cornell University.

Notes from the Arnold Arboretum.

THE season here is a very early one, at least twelve or fifteen days earlier than the average, and fully twenty days earlier than that of last year. There is hardly any frost in the ground, except in deeply-shaded situations, although it is unusually full of water. Broad-leaved evergreens and conifers, without exception, look unusually fresh and well; of deciduous plants it is still too early to speak with much confidence, as they rarely show the ravages of winter, until it is time for the leaf-buds to begin to swell.

The earliest shrub in flower (it has been in bloom for fully two weeks, and is still fresh) is the Japanese Witch Hazel (*Hamamelis Japonica*). As it now appears, covered with its bright canary-colored flowers, it is a cheerful and pleasing object, which may well find a place near the window of every northern home for this early cheerfulness, which does not succumb to hard freezing or to the inevitable spring snow-storm of New England. The Japanese species is very closely allied to our familiar American Witch Hazel, although the leaves are somewhat narrower, more inclined to be slightly lobed, of rather different texture and of a duller green. The flowers are produced in very early spring, instead of in late autumn, and the petals are narrower and perhaps brighter colored. In the flower on the Arboretum plant the calyx is yellow; but that it is sometimes purple or red appears from the figure of this species (*t.* 6,659) published in a recent volume of the *Botanical Magazine*. But this evidently is not a constant character, and was not considered by *Franchet & Savatier*, who discussed the differences between this and the American species (*Enum. pl. Jap. ii.*, 368). They found the best distinction in the number of the principal veins of the leaf; a character which does not, however, at all hold in our cultivated plants. The time of flowering very well separates the two species, however, for any garden purpose, at least; while the differences in habit and in the general appearance of the leaves are equally well defined and constant. *Hamamelis Japonica* becomes in its native country a small tree. It was introduced into Europe and thence to the United States by the Veitches. A third species (*H. mollis*, Hooker's *Icones Plantarum*, *t.* 1741) is one of the new discoveries in central China.

Erica carnea is beautifully in bloom, and so are the native and some of the foreign Alders. These were closely followed by several foreign species and varieties of Hazel, most of which bloom ten or fifteen days earlier than our native species. The two earliest (probably merely forms of the same species) are two north China and Manchurian plants, cultivated here under the name of *Corylus Manchurica* and *C. heterophylla*. They form neat, compact bushes, three feet high, with ashy-gray branches and handsome foliage, which turns brilliantly in the autumn. They now bear male and female flowers abundantly, so that there is a prospect for fruit, which has not yet been produced here. These are plants to be better known and more often seen in gardens, although, of course, they will never be favorites with people who only value shrubs for their showy flowers.

It is interesting, now that the winter is over, to look through the collection and see what plants have retained their fruit bright and fresh up to this time, and which are, therefore, the most desirable for the winter decoration of shrubberies. The list is not a very long one; six weeks ago it could easily have been made much longer, for it is the rains and the warm suns of February and March which cause the fruits of many plants to become discolored from decay. The fruit of *Berberis Thunbergii* is perhaps in the best condition of any in the collection. It is as bright and nearly as abundant as it was in November, and has not shrivelled perceptibly. The fruit has disappeared almost entirely from all the other species of *Berberis*. The scarlet fruit of *Viburnum Opulus* (the Cranberry-tree) is still hanging on the plants in considerable profusion, not having been devoured this year by birds, as is generally the case. The fruit shows the effects of hard freezing, but is almost as

bright in color as it was in the autumn. And this is true of the fruit of the Black Alder (*Ilex verticillata*), which birds do not seem to relish and which is still very abundant and fresh, making the plants conspicuous and beautiful objects. Many Roses a month ago were still covered with brilliant-colored hips, but these have now turned black on nearly all the species, native as well as foreign. The most conspicuous exception, however, is our common Swamp Rose (*Rosa Caroliniana*), which is loaded still with highly-colored fruit, and *Rosa repens*, with its slender, pear-shaped maroon hips. The fruit of *Rosa nitida* is still presentable, although less so than that of either of the species just named. Scarlet and red fruits seem to keep better, on the whole, than black ones (although, no doubt, the coincidence is quite accidental), but the exception is *Ligustrum vulgare*, whose jet black berries are as abundant and deeply colored now as at any time during the year. Birds, apparently, have nothing to do with them. The black fruit of *Cornus sanguinea* is still abundant upon the plants and fairly well colored, although losing fast its freshness. Of other black fruits there is hardly a trace left in the collection.

Among plants here which are conspicuous in winter on account of the highly colored bark covering their stems and branches, by far the handsomest and most desirable in every way is that variety of *Cornus alba*, sometimes known in nurseries of *C. Sibirica*. It is evidently a variety of the widely-distributed *C. alba*, but what its origin or history is I have not been able to discover. The bark is bright red, much brighter than that of *C. alba*, or of any other species of *Cornus*—a genus which furnishes some of the brightest objects which can be used for the decoration of winter gardens or shrubberies.

March 29th.

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

XV.—SEED-BREEDING.

AS we have already seen, a plant, for instance an Elm, is a community of individuals, and it possesses such a degree of unity between all the component parts, that in popular language we speak of it as an individual. This term "individual" can be used also in scientific language with convenience, and hence it is frequently customary to speak of a given elm, rose or phlox as an individual. When, now, we compare all the elms with all the roses and all the phloxes, we see at once that we are dealing with widely-separated kinds of individuals. These kinds are known as *genera*.

If, next, we restrict our observation to all the elms we know, we are struck at once by the existence of certain differences which render it necessary for us to divide the genus elm into minor groups, such as the Slippery-elm, the American Elm, the English Elm and the like. In the same manner we classify the roses into such groups as the Sweet-brier, the Dog-rose, the Prairie-rose, and so on. The phlox genus readily breaks up into such groups as Drummond Phlox, Panicked Phlox, Spotted Phlox, etc. These minor groups, into which the genus is divided, are known as *species*.

But these species comprise innumerable individuals which differ from each other in some particulars. For example, Drummond's Phlox is a species containing countless forms which differ from each other in the matters of color, height and smoothness. These divergent forms within the limits of the species are known as *varieties*.

It was formerly held by botanists that between varieties and species there exist absolute distinctions, but, of late years, the view has been gaining ground that species and varieties may grade into another. Between certain species there are numerous intermediate forms which conceal any line of demarcation. There are wide differences between the degrees of likeness and unlikeness presented by varieties; some varieties are almost like the general average of the forms which make up the species, while others are very different indeed.

There is another very marked difference between certain varieties: some of them can be perpetuated by seeds, while others cannot. The latter vary from the parent plant in many particulars, while the former come, as we say, "true to seed." Varieties which come true, or reasonably true, to seed are termed *races*. If, therefore, we have a choice race of plants, we can, with a fair degree of success, propagate it by means of seeds, and year after year we shall have substantially the same results. If, however, our choice form of plant is only a mere variety, we are compelled to propagate it by means of cuttings or by the transfer of buds in some way. In this manner we perpetuate desirable varieties of apples, pears and roses: by grafting or budding, by layering or by cuttings, as experience

has shown to be the best adapted to the particular case, the special features of the variety are kept with very little, if indeed any, change.

The question is still a mooted one, whether such choice varieties do not after a time wear out? The late Professor Gray was inclined to think that there are differences in this respect; some varieties appearing to lose a part of their distinctive characters, while others seem to maintain them with no loss whatever.

The close observer can, by careful selection of the seeds of the varieties of the plants which he has under cultivation, intensify nearly any given peculiarity which he wishes to keep. In other words, by selection of the forms which he thinks desirable, and using in successive seasons the seeds of those varieties only which he wishes to preserve, he can, within certain limits, direct the development of the variation. But there are two very important precautions which must be observed: (1) The pistils of all the flowers on the plants of the desirable variety must be fertilized by the pollen from flowers of the same plant, and (2) no pollen from other plants must be permitted to act on them. By this close-breeding variations can be led along up to a certain point, not always the same for all varieties, but in most cases where care is taken, the divergence from the ancestral type can be made very pronounced. It frequently happens that after several generations of this close-breeding the variety acquires the power of taking care of itself and can then come true to seed.

Now, as a matter of fact, this continuous close-breeding seldom, if indeed ever, occurs in a state of nature. There are a few plants which do not produce seeds to any extent; for instance, the common Horse-radish, the Banana, the Pine-apple and so on, but these have so long been under cultivation by bud-propagation that the formation of seeds has ceased or, at least, very rarely occurs. But when any variety of plant produces seeds, there is some provision for an occasional break in what might otherwise be uninterrupted close-breeding. As a result of this interruption, the varieties are crossed with others, which serve to check too great specialization. The gross result, then, of all the cross-breeding within the limits of the species is that the average is kept well up to the type of the species.

The varieties which we should cultivate if we had our own way are by no means those which are adapted to cope with their surroundings, in fact, their very specialization may wholly unfit them for success in the struggle for existence. In a state of nature, the varieties which we might regard as desirable to keep for our own wants are very likely to disappear after two or three generations by simply dropping out of a contest for which they are unfitted. In the majority of cases they are merged by cross-breeding with other varieties, and are thus brought up to the type of the species which, from the nature of the case, represents the form which is best suited to meet all the exigencies of the surroundings.

In nature, the cross-breeding between varieties of the same species is effected by the agency of the wind, insects, etc., which may carry the pollen of one variety to the pistil of another. The contrivances* for this purpose are among the most wonderful and complicated in organic nature. A comparison between the results of continuous close-breeding and cross-breeding can be made experimentally. Careful experiment must, for honest thinkers, outweigh all speculation and previous conceptions. Such experiments have been conducted by Mr. Darwin in the case of the common plant, Morning-glory, and the results can be readily seen in the following account:†

"The plants experimented upon in all cases were raised from carefully-ripened seed, and when ready to flower were placed under nets with meshes one-tenth of an inch in diameter, in order that all pollen-carrying insects might be excluded.

"A plant of *Ipomœa purpurea* (Morning-glory), growing in the green-house, was protected in the manner just described, after ten of its flowers had been fertilized by pollen from their own stamens, and ten others by pollen from a distinct plant of the same species. The seeds from the first ten flowers may be termed *self-fertilized*, those from the other ten, *crossed*. The two kinds of seed were placed on damp sand on opposite sides of a glass tumbler covered by a glass plate, with a partition between the seeds, and the glass was put in a warm place. As often as a pair of seeds germinated they were put on opposite sides of a pot, with a superficial partition between them, and the same procedure was followed until five or more seedlings of exactly the same age were planted on the opposite sides of several pots. The soil in the pots in which the plants

grew was well mixed, and the plants on the two sides were always watered at the same time; thus the seedlings were subjected to practically the same conditions from a very early stage.

"In the same manner, self-fertilized and crossed seeds were secured during ten generations. The results, so far as these can be shown by measurement of the plants, are exhibited in the following table:

IPOMœA PURPUREA.

Number of the generation.	Number of crossed plants.	Average height of crossed plants in inches.	Number of self-fertilized plants.	Average height of self-fertilized plants in inches.	Ratio between average heights of crossed and self-fertilized plants.
First.....	6	86.	6	65.66	100:76
Second...	6	84.16	6	66.33	100:79
Third....	6	77.41	6	52.83	100:68
Fourth...	7	69.78	7	60.14	100:86
Fifth.....	6	82.54	6	62.33	100:75
Sixth.....	6	87.50	6	63.16	100:72
Seventh..	9	83.94	9	68.25	100:81
Eighth....	8	113.25	8	96.65	100:85
Ninth....	14	81.39	14	64.07	100:79
Tenth....	5	93.70	5	50.40	100:54
All ten generations taken together.	73	85.84	73	66.02	100:77

The results of close and cross-fertilization, as shown by the weight of the seed-capsules, are given by Darwin thus: "The offspring of inter-crossed plants of the ninth generation, crossed by a fresh stock, compared with plants of the same stock inter-crossed during ten generations, both sets of plants left uncovered and naturally fertilized, produced capsules by weight as 100 to 51."

Similar experiments by Darwin upon other plants confirmed his experiments related above, and show conclusively the advantage which plants derive from occasional inter-crossing. But the manner in which this advantage to the species may counteract the work of the cultivator, in his improvement of special varieties, appears in its clearest light when we recall what has been said in regard to the diverse directions which variation may take. We can, by constant care, preserve the variations which we choose, but Nature keeps, in the long run, only those which are fitted for the surroundings.

Correspondence.

The Mutilation of Conifers.

To the Editor of GARDEN AND FOREST:

Sir.—About 600 feet from my house is a clump of Norway Spruces, some fifty feet high, of vigorous growth and in perfect health. During the winter and early spring months the ground under these Spruce is invariably covered with tips and branches from two to twelve inches long. For some years I attributed to squirrels the cutting of these branches, although I have never seen a squirrel on or near the trees. This clump of Spruces is the winter home of several pairs of blue jays, whose screams and noisy demonstrations enliven our neighborhood throughout the year. My present belief is that the jay is responsible for the broken tips in this instance. This opinion has been strengthened by the reading of Mrs. Olive Thorne Miller's charming little book, "In Nesting Time." Mrs. Miller's patient investigations and her acute observations of the habits of some of our every-day birds are exceedingly valuable. Her account of the eccentric behavior of a pair of blue jays which she sheltered and watched during one winter may help elucidate the present discussion. If your well-informed correspondents who have so admirably discussed the mutilation of Conifers will read pp. 176 to 203 in Mrs. Miller's work they will doubtless conclude that, if the jay be guiltless of the offense now charged, it is assuredly not from inability on the part of the jay. Should this bird prove to be the culprit, it is to be hoped that horticulturists will spare the jay on account of his many valuable qualities, his beauty and his cheerfulness.

* See Gray's Text-Book, Vol. I., Cross-fertilization.

† Gray's Text-Book, Vol. II., page 448.

Editor of GARDEN AND FOREST:

Sir.—I was glad to see your recent article entitled "How Trees Grow Tall," reproducing Professor Gray's clear explanation, for I had long wondered how so many people, familiar from their youth up with growing trees, could so constantly misunderstand their method of development. Here is another instance of almost incredible mis-statement which I clip from a little article recently published in the New York *Sun*, describing "Queer Trees" in Connecticut. "In Westfield," we were told, "a boulder weighing over half a ton is to be seen about ten feet from the ground, in the crotch of an enormous Apple-tree, and old residents say that they can remember when that boulder could be sat upon, so near to the ground was it when they were young." Perhaps the correspondent of the *Sun* did not believe the fable he reported, but undoubtedly the "old residents" had no idea they were telling an impossible yarn.

Periodical Literature.

The larger part of *Bulletin* No. 8 of the Botanical Division of the Department of Agriculture, recently issued, is devoted to notes upon grasses and related subjects, from the pen of Dr. Vasey. Most interesting to the general reader will be his description of the new grass experiment-station, lately established in Kansas by the Department under authority from Congress. The aims of the Department and the actual condition of these experiments are best made known in Dr. Vasey's own words:

"For several years past the Department of Agriculture has been making special investigation of the grasses of the West, particularly those of the arid districts, with a view of ascertaining what are the prevailing or prominent species, what is their range of distribution as to locality and soil, what their value for grazing purposes, and what kinds offer a reasonable prospect of being valuable for cultivation. Great interest has been felt in this subject both by farmers and cattlemen, and government aid has been invoked for the purpose of conducting suitable experiments, and such aid has been strongly recommended by the Commissioner of Agriculture.

"In response to these requests, Congress, a few months ago, made a moderate appropriation for the purpose of establishing grass experiment-stations. It was determined that one of these stations should be located west of the one-hundredth meridian. After careful investigation a location was selected at Garden City, in south-western Kansas, where a public-spirited citizen made a free lease to the government, for five years, of 160 acres of land on the high prairie two miles north of the city. This is so located that irrigation can be employed on such portion of the land as may be desirable. The chief object of the station is to experiment with grasses and forage plants, both native and foreign—with any kinds, in fact, which give promise of utility and adaptation to the climatic conditions of the arid plains, and furnish a substitute for the scanty pasturage now existing. This is a great necessity. In order to secure the permanent settlement of this portion of the country, it should be ascertained what can be depended upon in the occupation and cultivation of the dry uplands where irrigation cannot be applied. It is a vital question, affecting the interests of thousands of settlers over a great extent of country.

"Upon the location of the station the Commissioner appointed Professor J. A. Sewall, of Denver, as Superintendent of the station, and he has up to the present time had eighty acres fenced, forty acres plowed, a quantity of grass-sods transplanted into prepared ground; has put a small seed-house, and made everything in readiness for more extensive work next spring. The results of the experiments will be watched with great interest; but definite results cannot be expected without the allowance of a considerable period of time.

"The need of some grasses suitable to the climate of the dry region lying mainly west of the one-hundredth meridian has been long felt and acknowledged. It is estimated that there are in eastern Colorado, western Kansas, western Nebraska and southern Wyoming 120,000 square miles, or over 76,000,000 acres, of this arid, elevated country. This region was known to be covered principally by short grasses, called 'Buffalo' and 'Mesquit,' in some places thickly covered, in others more and more sparsely, while in some portions the amount of grass was exceedingly small. During the greater part of the last twenty-five years this region has been occupied for cattle and sheep ranches, for which purpose alone it was thought to be adapted. But even for this purpose its ability to support the domestic grazing animals was very small compared with its vast extent. This arises partly from the fact that only such portions as were within reasonable distance from water could be utilized, and partly from the scanty supply of grass. The

estimates as to the supporting capacity of these plains vary much according to localities, some statements being that forty to fifty acres are required to support one animal, others that twenty or thirty acres are sufficient, and yet others that ten to fifteen acres are enough.

"Sufficient time has not yet elapsed to determine what will be the ultimate success of general agriculture in this section, but there can be no doubt that the country is eminently adapted to pastoral uses, and the settlers would do well to bestow their attention largely on stock-raising and dairying. But it is evident that in order to make this business profitable for small farmers or men of limited acres, some means must be devised for an increased production of grass upon the land. This is the present most important problem for the arid districts. It is asserted that the commonly cultivated grasses will not be successful in these arid lands, except where irrigation can be applied. The native grasses of the region, which are mostly 'Buffalo grass' and 'Grama grass,' are acknowledged to be very nutritious, but the yield is so light as to require a large area for cattle to range over to obtain support. The inquiry naturally occurs, 'Cannot some grasses be obtained which will not only endure the aridity of the climate, but also make a more vigorous growth and a more abundant production?'

"It may safely be laid down as a principle that no great improvement in this respect can be expected without a cultivation of the soil. With this even the Buffalo and Grama grasses may be expected to double their production."

The second part of the *Bulletin* is devoted to vegetable pathology, and includes a number of papers prepared by Dr. B. T. Galloway, including essays upon the "Potato Scab," on the "Foot-rot of the Orange," upon "Parasitic Fungi in Missouri," etc. These are all papers of interest and value.

Exhibitions.

The Flower Show at Philadelphia.

THE Spring Exhibition of the Pennsylvania Horticultural Society, which was held last week, was probably equal in merit to the very best that have preceded it. It would have been still more attractive if the tables had been covered with moss or green cloth and if the broad zones of buff wrapping-paper, nailed about the stages to hide the trestles, had been replaced by a neat curtain of some more suitable color. From some points of view the obtrusive presence of the paper defeated well-meant attempts at an effective grouping of the plants, but the mass of foliage upon one side of the stage was most impressive. The plants in this group were from the famous gardens of Miss Baldwin, and her gardener, Wm. Joyce, deserves especial credit, inasmuch as the houses where the plants were grown are situated in the very heart of the city of Philadelphia. A superb *Kentia Forsteriana* had the place of honor, and it was supported by other rare Palms with noble *Dracænas*, Ferns and the like. Among the noteworthy specimens here placed were an immense variegated *Pandanus*, furnished to the ground, and a large *Cocos Weddelliana*, in fruit, and yet as green and perfect from bottom to top as a thrifty young plant two feet high.

No better Hyacinths were ever seen here than those shown by Wm. Janison, gardener to Mr. R. S. Mason, and they were well worthy of the gold medal offered by "the General Union of Holland for the promotion of the cultivation of Bulbs." The same exhibitor also received the medal for Tulips. In Orchids, the exhibition was unusually strong. The first prize went to Messrs. Pitcher and Manda, of Short Hills, New Jersey, and so did the first prize for cut Orchid-blossoms. Among the interesting plants of this collection was a *Cypripedium Boxali atratum magnificum*, *C. barbatum biflorum*, *Odontoglossum Andersonianum* and a fine specimen of *O. luteo-purpureum* with extraordinary spikes of bloom. The collection of Siebrecht & Wadley, which gained the second prize, contained the rare *Aganlina cyanea*; and the collection of Mr. Charles Dissel, which won the third prize, showed, among many other treasures, one of the largest plants of *Dendrobium nobile* ever grown. It probably bore 500 flowers. Near these Orchids were many fine specimen plants trained by David Emery, Mr. Dissel's gardener, among them a conical Azalea, Roi d'Holland, covered with flowers, and a finely-grown Fuchsia. Other attractive features of the show were a group of twelve Ferns, by Thomas Long, gardener to Mr. A. J. Drexel, and some wonderful Cinerarias by the same exhibitor.

But, after all, the interest of the exhibition centred in the cut Roses, which were shown in abundance and of the very highest quality. General Jacqueminot, Captain Christy, American

Beauty, Baroness Rothschild, The Bride, La France and Papa Gontier were all seen at their very best. But since pink Roses are in such exceptional demand this year the great rivalry was between the two leading varieties of this color, and it would be difficult, and perhaps impossible, to find specimens of Mrs. John Laing to excel those grown by Evans & Battles or of Madame Gabriel Luizet superior to those grown by Edwin Lonsdale.

Notes.

Among the fine specimen plants in the Drayton Garden is a *Pittosporum*, ten feet high and thirty feet in diameter.

The Grape Hyacinth (*Muscari botryoides*), grown in pots and arranged with Lily-of-the-Valley, makes a beautiful combination.

Forty-six Japanese gardeners are now employed, it is said, in California, where it appears that the taste for Japanese fruit and ornamental trees has greatly increased.

Dr. Charles Mohr, of Mobile, and Professor Eugene A. Smith, the state geologist of Alabama, have united in presenting their herbaria of Alabama plants to the University of that state. Dr. Mohr is at present engaged in cataloguing and arranging the collection.

Mr. Edward L. Davis, of Worcester, Massachusetts, to whom his native city is indebted for the generous gift of the land for its new park system, now proposes to build, at his own expense, upon the highest summit of Lake Park, a massive and stately stone observation tower, as a further gift to the people of Worcester.

The latest atrocity in the way of "fashionable" floral arrangements is a muff composed of flowers, for the use of bridesmaids at weddings. People seem slow to learn that there is a right way and a wrong way to use natural flowers, and that all ways are wrong that force them to simulate the form of some article of dress or ornament!

Nos. 165 to 169 of the Journal of the Linnean Society, being the first half of Volume XXV., are devoted to a list of plants of Kohima and Muneypore, collected in 1885 on a march from Galaghat, in central Assam, to Cachar, with descriptions of new species by Mr. C. B. Clarke. This important paper is illustrated with forty-four plants.

We have received the early numbers of a new monthly journal of horticulture—*L'Horticulteur*—published at Mons, under the auspices of the horticultural society of the district. Judged by these early numbers, the new journal is chiefly cultural in scope. M. Wesmael, the accomplished Belgian dendrologist, appears among the list of contributors.

The Duc de la Rochefoucauld has presented to the Agricultural Society of France the sum of \$20,000, the interest of which is to be given as a bounty to the author of an agricultural almanac, which must contain, in addition to the theoretical principles, a summary of the leading experiments in agriculture made during the year. A condition of the gift is that the book shall be sold for five cents.

The people of California are to be congratulated upon Professor Hilgard's decision to refuse the position of Assistant Commissioner of Agriculture, offered to him by the President, and to remain the Director of the California experiment station, where he can accomplish infinitely more than he could do in Washington, under the demoralizing political influences which beset the Department of Agriculture.

Mr. E. W. Reasoner, of Manatee, Florida, writes to the Agriculturist of that state that a seedling variety of the Southern Dewberry (*Rubus trivialis*), which was found growing originally among grass and rubbish in a rich part of an old cornfield, has proved very productive of delicious fruit, better in flavor than any Blackberry. This Dewberry ripens in Florida about the middle of April, and bears for three weeks. Mr. Reasoner considers it more profitable than the Strawberry, in his section of the state.

It is believed in California that the discovery of the fuel value of Peach and Apricot-stones will largely increase the dried-fruit industry in that part of the country. Peach-stones are said to make as good fuel for domestic purposes as the best coal sold in California. The present price is \$6 a ton; Apricot-stones do not burn as well, and sell at correspondingly lower rates. The great piles of stones seen in the neighborhood of fruit-drying establishments are gradually being sent

to San Francisco, and the profits of California fruit-growing are greater than ever.

The pest of ground squirrels has become so great in California that the farmers in some counties are organizing against them. It is proposed to pay a bounty, raised by local taxation of so much per acre, to every owner of land who shall keep it free of squirrels; and to appoint squirrel inspectors, whose duty it shall be to destroy the squirrels when the owners of the land neglect to do so, and who shall be paid for their services by the community. A bounty of fifteen cents an acre is suggested for the most seriously infested lands.

The *Manufacturer and Builder* gives some interesting statistics of the manufacture of tooth-picks in a factory at Harbor Springs, Michigan, which is said to be one of the largest of its kind in the United States. The wood of the Canoe Birch is used exclusively. The logs are sawed into pieces twenty-eight inches long, which are thoroughly steamed and then cut into veneer. The veneer is cut into long ribbons three inches in width, and these ribbons, eight or ten of them at a time, are run through the tooth-pick machinery, coming out at the other end, the perfect pieces falling into one basket, the broken pieces and the refuse falling into another. The picks are packed into boxes, 1,500 in a box, by girls, mostly comely-looking young squaws, and are then packed into cases and finally into big boxes, ready for shipment to all parts of the world. The White Birch tooth-picks are very neat and clean in appearance, sweet to the taste, and there is a wide market for them. The goods sell at the factory at \$1.90 a case of 150,000 picks, or 100 small boxes each containing 1,500, and the small boxes retail at five cents each, or 300 picks for a cent. This single mill produces about seven and a half million tooth-picks each working day.

We are indebted to Mr. John Harshberger, of Philadelphia, for flowers of *Eranthis hyemalis*, gathered in Bartram's Garden, where it has been growing for fifty years, at least, having become naturalized, and is now the first plant to bloom in the spring. Mr. Harshberger suggests "that this would be a good plant to set out in groups under trees in any lawn or garden, where, if once established, it would grow without care. The flowers appear earlier than those of the Crocus, the Daffodil or the Tulip, and their yellow color makes a very pretty showing. The plant seems to follow the habits of some of its sister Alpine plants, flowering almost before the snow is off the ground." *Eranthis hyemalis*, or, as it is popularly known, "Winter Aconite," from a resemblance of its leaves to those of the true Aconite, is a member of the Ranunculus family, and closely related to the Hellebores. It is a dwarf, perennial plant, two or three inches high, with fleshy roots, bright green, deeply divided leaves and bright yellow flowers an inch across. It is a native of western Europe, and for three hundred years has been a favorite in gardens, being one of the very earliest plants to open its flowers. There is a second species, *E. Sibiricus*, which is much less commonly seen in cultivation.

Several correspondents of the *Garden* (London) have protested of late against the use of cotton as a packing for fresh flowers and fruits. One, who signs with the initials of a well-known horticulturist—Mr. F. W. Burbidge—says: "Nearly every day examples come before us of the misuse of this material. As a packing material for cut flowers or living plants, cuttings, scions, etc., it is the very worst if employed in immediate contact with vegetable tissues. I saw some young plants of the rare pink-flowered Banksian Rose the other day which had been swathed up in dry cotton-wool, and the stems were blackened as if by fire wherever it had touched them. Flowers packed with this wool around them arrive limp and drooping, and over and over again have we seen Peaches with all their freshness and beauty destroyed by this substance. If fruits are wrapped up each separately in tissue paper, the wool may then be used with advantage as a soft padding, but if it comes into immediate contact with either flowers or fruit, they are always more or less damaged by it. The rule to observe in using cotton-wool is to wrap everything in paper before using it. It is most useful in packing fruits if this rule be observed, but for flowers and living plants and cuttings of all kinds, fresh, clean, wood Moss is infinitely better in all ways. We have received boxes of flowers packed in living Moss, and have admired the packing almost as much as the flowers themselves. Of course, very delicate white blossoms should also be wrapped in tissue paper before the Moss is placed near them, but as used in any way there is no better and safer packing material for flowers and plants than the fresh Hypnum Moss of our woods, and there is really no comparison between it and cotton-wool."

The Use of Arbor Day.

THE establishment of Arbor Day in so many of the States of our country is frequently referred to, by persons who write and talk about forestry, as an evidence or instance of a great advance in popular interest and intelligence regarding this subject. But unless more serious and intelligent attention is given to the use to be made of it, and to the character of the proceedings connected with it, the day will not long be observed. Addresses by persons who have no real knowledge of trees, or of their relations to the welfare of a community, are likely to have a tiresome similarity and monotony of character. When the novelty of Arbor Day observances has passed away they will soon cease to attract attention or awaken interest among intelligent people, unless in each town a few persons care enough about the matter to give to it the time, thought and labor required to make the day of some practical value. The reports of Arbor Day observances which come to us from some places indicate that the talk and ceremonies sometimes border closely on the farcical and ridiculous. In such cases it is necessary to remember that tree-planting in villages is not forestry, is no part of it, indeed, and has no direct relation to it.

The subject of forestry is, of course, an appropriate one for Arbor Day, if there is any person available who is competent to present or discuss it. Almost any time would be suitable for the intelligent treatment of this topic, if people will come together to hear and consider it. It is vitally related to the public welfare in a variety of ways, and serious injury to the prosperity and civilization of our country is almost certain to result from the lack of sufficient knowledge to enable our people justly to estimate its importance. Oratory without knowledge is of little value, and will not long be found entertaining; but knowledge regarding the subjects which are appropriate for Arbor Day can be acquired only as knowledge of other important subjects is acquired, by serious interest and application, by study and adequate observation.

The planting of trees by a person able to use it as an object-lesson for popular instruction by describing the

structure and functions of the various parts of the tree, and their relation to each other in its life would in many places be an admirable use to make of Arbor Day. The proper care of trees and shrubs in villages and along country road-sides, their economic value as related to bird-life and insect-life, their influence on health, and on the interest and happiness of human life, their value as a means of seclusion, and their effect in landscape everywhere, are all good subjects for consideration on Arbor Day, if they are seriously and intelligently presented.

If a few public-spirited young men and women in every town will read the new literature regarding these and similar subjects, they will soon be able to supply competent direction for Arbor Day observances, and, what is more important, to give good counsel, and to act intelligently when questions of pruning trees, widening streets and destroying road-sides are under discussion. We observe that in some towns which last year celebrated Arbor Day with much sentimental oratory many fine trees have since been unintelligently and barbarously slaughtered, and the beauty of charming banks and road-sides has been needlessly destroyed forever.

It is pleasant to be able to state that Nicholson's "Dictionary of Gardening" has been completed. The author, by his attainments and his position, was admirably fitted for the task; and he has produced a work which is an invaluable aid to every cultivator and every writer about plants. A work of this character necessarily soon gets out of date, and some arrangement, it is to be hoped, will be made which will enable the author and his publisher to produce, every few years, a supplement. We cordially indorse the plea of the *Gardeners' Chronicle* for the loyal adoption by horticulturists of the names of plants employed in the Dictionary, not because they are always correct, but because a standard international nomenclature of cultivated plants is now greatly needed, and this work is the best standard available for general use. In this connection we cannot do better than to reproduce, from our English contemporary, the following: "We do not mean to deny the right of any one to put whatever names he likes to his plants, so long as he does not publish them, but if he does so, then he should either use English names, concerning the value of which there can be no doubt, or, at any rate, he should not employ such names as by their construction imply that plants have been properly described and registered by a competent botanist. Half the difficulty in nomenclature is caused by the unauthorized use of names botanical in appearance, but purely horticultural or commercial in substance." Every nursery catalogue is filled with names of this character. Every year hundreds of new ones are made in half the States of the Union and in every country of Europe, and the mysteries of the nomenclature of garden plants are well-nigh unfathomable. The coiners of names themselves begin to appreciate the difficulties with which they are investing the successful practice of horticulture, and the time, perhaps, is not far distant when the various associations of nurserymen and of florists will take the steps necessary for a real reform in this matter. They can hardly do it too soon.

Senate Bill number 354, intended to prevent the construction of railroads across state lands in the Forest Preserve of this state, was so amended in the Senate before its passage as entirely to destroy its practical force and value. As passed it excludes only railroads not yet chartered, and as the real danger to the Adirondack forests is from railroads already chartered, the bill in its present shape is worthless. Its original character should be restored; it should be introduced in the Assembly and urged to its passage. Then it should be passed by the Senate and made a law. It is an important measure, as we have before pointed out. Its consideration rightly brings up the general subject of the value of the Adirondack forests to the people of this state, and the present is an appropriate

time for the discussion of this topic in all its aspects and relations. The press of the state, and of the country in general, can render most vital aid in pressing the matter upon the attention of the Legislature and of the people.

If the railroads which already penetrate the Adirondack region are extended across state lands through the Forest Preserve, nearly all the timber of the wilderness will be made easily accessible, and can be readily conveyed to market. It will be rapidly cut off, and as much of the soil will be destroyed by repeated burning, the forest will not be speedily reproduced, or only trees of very inferior quality will grow.

The people of the state should consider the subject intelligently and fully before they decide to permit the railroads to be extended across lands belonging to the state into those portions of the forest which are at present inaccessible. The permanent value of the great waterways of the state of New York depends in large measure upon the maintenance of forest conditions on the mountain slopes around the sources of streams and along their upper course. The varied attractions and interests of the region as a sanitarium, as a place of resort for rest and recreation, are all now menaced by the most serious danger which has ever threatened them. If the railroads are extended the region will be robbed of all the features which now make it of value to visitors and to the people of the state in general, and its attractiveness cannot be restored until centuries have passed away. It would be a most wise and practical step forward—a real advance in civilization—if the people should determine that the forests of the state lands shall be protected from further encroachment and injury, and especially that right of way across them shall not, under any circumstances, be granted to railroads.

Easter Flowers.

FOR generations the white Lily has been the accepted symbol of innocence. Purity is expressed by its aspect more plainly than any other quality is expressed by any other flower—not the shrinking, timid kind of delicacy which avoids even the gaze of criticising eyes, but the fearless dignity of an innocence that is too well assured of its spotless strength to be afraid of comment. References to the Lily as the type of innocence are scattered thickly through mediæval as well as modern poetry, and the force of the association is well shown in a belief which still persists in some of the rural districts of Germany that if a person be unjustly executed Lilies will spring up on his grave. It is easy to see, therefore, why the Lily, usually conceived as our common garden species (*Lilium candidum*), became the most familiar attribute of the Virgin Mary. Many other flowers were dedicated to her, and among them, of course, the Rose. But the Lily, above all, is the Virgin's flower. Very early pictures, like many of later date, portray her with a vase of Lilies by her side. There are usually three blossoms, each borne on a separate tall and slender stalk; and in the number we may divine, perhaps, a reference to the doctrine of the Trinity. The earliest pictures of the Annunciation show the Angel Gabriel bearing either a sceptre or a branch of Olive; but a Lily-wand soon took their place in his hand, and in the great period of the Renaissance, as well as in modern times, it is rare to find him pictured in a different way.

To-day in Protestant lands the Lily is chiefly associated with the festival of Easter. But if we accept the evidence in popular works on flower-lore, its connection with this special festival cannot be of very early date. Many flowers were recognized as Easter flowers. Among them was the purple Anemone (*Anemone pulsatilla*), which thus gained the name of "Pasque-flower," the white Broom and all white blossoms in general, and a so-called Easter-Lily or Lent Lily. But this last was not, as many readers of English books have doubtless believed, the common white Lily or, indeed, a Lily of any kind. It was the common yellow Daffodil, which is still often called "Easter-Lily" in England.

Many local European customs which now have a Christian significance, or are supposed to embalm such a significance long-ago forgotten, are in truth survivals of old pagan rites which incorporated themselves with the new faith in ancient days—either with the discreet connivance or in despite of the most conscientious efforts of the missionaries of Rome. Some such customs are still connected with Easter-tide. In Bavaria the peasants on Easter Day make garlands of Coltsfoot and

throw them into the fire; in the district of Lechrain (we read in Dyer's "Folk-lore") a sacred fire is lighted at Easter and every household brings to it a Walnut branch, "which, when partially burned, is laid on the hearth fire during tempests as a protection charm against lightning. . . . In Bareuth young girls go to a fountain silently, and, taking care to escape notice, throw into the water little Willow rings with their friends' names inscribed thereon; the person whose ring sinks quickest being the first to die."

Of course such customs as these have no existence in our country; but the use of flowers at Easter to decorate the church, to prove remembrance at the grave, and even to serve as gifts to living friends, is yearly becoming more general. There is no anniversary, indeed, when the use of flowers seems so appropriate as at Easter. Their blooming presence typifies the new birth of the year, and this in its turn the resurrection of Christ. Many flowers are employed in America for Easter purposes, but white ones chiefly, and, more than all, the white Lilies; and it is not strange, therefore, that the old name of "Easter-Lily," so long appropriated by the yellow Daffodil, should now be given to these flowers.

To Make a Lawn.

A SWARD thickly and evenly set with the finer grasses, cropped or cut so close as to reveal every undulation in the surface of the land and so smooth and even that the shadows of trees and shrubs as they rest upon it are clearly outlined—this is the foundation element of beauty in home grounds where grass will thrive. The lack of green sward is one of the most serious difficulties encountered by the landscape-gardener in regions like California, where there is a dry season, and in the South, where the grasses are coarse and rank. Even in the most favored parts of the United States our hot summers too often leave a lawn scorched brown, as if it had been burned over. Grass must have moist feeding-ground, and this means a deep and fertile soil. Good drainage is, therefore, essential, as it keeps the land from saturation in wet weather, and hard baking when the rains cease, and in place of these extremes preserves the moist condition most favorable for roots. Good drainage insures for roots more feeding room and more food. It allows air to penetrate the soil and makes it warmer, encourages the grass to an earlier start in spring, helps it to grow later in autumn and lessens the danger of heaving by frost.

Deep trenching is too expensive for large lawns, but at the outset they should be deeply tilled, with fine, well-rotted stable manure thoroughly incorporated with the soil; on land of ordinary fertility forty or fifty loads to the acre are recommended. If this is done in spring the land should be deeply harrowed, over and over, not only to make a fine seed-bed but to compact the soil, which has not had time to settle, and bring the particles closely and firmly together. After thorough harrowing the surface should be rolled and again lightly harrowed, when the seed can be sown, brushed in and rolled again. This is best done in April in this latitude, although seed can be successfully sown in early September if seasonable rains follow.

For a small lawn, it is preferable to use sod from an old pasture. These sods will contain the most persistent and finest grasses, which have survived the trampling of sheep and cattle and developed under close cropping into just such a turf as is desired. Sodding is too expensive, however, for lawns of any extent, and if seed is sown the best and purest should be selected. The so-called "lawn mixtures" cannot be recommended. Professor Beal, of the Michigan Agricultural College, published a few years ago the results of a careful analysis of several of these mixtures. In the best of them the great bulk of the seeds were of Blue Grass and Red Top, but they cost in the mixture two or three times as much as when purchased alone. Some of these mixtures, besides the seed of weeds, contained the seeds of Orchard Grass, which is coarse and bunchy; Perennial Rye Grass, which takes the best food of the soil for a few years and then dies out; Sheep's Fescue and Hard Fescue, which grow in tufts; Red and Pea-vine Clover, which are coarse and short-lived; Italian Rye Grass, which will perish the first winter; Hair Grass, which is a feeble grower, and other varieties altogether unsuitable for the lawn. Manufacturers of standard fertilizers give a guaranteed analysis of the amounts of the different elements of plant-food they contain. Until the venders of Lawn Grass mixtures give the same guarantee of the composition of their wares, buyers have no means of knowing what kind of seed they will sow or what prices they pay for each kind.

Kentucky Blue Grass (*Poa pratensis*) is one of the most common grasses in the north temperate zone, and its spread-

ing root-stocks fill the ground near the surface. It is a perennial, tenacious of life, starts quickly after cutting and in the spring, but does not become thoroughly established before the third year after sowing. Altogether it is the best grass for a lawn, and next to it comes Rhode Island Bent (*Agrostis canina*), which is rather finer than Red Top (*Agrostis vulgaris*, var. *alba*). It will thrive on thinner soils than will Blue Grass, and becomes fairly well established the first year. It is the best grass to mix in quantity with Blue Grass. If in chaff, two bushels of the Bent seed mixed with the same amount of Blue Grass seed should be sown to the acre.

A lawn thoroughly made will last for years, and, if properly cared for, will improve with age. Cut often and leave the clippings on the ground. Give a sprinkling of seed each spring, followed by a heavy rolling while the ground is soft, to fit the surface for the mower, and pack the soil about the roots where frost has loosened them. A dressing of fine compost, or of some complete commercial fertilizer, should be added.

Foreign Correspondence.

London Letter.

WHEN the history of English horticulture in the nineteenth century comes to be written its most remarkable feature will be the position held by the great Orchid family. In a period of less than fifty years the cultivation of Orchids has developed into almost a passion, and has become an important commercial industry. There are millions of pounds invested in Orchids in England alone. Collectors are in all parts of the world searching for them. They are objects of interest to all classes of the community. Society journals open their pages to long articles upon them, and all sorts of anecdotes about them, sometimes true and often fictitious, are told and listened to by all kinds of people. There are a few horticulturists who profess to despise Orchids, and who constantly discover that a reaction against them is setting in. But these plants are more popular now than ever, and this popularity seems on the increase. And yet there is no Orchid Society in England. Such plants as Chrysanthemums, Carnations, Auriculas and Roses have each their own society. Weak efforts to start an Orchid Society have been made, but they came to nothing. There is, however, special representation promised for Orchids now, the Royal Horticultural Society having decided to appoint a committee of specialists to adjudicate on Orchids alone. That such a committee is wanted is abundantly evident. The number of men who possess a knowledge sufficient to enable them to decide which Orchids are good and which bad, what is new, and what is simply an old plant under a new name, is quite limited. When one remembers that at the present time there are close upon 2,000 species in cultivation, not to mention the almost countless varieties and hybrids, the necessity for the step which the Royal Horticultural Society is about to take must be apparent. A man may know ordinary garden plants well, or be an authority on some special department of flower-culture, but that does not qualify him for the post of referee where Orchids are concerned.

Disa tripetaloides is another addition to the useful garden species of this large South African genus. It is not unlike *D. racemosa*, recently mentioned in GARDEN AND FOREST, and it requires the same treatment. Mr. O'Brien, of Harrow-on-the-Hill, has imported plants which have recently flowered. He writes: "It is not only the freest growing and most profuse flowering *Disa* I ever saw, but also the most easily grown of South African terrestrial Orchids." It bears spikes of from twenty to thirty flowers, each about an inch across, white, united with pink, and dotted with rose-purple; the dorsal sepal is helmet-shaped, with a short spur, the lateral sepals are oblong, obtuse, proportionately large, the petals are falcate-oblong and the lip linear. At Kew this plant is growing freely by the side of *D. racemosa*, than which no Orchid appears more easy to cultivate. Whilst writing of a new Cape plant I may notice the flowering of *Drosera cistiflora*, which is now at Kew in bud, having been presented by Miss North, who not only drew attention to it by her picture painted at the Cape, but who has introduced it into cultivation. *Droseras* are delightful plants, and, as a rule, easy to manage. At Kew there is a good collection of species, and they are a source of much interest to visitors. They are grown in a cool, sunny green-house along with a collection of Sarracenias, Darlingtonias and other "carnivorous" plants. Guards of wire-netting are placed in front of the stages, and it is amusing to hear the opinions of visitors with regards to these plants and their "cages." The Darlingtonia is the "Cobra plant," and is supposed to have a deadly

sting. *Dioncæa* is a kind of "vegetable octopus," and so on. The cages are meant to prevent visitors from being injured by these vicious plants! Although not at Kew, yet plants are in England of *Heliamphora nutans*, a very interesting Sarracenialike plant from the Roraima Mountain, and which was discovered by Schomburgk about fifty years ago. Messrs. Veitch are the lucky possessors of a stock of this plant.

Amorphophallus Rivieri.—A very fine example of this well-known Aroid was lately in flower with Messrs. Veitch. The scape was a foot high, the spathe trumpet-shaped and a foot across the mouth, whilst the erect club-like spadix was one and a half feet high by one and a half inches in diameter. The color was dull purple inside, and gray, with green spots, outside. Most gardeners know the foliage of this old Cochinchina plant, but few are acquainted with its flowers. They are extraordinary in appearance, and were it not for their abominable odor the plant might be recommended on their account alone. I believe all the *Amorphophalli* have this peculiarity in their flowers. A new species, *A. Eicleri*, is in flower at Kew now, the spathe being about the size of a wine-glass, but when the tiny flowers which clothe the lower part of the spadix were open the smell was so offensive that the artist who had to make a drawing of it was compelled to inclose it under a bell-glass. When *A. giganteus* is in flower many visitors will not venture into the house where it is. This offensive odor arises from the true flowers as they mature, so that after removing them with a knife, the smell disappears. The marvelous *A. Titanum* (*Conophallus*) is also in cultivation at Kew. Last year the tuber was like a large, flat Pumpkin, eighteen inches in diameter, the leaf-stalk eight feet high, straight and smooth as a gun-barrel, and eight inches through at the base; the blade was divided into three main branches, from which spring numerous smaller ones, the whole forming a huge canopy thirty feet in circumference. This leaf was developed in less than two months, and remained on the tuber till winter. Now the tuber is at rest, and hopes are entertained, from its size and health, that it will flower this year. The inflorescence was described by Dr. Beccari, who discovered the plant in Sumatra about ten years ago, and a life-size picture of it is in the Museum at Kew. In this the spathe is three feet in diameter, and the thick spadix six feet long. Apart from its flowers, this Aroid is one of the handsomest and most interesting of the tropical foliage-plants grown at Kew.

The exhibitions of spring-flowering plants held in the Botanic Society's gardens at Regent's Park are always of exceptional interest and rich in display; that held on Wednesday last being voted one of the best seen in London for years. Besides the usual spring-flowering bulbs, such plants as *Cyclamens*, *Clivias*, *Deutzias*, *Cinerarias*, *Primulas* and *Hippeastrums* were shown in abundance, and with scarcely an exception were splendid examples of culture and selection. Mr. James, of Slough, whose strain of *Cinerarias* is remarkable for dwarfness, largeness of flower and fine colors, surpassed his previous efforts by the group he showed on Wednesday. Messrs. Carter & Co., of Holborn, sent a group of their new seedling *Cineraria*, Emperor Frederick. It is remarkable in having the ray-florets quilled at the base, and colored violet, the spreading portion being maroon-purple. Messrs. Cannell & Sons also exhibited a very fine strain of *Cinerarias*. The *Cyclamens* from the St. George's Nursery Company, Hanwell, and from Mr. Odell, were especially good, both in size of flower and in color. The cultivation of these plants is an art known to only few, if one may judge by the wide difference between the *Cyclamens* of the ordinary garden and those of the specialist. If the latter is asked how the trick is done, he says we must have special houses, special treatment and specially good luck in regard to position, water, etc. Two new seedling *Cyclamens*, which were awarded certificates, were Faust, with flowers of a uniform deep crimson color, and Striatum, with large flowers, purplish-crimson, with a broad band of rosy-white down the middle of each segment. Should this last reproduce itself from seeds it will give us an entirely new race of *Cyclamens*, so far as regards color. It was shown by Mr. Odell, of Hillingdon. *Hippeastrums*, both new and old, were represented by several large collections. The best of the new kinds were: Lustrous, with flowers six inches across, of good form, and almost wholly deep scarlet, with crimson veins (Veitch); Optima, flowers very large, nearly a foot across, bright crimson (Veitch). Amongst the Roses shown by Paul & Son were fine examples of the pretty little fairy roses called Mignonette and Golden Fairy, both forms of *R. polyantha*. As pot plants for the green-house these bunch-flowered little roses are of great value. *R. Hardyi* was also shown in bloom. It is a delightful rose, with flowers like those of *Cistus laurifolius*, but yellow, with a crimson blotch at the base of each petal. *Boronia heter-*

ophylla was shown superbly by Messrs. Veitch. Whatever may be the opinion of horticulturists generally with regard to *Boronias*, there can be no question of the great beauty of this species. It forms a compact, globular little bush, a foot high, and every branch is heavily laden with bell-like flowers as large as peas and bright rosy-purple in color. For the introduction of this plant to English gardens we are indebted to Miss Marianna North, who, when in Australia about seven years ago on a sketching expedition, sent seeds of the *Boronia* to Kew, where it was successfully grown and flowered. It afterwards passed into the hands of Messrs. Veitch, who have been wonderfully successful in its propagation and culture. *B. heterophylla* is as delightful a garden plant as *Erica hyemalis*. Amongst the Orchids exhibited were *Brassia picturata*, *Dendrobium Brymerianum*, *Neottia corallina* (*N. speciosa*), *Lælia cinnabarina*, a very fine variety, the flowers fully three inches across and of the brightest scarlet. These were sent by Messrs. Sander & Co. From the collection of Messrs. Veitch came a fine specimen of *Calanthe vestita gigantea*, a variety which ought to be in every collection where *Calanthes* are grown. *Dendrobium Schneiderianum*, the hybrid referred to in my last letter, and *D. splendidissimum* were also shown. The newest feature in the exhibition was the *Clivias*, of which Mr. B. S. Williams sent a collection of good sorts. A group of the old *C. miniata* spoke well for the type, and also showed what progress had been made in the improvement of this plant, some of the varieties shown by Mr. Williams having flowers twice as large as the type, as full as a *Vallota*, and much brighter in color. Perhaps I ought to mention that *Clivia* is the correct name for the plants commonly known as *Imantophyllums*.

March 22.

W. Watson.

New or Little Known Plants.

Hypericum aureum.

IT was in the month of July, 1776, that the younger Bartram discovered this plant upon the bank of Patse-Lega Creek, a branch of the Flint River, in Georgia, and the account of this discovery, which he afterwards published in his "Travels," gives an excellent idea of it as it now appears in cultivation. "I observed," he says, "growing on the steep, dry banks of this creek, a species of shrub *Hypericum* of extraordinary show and beauty (*Hypericum aureum*). It grows erect, three or four feet high, forming a globular top, representing a perfect little tree; the leaves are large, oblong, firm of texture, smooth and shining; the flowers are very large, their petals broad and conspicuous, which, with their tufts of golden filaments, give the little bushes a very splendid appearance." Afterwards the plant was found to extend from South Carolina to Alabama and to eastern and central Tennessee, although nowhere very common; but its merits as a garden plant were overlooked until a few years ago, when seeds were sent to the Arnold Arboretum by Dr. A. Gattinger, of Nashville, who thus writes of its distribution in Tennessee, where it is more common than in the Atlantic States: "The *Hypericum aureum* is addicted to rocky situations in the Cedar-glades and on bluffs and cliffs along the Cumberland River and its affluents. It is also on the base of Cumberland Mountains as far up as the carboniferous lime-stone reaches. It is not found in silicious or argillaceous soils or in swamps, but prefers such situations where the moisture is longest retained and shade is provided. It associates in the Barrens with *Rosa humilis*, *Forestiera ligustrina*, *Ptelea trifoliata*, *Rhus aromatica*, *Rhamnus Caroliniana*, *Crataegus subvillosa*, *Gonolobus obliquus*, *Nemophila microcalyx*, etc. It is generally not very floriferous, but I have found on the rocky ledges near the water-line on the Cumberland River, specimens with a great profusion of flowers. It grows three to five feet high."

Hypericum aureum is by far the showiest in flower among the considerable collection of *Hypericums* in the Arnold Arboretum, where it is perfectly hardy. It begins to flower about the twentieth of July, and continues in bloom during several weeks.

The branches are angled, covered with thin exfoliating red bark and widely paniculate near their upper extremity.

The leaves are simple, rather coriaceous, oblong-obtuse nearly entire, tipped with a minute mucro, and pale on the lower surface. The flowers are an inch and a half to two inches across when expanded, with coriaceous, reflexed, orange-yellow petals, which are longer than the ovate, unequal sepals and very numerous, golden-colored stamens. The capsule is red, ovoid conical, and acuminate with the connate styles.

There are few dwarf shrubs better worth a place in the garden. Mr. Faxon's drawing is from a specimen grown in the Arnold Arboretum. C. S. S.

Cultural Department.

Cultivation of the Bermuda Easter-Lily.

ON the Island of Bermuda, which lies 700 miles directly south-east of New York, 800 miles due east of Charleston, South Carolina, and 100 miles east of the Gulf Stream, where the yearly range of temperature is from 54° in winter to 85° in summer, there has grown up lately an industry which will soon change the character of the trade between Bermuda and the outer world.

A few years ago an American gentleman, General Russell Hastings, who had grown to like this equable climate because of its benefit to a constitution impaired by wounds received in the war for the Union, began to experiment in the cultivation of the Bermuda Easter-Lily, which he found growing there most vigorously in everyone's flower-garden. The natives looked upon him as a dreamer for supposing that anyone would buy so common a bulb as "our Easter-Lily." And how could a large market be built up for a mere flower which no one could eat or wear? But the most sleepy Islander now begins to see that the Onion has a rival, for in the richest corner of every little farm a patch of Bermuda Easter-Lilies can be seen, while on larger farms acres are devoted to the same purpose, as may be seen from our illustration on page 187.

A market is readily found for the hundreds of thousands of these bulbs, and the supply has never equalled the demand. The Lily blossoms from January to May; the bulbs ripen in July and August, and can be put down in New York, London or Paris by the middle of August, where florists and amateurs by potting them immediately and forcing them hard under glass can obtain flowers for the holidays, or by potting later and at different periods flowers can be had all winter, and especially for the Easter decoration of churches. An effort has been made to utilize the flowers by shipping them to New York, and a box has been invented with a pasteboard receptacle for each flower, but the three-days' sea voyage damages the flowers, and when placed by the side of those grown in the northern green-house they make a poor show. General Hastings does not recommend the shipment of flowers, first, because they do not arrive at their destination in good order, and next, because it is bad business policy to offer bulbs to the northern florist, and then go into the market to compete and disturb it with inferior flowers.

It seems as if the perfume of the millions of blossoms grown here each winter might be utilized in some way. It is a delightful, though rather powerful, odor, and during the flowering season the whole island is fragrant with it. Sailors say they can smell Bermuda when far at sea.

The Bermuda Easter-Lily, sometimes known in the United States market as *L. Harrisii* (which is a misnomer), is a well-known Japanese plant, botanically named *L. longiflorum eximium*. The flower is pure white, bell-shaped, with the segments well bent back at the extremity. The perianth is about six inches long, the root is a scaly bulb, the stem herbaceous and simple, from two to four feet high, bearing the flowers at the summit, which number from eight to forty, though one monstrosity grown here in 1882 produced 145 perfect flowers.

The method of cultivation is very simple. First, very rich red soil, with an enormous amount of well-rotted stable manure is a necessity, as the Lily does not take kindly to any of the artificial fertilizers yet tried. It is a voracious feeder, as long roots are sent out from the base of the bulb, and another set of feeding roots come out from the stalk above the bulb. For successful cultivation these roots must at once strike into rich feeding ground. The bulbs are planted in August, September and October, the large bulbs in rows eighteen inches apart, and the smaller bulbs in beds like Onions. The flower-stalks appear above ground in November, and from time of planting until harvest the grower has to keep constantly weeding during every one of the twelve months of the year.

The harvest season is from the middle of July to the middle of September, at which time all the bulbs in the field, great and small, are dug and carried to the sorting house, where those large enough for the market (from five to nine inches in circumference) are selected out, packed in sawdust and immediately shipped to the United States and Europe. Those bulbs not large enough for the market are sorted into three sizes and replanted for the next year's crop.

The power of this Lily to propagate itself is most wonderful in this climate, and new bulbs are formed in many ways: from seed, from offshoots, from scales of the bulb, and from cut-

These large bulbs which have been stripped of scales are planted, and in two years can be stripped again, and so on forever. Many bulbs propagate themselves by offshoots of the healthy growing bulbs in the field, and a field planted out to Lilies for several years becomes alive with new bulbs from offshoots and bits of scales broken off when the crop is harvested. These bulbs coming up between the rows are spaded under when the soil is cultivated.

The question is often asked, Cannot the business be overdone? This hardly seems possible, as the florist who forces the bulbs in his northern green-house throws them away at the

Fig. 103.—*Hypericum aureum*.—See page 184.

tings of the flower-stalk planted in the ground after blossoming. Even the leaves of the flower-stalk, stripped off and planted in the ground, will form bulbs, and a flower-stalk cut and placed in a bottle of water will form bulbs from top to bottom. The method most in vogue, however, is to take well-ripened bulbs two or three years old, having a circumference of about twelve inches; tear off all the scales, scatter them in a shallow trench and cover with about two inches of soil. Each scale will make from two to six new bulbs, which will grow the first year from the size of a pea to that of a large Hickory-nut, and probably one-third of these bulbs will grow large enough for the market at the end of the second year.

end of the season, and buys again the next year, as he cannot economically "ripen off" his bulbs, and, even if he could, they would not flower well the second year. Again, the demand comes from so large an area—from the United States, England, France, Germany, Austria and Russia—a market field large enough, surely, for a little island containing but 1,200 acres of arable land.

This bulb is grown to some extent in Japan, but it is not possible to get the crop from Japan into the United States and European markets before November, and even then the bulbs are not as floriferous as those grown in Bermuda.

Carnations for Winter Blooming.

NEARLY all the varieties of Carnations grown in America for winter blooming are of American origin. Many of the best English kinds have been tried, but few have proved useful. Most of the imported kinds are too vigorous—"too grassy," to use an old grower's expression. The flowers are too full as a rule, and incline to burst. The majority of our varieties are dwarf in habit, being almost self-supporting. The flowers are thin, but of fine form, and I think these varieties would be useless out-doors in England owing to this very fact.

Mr. Tailby, of Wellesley, who raised Grace Wilder, a very popular variety, with rose-colored flowers, says that when Americans began to grow Carnations, planted out on beds and benches, they found the old English varieties, which they had been accustomed to grow in pots, unsuitable, and therefore commenced to raise seedlings, and they selected the dwarf semi-double ones, which to most people would appear worthless, using these as parents, though occasionally crossing them with others of good habit and color, but with flowers of indifferent form, to produce, if possible, the kind adapted to our needs. The work was tedious, and only those having a real love for it could continue, for good time and space often went for nothing. Many of the seedlings, when first blooming, would appear satisfactory, but when propagated and prepared in the usual way would turn out worthless, and, again, others taken up, after being virtually discarded, have turned out well.

We have excellent scarlets in Alegetaire, Florence and an unnamed seedling; good crimsons in Anna Webb and Orient; violets in Victor and Century; salmon in Madame Rollicker and another unnamed seedling. The only excellent rose-colored variety we have now is Grace Wilder. The good yellow, for winter blooming, has yet to be found. Pride of Penshurst has lovely form and color, but poor habit, and is very late, as also is Belle Halliday. Andalusia is early enough, but of poor habit and form. Of striped yellow varieties of moderate earliness and fair form, Buttercup is the best. Madame Carle is the best white we have, of fine form and color, a free bloomer, of good habit, but a little late. Snowden is an old stand-by, likely to hold its own. The flowers are of good form, but small. Mr. Tailby has a pure white sport from Grace Wilder, which he intends naming Our Mary.

The practice is to strike cuttings in benches or boxes filled with rather coarse sand, with just enough plastic matter in it to retain moisture, and made very solid by beating with a brick. The cuttings require very little preparation. An experienced man would put in 2,000 per day. No knife is used, the tips, with only two to three joints, being snapped off. They are put in with a common dibbler, which is not driven into the sand farther than is necessary to insert the cuttings, and there is little prospect of their rooting unless set firmly in the sand.

The cuttings are kept saturated with water and shaded until they stand well up under sunlight. Pricking off into boxes, or potting into thumb-pots, is the next work. Sandy loam should be used, and made firm in the pots. As soon as established, and growth enough made to allow the tips to be pinched out, this is done and continued until about the second week in July, when they are allowed to develop flowering-stems. A good, heavy loam is the most suitable soil to grow them in, both in the houses as well as when in preparation out-doors. A good, airy house, with night temperature of 50° suits the plants. The foliage should never be wet unless a bright day is assured. During January a top-dressing of wood-ashes and leaf-soil is given, which helps the blooming along until May.

Memoranda from a Northern Garden.

FOR several years I have been interested in a little native plant found, according to Mr. Pringle, in few localities in Vermont—the Strawberry Blite—*Blitum capitatum*. Spinach will not winter in my grounds, but the Blite does not mind the cold, however severe; and as it starts into growth the moment the snow departs, it makes as early greens as the Dandelion, and to my taste quite as good as Spinach. The Blite is a pretty persistent weed, so far as reproduction from seed goes; and the seeds are almost as small and quite as numerous as those of Purslane, yet it is easily killed with the hoe. The brilliant crimson color of its pulpy but insipid fruit, with its abundance, makes the Blite a pretty plant in the flower-garden, when well grown.

Speaking of Purslane reminds me that though it grows here as freely and as rankly as it grew in my old Kentucky

home, it is worth nothing for greens, for it will not cook tender when grown so far north. I find the same trouble with Okra, the dwarf, early form of which grows and forms pods freely enough in my garden; but they are worthless for use, being hard and woody before they are half grown.

In most years I manage to get fairly good Water-melons and Musk-melons in my garden, from seed started in pots under glass, and transplanted about the tenth of June. Even last year my whole crop of Christiana ripened nicely before the frost of September 5th destroyed the vines; but the first ripe one was twelve days later than the season before. Of course we can grow later sorts by giving each hill a hot-bed to itself, and not moving them. The famous Montreal melons are grown in that way.

Growers about New York decry the Montreal melon as large, but coarse and insipid. Those who have eaten it in its home know much better than that, and some in New York, at least, have had a chance to try those which have been shipped in from Montreal, as they have been quite abundantly in some seasons. The whole secret is, I think, that the Long Island and New Jersey gardeners have not learned the trick of growing them properly. These big melons are gross feeders, and must have ground much richer than that on which smaller sorts will succeed.

Heating Green-houses.

PROFESSOR S. T. MAYNARD has been conducting some interesting experiments to ascertain the relative value of steam and hot water for heating green-houses, and a report of the conclusions reached are given in a late Bulletin of the Massachusetts Agricultural College Experiment Station. Two green-houses of the same size—seventy-five by eighteen feet—were constructed as nearly alike as possible in every particular. Two boilers of the same pattern and make were put in, and one was fitted for steam to heat the east house, and one for hot water to heat the west and more exposed house. Records of temperature were made five times a day, and from these the following averages are taken for the month of January: Average out-door temperature, 29.1°. For the house heated by hot water the in-door minimum daily temperature averaged 42.7°; maximum daily temperature, 55.1°. Average in-door temperature, 47.5°. In the steam-heated house the temperature varied between 41° and 55.1°, with an average of 45.9°. The coal consumed in the hot-water house was 2,532 pounds, and in the steam-heated house 3,220 pounds. In February the average in-door temperature of the hot-water house was 49.6°, with a total coal consumption of 2,642 pounds, and of the other house the average temperature was 47.9°, and the coal consumption 3,362 pounds. According to this test hot water, with nearly twenty per cent. less coal, gave a temperature 1.7° higher, and a temperature, too, more uniform than that furnished by steam heat.

This only shows that for this mild winter, and with these particular machines, hot water has proved more economical and satisfactory as a method of heating than steam in houses constructed like these two. Still, so far as it goes, it is a fair test, and we are not aware that any similar trial has been conducted. In larger houses and in a colder winter the result might have been different, and Professor Maynard is preparing for careful and accurately recorded comparisons for another year. Meanwhile he invites all who have kept records of the temperature of their green-houses, together with the amount of coal consumed, to send him the figures, giving also the size of the house and the kind of apparatus used.

Spring Flowers.

OWING to the exceptionally mild spring, hardy-flowering plants and bulbs are making a display fully two weeks in advance of their usual flowering period. First in the order of flowering comes *Ranunculus anemonoides*, with its masses of Anemone-like, pale pink flowers, an inch across, produced in advance of the much-divided, glaucous-green leaves. This plant is comparatively new, being introduced into cultivation from the Styrian Alps in 1883, and it is a charming little plant. *R. anemonoides* succeeds well in a moist position in the open border. *Fritillaria pudica* has been noticeable for its pretty, pendent yellow flowers, usually solitary, on stems six to eight inches high, and lasting a month in good condition. This plant is a native of the western states. Coulter in his "Manual" gives it as distributed through "Utah and Montana to the Sierra Nevada and British Columbia." It cannot, however, be very plentiful, as collectors refuse to supply it at any

price. This is to be regretted, as *F. pudica* has a chaste beauty peculiarly its own. *Iris reticulata* is now at its best. As soon as frost leaves the ground the flowers of this pretty Iris are produced simultaneous with the leaves, and is a good plant for planting en masse for spring effect. Its variety, Krelagei, is a few days earlier, of a paler color, and devoid of perfume, which latter the species possesses to a pleasing degree. *I. reticulata* produces offsets from the bulbs quite freely, and these may be relied on to flower the second year. Beds of *Bulbocodium*

cold, but unless protected by snow or some other covering, bright sunshine scorches the tops in very cold weather. *Eranthis hyemalis*, the Winter Aconite, *Scilla Sibirica* and the Crocusses are all in bloom, making the hardy flower-garden an attractive spot, even though frost does visit us every night.

E. O. Orpet.

Hot-beds and Forcing-houses.—Hot-beds must go, at any rate for commercial business. Forcing-houses are cheaper in the

A Field of Lilies in Bermuda.—See page 184.

vernum have a pleasing effect already, their purple Crocus-like flowers being produced in advance of the foliage. When these are planted *Colchicum autumnale* should be mixed with the *Bulbocodiums*. This will give a corresponding crop of bloom, of the same appearance in fall. *Erica carnea* is blooming more freely than it has ever done. One plant here a yard across makes a striking display, being literally smothered with its pretty pink flowers. Many think the Heather is not hardy in this section. It is hardy enough here as regards standing the

long run, safer, and give better plants. Any man with a stroke of ingenuity can engage a carpenter and build his own. Build low, with a very flat roof. Heat with steam. Get the tables near the glass. I like a two-thirds span if I can get a nice southern exposure. Ventilate by raising the whole sash. Have all sash removable. Use gas-pipe for pillars. I have just completed a nice house, 20 x 60 feet, for \$800, heat and all complete, and have heating capacity for one or two more of the same size. It is a fine, substantial house.

Plant Patents.—It is certainly desirable that the originator of varieties should be protected. But I cannot see that plant-patents could be feasible, even if possible. In the first place, it is exceedingly doubtful if a patent could be had for those varieties which spring up from a chance seeding, and it is a fact that most of our varieties come in this way. But granted the patent, there are cases innumerable in which no jury, even of experts, could agree concerning the identity or distinctness of varieties. There are those who contend that no two varieties can be alike if they originate in different places, even though there are no characters to separate them. Of this class is Jacob Moore, perhaps the leading advocate of plant-patents, and he argues that expert growers will not confound such varieties. The facts, however, are against this theory. On the whole, there appears to be no better way than for the originator to adopt more business-like methods of handling his new sorts, and to sell under a copyrighted trade-mark.

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

XVI.—HYBRIDIZATION.

IN what we have called cross-breeding, we keep within the limits of the species, using the pollen of one variety to act on the pistil of another variety of the same species. And, of course, we can cross races in the same way.

Now if we pass beyond the confines of the species and attempt to cross two different species, using the pollen of one to act on the pistil of another, we are undertaking what is known as hybridization. A hybrid is a cross between two species. The term has, however, been rather loosely applied; in fact, some writers have included crosses between varieties as hybrids, and such variety-hybrids frequently figure as true hybrids in some catalogues of plants. In the present paper it is designed to restrict the word wholly to crosses between what are accepted as true species.

First, as to the occurrence of hybrids in nature, little need now be said. That there are some well-marked hybrid Willows and hybrid Oaks is generally believed by all botanists, but the evidence on which such conclusions rest is, of course, inferential. Therefore it is better for us to turn at once to the consideration of artificial hybridization and note its methods as well as its results.

The method is simple theory, and not difficult to put into practice. The flower which is selected as the female is carefully freed from all of its stamens, with their pollen-bearing anthers, and then its stigma crowning the pistil is to be carefully dusted by pollen from the flower selected as the male. The transfer of the pollen can be effected by means of a sable pencil or camel's-hair brush. It is not necessary in all cases that the pollen should be absolutely fresh, for the pollen of some plants can maintain its vitality for a long time, but care must always be taken to see that the pollen is perfectly ripe. Moreover, the stigma of the pistil to which the pollen is applied must be just mature and receptive. If it is not mature, or if it has passed its period of complete receptivity, the pollen will not have its full effect; in fact, it would probably not have any effect at all.

After application of the pollen has been made, care must be observed that all insects are excluded, and that no foreign pollen is conveyed in any manner to the flower. Further than this, no special caution need be exercised. If impregnation has been effected the seeds will "set," and the fruit will go on to ripeness. It is worthy of note that in many cases of hybridizing, the fruit will apparently ripen and the seeds will seem to be good, while in point of fact they are worthless. In general it should be said that, in hybridizing, the blanks are many and the prizes are few.

The range of selection of species between which this process can be tried with a fair chance of success is wide. It is not possible, however, to state beforehand whether a given trial will prove successful, for there are some instances in which the process is not even reciprocal; that is, there are cases in which the species A can be used with success as the female element in the experiment, but will utterly fail if it is employed as the male, whereas the species B may behave in just the opposite manner, being capable of furnishing pollen which will be efficient, while its pistil might not prove receptive.

In general, the species selected should be nearly related. There are a few cases on record in which species belonging to different though closely allied genera have been successfully crossed, but it may well be that the limits of such genera

are yet to be changed by systematic botanists. This has already been done in the well-known genera *Azalea* and *Rhododendron*. Certain species of these two genera can be made to cross with each other, and their cases have formerly been cited as showing that different genera can be hybridized. Recent classification, however, has placed these two genera under one head, and the two are now known as *Rhododendron*.

It is an interesting fact that frequently in a genus there is one species which seems particularly well adapted to serve as the male or female factor in hybridization. Among the *Rhododendrons* the species called *Rhododendron Catawbiense* has played this part in the innumerable successful crosses with the tender species of the Himalayan Mountains.

Hybrids generally share, but not in an equal degree, the characters of the two parents. In some instances a sort of average is struck between the two; this, however, is rare. The influence of one of the two parents is sometimes so preponderating that the effect exerted by the other can hardly be discerned. This was the case in the well-known cross produced by Mr. Francis Parkman between the two species, *Lilium speciosum (lancifolium)* and *Lilium auratum*. Of the offspring from this cross only a single plant shared to any marked degree the characters of the two parents, but the wonderful and beautiful exception appeared to combine, in almost equal amount, the striking and desirable peculiarities of both.

As a rule, the roots, stems and leaves of hybrids are stronger and the flowers are more showy than those of either parent, but there is a marked diminution in the reproductive power. Hybrids incline to be sterile, but this sterility is by no means complete. There are many cases of fertile hybrids.

The offspring of hybrids possess a remarkable tendency to vary. The progeny have been said to cut adrift from the ancestral moorings, and they appear to drift passively in subsequent generations. This curious fact has been made use of by cultivators who have desired to obtain variant forms. They first of all secure a fertile hybrid, and employ this for careful seed-breeding.

Since hybrids are so rarely wholly fertile and, besides this, have a marked tendency to vary in their offspring, it is generally best to propagate by means of their buds in some way.

Derivative hybrids are those which result from the union of a hybrid with one of the parent forms or with a hybrid from a totally different source. In all these cases there is a tendency towards reversion to one of the ancestral types.

One of the most puzzling cases of blending of different characters is that known as *graft-hybrids*. When some of the variegated forms of *Abutilon* have been grafted on green-leaved forms, a few of the subsequent shoots of the stock have been more or less affected by the variegation. The most remarkable case of this is that of *Cytisus Adami*,* a plant which presents a form midway between *Cytisus Laburnum* and *Cytisus purpureus*. While there are many who believe that we have here a case of a hybrid produced by seed, the history as originally given indicates that the blending resulted from placing a bud of the former in the stem of the latter. The case is not wholly without its bearing on what has been noticed in some of our fruit-trees.

Cambridge, Mass.

George Lincoln Goodale.

Recent Publications.

A Manual of Orchidaceous Plants. James Veitch & Sons. Part IV. *Cypripedium*. London, 1889.

The present number of this excellent publication is devoted to a description of the tropical *Cypripediums*, which are, perhaps, just now occupying the attention of the horticultural world more strongly than any other class of plants. We cannot give a better idea of the general characteristic of the work and the method in which the subject is treated than by laying before our readers some rather extended quotations from its pages, which abound in interesting information and sound practical advice. After speaking of the fact that the peculiar structure of the flower of the *Cypripedium* shows that many relative or intermediate forms have been swept away, leaving this single genus as a record of a former and more simple state of the great Orchidaceous order, the author goes on to show "that the structure of the flowers does not furnish the only evidence of the *Cypripedes* being a more primitive race of Orchids than any other existing forms. The geographical distribution of the genus, especially of the two sections of it that form the subject of these pages, reveals some remarkable facts respecting the present history of the included species, all of which tend to the conclusion that the individual plants comprising them must at one time have existed in great numbers,

* See Gray's Text-Book, vol. 2, p. 445.

and have been spread over a much larger area than they at present occupy in a wild state, and that a gradual process of extinction has been as surely in operation here as it has been with more primitive types in other Natural Orders that are now become only subjects for the study of the geological botanist, although, of course, the epoch of final extinction may be yet far remote, and the race may be preserved indefinitely by the hand of man. Paradoxical as this may appear to the horticulturist habituated to regard the *Cypripedes* as being among the easiest of Orchids to propagate, the following considerations will go far to show that the statement here offered rests upon a good foundation. Although the *Cypripedes* are still spread over large portions of the earth's surface, both in the eastern and the western hemispheres, the included species have, almost without exception, retreated to sections that are extremely restricted in area, and frequently isolated and remote from each other; so that while some species are abundant in their known habitats, and have been and are still imported into Europe in quantity, it is very different with other species; for example, the habitat of the beautiful *Cypripedium Fairieanum* is practically unknown, and all the existing plants in cultivation have been derived from the three or four that were first casually imported. Two plants only of *C. superbians* that appeared accidentally among importations of *C. barbatum* are believed to be the progenitors of all at present known, and it is quite uncertain whether the species still exists in a wild state. *C. Mastersianum* has been but once imported, and its habitat is unknown to science. *C. tonsum* was sent to us in company with *C. Curtisii* unknown to its discoverer, who informs us that the last-named is quite rare, while its near ally, *C. ciliolare*, although somewhat more plentiful, has retreated to a remote corner of the Philippine Islands. *C. purpuratum* has become almost extinct as a wild plant in Hong Kong, and it is fast disappearing before the pressure of population on the Chinese mainland. The *Cypripedes* of South America present a similar case in their history. *C. Boissierinum*, one of the first species discovered on that continent, has been found only in a sequestered valley high up on the Andes of Peru, while thousands of miles distant from that lonely spot, on the Roraima Mountain of British Guiana, *C. Lindleyanum* and *C. Klotzschianum* have their home; and still further remote from either, on the Organ Mountains of southern Brazil, *C. vittatum* occurs, and nowhere else. Nor are there instances wanting among the hardy *Cypripedes* to prove that the same process of extinction is still in operation. Our native *C. calceolus* has become virtually extinct in this country as a wild plant, although, owing to its extensive distribution over central Europe, it is still comparatively abundant in some spots, while in others it is visibly yielding ground to the pressure of cultivation and the presence of a dense population; and this is also true of all the Japanese and of several of the North American species.

"The true cause of the gradual extinction of the race is probably to be sought for in the reproductive organs of the flowers. A very cursory examination of these must satisfy most observers that self-fertilization is impossible, and the sexual apparatus is so constructed that few among existing races of insects are found capable of effecting the necessary act of fertilization that secures the perpetuation of the plant by seeds.

"That the tropical *Cypripedes* are similarly circumstanced in their relation to insect visits is in the highest degree probable, for direct observations are, unfortunately, altogether wanting; and the probability is strengthened by the fact that among the thousands of plants imported by us during the past thirty years we have rarely noticed a single seed capsule. The inference is thence by no means an unreasonable one that the fertilization of the flower by insect agency is a rare, or comparatively rare, occurrence, and the perpetuation of the species must depend chiefly on new growths from the rhizome, by which the plants spread laterally, so far as food materials are at hand to support them. But the stations in which, for the most part, they are found, and where they must have originally sprung from the stray seeds that lodged there, are in the crevices of the rocks, and in a few cases on the branches of trees, where there is necessarily an extremely restricted accumulation of vegetable matter; their spread by this means is thence reduced to the narrowest limits."

The restriction of the genus first proposed by Reichenbach, by the exclusion of the South American species, now referred to *Selenipedia*, is only attempted under protest, as it were, as the following extract explains:

"We have, however, strong grounds for believing that this dismemberment of the *Cypripedia* is not final; for, notwithstanding the very important difference in the structure of the ovary of the South American species, these cross with the *Cy-*

pripedia of India and the Malay Archipelago, and progenies derived from this hybridization have been for some time in existence, and are receiving yearly additions to their number from various operators. The facts of the case, as it now stands, must, however, be fairly stated; the East Indian species cross freely with each other, and a numerous progeny of hybrids has resulted therefrom; the South American species also cross freely with each other, and many new forms have been obtained; the hybrids in both sections flower within a few years from the germination of the seed. But in the case of the crossing of the Indian with the South American species, the process has been much slower in producing results; an infinitely smaller proportion of seed germinates, and those seedlings that survive are so slow in arriving at the flowering stage that up to the present time, so far as we are aware, not a single plant has flowered, although the plants in our houses continue strong and healthy in appearance and yearly increase in size. Till these plants flower—and there is no apparent ground for belief that they will not—and the structure of the ovary of their flowers shall have been examined, we prefer to adhere to the original circumscription of the genus, certainly a very natural one, and to regard the ovarium character as of sectional value only. This view is strengthened by the discovery and introduction of the remarkable *Cypripedium Sanderianum*, a Malayan species that brings the relationship between the East Indian and South American *Cypripedes* morphologically still nearer than its previously known allies, *C. Parishii*, *C. Stonei*, *C. Philippinense*, etc., have done."

Of the true *Cypripedia*, exclusive of those inhabiting the north temperate parts of the world, "about thirty species are well authenticated, all natives of a region lying between the 27th parallel of north and the 10th parallel of south latitude, and between the 75th and 150th meridians of east longitude; they are altogether absent from Australia, and so far as at present known, from Africa and Madagascar; they are thence confined to a comparatively limited space within the Indian monsoon-region. They either follow certain mountain chains on which the species occur in groups of twos and threes, or are isolated and far remote from each other, or they are confined to particular islands or group of islands. In the former case they usually occur at a considerable elevation, where the rain-fall is copious and frequent, and the dry season of short duration; in these elevated situations they are found growing chiefly on the ledges and in the crevices of the limestone rocks, which constitute the chief geological features of these mountain ranges, in places where there is a small accumulation of decaying vegetable matter. These localities are often steep and precipitous, extremely difficult of access, sometimes fully exposed to the sun's rays, but more frequently in partial shade afforded by projections and overhanging trees. The insular species usually occur at a much lower elevation, not infrequently close to the sea-shore, and where the mean average temperature is naturally higher than that in which the mountain species grow. At least three species have been observed to have their homes on the stems and in the forks of the branches of trees, sometimes growing on the decaying fibrous roots of ferns.

"By far the greater part of the Indian and Malayan *Cypripedia* region lies within the equatorial zone, and is thence subject to all the climatic phenomena peculiar to that zone; these are fully stated in the introductory notes to *Dendrobium*. The species found outside this zone are chiefly north Indian, and occur on the Sylhet, Khasia and Garro Hills, also in parts of the lower Himalayan range, extending from Sikkim to Eastern Assam, succeeded still further eastward in Hong Kong and in the mountains in southern China by *Cypripedium purpuratum*; the climate of this part of the region is also described in our notes on the geographical distribution of *Dendrobium*, to which the reader is referred."

Of the production of hybrids no one can speak with greater authority, and the following cultural notes are therefore of real practical value: "No genus or race of Orchids that has yet been brought under cultivation has yielded so readily, and, we may add, so strikingly, to its influence as the *Cypripedia*. This is not only apparent in the results of hybridization, which will be noticed more particularly after the description of the species, but also in the species themselves, especially in those that have been longest under the cultivator's care. The most obvious effects of the cultural influence have been the development of more robust foliage of a brighter color, especially in those species with tessellated leaves; the normally one-flowered scape occasionally becomes two-flowered; the scapes themselves are more robust, often more elongated, and produce larger flowers, generally attended with some modification of color. Doubtless the chief cause of these changes is the more

abundant and the more regular supply of food material, by which the plants acquire a vigor rarely seen in those imported from their native countries.

"The geographical distribution of the *Cypripedia* included in this section sufficiently indicates the temperature in which they should be cultivated in the glass-houses of Europe, which is that of the East Indian house for most of the species and hybrids, that is to say, a house in which the night temperature in winter is never allowed to sink below 15° – 12° C. (60° – 55° F.), with a gradual rise as the season advances to 18° – 21° C. (65° – 70° F.), at which it should be maintained from May to August. The day temperature, by fire-heat alone, should be about 3° C. (5° – 6° F.) above those of the night. A few species, chiefly insular, including *Cypripedium concolor*, *C. niveum*, *C. Godefroya*, *C. Philippinense*, etc., thrive best in the higher temperature of the Phalænopsis house; on the other hand, *C. insigne*, *C. venustum*, *C. Fairieanum*, and the hybrids obtained from them may be cultivated in the intermediate house.

"It is evident, too, that as the great majority of the tropical species occur within the equatorial belt, or sufficiently near it to come under the like climatic conditions, of which the most noteworthy are the remarkable uniformity of temperature and the high degree of atmospheric humidity throughout the year, there is practically little or no interruption in their vegetation in their native homes. But when transferred to the glass-houses of this country, it is equally clear that such a uniformity of climatic conditions cannot be so strictly maintained by artificial means, owing to the succession of the seasons; hence there is, at least, a partial cessation of growth, if not absolute rest, during the coldest months of the year. Advantage should be taken of the recommencement of their growing seasons to re-pot the plants not then in flower; they should be potted in a compost of sphagnum moss and fibrous peat in about equal proportions; the drainage should be kept quite free; it should consist of clean broken crocks, with which the pots should be filled to one-half or even two-thirds of their depth, according to the size of the plants. As the roots of *Cypripedium* grow vigorously, ample provision should be made for their development.

"The plants must at no time be suffered to get dry at their roots during the growing season; a high degree of moisture must be maintained in the atmosphere of the house, the amount and frequency of the watering and the sprinkling of the floors, etc. of the house being, of course, regulated by the season of the year and the external circumstances of the weather, etc. The ventilation must also be regulated according to external influences, but it should at all times be as free as is consistent with the well-being of the plants, avoiding cold draughts and sudden changes of temperature. In the summer months the plants should be protected by shading from the direct rays of the sun; a very slight exposure to direct sunlight at that season causes the foliage to change color; this is particularly the case with those species that have tessellated leaves."

Of the *Selenipedia*, or South American Lady Slippers: "About ten species are known to be genuine, of which six inhabit the Cordilleras of western South America, from Bolivia to Chiriqui in Central America, at elevations of 3,000 to 5,000 feet; three occur on the mountains of British Guiana, and one on the Organ Mountains, near Rio de Janeiro. The localities indicated on the accompanying map must, in several cases, be accepted only as approximately true; the names given by plant collectors are often not to be found on any map within reach, and are, moreover, frequently misleading.

"CULTURAL NOTE.—The cultural treatment of all the members of this section, both species and hybrids, is the same as that of the East Indian *Cypripedes*, with the exception of the temperature, which, on account of the altitude at which the species occur in a wild state, should be 3° – 5° C. (5° – 9° F.) lower. All the species in cultivation, with the exception of *Cypripedium Schlimii* and, perhaps, *C. Klotzschianum*, whose scapes are few-flowered, continue in flower for several months.

"HYBRIDS.—In our introductory notes we have adduced the principal evidence upon which rests the hypothesis that the flowers of *Cypripedium* in a state of nature rarely produce seeds, owing to the absence generally of the agencies by which they can be fertilized. Under such circumstances, therefore, natural hybrids cannot be expected to occur, even where two species are found growing intermixed if in close proximity to each other; and it is a remarkable fact—a fact that unquestionably tends to strengthen the evidence we have cited, circumstantial as it is in some points—that no *Cypripedium* having the aspect of being a natural hybrid between two recognized species has ever yet appeared among importations of the species, as undoubted natural hybrids have appeared

among importations of *Cattleya*, *Lælia* and *Odontoglossum*. In strong contrast to this stands the multitude of hybrids raised artificially in the glass-houses of Europe, among which are new forms of exceptional interest, and of so vigorous a constitution that they may, in truth, be regarded as the forerunners of new races. Without attempting to anticipate results to be hereafter obtained from the intermixture of these races with each other and with the pure species, it may be safely affirmed that no greater triumph has been achieved in modern times by the gardener's art than the production of these hybrid *Cypripedes*.

"The first hybrid *Cypripedium* was raised by Dominy, from *Cypripedium villosum* and *C. barbatum*, more than a quarter of a century ago, at our Chelsea Nursery, and was distributed in 1871; it is appropriately named *C. Harrisianum*, in compliment to the late Dr. Harris, of Exeter, who first suggested to Dominy the feasibility of hybridizing and raising Orchids from seed. This was followed at short intervals by *C. Dominianum* and *C. vexillarium*. The first seedling raised by Seden is the well-known hybrid that bears his name, and which was distributed in 1874; this has been followed up to the present time by an uninterrupted series of results which, apart from successes obtained in other genera, has secured for the raiser's name a permanent place amongst British hybridists."

But we have already drawn liberally from Mr. Veitch's pages, and for further information about these plants, and for detailed instruction about the cultivation of the different species, we must refer our readers to the book itself. They will find it one of the most interesting and instructive works of horticulture which has appeared for a considerable time. The subject is admirably treated, and this makes it all the more to be regretted that the faults in book-making, to which we have already alluded in noticing earlier issues, are still adhered to—faults which must always injure its value as a work of reference.

Periodical Literature.

The *Popular Science Monthly* for April contains an excellent and timely article by Dr. Shufeldt on "Zoölogical Gardens, their Uses and Management." It is unnecessary to summarize the paragraphs which detail the direct services of such gardens or the many ways in which they may indirectly further the interests of public education and scientific progress. All intelligent persons know that they have a value far beyond that of affording a lounging-place for curiosity seekers. But it is important to emphasize the author's declaration that they infallibly degenerate into such lounging-places if the collection is "heterogeneously collected" and "purposelessly arranged." To be useful in any degree the selected site must be suitable for its purpose, and the collection must be arranged and managed on strictly scientific principles. "If possible," says Dr. Shufeldt, "the form of the grounds should be a regular figure, an oblong being one of the best, with a long side toward the direction whence come the prevailing winds, as this assists in securing good ventilation, and the area should include at least 200 to 250 acres. . . . Another matter of great importance is the character of the country, which should be as diversified as possible, and the enclosure should contain a few sizable ponds or a good, strong stream of water, in which event the former can easily be constructed artificially. Old trees in groups, some low, level, marsh land, and some hills and rocky portions are all points of extreme natural advantage. These latter features, if marked, usually insure, too, another benefit, for then hilly or broken country is likely to be found immediately beyond the limits of the garden, which, though conducive to the building of handsome suburban residences, is not likely to fill up entirely with houses as the city increases in size, and thus excellent ventilation is secured for all time." Of course, common sense, as well as a desire to create an attractive place of resort, demands such a site as is here indicated. Quoting from Professor Flower the author continues: "The old idea of keeping animals in small, cramped cages and dens . . . still lingers in many places. We have a responsibility to our captive animals, brought from their native wilds to minister to our pleasure and instruction beyond that of merely supplying them with food and shelter. The more their comfort can be studied the more they are surrounded by conditions reproducing those of their native haunts, the more enjoyment and instruction we shall obtain when looking at them." For these reasons, it is clear, the area of a zoölogical garden should be large and its surface should be varied to give proper homes to animals of different habits. Can any one deny the truth of these words? or, after reading them, can any one think that there is room within our Central Park for the establishment of a

zoölogical garden worthy of the name? The area which Dr. Shufeldt, who has carefully studied the subject in foreign lands, declares barely sufficient, means one-third of the whole area of this park. The remarks which he adds upon these accompaniments in the way of libraries, lecture-rooms, dissecting-rooms and museums which should be found in a zoölogical garden do not so nearly concern us here. Everything that he asks is desirable, indeed essential, to the creation of an ideal zoölogical garden, and almost everything could be secured in New York did public interest rise to the level of the occasion. There might be a little longer distance between the garden and the city museums and libraries than he thinks desirable, but New Yorkers are used to long distances, and nothing but money enough and a selection of wise and disinterested managers, who shall not be politicians, is needed to secure all other convenient and useful conditions. But the clearer and wider becomes our idea of these conditions the more absurd it seems that anyone should fancy for a moment that the Central Park could be arranged to afford them, even though it were entirely ruined, as a park, in the process of adaptation.

Correspondence.

An Interesting Garden and a Good Gardener.

To the EDITOR OF GARDEN AND FOREST:

Sir.—Good, all-round gardeners are rare in these days everywhere; perhaps they have always been difficult to find, but they are especially rare in the United States. Modern fashions in horticulture have been a serious hindrance to real advance except in a few very limited directions. Gardeners who have learned their business in the last thirty or forty years have learned a great deal about propagating and growing a few varieties of soft-wooded, tender plants, and about massing them together for the summer decoration of unnatural gardens, and they have learned, too, and most successfully, how to flower Orchids and how to develop all the beauty of leaf-coloring of many inhabitants of tropical swamps. But this has often been done at too great a sacrifice, and it is now rare to find a gardener who is as much at home with fruits and vegetables as he is with Orchids or herbaceous perennials, or one who knows much about trees and shrubs or about forcing, or, what is rarer still, one who knows and can grow hard-wooded, green-house plants.

These thoughts came into my head lately as I was walking through one of the old gardens of the Boston suburbs, that of Mr. John L. Gardener, of Brookline, which for nearly a quarter of a century has been under the entire charge of Mr. C. M. Atkinson, one of the few old-fashioned gardeners now left in America, and one of the most successful men in all departments of gardening who has ever been in this country. It is always instructive to visit these gardens, and the visitor never comes away without at least one valuable bit of information, conveyed in quaint and picturesque language, about some now little known or half-forgotten plant.

There is no garden I know where the good old hard-wooded plants are grown so successfully, or where so many different classes and varieties of plants in the different departments of the garden may be seen in better condition. But the hard-wood plants are best worth mention, perhaps because they are less often seen now than any others, and because they are, it seems, more difficult to grow. The variety is not very great, but there are admirable plants of *Eriostemon intermedium*, one of the most beautiful of the winter-blooming Australian shrubs, which, perhaps, cannot be matched now anywhere, and which would have done credit to the great day of English horticulture, when Mrs. Lawrence reigned supreme in the London flower-shows. *Eriostemon* belongs to the same family as the Orange, and its flowers, although slightly tinged with pink and quite destitute of perfume, resemble those of the Orange in size and form. It is a compact shrub, three feet or more high, of excellent habit, and it lasts in flower during eight or ten weeks. One of the plants, the result of twenty years of careful cultivation, was once exhibited at a meeting of the Massachusetts Horticultural Society for a prize offered for the best specimen plant. The prize went to some quick-growing, foliage stove-plant with a spot or a band which had not been noticed in any of its like, the Committee hardly considering the forgotten Australian shrub worth notice. Mr. Atkinson never will forget this incident, or lose an opportunity to repeat it. There are fine old plants of some of the old-fashioned Azaleas, like *Decora*. Heaths are well done and so are Chozemas, of which a large collection is grown. Here I saw, too, for the first time in America, a plant of *Anopterus*

glandulosa, a native of Van Diemen's Land. It is a member of the Saxifrage family, with handsome evergreen foliage and erect racemes of white or rose-tinted flowers.

These gardens are famed for their Japan Irises and for the great masses of spring-blooming shrubs and bulbous plants.

Hinsdale, Mass.

Injuries to Conifers.

To the Editor of GARDEN AND FOREST:

Sir.—During several weeks past many observers have been noticing the large number of twigs of Norway Spruce that have been scattered on the ground about the trees. In a number of instances red squirrels have been seen on the limbs cutting the young twigs, from which they usually take the buds, and perhaps a part where the twig was severed. It was interesting to notice the varied replies to questions put to people who had seen the twigs on the ground. The twigs come off too hard to warrant the conclusion that they separate spontaneously. Most of them look as though they had been pulled or torn off, and not cut smoothly, although the squirrels caused the mischief. The twigs preferred are those that made short growths last year. Examination reveals the fact that this kind of work has been going on for some years at this place, and some persons remember to have observed this twig-cutting in former years.

Our squirrels here have no difficulty in reaching any part of the trees, even to the ends of slender twigs. In a very few instances the Scotch Pines have suffered in the same manner as the Spruces.

Agricultural College, Mich.

W. J. Beal.

To the Editor of GARDEN AND FOREST:

Sir.—Since writing in regard to possible causes regarding the injury of Norway Spruces, I have found, experimentally, that a high wind alone, unattended by frost, is sufficient to produce the damage. If you will take hold of a branch of the Spruce and give it a sharp shake, you will strew your lawn with broken twigs of all sizes. Your shake does not need to be any stronger than that produced by a sudden gust of wind. We had quite a strong wind (north-west) last week, and I found a considerable number of twigs, all freshly broken, on the north-west side. Spruces standing right behind, but protected against the north-west, had no twigs broken on the opposite (south-west) side, where the force of the wind was sufficiently checked.

Recent Plant Portraits.

LOURYA CAMPANULATA, *Revue Horticole*, March 16: The type of a new genus of *Hamodoraceæ*, near *Peliosanthes*, recently dedicated by Baillon to the head of the indoor department in the *Jardin des Plantes*. *Lourya* is a native of Cochin China, where other species of this genus have lately been discovered. It has the port and the general appearance of an *Aspidistra*, while the flowers which are borne in compact umbles close to the ground and at the base of the leaf-stalk, resemble those of the Lily-of-the-Valley, although nearly twice as large. The plant requires the temperature of the stove.

MARMODES LUXATUM, *Revue Horticole*, March 16, an admirable colored figure of this Mexican Orchid, which has long been known in gardens.

LONICERA FRAGRANTISSIMA and L. STANDISHII, *Gardeners' Chronicle*, February 23d.

Notes.

The Department of Agriculture has just issued a circular on "Arbor-Day Planting in Eastern States." It has been prepared by Mr. B. E. Fernow, Chief of the Forestry Division, and it gives excellent advice as to the treatment of trees before and after transplanting, and the proper method of planting.

An international Congress of Pomologists will be held in Ghent in the month of September next, and in connection with it a large fruit-show. In the same city an International Exhibition of Chrysanthemums will be open from November 23d to December 1st, in celebration of the centennial of the introduction of the plant into European gardens.

It is interesting to note that American methods of Rose-culture are attracting attention abroad. An account of several of our famous Rose-growing establishments was recently printed in the *Gardeners' Chronicle* (London), accompanied by practical explanations with regard to the processes which result in the production of their fine winter crops; and a similar chapter was published in the March number of *Gartenflora*.

It has been decided by the Park Commissioners of Brooklyn to devote from \$200,000 to \$250,000 in preserving and beautifying certain portions of the city lands which lie to the eastward of its streets. About seventy-five acres, eleven acres of which are occupied by the reservoir, will be laid out with walks, drives and play-grounds, and, including the slopes of the reservoir, will be suitably turfed and planted. Ultimately, it is thought that portions of the ground may be devoted to the erection of public buildings, but meanwhile they will be made as useful and attractive to the people as possible.

Thousands of acres have this year been planted with fruit-trees in those districts of southern California where the "land-boomer" recently set all the world mad with speculation. In the San Joaquin valley large numbers of new settlers have lately established themselves in colonies for the purpose of fruit-growing, dividing their land into twenty and forty-acre tracts. In San Diego county the acreage devoted to this industry is five times as great as it was a year ago, and in Los Angeles and many other counties it is one-third greater. And, moreover, the old "placer-mining" counties are rapidly transferring their attention to fruit, and it is now the richest crop of Tuolumne, for example, once a conspicuous centre of gold production.

For many years the prizes offered by the Massachusetts Horticultural Society have been open to all competitors, whether they were members of the Society or inhabitants of Massachusetts or not. Several months ago a few members, who are in the habit of exhibiting strawberries, finding that outsiders living in a neighboring state were carrying off the prizes from the home talent, quietly went to work and secured the adoption of an amendment of the constitution, restricting competition to members of the Society. The movement and the method by which it was carried out have been considered unfortunate by many members of the Society, and at its last meeting the matter was reconsidered, and the prizes, by a large vote, are again opened to the whole world.

At the Massachusetts Experiment Station the black knot on Plum trees has been treated with linseed oil, turpentine and kerosene. These remedies were applied with a brush as soon as the warts began to appear, and as they do not all come at once, applications were made three times during the summer, all the warts being painted over each time. In the autumn, microscopic examinations found no spores in the warts, in fact, none of the sacks (perithecia) were developed enough to produce spores before the warts were destroyed by the remedies. Where kerosene and turpentine were applied so liberally as to spread about on the branch and run down over it, the branch was killed. No such injury came from using the linseed oil. The warts should be saturated in every case. The treatment of black knot hitherto recommended was cutting off the diseased branch and burning it. If this dangerous fungus can be controlled by any less heroic treatment it will be a great gain to plum growers.

At the late exhibition in Ocala, Florida, a scale of 100 points was used for judging oranges. Ten points were given each of the following characters, the first five being grouped as "physical" and the second five as "juice" characters: (1) size, (2) appearance, (3) thickness of peel, (4) absence of tissue or "rag," (5) absence of seed, (6) juiciness, (7) sweetness, (8) sub-acidity, (9) vinous flavor or bouquet, (10) absence of free acid. The standard of perfection for thickness of peel, absence of seed, and absence of tissue, was a full one-sixteenth inch peel on a 200-size, seedless orange, with a one-fourth inch core. An orange which sank in water scored ten for weight, that is, for juiciness. Every seed shown counted half a point off, and two rudimentary seeds counted for one. The unanimity of the tasters was remarkable, showing that the four different elements in estimating the quality of the juice were not fanciful distinctions. Several individual oranges under this rigorous test scored ninety-seven and a half.

Pinus Jeffreyi is well figured in the number of the *Gardeners' Chronicle* published on March 23d; the male flowers for the first time. It is one of the few California Conifers which grows satisfactorily in the eastern States, and those persons who have seen the handsome group of this tree in the park at Buffalo will hardly endorse the opinion expressed in our English contemporary "that a well-grown *Pinus ponderosa* is a very handsome object, the best *P. Jeffreyi* that I have seen is scarcely an ornament." As the two trees are seen here the latter is in every way the more satisfactory. As it appears on the eastern slopes of the Sierra Nevada, where this species abounds, and on Scott's Mountain, in northern California, where it was first discovered by the collector whose

name it commemorates, *Pinus Jeffreyi* is certainly one of the handsomest of the family, as it is one of the largest, being surpassed in size only by *Pinus Lambertiana* and by occasional specimens of *P. ponderosa*, grown in favorable situations on the west or moist side of the California mountains.

A large picture of the conservatory at Castle Ashby, in Northamptonshire, the seat of the Marquis of Northampton, was recently published in the *Gardeners' Chronicle* (London). It is interesting to American horticulturists as showing a conservatory of a kind which has few examples in this country. It is a so-called "architect's conservatory," built for architectural effect rather than for practical efficiency. "It is a place of handsome proportions and good workmanship, and an ornament to the grounds, but the gardener abominates it, for do not his best plants lose their leaves and lower branches and become attenuated objects of no decorative value, often falling a prey to insect enemies?" It was designed by Sir Digby Wyatt, and is 140 feet in length by thirty feet in width. The roof is of glass, sloping up to a ridge in the middle, and in the centre of the house it rises into a dome forty feet in height. But the lofty walls are solid, and a double row of columns, supporting iron girders, runs the entire length of the house. These columns are monoliths of Bath-stone, with rich capitals in the Composite style; and however great the practical disadvantages of such an interior may be, it has great beauty of effect, the columns composing admirably with the tall Palms and Bananas that are most conspicuous among the plants.

A correspondent of a German horticultural journal recently called attention to the fact that the current love for Orchids and ornamental foliage-plants has led to the neglect of those great collections of Orange-trees which were once so highly esteemed in the Fatherland. Fifty years ago every royal and princely establishment had its Orangery—a large building of fine architectural aspect, filled in winter with a mass of Orange and Lemon trees, which in summer were set out in ornamental boxes in the pleasure-garden, and at all seasons could be transferred to the palace itself if an occasion of ceremony required its adornment. These trees were often of great age and enormous size, and to keep them in proper shape and bring them into profuse bearing was the chief task of the gardener. Now, however, they have fallen out of favor to such a degree that an Orangery most often presents but a forlorn and neglected appearance. One can well understand why the writer from whom we quote should protest against such a state of things and should ask whether it might not be possible, by means of some "congress or exhibition" to excite renewed interest in these historical collections. There are, indeed, few green-house plants which can vie in beauty with well-grown Orange-trees in full bloom or fruit, and their presence is almost essential to the right effect of a garden designed in the old architectural way.

The sales of plants at auction began a fortnight ago at the rooms of Young & Elliot, in this city, and will be held every Tuesday and Friday until the 1st of June or later. Fair prices have thus far been realized, although the demand for bedding-plants will be more brisk later in the season, when as many as 50,000 are often disposed of in a day. They are offered in lots of 100 or 50, ready packed for transportation, and are bought largely by country florists, who grow them on and sell them at retail. Small plants of Verbena, Lobelia and the like are often disposed of for a dollar or so a hundred. But, besides this cheap material, more expensive plants, like Palms, Dracænas and Crotons, some of them fine specimens, are often sold. Large importations of Roses and ornamental trees, shrubs and vines have already been disposed of. The latter are often in assorted lots, each containing five varieties. In a lot of twenty bundles, for example, each bundle will contain a Golden-leaved Elder, a Red-flowering Horse-chestnut, a Chinese Lilac, a double pink Deutzia and a purple Hazel. In each of a dozen other lots the selection will be entirely different. Finely-grown specimens of Tree-box, four or five feet high, with many Ghent Azaleas, Rhododendrons and the rarer Conifers, were on the list last Friday. Besides dealers in plants, many persons with large places find it profitable to make purchases here. Altogether, these auction-rooms, on sale-days, are never without their attractions, and visitors to the city who take an interest in plants should not fail to look in.

The Care of Small Tracts of Woodland.

WE have many letters from owners of small tracts of woodland complaining that their trees are dying, that many of them blow down, and that their “woods are running out.” The writers wish to know what is the matter, and what they can do to save their wood-lots. We note that most of these inquiries come from men who live in cities, or who have lived there, but who have places in the country which they desire to improve and enjoy, and some of them say that the more care and pains they bestow on their woodlands, the worse appears to be the condition of the trees. That comes pretty near telling the whole story ; but let us look into the matter a little.

Nearly every farm of any considerable size should have a due proportion of woodland, a tract where forest conditions upon a small scale shall be permanently maintained. The importance of preserving and perpetuating their wood-lots is not, as yet, sufficiently appreciated or understood by the farmers and land-owners of this country. This is, in part, only a special instance or form of a feeling or mental condition which exists widely among our farmers—that is, a degree of discontent with farming as an occupation and investment, a feeling which leads multitudes of them to desire to escape from agriculture and “do something better.” This has resulted from the habit of migration from the older portions of our country to the newer regions of the West, for the sake of richer and cheaper lands, and is reinforced by the restlessness and illusion which are elements of human nature. At present it imparts to nearly everything connected with the farming interest in America a quality of transitoriness and uncertainty, so far as particular persons and their possessions are concerned. A large proportion of our farmers are men who do not yet heartily accept farming as their occupation or business, and this uncertainty regarding the permanent ownership and occupancy of farm lands has a bearing upon many things connected with our national interests and civilization. We shall have occasion from time to time to discuss this element and its various effects ; at present we merely recognize it as one of the causes of the prevailing low estimate of the value of farm wood-lots.

It is encouraging to see any signs of increasing attention to this kind of property, even if, as often happens, the new interest has an injurious or fatal effect. The intelligent observation and comparison of facts will lead to wiser methods of treatment.

The first thing a man from town usually does, when he comes into possession of a place in the country, is to clear out all the underbrush. He says he wishes to be able to see all over his wood-lot. Perhaps the ladies of his family desire to walk about in it, as in a kind of larger door-yard or lawn, and in order that movements and vision may be free all the bushes and small, “worthless” trees are removed. Let us attend to each point as we go along. If our friend wishes to walk in his woods, to enjoy their beauty, coolness and quiet, why does he not open winding paths through them, leading to the places of greatest interest? The first effect of removing the undergrowth, so as to permit an unhindered view of the whole tract of woodland from every part of it, is greatly to reduce its apparent extent, and as a consequence the sense and charm of possession—of ownership—is diminished in the same proportion.

Let us next note the fact that the removal of the undergrowth, and of all barriers to an unlimited view, destroys entirely the element of mystery, of surprise and expectancy, the quality which tempts and rewards the explorer, the impression and promise of something still before us and beyond what we can see, which may minister a fresh delight. When one can see all over a tract of woods at once, its beauty, its real attractiveness, has been eliminated—thrust beyond the threshold. It may still be a good place to look away from ; as a mere point of view it may be worthy of resort or possession, if from it one can see distant-wooded hills, or long, upward-stretching mountain slopes with cloud-shadows drifting across them, or far-away gleams of the blue sea. But any beauty or charm which the place may have had in itself, or which might have been developed or created in it by judicious management, has been destroyed, and the woodland thus treated will not afterward have any spell or power to minister to the happiness or peace of any human being.

Why do the trees die, if they are not blown down? They usually and naturally die because of the increased desiccation of the ground about their roots, and the abrupt access of heat and light produced by the destruction of the undergrowth. The impoverishment of the soil also contributes to the death of the trees. The undergrowth, while it remained, acted as a mulch for all the trees, large and small. It detained the dead leaves until they decomposed where they had fallen. Where forest conditions are maintained the land grows richer perpetually. Now that the underbrush has been destroyed, the fallen leaves are blown away beyond the limits of the land which produced them, and are wasted wholly, or they feed and replenish the soil of another owner. In woods sustained by undergrowth this natural mulch retains the water supplied by rain, and the trees are fed throughout the summer. Now the water mostly runs off at once, and the effect of the heaviest rain lasts but a short time. When trees have nothing to drink they cannot eat, so they die.

To sum up, the natural conditions which have produced and maintained the trees in these pieces of forest or woodland have been interfered with and changed to such an extent that the trees inevitably perish. The passion for “improvement” often leads to draining the woodlands, thus hastening the catastrophe. In general, the best way to take care of small pieces of woodland is to let them mostly alone, keeping out all domestic animals, and taking needed precautions against fires. Open paths, of course, wherever they will enhance the interest of the woodlands and increase their charm for lovers of natural beauty. But in most of the settled regions of our country the woods will not bear any great increase of sunlight about the roots of the trees, or any considerable change in the natural conditions which produced the for-

est growth, and which have hitherto reproduced and maintained it. In such cases as we have considered the owner might almost as well have girdled his trees at once.

The first great improvement in rural cemeteries was made when the bounds between lots were abolished and the so-called "lawn-system" was adopted. In the earliest rural cemeteries, like Mt. Auburn, each owner of a lot was allowed to surround it with such a fence or hedge or stone curbing as suited his fancy. But the boundary-wall offered nearly as good an opportunity for the display of pretentiousness and individual bad taste as the mortuary monument itself, and cemeteries were converted into stone-yards, to which lavish horticultural expenditure gave no effect of rural restfulness or sanctity. The evil, like many others of the kind, cured itself in time; and now in all cemeteries where modern notions prevail no lot is sold without the special provision that the purchaser cannot in any way define its boundaries except by corner-stones sunk below the surface of the ground. The monument, however, remained, and as wealth increased, developed from year to year into a more hideous inappropriateness and vulgarity; and it became evident that without some active control in such matters on the part of the managers of cemeteries, they must fail in those very directions where, it was believed, American burial-grounds were better than those of any other country.

There is in Brookline, Massachusetts, a small rural cemetery belonging to the town, and governed by a Board of Trustees elected by the people. These Trustees, it appears, have taken the lead in instituting a much-needed reform by prescribing the manner in which monuments can be erected in this cemetery. They have had a number of different designs for simple gravestones made by a skillful architect, and if a person wishes to buy a lot he can do so only upon the condition that he will select one of these designs, or if none of them suit his taste, that he will submit some other to be approved by the Trustees.

The idea that underlies this system is the same which has done away with prominent bounds. It is the idea that no individual lot-owner has the right to do anything on his lot which will injure the aspect of the cemetery as a whole. The Brookline Trustees have further declared, on the same principle, that no monument or headstone of white marble shall in future be erected in the cemetery; they regulate for the general good, the selection, by lot-owners, of plants, baskets and other decorations; and discourage expensive architectural tombs. There is no extravagant horticultural establishment connected with the Brookline Cemetery; no beds of glaring flowers, no novel or misshapen trees, no attempts at display. It relies for its attractiveness upon natural woods carpeted with wild flowers, native shrubs and well-kept lawns bordered here and there by noble masses of natural rocks, after the striking feature of much New England scenery.

The idea of controlling the character of monuments in a cemetery is so novel, and indicates such a long step forward in the right direction, that we have obtained from the Board of Trustees the permission to reproduce, for the benefit of the public, and more especially for the benefit of the Trustees and managers of other cemeteries, the selection of their designs which appear upon later pages of this issue.

Hardy Deciduous Shrubs.

PERSONS who have not given direct attention to the matter rarely appreciate the richness and variety of the flora of our Atlantic States in trees and shrubs. One can hardly walk a mile over a road in any hilly section of these States where the waysides have been left with any liberty to clothe themselves with vegetation, without passing at least twenty species of trees and as many, perhaps, of shrubs. We have in mind a short water-course in northern New Jersey where a little brook, rising in apiece of springy upland, hurries down across three pasture-lots to unite with a larger stream in the meadows. At one

point a rather steep bank rises from the brook to a height of thirty or forty feet, and along this bank for a dozen rods the trees and shrubs have been left to grow. Further down there is a little swamp, but elsewhere all is open grazing land, with single trees scattered sparsely over the fields and along the fences, or drooping over the brook. A visitor recently followed this little stream from its source to where it empties into the larger one, a distance of less than half a mile, and counted thirty species of trees. Here is the list: Tulip-tree, Basswood, Red Maple, Sugar Maple, Black Cherry, Wild Plum, Scarlet Thorn, Juneberry, Flowering Dogwood, White Ash, Black Ash, Sassafras, White Elm, Slippery Elm, Mulberry, Black Walnut, Butternut, Shagbark Hickory, Pignut Hickory, White Oak, Scarlet Oak, Black Oak, Pin Oak, Chestnut, Beech, Hop Hornbeam, Ironwood, Sweet Birch, Aspen, Smooth Alder and White Willow, the last a naturalized foreigner. As many kinds of shrubs and woody vines could, no doubt, be named, and perhaps a dozen other species of trees could be found within a radius of a mile, among them the White Pine, the Pitch Pine, the Hemlock Spruce and the Red Cedar.

This list is not quoted to prove the exceptional richness of this locality in species of deciduous trees and shrubs. There are places among the mountains of North Carolina, for example, where many more could be found. But the small number of coniferous trees, when compared with the others, is worth considering. Except in a few favored locations the ratio between the number of conifers and broad-leaved evergreens, on the one hand, and the number of deciduous trees and shrubs on the other, is very small throughout the central and northern Atlantic States. This would seem to indicate that plantations should be largely composed of deciduous trees and shrubs. On our Pacific coast, conifers form a much larger proportion of the forest-growth, and in England, where the climatic conditions approach those of our Pacific states more nearly than they do those on this side of the continent, coniferous trees and broad-leaved evergreen shrubs are among the most conspicuous ornaments of the garden. It was natural that the earliest attempts at gardening in this country should have followed English models, and, as a matter of fact, many gardens in this country have fallen into premature decay because they were largely planted with conifers and evergreens, which have proved sickly and short-lived in our climate.

But because our hot summer suns and icy winters and long, dry autumns are unfavorable to this class of plants, there is compensation in the fact that these are just the conditions which enable deciduous shrubs to make a strong, healthy growth, to ripen their wood well, to bear flowers and fruit in abundance and to develop into a beauty which they can never attain under the soft, moist airs and equable temperature of western Europe. Not only are our native shrubs beautiful at all seasons, but there is hardly a day in the year when a garden composed of them exclusively would not wear some special attraction. Along the brook referred to at the beginning of this article, the bright fruit scarcely falls from the Black Alders before the Spicewood is in bloom. Flower follows flower all summer, and the wild Roses are still opening when the autumn colors begin to kindle in the foliage of the Sumachs. Even when the leaves are gone the Witch Hazel is covered with blossoms. If we add to such local groups the treasures of our colder northern woods and of the southern Alleghenies we can begin to understand how rich and varied a garden could be made from native shrubs alone. And, again, it cannot be too often repeated that for a combination of good qualities no small trees can be found in all the world to excel our Dogwoods, Viburnums, Thorns, Sumachs, Fringe-tree and several others. In foliage, flower and fruit; in form, habit and autumn color they make so effective an addition to the shrubs that we find no occasion to envy the gardens of England for their superiority in conifers.

But this is not all. Deciduous shrubs from other countries flourish here as well as our own. The trees of Europe, as a rule, do not thrive here, but the shrubs of Europe and those that have been produced in European gardens are readily established here, while those from eastern Asia and Japan can be found in every door-yard. Indeed, the Forsythias, the Spiræas, the Flowering Quinces, the Mock Orange, the Lilacs, the Snow-balls, the Tartarean Honeysuckles, the Weigelas, the Deutzias, the Rose of Sharon—the shrubs most commonly planted—are all of foreign origin, and among those recently introduced into cultivation are many quite as interesting as those of established reputation. Practically the number to choose from is almost limitless. In the Arnold Arboretum more than 1,200 species and varieties of shrubs are now growing, and further south a still larger collection could be gath-

ered. Most of them are easily raised. All they ask is ordinary kindness and they will increase in beauty every year. Best of all, they are adapted to small gardens, and small gardens in this country will always greatly outnumber the large ones. There is no village lot with a square rod of turf which cannot be beautified by a border of hardy shrubs, and there is a place for them, and a place of honor, too, in the most spacious and the most elaborate grounds. They are useful for massing and for single specimens, and the planter who knows how to handle them properly can find a place for them in comprehensive landscape effects as well as in the construction of cabinet pictures—in the middle distance as well as in the foreground of his compositions.

If there is to be anything distinctive in the gardens of eastern America, it will grow out of the freer use of deciduous shrubs, and in years to come those parks and gardens will be most interesting where these shrubs have been planted with the greatest intelligence and skill.

Tombstones for Rural Cemeteries.

MR. J. A. SCHWEINFURTH, a well-known architect of Boston, recently prepared twenty-five designs for simple cemetery monuments, and has kindly joined the Trustees of the Brookline Cemetery, at whose request the drawings were made, in consenting that a few of them should here be reproduced. It was difficult to choose eight as the most interesting, where all were very good; and those we give may be accepted not as better than the others, but simply as showing several different types which, with sundry others, were variously developed by the artist.

The first thing to be remarked in these stones is their simplicity; and it need hardly be explained that this is the most important quality they could possess. There may be many places where highly ornate sepulchral monuments are appropriate, but a rural cemetery is not one of them. But, on the other hand, simplicity should not mean crude ugliness, even in the smallest and most thoroughly rural burial-ground. Stones should be at once unobtrusive yet artistic, plain yet beautiful. Good taste should speak not only in the restricted use of ornament, but in its tasteful application and skillful designing. The artistic excellence of these eight designs will, we believe, be as readily appreciated as their lack of ostentation. In place of the bald shapes, clumsy profiles and mechanical inscriptions with which our simple tombstones in the past have made us familiar, here we have carefully studied proportions, graceful contours and the suggestion of a kind of lettering which, easily executed and easily read, has yet a certain decorative charm.

Perhaps the best of all the designs is No. IV. A flat slab, covering the place where the cofined form has been laid to rest, is undoubtedly the earliest form which the Christian monument assumed when it was placed in an open, grassy spot; and it seems the most natural and expressive form, explaining its purpose and marking the site it consecrates more exactly than an erect stone can do. Its inscription can be easily perused by those who stand beside the grave; and the fact that it is invisible at a distance may be counted a merit, as the last hint of ostentation is thus avoided. Countless memories come to mind of famous men whose tombs are marked by flat stones in those cemeteries of the Old World which most nearly approach in idea to ours; but we need only recall the fact that such a stone was thought sufficient to mark the grave of Albert Dürer in the suburban graveyard at Nuremberg. Those who seek it to-day where it lies embosomed in grass, and read its simple inscription, "*Emigravit*," receive an impression the appropriateness and adequacy of which must convince them that no more conspicuous memorial is needed even for the resting-place of a very noteworthy man. There is a Christian humility and dignity and a simple pathos in the aspect of a stone like Dürer's, or like the one here pictured, which is lost, perhaps, even in the most modest stone which stands erect. And from the point of view of the repose and sanctity of effect which a cemetery as a whole should have, flat stones are palpably preferable to all others.

No. VII. shows a modest type of headstone which is redeemed from poverty by its graceful proportioning and by the simple band of classic adornment which encircles the lettering. No. V. is another classic design which is given a less severe look by a nicely profiled base and cornice. No. VIII. is sturdier, again, in its proportions, and those who think classic ornamentation a little cold and inexpressive on a modern tombstone may be attracted by the Palm-branch which forms its decoration. Here a place for a possible second inscription is indicated on top of the stone, nor is there any reason why

all its sides could not be used if the lettering were discreetly applied; and a single monument, bearing the names of several individuals, is often more desirable than many, being less obtrusive as well as much less costly. Too often we see a pretty lot, where a single attractive monument should have stood, encumbered with a row of stones which, if they are all alike, produce the unfortunate effect of things bought by the quantity or, if they are unlike, contrast unpleasantly with one another. No. I. shows another squarish stone, but with a canted space on the side for the inscription. In another design, not reproduced here, Mr. Schweinfurth varied this idea by making the stone still thicker and inclining both sides to give room for two inscriptions. No. VI. shows a stone which is extremely plain in outline but wins beauty from the decoration. It is intended, of course, for use upon a soldier's grave, and in the artist's series it was accompanied by a second, which was appropriate for a naval officer or sailor.

At the time of the Reformation, or more exactly, in Puritan days, the cross was so generally associated with the rites and usages of the Catholic Church that it was wholly banished from Protestant graveyards. No crosses can be found among the old tombstones of New England, and in Protestant Germany they are still rare. Modern American feeling, however, has again accepted them as the natural symbol of every Christian sect, and the form constantly occurs in all our cemeteries. We are unable to give our readers a strictly simple cross-form from Mr. Schweinfurth's hand; but something better, we think, is offered in the picture No. III. This is one of the very earliest of Christian gravestone-forms reduced to its simplest elements. It shows that combination of the cross and the circle—the emblem of Christ and the emblem of eternity—which more constantly appears than any other design in the oldest sepulchral monuments of the northern nations of Europe. In many parts of the British Isles gravestones may still be seen—not, of course, in their original positions, but preserved in church or cloister, or in some antiquarian collection like the rich and interesting one in the library of Durham cathedral—which antedate not only the Norman, but the English conquest. They have come down to us from that early British Church which flourished when the Romans bore sway in the land, which was wiped out of England proper by the deluge of Anglo-Saxon heathens, but lived on in Ireland, thence extended its influence to Scotland, and from Scotland came back into the north of England again when the missionaries of Rome were converting the more southerly districts. And on almost all these monuments—separated from one another, perhaps, by several centuries of time, but akin in that artistic character which is popularly called "Celtic"—the cross within the circle appears. Sometimes it forms the body of the stone, as in our picture, although seldom so simply treated as here. Sometimes it is carved in relief, sometimes incised; but in one shape or another it is the prevailing motive. Surely, therefore, there can be no motive which is more appropriate for the use of modern Christians descended, as a rule, from the inhabitants of the British Islands. None could have greater historical sanctity, none could be more expressive in its meaning, and none could be more attractive to the eye. It was, indeed, because of its many claims to attention that two designs were selected for reproduction in which this symbol appears. In No. III. it forms the monument; in No. II. it is carried upon a plainly outlined headstone, and interwoven with those ribbon-like lines which were the great and inevitable feature in all kinds of "Celtic" ornamentation. This stone might almost be accepted as a genuine relic of the early British Church, and seeing that it is wholly unaffected, appropriate and modern-looking, the fact will undoubtedly recommend it to those who care for artistic, historical, or ecclesiastical suggestiveness.

There is another merit, we may add, in designs as simple as these besides the great merit of appropriateness to their place. They are not difficult to execute; they can be well formed and carved by any intelligent stone-mason, while an elaborate design with very varied profiles and intricate carvings needs a skillful sculptor for its right execution. Even where money is not grudged is usually difficult to find such a sculptor just when and where he is needed for such a purpose. The original designs which Mr. Schweinfurth prepared were drawn on a larger scale than our reproductions, and were accompanied by sections from which any careful mechanic could work with success.

Of course the good that may spring from the publication of this little series need not be confined to actual imitation of the designs portrayed. Each of them suggests much more than it reveals; each of them may become the text for a large number of variations. Only, it should be borne in mind that to

vary such designs and secure a corresponding degree of excellence is not a task which the client should assume himself or should confide to the average stone-cutter. They are excellent and attractive not because they are simple, but because their simplicity is artistic; and it is artistic because an artist was employed to make them. Yet this fact need not deter any individual or association, however modest the sum of money at command, from attempting to secure their like. The task is one for an artist, but for an artist it is not a very difficult task. There are many young architects in America who could design good gravestones now that Mr. Schweinfurth has pointed out the direction which their efforts should take; and their fees would doubtless not be large for a single stone, or even for a number sufficient to serve as a sample stock, so to say, for the trustees of a rural burial-ground. An architect, be it remembered, and not a sculptor, is the proper person. Quite apart from the fact that well-trained architects are more frequently found in this country than well-trained sculptors, it may be explained that a sculptor's training does not prepare him to deal with formally-shaped blocks of stone, much less with ornamentation of an architectural character, such as incised bands of decoration, and especially profiled bases and cornices. The better sculptor he is, the more certain he will be to recognize this truth. Indeed the best sculptors make no secret of the fact that whenever an architectural element, no matter how small and simple, occurs in their work, they call upon an architect for assistance.

If Mr. Schweinfurth's designs excite the interest they should, if they stir up those who purchase monuments to demand something better than the stone-cutter's clumsy and mechanical wares, and inspire his professional brethren with a wish to show what they can do in the same direction, the public will owe a great debt to him as well as to the Brookline Trustees who employed him. We believe that only in very exceptional, isolated instances has an artist hitherto been called upon to design a simple headstone for a grave; and we are certain that no series of such memorials, designed by an artist, has hitherto been published.

New or Little Known Plants.

New Japanese Chrysanthemum, Wm. H. Lincoln.

IN this new Chrysanthemum, another of the interesting Mrs. Alpheus Hardy collection, we have a combination of qualities seldom displayed in one variety. The habit is strong and bushy, the foliage fine; the flowers are of enormous size, and of a desirable rich yellow color, similar in shade to those of the variety *Jardin des Plantes*; they are supported by unusually stout stems, which always hold them in an upright position. The petals are long, tubular for about half their length, the outer portion nearly flat, with slightly incurved tips.

The illustration shows a flower considerably less than natural size.

A. H. F.

Foreign Correspondence.

London Letter.

BITING north-east winds, with sharp frosts now and again in the early morning, are causing fruit-growers a little anxiety, but the sunshine is calling forth flowers in all sorts of nooks and corners, and the Daffodils are almost in their full glory. Amongst a host of varieties, big and little, distinct and not distinct, there are several which are delightfully good. Among these are *N. cyclamineus*, one of the Calathinus group, whose history appears to be almost as romantic as that of the *Shortia*, *N. minimus*, a pretty little flower, and *N. Santa Maria*, one of Mr. Barr's discoveries, and the darkest yellow I have yet seen. The flowers of the latter are very large, and not unlike the Major variety of *Pseudo-Narcissus*. Erythroniums of various sorts, chiefly of *E. dens-canis*, although your *E. grandiflorum* is also well represented, are beautiful both in leaf and flower. *Primula denticulata*, *Chionodoxa Sardensis* and *C. Luciliae*, the two last being sheets of the brightest blue, and the old *Scilla Sibirica* are almost, if not quite, as pretty. These three plants are largely used at Kew for outdoor effect in early spring, the *Scilla* greeting one in beds and in the grass in all parts of the garden. *Anemone blanda* is still beautiful with flowers; as also are the Hepaticas. Primulas of many kinds are in bloom, most of them in pots in a frame or cold green-house.

Daphne mezereum is now at its best, several large beds of it at Kew being just now a great attraction. Planted in a peaty soil in a moist, somewhat shaded position, this Daphne becomes a large shrub, and flowers most profusely. *Prunus*

divaricata is in full bloom, a large, spreading tree of it being a prominent feature on one of the lawns.

Drosera cistiflora is at last flowering at Kew, and bears out all that has been said and written in its praise as a beautiful flowering plant. The stem is erect, five inches high, with linear leaves two inches long and covered with reddish, glandular hairs. The flower is terminal, saucer-shaped, two inches across, and colored a brilliant poppy-scarlet. *Godwinia gigas*, an enormous-flowered, tuberous-rooted Aroid, is also in flower at Kew. The spathe is boat-shaped, two feet long, very stout, and colored deep vinous purple. The plant is a native of Nicaragua.

The Hyacinth, its history and cultivation, was the subject of three papers read before the last meeting of the Horticultural Society, two of the papers being by well-known Dutch growers of these plants, the third by Mr. Douglas, a noted grower and exhibitor of Hyacinths in England. Amongst much that was of interest, nothing particularly new was started, except a fresh theory as to the origin of the garden Hyacinth, and the suggestion that there does not appear to be any good reason why the Dutch should hold a monopoly of the Hyacinth trade. At Kew some experiments in Hyacinth cultivation have been and are still being made, and as far as they have gone they show unmistakably that these plants, like the Tulip, Crocus and Daffodil, may be grown year after year with as good results in some cases as anything from Holland. Miller preached this practice a hundred and fifty years ago, and it is true several attempts have been made since then by English horticulturists to wrest at least a portion of the Hyacinth trade from the Dutch, but they failed because of the prejudice in favor of the Holland bulbs. The natural conditions which in Holland are said to be exceptionally favorable to the Hyacinth and other bulbs are not really so. I mean, that so far as the real wants of the bulbs are concerned the conditions are just as favorable in many parts of England, and probably in America also. It is simply a question of labor and prestige. There are some even now who recommend Dutch *Narcissi* before English grown, in spite of the superiority of the latter, as has been shown again and again. We know that tulips can be grown at least as well here as in Holland. But the Hyacinth has yet to be grown here. There is something peculiar about the life-history of the latter which I do not yet understand. As a rule, after the bulbs have been once flowered in England they are considered of no further value. Mr. Douglas, in his paper, recommended distributing them among the poor. Is there any reason why the garden Hyacinths should not grow on and improve from year to year, as, for instance, Lilies, *Narcissi*, and many other similar plants do? At Kew we find that the bulbs of many of the sorts after flowering develop two to four crowns, so that there are several spikes, smaller ones, naturally, the year following. In such cases it is likely that the crowns should be pulled apart and grown on as if they were young bulbs. All the garden Hyacinths have sprung from *Hyacinthus orientalis*, a comparatively poor plant, not much, if at all, better than our wood Hyacinth, and, like it, blue-flowered. It is remarkable that, although the first record of the cultivation of the Hyacinth was about the year 1585, there was a white variety in 1602, all colors in 1614, and in 1657 double-flowered forms were known. In 1725 no less than 2,000 named varieties were in cultivation. There appears to have been a Hyacinth, as well as a Tulip mania, such sums as £133 8s 6d having been given for one large and eight small bulbs of a double, blue variety. Nowadays a shilling is a good price to pay for a good Hyacinth.

In Holland the Hyacinths are grown in fields, which are well-manured with cow-dung, cropped once with potatoes, and then the bulbs are planted in September. As soon as the flowers expand the spikes are cut off, and in June the bulbs are lifted, dried and stored till the following September. This is done annually till the bulb is large enough for the market. They are propagated from bulbils produced at the base of old bulbs, which have been cut several times across the bottom or the base scooped out. It takes from four to six years to grow a full-sized bulb from one of these bulbils, and about eight years from seeds. The latter, however, are never employed except by breeders. I wonder what the Dutch growers do with the matured bulbs which remain on their hands unsold? This year Hyacinths have been below the average, owing, no doubt, to the absence of sunlight and warmth during the early part of last summer. Those who have a quantity of bulbs on hand after they have flowered in pots should plant them on lawns or grassy banks in a sunny position. They will take care of themselves and make a beautiful display in spring. There is a bank of them in the wild garden at Kew, and they are, at least, as great an attraction as the thousands of Daffodils and

carpets of Crocuses, which are also a feature of this wild garden.

The following plants were amongst those exhibited at the "Hyacinth Conference" and were noteworthy: *Cyrtopodium Saintlegerianum*, a magnificent Orchid with a spike a yard high, freely branched and bearing over a hundred flowers, which were yellow, thickly barred and blotched with chestnut-red, prettily undulated, and formed so as to resemble butterflies. The large bracts at the base of the branches were as brightly colored as the flowers. It is probably only a variety of *C. punctatum*, an old garden Orchid, though rarely flowered. *C. cardioclena*, a yellow-flowered species was also shown. It is very similar to *C. Andersoni*, differing chiefly in the form of

anum, a very pretty species, or probably a natural hybrid between *O. cirrhosum* and *O. crispum*. *Spathoglottis Kimballiana* (*S. aurea*), a grand Orchid, which a friend well described as a "big, yellow-flowered Phalænopsis." *Dendrobium micans*, said to be a hybrid between *D. Wardianum* and *D. lituiflorum*, but not perceptibly different from some forms of the last-named species, was sent by Messrs. Veitch and obtained a first-class certificate. The same firm sent beautiful little examples of *Boronia heterophylla*, and some new *Hippeastrums*. A *Clivia* named John Laing was exhibited by the nurseryman whose name it bears, and was generally admitted to be the largest-flowered and deepest-colored of any yet seen.

the crest on the labellum. A magnificent spike of *Odontoglossum crispum* var. *Stevensii*, with flowers four and a half inches across, of perfect form and heavily marked with large chestnut blotches, was shown by Baron Schroeder. *Oncidium superbiens* and *O. macranthum* were shown in first-class condition. These two are among the very choicest of *Oncidiums*, indeed, one might say of all Orchids. The last named had a spike eight feet long, and the flowers were each three and a half inches across, with dusky yellow sepals, bright yellow petals, a curiously formed fleshy-purplish lip, bearing a prominent white crest. *Dendrobium melanodiscus*, a hybrid from *D. Ainsworthii* and *D. Findlayanum*, was shown by Sir Trevor Lawrence. He also sent a plant of *Odontoglossum Ruckeri-*

Cultural Department.

Evaporated Sulphur in the Green-House.

THE value of this remedy against many parasitic fungous growths and minute insects which infest plants grown under glass has long been recognized, but the results of some experiments made by Professor S. T. Maynard are so interesting they are worth the attention of everyone who grows plants under glass. The report was made in a bulletin of the experiment station connected with the Massachusetts Agricultural College.

This remedy consists in keeping a kettle or basin of sul-

SELECTIONS FROM TWENTY-FIVE DESIGNS MADE FOR THE TRUSTEES OF WALNUT HILLS CEMETERY. JAS. SCHWEINFURTH ARCHT. BOSTON.

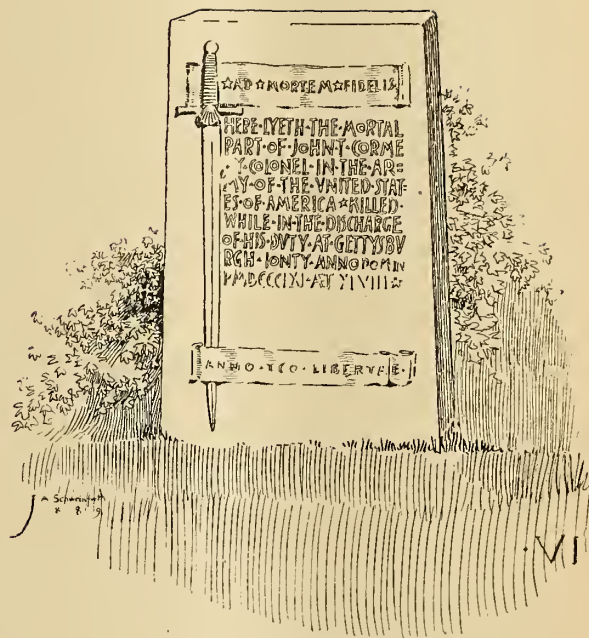

phur (brimstone) heated to nearly the boiling point, in the room for three or four hours, twice or three times a week. The apparatus used at Amherst was a Florence or Monarch hand-stove with the sulphur in a thin iron kettle. Enough sulphur must be evaporated to fill the room with the vapor, so that it will be visible and give something of the odor of sulphur.

Rose mildew (*Erysiphe pannosa*) is a very common difficulty in green-houses not properly constructed. It may be brought on by the exposure of plants while growing rapidly to draught of cold air, by high temperature night and day, by watering and syringing late in the day, by lack of plant-food, bad drainage, extreme dryness, or anything, in short, that may weaken the plant. This mildew was abundant, but after the use of the

sulphur it quickly disappeared totally. The remedy had the same effect on the Rose-leaf blight, *Actinomena rosea*.

The greatest obstacle to the growth of good Lettuce under glass is perhaps the Lettuce mildew (*Peronospora gangliiformis*). A fair trial of evaporated sulphur led to the conclusion that it will prevent the development of the mildew, but when the fungus is once established it will not destroy it. Before trying remedies Professor Maynard suggests, as preventive measures, that Lettuce under glass be grown at low temperature, ranging from 35° to 40° at night to 50° to 70° during the day; that an abundance of plant-food be supplied at all times; that soluble nitrates are valuable in quickly developing a resistant vigor of leaf; that an abundance of water must be

used, but the drainage should be good and the watering done in the morning and on bright days only; that sudden extreme changes of temperature must be avoided.

The reasons for these precautions are that in order to have perfect assimilation and growth in plants under glass, that temperature must be provided under which they grow most vigorously out-of-doors. In the garden we find the night temperature averaging from fifteen to twenty-five degrees lower than that of the day. In the summer when the temperature is high and ranges about the same, night and day, mildew, blight, rust, smuts and all manner of parasitic plants grow rapidly. Now, if in our green-houses we ventilate during the day-time, and at night start up the fires so that the temperature

is as high at night as during the day, we have just the conditions under which mildews develop outside, and if a record of the temperature were kept in those houses most afflicted with mildew this condition of things would, no doubt, be found.

As with the Rose mildew, a sudden chill, when the Lettuce plants are growing rapidly, will check their growth and so weaken them that the cells develop food in the proper condition for the rapid growth of such parasitic plants. That a plant in a vigorous, healthy condition will resist the attack of the mildew longer than a sickly one is shown by the fact that the weakest plants are always first injured by it. It is to guard against such weakness that all the elements of plant-food must be supplied in abundance, and especially in a quickly

soluble form. In an experiment made with Sulphate of Potash, Muriate of Potash, Nitrate of Soda, Nitrate of Potash, Sulphate of Ammonia, Bone-black, Dried Blood and seven other mixed fertilizers, it was found that the Nitrates of Soda and Potash, applied to a soil liberally supplied with stable manure, produced a vigor of leaf that was much less injured than where the other elements were used.

The reason for watering in the morning is that the Lettuce mildew, like most plants of its kind, can only grow under conditions of a close, moist atmosphere and a high temperature, and if the watering is done in the morning, and especially on sunny days, the moisture gets dried from the leaves before night, and the mildew is less liable to grow.

In using evaporated sulphur it should always be borne in mind that burning sulphur is quickly destructive to all plant growth, and every precaution should be taken that it is not heated so hot as to take fire, or that the kettle does not get upset. The lamp or stove should have a broad base or the kettle be placed on a tripod with feet well spread. It should be placed under the bench where it can be readily seen, but where the clothes of a person passing by may not catch upon it and upset it.

The vapor of sulphur also proved effective in cases of Grape mildew and the leaf blight of Chrysanthemums. It routed, too, the red spider, one of the worst pests of the green-house.

Cattleya Lawrenceana.

SIR RICHARD SCHOMBURGK, while exploring British Guiana during the years 1840-1844, was the first to discover this handsome *Cattleya*, which he mistook for *C. Mossiæ*—a species which has only been found in Venezuela. For many years collectors of various firms undertook perilous journeys in search of this *Cattleya*, but all their efforts were unsuccessful until as recently as 1884, when it was rediscovered in the Roraima region of British Guiana, growing along the banks of the Kookenaam River among rocks and on the trunks of trees. Although the introduction to cultivation of this species is comparatively recent, it has nevertheless become already one of the greatest favorites with amateurs and horticulturists, who value it on account of the great beauty, richness and distinctness of its flowers. The spikes have generally from three to five flowers, and sometimes more, each about six inches across, with oblong sepals, and elliptic, wavy petals, varying in color from pale rose, to deep rosy-purple, the tips of the petals being usually darker. The funnel-shaped lip is usually of a very rich crimson-purple, the intensity of which renders it conspicuous at a great distance; the throat is creamy-white, lined with rose. The flowering season begins in April, just when *Cattleya Trianae* and its innumerable forms are finishing, and lasts until *C. Mossiæ* and *C. Mendelii* begin to bloom.

Growing as it does among rocks and trees in its native home, this species may be grown with equal advantage either in pots or baskets, as the cultivator thinks suitable, and placed in the usual compost of good, fibrous peat, with a layer of clean crocks underneath. It thrives best in a warm corner of the *Cattleya* house, where the pots or baskets, as the case may be, should be suspended from the roof in a position to allow as much sunlight as possible. During the growing season, that is, early in the year, plenty of water should be given, and only on certain occasions, when the rays of the sun may be considered exceptionally powerful, should any shading be given. During hot days air may also be freely given; but the instinct of the cultivator must guide him in all these things. When the flowering season is over, water should only be given sparingly, in fact, only just enough to enable the plants to retain their plumpness. Shifting the plants at this time into a slightly cooler house would be beneficial, so as to ripen the growths, and encourage them to flower freely when the season for doing so comes round again.

St. Albans, England.

John Weathers.

Roses for Out-door Planting.

IN making preparation for planting or re-planting out-door Rose-beds, deep cultivation, good drainage and the liberal application of manure well worked into the soil are essential. Well-rotted stable manure is usually found the most satisfactory fertilizer. In the planting of permanent beds of hardy Roses it is generally found that plants on their own roots are better than grafted ones, from the fact that the latter are more likely to be winter-killed, unless they are grafted very low down on the stock, so that the point of union may be entirely covered with earth in planting out. If this is done the plant will frequently send out roots from the base of the graft, and

thus become more or less independent of the stock. If the plants have been grown in a warm house they should be gradually hardened off for the change. When the plants are dormant, having been grown in a cold frame or some similar structure, or merely heeled-in for the winter, it is well to plant them out as early as possible, as plants in this condition require a little more time to become established than young plants in active growth.

To those who have not yet decided what varieties to plant, the following brief list of well-tested Roses is added. Among hybrid perpetuals are:

ALFRED COLOMB.—A bright crimson descendant of General Jacqueminot; very fragrant and most desirable in every way.

ANNA DE DIESBACH.—Yielding large flowers of a pleasing shade of carmine.

EUGENIE VERDIER.—Silvery-pink in color, large and of beautiful form. An improvement on Victor Verdier.

FISHER HOLMES.—Deep crimson, and of good form. Considered by many growers an improvement on General Jacqueminot.

GENERAL JACQUEMINOT.—Too well-known to need description, and still growing in popularity.

JOHN HOPPER.—A free grower and profuse bearer of bright, rose-colored flowers.

MARIE BAUMANN.—Carmine-crimson, a lovely shade of color, and also of fine form. Very fragrant, and altogether a charming Rose.

Among Tea Roses, Bon Silene, Souvenir d'un Ami and Marie Van Houtte are about the most satisfactory for out-door culture.

The best known Bengal variety, Souvenir de la Malmaison, though old, still retains a place in the front rank of popular sorts.

In the foregoing list, pure white varieties have been omitted, and this deficiency may be met by the addition of Madame Plantier (Hybrid China), for early flowering, and the Hybrid Noisette, Coquette des Blanches, for later blooms, the latter being a very useful variety for summer flowers.

A few Polyantha Roses will also prove a pleasing feature among out-door Roses, with their abundant miniature blossoms.

MIGNONETTE, with flowers of a delicate, light rose color, and Paquerette, pure white, are two of the best of this section. If a representative of the Hybrid Teas is desired, La France is decidedly the most satisfactory, but like most of its class, and also the pure Teas, it needs some protection in severe winters, at least if planted in an exposed position.

Holmesburg, Pa.

W. H. Taplin.

Tulipa Turkestanica.—This is perhaps the earliest-flowering species of this numerous family, coming in with the earliest of spring-flowering bulbs. *T. Turkestanica* has pretty, yellow flowers, which are produced as many as six on a stem. Our plants have been grown in the open ground for several years without any protection whatever, and flower annually. This plant, as the specific name implies, is a native of Turkestan. We are indebted to Dr. Regel, of St. Petersburg, for this and many other interesting plants.

Puschkinia scilloides, or Striped Squill, is a remarkably pretty little plant from Asia Minor, much resembling a Scilla in size and habit. The flowers are white, and are produced in dense racemes, each of the divisions of the perianth being prettily striped on both sides, with blue down the centre. When planted with *Scilla Sibirica*, *P. scilloides* has a charming effect.

Chionodoxa Luciliæ has been sufficiently catalogued to need no description, but too much cannot be said in its praise as a hardy spring-flowering bulb. We find the bulbs do not deteriorate, but come stronger year after year, and no matter what may happen the plant, even to being plowed under, the pretty, starry flowers are sure to appear at their appointed season. All the above thrive best in a sandy soil, where there is no fear of too much moisture during their resting season, and the best results are obtained when the bulbs are lifted every second or third year and re-planted, adding some well-decayed manure to the soil before doing so.

Anemone Pennsylvanica.—For naturalizing in semi-wild places there is no Anemone so suitable as this fine, native species, not excepting the cosmopolitan *A. nemorosa*. We remember to have seen *A. Pennsylvanica* holding its own among tall grass in an open, dry spot by the road-side. The flowers are of the purest white, rivalling the Japan Anemone in size and purity. Owing to the rapidity with which this plant spreads it is not to be recommended for the flower-border proper, but should be planted where it may have plenty of

room to occupy, as single plants the second year after planting will have taken possession of a square yard of ground, giving in return an abundance of bloom in June and July.

Passaic, N. J. *E. O. Orpet.*
Spring-Flowering Irises.—I am pleased to observe from a note in your paper that *Iris reticulata* is now also appreciated in America. I beg to state that the typical plant will soon be eclipsed by improved varieties having all parts of the flowers much larger. The color, too, begins to become more varied in seedlings, and very soon we shall have this plant in all shades, from blue and blackish-red to white. I was successful last year in producing a splendid novelty in the shape of the closely allied *I. Bakeriana*; this has standards and claws of sky-blue; falls, white, spotted with violet and the lamina of a blue-black color. This makes altogether a lovely combination, quite as hardy and early as *I. reticulata*, and also fragrant. *Iris rosenbachiana* in its striking coloration looks rather Orchid-like, and ranks among the earliest and most valuable spring flowers. It has a white ground, with shades and blotches of purple-red and slaty-blue. The flowers are rather large, and deliciously sweet-scented. It is a native of central Asia.
Max Leichtlin.

Baden-Baden.
About Peas.—There is no necessity for planting dwarf Peas now in a home-garden where neatness should prevail, and it is impossible to secure neatness where Pea-vines tumble about as they will. Even when such Peas are planted they should have some support, especially since galvanized wire-netting of any width can be had at three-quarters of a cent for a square foot. A trellis of netted wire is almost invisible when bare, and entirely so when covered with vines, and it is as good for Sweet Peas to flower upon as it is to support ordinary garden Peas. With this cheap trellis, which can be rolled up and kept for years in good condition the question of the height to which a Pea-vine grows assumes less importance, and since unsightly brush can be dispensed with it adds much to the neatness of a garden.

It is too late now for the very earliest planting of Peas, except in the most northern portions of the country. This should be made just as soon as the ground is in working condition. The early market Pea, sold under a different name by every dealer, should never be planted in the home-garden. What the market-gardener wants is a Pea which is early and matures its crop all at once, so that he can clear away the ground and prepare for a succession. For the home-table an early Pea is wanted, and one that will continue to supply the table for some time. Fine flavor, too, is essential, and productiveness of less importance. Of late years wrinkled varieties of the richest quality have been produced, which are scarcely behind the hardy little Daniel O'Rourke in earliness. All things considered, Alpha is as good as any for first crop. Then it is well for a second planting to put in four varieties on the same day—Alpha, Premium Gem, McLean's Advancer or Stratagem and Champion of England. These will be fit for use one after the other, and keep up a succession for three or four weeks. A second and third planting of Champions, at intervals of ten days, will furnish the table with green Peas until their flavor begins to decline in the hot, dry weather.

A late crop of Peas can be had about the time of early frost by sowing Premium Gems in early September. It is always best to sow these late Peas in deep furrows, cover them lightly, and gradually draw the earth to them as they grow. If the weather is favorable a fair crop may be had, but mildew is an enemy to autumn Peas, which it is difficult to prevent entirely.
Crozet, Va. *W. F. Massey.*

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

XVII.—THE FRUIT AND SEED.

THE ovary of the flower contains the ovules, and when ripened the whole becomes the fruit, enclosing the seeds. For instance, the ripening pea-pod consists of a parchment-like ovary filled with maturing ovules. Each pea-pod remains distinct from all others, and is free from union with any other parts. Many ovaries, on the other hand, are composed of what we may regard as two or more fruit-leaves united. Again, many ovaries during their formation and ripening become conjoined to some neighboring parts which undergo processes of change simultaneously with them. The ovary of the apple and pear is compound, and, furthermore, comprises certain parts of the flower-stalk (or receptacle) and the outer row of modified leaves of the flower, all of which form at maturity the fruit as we know it. But, strictly speaking, only the apple-core is the fruit, in the sense of its being

the ripened ovary with its ripe seeds. The instances of the combinations of neighboring parts with the ovary are innumerable, and the modifications are extremely diversified. In the ripening of the fruit changes take place in the whole structure and texture; in fact, we may range from the most juicy pulp to the most flinty stone.

In these changes during ripening there is a remarkable accumulation of food materials such as starch, sugar, oil and the like in the fruit and seed, and between the two parts there exists an interesting compensatory relation. Thus, in the peach, the greatest accumulation of food is found in the pulp surrounding the peach-stone, while in its nearest of kin, the almond, the food is collected in largest amount in the seed itself. The two well-known allied fruits of the Tropics, the Coconut and the Date, furnish another case of the same sort.

The treasuring up of food in the fruit and seed is accompanied by more or less oxidation. This is to be expected, for we have here a case of rapid growth, and as we have seen, oxidation is one of the principal phenomena of growth in general. Now the rate at which the process of growth proceeds in the fruit and seed is measurably under our control. If we detach a fruit from the parent plant when yet unripe, and keep it under conditions where it can obtain a moderate amount of oxygen sufficient for its needs, it will continue to ripen. There is one well-known condition necessary to this continuance of the process—the surroundings must reach a certain temperature. If there is not sufficient warmth, the process is arrested, and the fruit can be kept for a long time without marked change. This is the principle on which the cold-storage warehouses are now conducted with success. Another important advantage is gained by keeping the fruits in a cold place—they are far less liable to be attacked by the organisms which cause decay.

The seed contains a ready-formed plant in miniature, with an adequate supply of food for its earliest period of germination. The parts of this miniature plant are: (1) Root, foreshadowed by the cone at the extremity of the stem. (2) The stemlet. (3) Seed-leaves. (4) First bud. During the process of germination, to be described in the next paper of this series, these parts increase in size at the expense of the food stored within the seed, the supply being sufficient to help the plantlet through its early days until its expanding green leaves have the opportunity of manufacturing food out of the inorganic materials taken from the air and the soil. The food is generally an admixture of oils with other matters, but there are a good many seeds in which the amount of starch far exceeds the amount of oil. If the food is plainly distinct from the germ it is known as the albumen; if the whole store of food is in the embryo itself, the seed is said to be ex-albuminous.

Perhaps the most comprehensive view of the food in a seed, can, for our purpose, be gained by a brief examination of that which is treasured in a grain of wheat. (1) The presence of mineral matters in the seed is shown by the ash left after combustion in the open air; this ash consists essentially of the inorganic constituents shown in a former paper to be absolutely necessary to the healthy growth of the plant. (2) Starch, sugar and oil in the seed are easily demonstrable by simple processes of separation. (3) Nitrogenous substances, forming the viscid mass left when moistened flour is washed with water. These latter matters are complex, but, as we have seen before, they may be roughly classified together as the substances which are akin to the flesh of animals, namely, the albuminoids of various kinds. Part of the latter represents, of course, the very flesh of the plantlet itself, to wit: the protoplasm of living matter in which its activities are manifested.

The length of time which can elapse before a seed loses its vitality is very different for different plants. The periods have been determined with great accuracy by Vilmorin for a good many of our cultivated plants, especially those of our vegetables, a few of which data, including also weights and numbers are given in the table below. It must be understood that these figures represent only the average of merchantable seeds.

Name of Plant.	Weight, in grammes, of one Litre	Number of seeds in one gramme	Duration of germinative power.	
			Average.	Extreme.
Beet,	250	50	6 years.	10 years.
Carrot,	240	700	4 to 5 "	10 "
Celery,	480	2,500	8 "	10 "
Cucumber, . . .	500	35	10 "	10 "
Beans,	625 to 850	75 to 800	3 "	8 "
Maize (Sugar-corn)	640	4 or 5	2 "	4 "
Peas,	700 to 800	2 to 5	3 "	8 "
Turnip,	670	450	5 "	10 "

These figures are considerably lower than those which were given by a committee in its report to the British Association for the Advancement of Science, in 1850. They found that the seeds of plants from twenty genera germinated after from twenty to twenty-nine years' separation from the parent plant. It should be stated in connection with the vitality of seeds that there is no positive evidence that wheat-grains from the wrappings of mummies have been made to germinate. All trustworthy evidence is to the contrary.

The degree of ripeness of seeds has some influence upon their power of germinating readily. One observer has shown that certain seeds which are not perfectly ripe germinate somewhat sooner than those which are mature, and he has also pointed out the interesting fact that seeds separated from the plant, but still enclosed in the fruit-vessel ripen.*

Seeds can be seriously injured by cutting or other mutilation without losing their germinating power. The repair is prompt in some instances, even to the extent of restoring one-half of the seedling plants. Van Teighem's experiments, in which seeds of the Sunflower were divided in halves, each half yielding a good plant, show how patient plants in their youngest stage can be under very untoward conditions. This power of repair in germs and seedlings has been compared to that observed among some of the lower animals.

Lastly, it should be noticed that in most seeds the supply of food is more than sufficient for the needs of the young plant, so that in case of any accident by which the seedling is injured, a fresh demand can be made upon the remainder of the store of food.

The manner in which the food is used by the seedling is to be examined in the next paper of the series.

Cambridge, Mass.

George Lincoln Goodale.

Correspondence.

To the Editor of GARDEN AND FOREST:

Sir.—In the report of the U. S. Commissioners of Inquiry to Santo Domingo, 1871, on page 79, line 5, I read: "A great highway, about one hundred feet wide, lined on either side with a Sabea hedge, the trees now averaging more than a foot in diameter, by fifty or sixty feet high, and extending nearly the whole distance from Guerra to Santo Domingo City."

Will you oblige me by saying what "Sabea" is, and where I can learn of it?

Cambridgeport, Mass.

Chas. H. Hall.

["Sabea" is evidently a mis-print from Ceiba, one of the names of the Cotton-tree of the West Indies and Central America (*Ceiba viticis foliis cudice aculeato vel glabro*, Plumier, *Pl. Am.* 42), now the *Eriodendron anfractuosum* of botanists. It is related to the Bombax of the Old World and is the largest of the West Indian trees. Enormous buttresses strengthen the tall, straight stems which support broad masses of foliage high above all the surrounding vegetation, and add to the majestic appearance of this noble tree. The leaves are palmately digitate, the flowers rose-colored and abundant, and the seeds, contained in large capsules, are each enveloped in copious light-colored wool, to which it owes its popular name. This tree is propagated by sticking large-sized branches into the ground, which root and grow with great rapidity. The wood is light and very soft, and the large trunks, hollowed out, furnished the Caribs with canoes; the wool from the seeds is sometimes used for stuffing mattresses. The specific designation, anfractuosum, is derived from *amb* and *frango*, and means the winding or bending of a road or path, in and out or backwards and forwards—a name bestowed on the tree (according to Macfadyen, "Flora of Jamaica," 93) on account of its size, which caused the deflection of roads, it being easier to change the course of a road than to cut through the buttresses of one of these giants; and perhaps a superstition of the negroes may have played its part in preserving these trees; for, according to Macfadyen, "even the untutored children of Africa are so struck with the majesty of its appearance that they designate it the 'God-tree,' and account it sacrilege to injure it with the axe, so that, not unfrequently, not even the fear of punishment will induce them to cut it down. Even in a state of decay, it is an object of their superstitious fears;

they regard it as consecrated to evil spirits, whose favor they seek to conciliate by offerings placed at its base." There is much curious information about the Cotton-tree in Sir Hans Sloane's "Voyage to Jamaica," ii., 72, published in 1725, and no tree is so often alluded to in the accounts of early voyages to the West Indies and the Spanish Main. —Ed.]

Ornamental Trees in California.

To the Editor of GARDEN AND FOREST:

Sir.—There are many fine specimens of rare trees in the grounds about the summer residences of the wealthy Californians in this lovely valley, which is now at its best, covered with a carpet of richest green and dotted over with Live-Oak trees. Beautifully rounded green hills two miles distant, are backed by the Coast range on the side toward the ocean, while on the opposite side is the bay, hemmed in by another range on the further shore. The mildness of the climate may be inferred by noting the vegetation. Callas and Heliotropes showed the effect of light frosts a week or two ago, but are now beginning to flower freely.

I took special notice of two Almond-trees in full bloom a fortnight ago, and since then we have had several frosty mornings that would certainly have destroyed fruit blossoms in the east. The fruit on these trees is now set fully, and with not one sign of an injured blossom.

Araucaria Bidwillii, *A. Brasiliensis* and *A. imbricata*, are perfectly hardy here, as shown by perfect specimens twenty feet high, with no sign of ever having been injured in the winter, and as much at home here as in southern California, although the Norfolk Island Pine, the Grevillia, the Rubber-tree and a few others that are hardy in the south will not stand here.

The variety of tender and half-hardy trees and shrubs is wonderful when compared with the number that will grow in the east. There are here Acacias, apparently without number, Palms, Yuccas, Dracenas, Agaves, all the Magnolias, evergreen and deciduous, many now in full bloom, Camellias and Rhododendrons, with the brightest of foliage and covered with flowers.

Most interesting to me were the magnificent conifers, *Sequoia gigantea* and *S. sempervirens*, perfect specimens quite at home, and forty to sixty feet high. *Cedrus Deodara* and *C. Libani*, *Cryptomeria Japonica*, *Pseudotsuga Douglasii*, *Picea Sitchensis*, *Cupressus Lawsoniana* and many others, forty to sixty feet high. I was disappointed in not finding good specimens of *Abies concolor*, *A. nobilis* and *A. grandis*, etc., but fine specimens are rare compared with the number planted, for overcrowding here is the rule as far as I have seen. It is only in rare instances, and then apparently by accident, that a fine tree of the largest size has had an opportunity to develop fully. Fortunately among these are many fine Araucarias, Deodar Cedars, Douglas Spruce, Lawson's Cypress and Sitka Spruce. The last-named tree hardly met my expectations, as I had been led to believe that it resembled *Picea pungens*, which went for some time under the same name (*Abies Menziesii*).

It is a fine tree, however, a compact grower, well-filled in, and a broad pyramid in form. Many of the specimens show the peculiar shade of light blue on the new growth, resembling the darker blue tint in *Picea Ajanensis*. Indeed, this tree has a closer resemblance to *P. Ajanensis* than to *P. pungens*, as the branches incline upwards, as in *P. Engelmanni*, while *P. pungens* grows in whorls, one tier of branches rarely, if ever, running into and mixing with the tier above it. In the cone, also, and in the consistency of the leaf it resembles *P. Engelmanni* more closely than *P. pungens*.

I have only seen two specimens of *P. pungens* in this state. These are on the grounds of Senator Stanford, and they are fine specimens of the lightest shade. On the same grounds are a few fine specimens of *A. concolor*, four to eight feet high, and the only good ones I have seen. Other specimens of the tree and of the other California Silver Firs which have come under my notice, have been ruined by close planting.

The Douglas Spruce is a grand tree hereabouts, indigenous in the mountains a few miles distant. Under cultivation it can be used freely without producing sameness, as it varies very much in both form and color. But the one tree of all others which I admired most, and which can be used in greater quantity than any other native spiral-topped tree, from the variation of form and color in the individual specimens, is Lawson's Cypress. Specimens sixty feet high, perfect in form, with foliage of deep green, shaded with deep blue, are common. Others are so light in color that they would compare favorably with some of the so-called "golden" trees in cultiva-

* Gray's Text-book, Vol. II., p. 460.

tion. In form the trees vary greatly, some being broad and flat-headed, and others extremely slender, with drooping branches hanging close to the trunk.

It was a pleasure to see among all these new faces a few old friends, which seemed perfectly at home. The Norway Spruce, so common in the east, does remarkably well, and occasionally I see a specimen with a peculiarly graceful sweep of the lateral branches, which is equalled only by the Himalayan Spruce (*Picea Morinda*). I have only seen two of these trees here, both on the Flood estate. In contour they resemble those Norway Spruces, which throw out their arms a little below the horizontal. But beyond this there is no comparison between the trees. The leaves of the Himalayan Spruce are twice as long as those of the other, much stronger, set evenly around the branches, and in color are an indescribably lovely green on both sides. The dark-colored buds are remarkably large, and the male flowers much larger than those of the Norway Spruce. The cones, too, are much larger, with scales over half an inch wide, rounder, thicker, of a warm cinnamon color, and looking like a fine piece of cabinet-work, with an oil finish.

In place of the native Firs, which I missed, I find *Abies Nordmanniana*, doing wonderfully well, and making a perfect tree when standing alone.

Palo Alto, Cal., March 10th.

Robert Douglas.

Recent Publications.

The Folk-Lore of Plants. By T. F. Thistelton Dyer. D. Appleton & Co.: New York. 1889.

No more charming book as a gift for the lover of flowers could be found than this one of Mr. Thistelton Dyer's, which recently appeared in England, and has been re-issued here, in attractive shape. The author says, in his preface: "Much has already been written on the folk-lore of plants, a fact which has induced me to give in the present volume a brief summary—with a few illustrations in each case—of the many branches into which the subject naturally subdivides itself." Perhaps the best-known book of its class is Friend's "Flower-lore." But this consists of two large, thick volumes filled with a mass of information and anecdote that, valuable in itself, is badly arranged, confused by frequent repetitions, and too voluminous to attract any but the most enthusiastic student. Other writers, who have taken up the entire subject or have devoted themselves to some single branch, have usually published their essays in periodicals which are difficult to obtain, and sometimes have written in a rather dry way from a strictly scientific point of view. There was a real need, therefore, for a small book which should cull the most interesting facts and fancies from previous publications and present them in a clear and readable form. This book Mr. Thistelton Dyer has given us. The information it contains will satisfy almost all readers, while its copious foot-notes will lead more inquiring minds to other reservoirs of knowledge.

The first chapters deal with primitive and savage notions concerning plants and with the plant-worship of ancient peoples. Plants in demonology, in fairy-lore, in folk-medicine, in religious ceremonials and in the calendar are severally discussed; and chapters are given to plant-names, to children's games, to dream-plants, love-charms and a number of similar subjects. Of course a book which consists of a mass of anecdotes, brief bits of information, quotations and illustrations cannot be systematically reviewed. All one can say of it in a general way is that it covers a wide field, all parts of which are equally well filled, and offers many interesting and curious facts, not only to the lover of flowers, but to the student of myths, traditions and ethnographic relationships. Yet, as it is a book to be sincerely recommended, we may try to prove the interest and variety of its contents by extracting a few passages at random here and there.

"Briefly noticing the antecedent history of plant-worship," says the author, "it would seem to have lain at the foundation of the old Celtic creed, although few records on this point have come down to us. At any rate we have abundant evidence that this form of belief held a prominent place in the religion of these people, allusions to which are given by many of the early classical writers. Thus the very name of Druidism is a proof of the Celtic addiction to tree-worship, and De Brosses, as a further evidence that this was so, would derive the word kirk, now softened into church, from *Quercus*, an Oak, that species having been peculiarly sacred. . . . One of the last and best-known examples of the veneration of groves and trees by the Germans after their conversion to Christianity is that of the 'Stock am Eisen,' in Vienna," which, as Fergusson explains, is "the sacred tree into which every apprentice, down to recent times, before setting out on his *Wander-*

jahre, drove a nail for luck. It now stands in the centre of that great capital, the last remaining vestige of the sacred grove round which the city has grown up, and in sight of the proud cathedral which has superseded and replaced its more venerable shade."

The Rowan-tree, or Mountain Ash, "has long been considered one of the most powerful antidotes against works of darkness of every kind, probably from its sacred associations with the worship of the Druids. Hence it is much valued in Scotland, and the following couplet, of which there are several versions, still embodies the popular faith:

'Rowan-tree and red thread,
Put the witches to their speed.'

But its fame has not been confined to any one locality, and as far south as Cornwall the peasant, when he suspects that his cow has been 'overlooked,' twists an ashen twig round its horns.

"In Brittany young people prove the good faith of their lovers by a pretty ceremony. On St. John's Eve, the men, wearing bunches of green Wheat ears, and the women, decorated with Flax blossoms, assemble around an old historic stone and place upon it their wreaths. Should these remain fresh for some time after, the lovers represented by them are to be united; but should they wither and die away, it is a certain proof that the love will rapidly disappear."

Many flower-lovers must have wondered why an humble, graceful little herb (*Galium*) is called Bed-straw. This book will tell them. It was formerly "Our Lady's bed-straw," because it had filled the manger in which she laid the infant Jesus. Ribbon-grass is called in rural England "Our Lady's Garters," and the Dodder her "Laces." The Lilies-of-the-Valley are her "Tears," and the Maidenhair-Fern is "Virgin's hair." A curious fact is that while at the dawning of Christianity numerous plants which had been consecrated to heathen goddesses were re-dedicated to the Virgin; in Puritan times they were christened afresh under the name of Venus—the bitter hatreds of the time making even a pagan deity seem a less dangerous person to invoke or reverence than the Mother of God.

"The St. John's Wort gets its name from the belief that its blood-like little spots made their first appearance on the day when the saint was beheaded. A German legend informs us that as the Holy Family took its flight 'they came into a thickly-wooded forest, when, on their approach, all the trees, with the exception of the Aspen, paid them reverential homage.' The disrespectful arrogance of the Aspen, however, did not escape the notice of the Holy Child, who thereupon pronounced a curse against it, whereupon its leaves began to tremble, and have done so ever since. . . . The mournful tree which formed the wood of the cross has always been a disputed question. . . . According to Sir John Maundeville it was composed of Cedar, Cypress, Palm and Olive . . . the notion being that those four woods represented the four quarters of the globe. Foremost among the other trees to which this distinction has been assigned are the Aspen, Poplar, Oak, Elder and Mistletoe. Hence, is explained the gloomy shivering of the Aspen leaf, the trembling of the Poplar, and the popular antipathy to utilizing Elder twigs for fagots. But it is probable that the respect paid to the Elder has its roots in the old heathenism of the north, and to this day in Denmark it is said to be protected by 'a being called the elder-mother,' so that it is not safe to damage it in any way. The Mistletoe, which exists now as a mere parasite, was, before the crucifixion, a fine forest tree; 'its present condition,' says Baring-Gould, in his 'Myths of the Middle Ages,' 'being a lasting monument of the disgrace it incurred through its ignominious use.'"

Here, finally, are a few old rhymed proverbs with regard to the weather:

"If the Oak is out before the Ash,
'Twill be a summer of wet and splash;
But if the Ash is out before the Oak,
'Twill be a summer of fire and smoke."

"When the Hawthorn bloom too early shows,
We shall have still many snows."

"Onion's skin very thin,
Mild winter's coming in;
Onion's skin thick and tough,
Coming winter cold and rough."

"When the Oak puts on his goslings grey
'Tis time to sow Barley night or day."

"When Elm leaves are big as a shilling,
Plant Kidney beans if you are willing;
When Elm leaves are as big as a penny,
You *must* plant Kidney beans if you wish to have any."

Notes.

Dr. Peyritsch, well-known for his studies of the morphology of plants, died recently at Botzen.

The National Society of Horticulture of France has decided to give in Paris, in November, an exhibition of Chrysanthemums.

The death of C. F. Martin, a veteran French botanist, and for many years director of the Botanic Garden of Montpellier, over which the great De Candolle once presided, is announced.

Marsh Marigolds from New Jersey swamps and meadows were in great abundance on the street flower-stands on Saturday, and no brighter yellow was seen among all the Easter flowers.

The Spring Meeting of the Pennsylvania Forestry Association will be held in the Chapel of the Normal School, Westchester, on Friday the 26th inst., at 7.30 P. M. Mr. B. G. Northrop will address the Association upon the subject of Arbor Day. All persons interested in the preservation of our trees and forests are invited to be present.

Easter Lilies, in large quantities, from Bermuda, were on sale in this city last week. They do not endure transportation well, and are much inferior to home-grown flowers, the prices of which were but slightly affected by the imported Lilies. The demand for all kinds of flowers seemed greater than ever, but owing to the lateness of the season the market was well supplied, and prices were not exorbitant. Roses and Daffodils were in greatest demand. In the decoration of churches branches of Japan Quince, Forsythias, Genista and other shrubs in flower were used very generally, and with good effect.

In Philadelphia the Bermuda Lily and *L. longiflorum* were both unusually abundant in the Easter flower-markets, and prices declined twenty per cent. The highest retail price for these was forty cents each for every open flower and unexpanded bud upon the plant. Azaleas were abundant and sold at profitable prices. Tulips, as cut flowers, except the lighter varieties, were in slight demand. Roses were sought for more than any other flower, and brought good prices. There seemed to be no notable preference for any particular flower. Flowering plants of Hydrangea of various kinds were sold in great numbers, but they are always popular as gifts at this season.

The Swiss Alpine Club and a newly-formed society for the protection of native plants have recently joined in establishing a garden in which Alpine plants are to be grown and the directors of which will endeavor to spread among the people a knowledge of the great necessity which exists for preserving them from extermination. Not only the famous "Edelweiss" but numberless other Swiss plants are in danger of being swept from the face of the earth by reckless tourists and by native collectors, who pick them in large quantities to press and sell to foreigners. The garden is to be called "Linnaea," and the place chosen for it is near the town of Fionnay, in the commune of Bagnes, Valais, at a height of some 1,500 metres above the sea-level.

The leading article in the *Gardeners' Chronicle* for March 30th was a reprint of the one on Mr. Hunnewell's "Italian Garden" at Wellesley, which was recently published in these columns. The full-page picture which formed the supplement of the same issue was not, however, a duplicate of ours, but a different view of the gardens, taken last year from the lake. Its label inaccurately gave the site of the garden as "Boston, Massachusetts." Wellesley lies, in fact, some dozen miles from Boston, in the town which derives its name from Mr. Hunnewell's estate, and of which the chief feature, as is well known in this country, is Wellesley College, one of the largest establishments of the sort in the world devoted exclusively to the education of women.

A correspondent of an English horticultural journal wrote as follows with regard to the Orchid Exhibition held not long ago in the Eden Musée in this city: "Being the first horticultural show that I had ever witnessed in the United States I was somewhat desirous of observing in what points it would vary from one in the old country. It was astonishing to note so great a difference in the methods and manner of exhibiting the plants, there being none of that stiff formality so characteristic of the English flower-show, but all was grace and elegance, even to the tables, which were not overcrowded or in straight lines, showing off the exhibits to advantage. . . . The largest and most meritorious exhibit was that of the firm of Siebrecht & Wadley." Mr. W. S. Kimball was mentioned as chief among the amateur exhibitors, although the collections of others were named with praise.

The death was recently announced of Ernst Rudolph von Trautvetter, who was born in Germany in 1809, but spent most of his life in Russia. In 1835 he was appointed assistant to the director of the Imperial Botanical Garden in St. Petersburg, and a little later professor of botany at the University of Kiev, where he founded a botanical garden. In 1850 he became rector of this university, and in 1866 was made director of the St. Petersburg garden. More than eighty botanical treatises were published by Trautvetter, most of which relate to the flora of the far northern parts of Russia and Siberia, and of the Caucasus, and the most southerly parts of European Russia. He was recognized as an authority on the plants of the empire, and his chief works—"Flora Rossica Fontes" and "Incrementa Florae Phanogamæ Rossicae"—are indispensable to all botanists who desire to carry his investigations further.

The Rev. Dr. R. S. Storrs has retired from the Board of Park Commissioners of Brooklyn. In his letter of resignation he explains that this step has been rendered necessary by a recent interpretation of the law by which the functions of the Board are regulated. Under this interpretation the Board has no authority to expend, according to its own judgment, and under its responsibility to the city, the moneys specifically appropriated for its use in the care and maintenance of the parks. Dr. Storrs says: "It is quite impossible for me to devote time and labor to the work of making suggestions which, after they shall have been discussed, matured and adopted by the Board, may or may not prove acceptable to others having the real authority in the premises. My time and thought are too much engaged upon other things to allow them to be given to such ineffective skirmishing in the air; and it is painful to me to see the Park already suffering, and destined to suffer more and more for want of work which the Board has no power to order to be done, yet for which the feeling of the city holds it responsible."

The windows of the flower-shops in Boston have never been so well filled as they are this year. They have not before displayed such a variety of flowers, or such well-grown specimens. Not even in Paris can displays of this sort be seen so tastefully arranged. Roses, in very great variety and of surprising excellence, are the great feature in these windows; but there is a marked increase of comparatively rare flowers—Orchids, Lilies, Amaryllis with forced Rhododendrons and Gladioli, besides the usual forced bulbs in great variety, Azaleas, Violets, Pansies, Carnations and other familiar flowers. There is no other city where such displays can be seen, or where such free object-lessons are offered to every passer-by. The number and the excellence of the flowers sold in the streets by itinerant dealers, at prices which can hardly make much return to the growers, is simply astonishing. Boston is more than holding its own as a great centre in the world of horticultural development and horticultural taste, and the labors of the men who founded and maintained the Massachusetts Horticultural Society is now bearing its legitimate fruits.

Continuing his articles on the cultivation of Roses for the production of attar, to which we have already referred as an interesting feature in recent numbers of the *Gartenflora*, Dr. Dieck gives the following account of planting operations in Roumelia: "In the autumn, sections of ripened wood, about one foot in length, are laid in trenches at the distance of two or three feet apart, and covered with two or three inches of soil. The sprouts, which spring from the eyes in the wood, take root without difficulty and grow into hedges, which often bear as early as the second year, although it is only in the fourth year that complete development is reached and a full harvest can be gathered. The hedges are formed one or two metres apart, according as it is desired or not to grow vegetables between them. In the autumn, and in the spring until harvesting time, the ground is diligently hoed and loosened, and, in certain places, the bushes are covered at the advent of winter, as in the higher districts harmful frosts are not uncommon." The methods of culture pursued in Asia Minor are similar. But the planting is carried on in a "truly Turkish way," which reveals the fatalistic Mohammedan belief that if Allah wills a tree to grow the help of man is superfluous. "The worthy Turk of Bithynia simply makes a hole about two feet deep in the place where he wishes a new Oil-rose to grow. Then he cuts off from a Rose-tree a bundle of twigs, throws them in the hole, with a pile of horse-dung on top of them, fills up the hole, and leaves the rest to Allah. The only remarkable thing is that almost invariably some one of the buried buds manages to sprout, pushes up through the dung and the heavy layer of earth, and justifies the faith of its planter."

School Grounds.

FOR several months in the year a large proportion of the children of this country spend at least half of the hours of daylight, for five days of the week, in or about the school-house. At the most susceptible period of life the influence of these surroundings must in the aggregate be considerable. A neat and tidy room, with simple and cheerful decorations, will be a constant object-lesson to every eye. A room with decrepit furniture upon an unclean floor, and with walls and ceiling broken and stained, will teach its lesson, too, in taste and morals, but it will be quite a different one. It is due to the health of children that they be supplied with abundant light and air. This means a detached building, with ample, open space about it, even in the city. Exercise is also essential to the healthful development, as well as to the happiness of children, and play is the natural and spontaneous exercise and refreshment for both their minds and bodies. A playground may, therefore, be considered a necessary adjunct to every school. Children will play wherever they have room, but it will hardly be argued that a bare space of earth, which will be dusty or muddy as the weather changes, offers every advantage that children should be able to derive from their school-grounds. If the school-room can be made to give lessons in cleanliness and order and taste, the surroundings of the building should be arranged to enforce the same lessons.

That properly ordered school-grounds can aid in this direction, and, besides this, be made an important educational auxiliary in some branches of natural science, was the thesis of an interesting paper read two months ago before the Massachusetts Horticultural Society by Mr. Leverett M. Chase, Master of the Dudley School, in Roxbury. Mr. Chase argued that the ideal school-ground should be separated into two distinct portions—one devoted to the purposes of an out-door gymnasium, and the other an area of green sward, properly planted with trees, shrubs, vines—in short, a pleasure-garden for the children. They should be taught that the garden is theirs, and a feeling of responsibility for it should

be encouraged. That this sense of ownership will engender such a personal interest that the exuberant destructiveness, so often manifested by school-boys, will give place to a sentiment of affection, and a desire to protect their shrubs and flowers has been proved in many instances. If the plants are all carefully labelled and catalogued; if the children are invited to aid in cultivating them, under proper direction, they will gain much practical information as to the laws of plant-growth, and if a serious attempt at systematic instruction in certain branches of botany is connected with the care of the grounds, many lessons which it would be an irksome task to acquire otherwise, will be learned without effort, and even with positive delight. From the knowledge thus gained, and the interest aroused in the school-garden, we may reasonably look for a growing love of Nature—an increasing appreciation of the beauty of trees and their value. If this generation of children were reared under such influences ours would be a land of fair gardens in a quarter of a century, and there would be no difficulty in securing proper legislation for the preservation of our forests. Indeed, it is to be feared that a distinctively American forest-policy which shall embrace in its scope the wisest administration of the nation's forests, and the most intelligent care of the farmer's wood-lot, will never be adopted until the interest and sympathy of the children are enlisted, so that they will grow up with sound views and generous sentiments as to the importance of trees and forests as an element of the national welfare.

Of course, grounds sufficiently spacious for a garden cannot now be found connected with every school-building, and in crowded cities large school-gardens will not be practicable. But there is room for a beginning everywhere. A narrow border along the foundation of the school-house may be made beautiful with flowers from the time when Snow-drops appear until frost kills the latest Aster. There are few school-yards where a place cannot be found for some tree or shrub, or where a vine cannot be trained so as to show its own beauty and hide some unsightly object. At all events, some house-plants can be used to brighten up the school-room and to illustrate by living examples the elementary facts in botany and horticulture. One disadvantage will be that the teachers and trustees who must take the lead in this enterprise know so little themselves of the subjects in which it is proposed to interest the children. The beginnings of this reform—for a genuine reform it will be—will be feeble and much honest effort will be misdirected. Unsuitable trees and shrubs will be often selected and they will be badly planted in improper places. But the very fact that the lack of knowledge on these points is so lamentable is the strongest reason that a beginning should be made. The attempt will excite inquiry and criticism, and knowledge will come from the study and discussion thus aroused. Fortunate are those places already provided with teachers like Mr. Chase, and Mr. Endicott, master of the Gibson School in Dorchester, who at the meeting above-mentioned added some valuable testimony to the soundness of the positions taken in Mr. Chase's paper.

A final suggestion made by Mr. Chase is worth considering in other States as well as in Massachusetts. It was that prizes be offered for the best-kept and most tastefully-embellished school-grounds.

Innumerable fires are, or a few weeks ago were, common sights in the suburbs of all our cities. These fires are set year after year to burn up the dead grass from lawns and fields and to get rid of dead leaves and other refuse. Such fires are dangerous and expensive. Where fires are used to clear up a piece of ground compost heaps are small, and year by year the land is robbed of its fertility; and such fires often get beyond control and injure shrubs and trees, or damage or destroy fences and hedges. The same practice prevails to a very large extent upon farms all over the country; and brush-fires set to get rubbish out of the way are the cause of nine-tenths of all the forest

conflagrations which occur in the farming-regions of the United States, and which every year sweep over tens of thousands of acres during the few weeks of dry weather, which follow the melting of the snow in spring before the appearance of the new leaves, which generally put a stop to these early fires. Rarely does a spring pass without the atmosphere over Long Island and New Jersey being filled with the smoke of forest-fires, which can be traced to this wasteful and careless method of farming; and what occurs in this neighborhood occurs pretty generally all over the territory of the United States wherever farms are cultivated. Such fires are set without much attention to the state of the weather or the direction of the wind; they are carelessly watched, or not watched at all, and soon reach leafless shrubs and trees, and a forest-fire which may sweep over thousands of acres is started.

Dead grass and leaves should never be burned. It is an expensive and wasteful custom, and a sure indication of extravagant and therefore bad management. Where it is desirable to make the ground about a house neat, or to prepare it for the lawn-cutter, the dead leaves and grass should be raked up into piles and carried away to the compost heap, or to be used for the bedding of animals. Such refuse material is well suited for this purpose, and should be freely used. The manure pile can be greatly increased in this way; or, if dead leaves and grass are piled up and turned over occasionally they will be converted into leaf-mould at the end of a couple of years, and so furnish the very best material possible in which to plant many trees and shrubs. A pile of leaf-mould is essential in every good garden, and the bigger it is made and the more freely this vegetable-mould is used, the better the garden will be. In the case of larger fields which cannot be raked over every spring, the dead grass and leaves should be allowed to remain on the ground, which they serve to mulch and enrich. It is a poor policy and thriftless management which burns up plant-food in large or in small quantities, and sooner or later it will make the best land sterile.

Very interesting is Bulletin No. 45, lately issued by Professor Beal, who is at the head of the Department of Botany and Forestry at the experiment station connected with the Agricultural College of Michigan, as well as one of the Directors of the State Forestry Commission. In an imaginary conversation a farmer in one of the older settled counties of the State is made to say:

"Generally, of late years, when there is a heavy fall of snow, it is soon so unevenly distributed that we have little idea of how much has fallen. It piles up along the north and south roads, and blows from some parts of the east and west roads. The wheat-field has many bare spots, while in other places the drifts are deep. Since I cut off that piece of timber down there and brought to view the farms over west for a couple of miles, the wind has frequently swept over my fields with a great deal of force, sometimes making things fairly jingle, and when cold, the air seems to penetrate the smallest cracks in my pens, sheds and barns. The pigs squeal, the cows give less milk, the horses shiver and even the hen-coop is too freely ventilated. I believe the animals at such times eat more grain and fodder than they do when there is less cold air in motion. The house, too, gets colder in the night than it used to when there were few strong winds. I am sure I have to lay in a larger supply of fire-wood than I used to. When I came to this neighborhood much of the land was still covered with a dense, virgin forest, and as one block of woods after another disappeared, I noticed the winds became more frequent and penetrating."

As a partial remedy against these winds which drift the snows and freeze out the wheat in winter, and shake off the fruit and lodge the grain in summer, the Bulletin suggests the planting of a grove to the west of the farm buildings. Professor Beal shows how little it will cost to plow a strip a rod wide and ten or fifteen rods long, to harrow it as if fitting the field for corn, and to plant in it small trees which can be bought in quantity at considerably less than a cent apiece. If the furrows are cut four feet apart,

and a tree set every four feet in the row, they can be cultivated by horse-power for a few years, and will then furnish a screen as protection against the wind, a stick for a sled-tongue or vine-trellis now and then, and every autumn hickory nuts, walnuts and chestnuts in abundance for the children. Admirable directions for selecting trees for planting and caring for them afterwards are given, and the Bulletin will prove of value to many people besides those of Michigan, to whom it is particularly addressed.

The Gardens of Levens Hall.

THERE appeared in a recent issue of GARDEN AND FOREST a view of the terraced garden at Wellesley, Massachusetts—the finest example of topiary gardening in America. The illustration upon page 211 represents one of the best examples of work of this sort which exists in England—the old gardens of Levens Hall, near Milnthorpe, in Lancashire, a mansion which, it is said, dates in part from the eleventh century, and which is famous for its splendid old oak carvings. The gardens contain seven acres of clipped trees, planted and first brought into shape by the gardener of James I. A large part of these trees and of the grand old hedges which serve to divide the garden into different compartments are Yew and Box, although there are closely-clipped Hollies often more than thirty feet in height. Here are still preserved examples of the old pleached alleys of Shakespeare's time, and green paths laid down two hundred and fifty years ago on slate slabs, placed eight inches below the surface, once used for bowling-greens, and still as level as a billiard-table.

The Art of Gardening—An Historical Sketch.—IV. Mesopotamia and Judea.

THE building of pyramidal hills for one purpose or another has not been confined to Mesopotamia, whence, of course, Jewish writers must have drawn such ideas as they expressed in the tale of the Tower of Babel. Nor has Babylon been the only place where these terraced hills have been laid out as gardens. The sides of the mausoleum of Hadrian, in Rome, now called the Castle of St. Angelo, were originally planted, in part at least; a garden similar to Nebuchadnezzar's is indicated, perhaps, in a vast temple inclosure which now stands in a ruinous condition on the island of Java; and—allowing for radical differences in vegetation—we may get from the terraced sides of Isola Bella in Lake Maggiore some idea of the effects which so delighted Alexander when he sought repose in the hanging gardens of Babylon.

Diodorus says that two other great gardens were ascribed to Semiramis. In approaching Chaone, a city of Media, he reports, she "took notice of an exceeding great and high rock, where she made another very great garden in the very middle of the rock, and built upon it stately houses of pleasure, whence she might both have a delightful prospect into the garden and view the army as they lay encamped below in the plain." And near Mt. Bagistan—on the high-road which led eastward from Babylon through what are now called the Koordish defiles—she laid out a garden "twelve furlongs in compass. . . . It was in a plain champaign country, and had a great fountain in it, which watered the whole garden." The flank of the mountain "towards one side of the garden has steep rocks" seventeen furlongs in height; and on this wall she caused to be cut a great relief depicting herself surrounded by one hundred of her guards, with an inscription recording the fact that she had ordered all the harness of her innumerable beasts of burden to be piled up and had used it as a stairway to mount to the summit of the rock. The latter part of this account is, of course, the purest fantasy. The great reliefs which may still be seen in a crumbling state at Behistan are of Persian origin, represent Darius Hystaspes triumphing over the "false Smerdis," and date, therefore, from about B. C. 500.* And the great gardens themselves, including one in Armenia, which was likewise attributed to Semiramis, may confidently be assumed of Persian origin.

Of Assyrian gardens we know even less than of Babylonian. Trees and vines are represented on the bas-reliefs in such a way that we must believe the king was accustomed to repose

* See Mrs. Mitchell, *History of Ancient Sculpture*.

beneath their shade.† The "sacred tree," which, in a conventionalized design, constantly recurs in scenes of sacrifice, doubtless indicates those sacred groves—used for religious rites by many Oriental nations, as well as by the Druids of the north of Europe—which had had their first origin in the tree-worship of primitive races. Royal lion-hunts are portrayed with landscape backgrounds, and may have taken place in parks especially prepared for the purpose, as we see the beasts being freed from cages, and as such hunting-parks are described in the annals of the later neighboring kingdom of Persia. Moreover, it is impossible to doubt that the vast open courts which formed such a conspicuous feature in Assyrian palaces, and even the flat roofs, were adorned with a multitude of trees, shrubs and flowers. No pleasure-loving Oriental would dispense with their presence if they could possibly be had; house-top and court-yard gardening is still a familiar practice everywhere in the East, and nowhere could it have been elaborated on so magnificent a scale as in these vast royal residences, set on their high artificial hills. But with regard to the character of Assyrian gardens we know nothing except that they must have been formal, architectural in arrangement; nor can we say much more of the plants that filled them than that the Palm, the Cypress, the Vine and the Pine were prominent.‡

Dwelling amid more varied and picturesque surroundings than the Egyptians and Mesopotamians, the Jews can have felt, no such imperious desire to create large parks and gardens. Nor were they a people given to sumptuous forms of private life, nor did their religious ritual sanction a systematic use of flowers in its ceremonies. As we might expect from these facts, there is little evidence to show that gardening art was largely practiced in Judea. Like all other races the Hebrews did, indeed, imagine that the first man lived in a garden, but its charms are not dwelt upon as, for example, Homer dwells upon the charms of the gardens he mentions. We can but divine that the Garden of Eden was thought to have been formally disposed with the Tree of Life in the centre, four great rivers flowing in four different directions, barriers all about it, and a gate which could be closed. The idea we have to-day of Eden comes not from the Bible's, but from Milton's pages.

When the riches and happiness of Job are declared we read nothing of natural beauties or of works of art—his treasures seem to have been flocks and herds and the mere consciousness of great wealth. When the building of Solomon's temple is described in Chronicles and in Kings there is no word about gardens or plants; nor is there in the elaborate account which Josephus gives of this temple and the monarch's palace. We are told that Solomon wrote about plants "from the Cedar tree which is in Lebanon to the Hyssop that springeth out of the wall;" but he wrote also "of beasts and of fowls and of creeping things and of fishes," and we must imagine a scientific, not an æsthetic or horticultural treatise. When it is said, again, that "Cedars made he to be as the Sycamore trees that are in the vale for abundance," not growing trees are denoted but materials for building.§ Unlike the sacred tanks of the Egyptians, Solomon's was a great lifted basin, and we cannot fancy that plants grew in it or around it.

Of course these omissions do not indicate that gardens were unknown in Judea. Casual references to them are not infrequent in Holy Writ, and "the gate between two walls which is by the king's garden" is more than once mentioned—for example, in the account in II. Kings of Nebuchadnezzar's attack upon Jerusalem. This royal garden seems to have been near the pool of Siloam, where the valleys of Jehoshaphat and Ben Hinnon meet, and to have been approached (Neh. iii. 15) by stairs that went "down from the city of David." Josephus tells us "there was a certain place, about fifty furlongs distant from Jerusalem, which is called Etiam; very pleasant in fine gardens, and abounding in rivulets of water." Thither did King Solomon "use to go out in the morning, sitting on high in his chariot." The commentary, called the Mishna, says there was a

Rose-garden westward of the temple mount which had existed from the time of the prophets within the city walls—an exception to the usual Jewish practice of constructing gardens in the suburbs. In the Book of Esther the king comes "into the palace garden," and a great feast is held "in the court of the garden of the king's palace;" but the scene of this story is laid in Persia, not Judea. The Garden of Gethsamane seems to have been but an Olive-orchard.

New York.

M. G. Van Rensselaer.

Chrysanthemums in the Imperial Garden at Akasaka, Tokyo.

THE following is a translation from *Hochi Shinbun*, the *Tokyo Post*, of an account of the latest of the famous annual Chrysanthemum shows in that city. The translation was made by Mr. K. Miyabe, the Japanese botanist now in Cambridge, Massachusetts.

According to the yearly practice, the gardeners in Tokyo and Saikyo raised many rare and splendid varieties of Chrysanthemums for the Imperial Garden by the special order. On the 8th of November the members of the cabinet, the foreign ministers and a few others were invited by the court to the "Chrysanthemum Banquet." On the day following, the higher officers of the government and nobles were allowed to see the show.

The following accounts are written from what we have heard from one who enjoyed this special privilege: The first bed, eighteen by 120 feet, was placed just behind the Senkin-kaku (arbor). The entire bed was roofed with screen mats made of reeds, in order to protect the flowers from frost and sun. From post to post on three sides of the bed a curtain or screen, made of purple silk, with the imperial badge, the Chrysanthemum, relieved in white, was tied round with crimson tasseled ribbon. The flowers were at their prime. They were of different colors, and their diameters seemed to be about three to four inches. Several hundred of these plants were arranged without any regular order in the bed. Among them, one called the Sugawara, with petals red inside, and yellow on the outer sides, and the Kagaribi, with its crimson flowers, attracted a great deal of attention.

The next bed to the left was roofed with oiled-paper screens, the rest of the surrounding structures being just the same as the first. In this bed all those varieties having the filiform petals were arranged. A white flower called the "Aunobiki" is worthy of note; the petals were fine as threads, drooping down in tassels like a water-fall. One variety with crimson petals tipped with yellow was very conspicuous.

To the right of Shuhotei there was one bed twelve by sixty feet, planted with thirteen different root-stocks, each supporting numerous grafted branches rising from the stem a little above the ground, and crowned with flowers of different colors and shapes.

Next, to the right, was a bed (eighteen by sixty feet) for large-flowered varieties.

Parallel to this was a bed in which only three plants were set out. The first one, called the Golden Dew (*Ogonno Tsuyu*), was decked with 338 blossoms, all golden-yellow. The next named, the Hanakai, had 253 blossoms of red color. The last, the Sanono Watari, was covered with 173 white blossoms, and impressed one as the best of the three. The flowers were all about one and one-fifth of an inch in diameter.

The next bed contained about 420 plants of about sixty different varieties. Each plant was allowed to bear only one flower, and the diameter of the flowers was mostly about fifteen or sixteen inches. This bed seemed to be the crowning show of the day. The banquet was held in an arbor set up on the lawn just in front of this bed.

Foreign Correspondence.

The Kew Arboretum.—V.

IN England the words Pine and Fir are very frequently used without any definite idea of their meaning; indeed, some people make them apply to almost any Coniferous plant. Even nurserymen and foresters use the word Fir indiscriminately for both the Spruces (*Piceas*) and the Silver Firs (*Abies*). Cobbett, in "The Woodlands," published by him more than sixty years ago, includes Pines in his sweeping condemnation of the "villanous race of Firs." That energetic writer expresses himself in terms as vigorous when occupying him-

† As an instance of the inaccuracy of classic writers it may be noted that Strabo says the Vine did not grow in Susia "before the Macedonians planted it, both there and in Babylon." Yet Vines with their leaves and clusters of grapes accurately displayed may be seen on reliefs from Kouyundjik, now in the British Museum, which date from the period of Assyrian supremacy; and whatever was known in Ninevah must have been known in Babylon and all adjacent Asiatic countries, especially so all-important a plant as this.

‡ The Pine cone appears as an adjunct to sacred rites in Assyria, as the Lotus-flower does both there and in Egypt, held in the hand of priest or king.

§ It would be interesting to know just what trees are meant by Josephus when he speaks of the Pine trees which were brought to Solomon from Aurea Chersonesus. "Let no one imagine that these Pine trees were like those which are now so named, and which take their denomination from the merchants, who so call them that they may procure them to be admired by those who purchase them. For those we speak of were to the sight like the wood of the Fig tree, but were whiter and more shining. Now we have said thus much that nobody may be ignorant of the difference between these sorts of wood, nor unacquainted with the nature of the genuine Pine tree."

self with trees as he does when, in his "Weekly Register" or "Twopenny Trash," he baits the government which prosecuted, fined and imprisoned him. The subject of these notes will be the Pines in the Kew Arboretum, of which it will be impossible to do more than give a few hasty sketches. Independently of isolated examples of many species scattered over the whole of the Kew domain, the Pine collection proper is arranged along the side and end of a fine stretch of ornamental water almost in a line between the great Palm Stove and Sion House, the residence of the Duke of Northumberland, on the other side of the river Thames. Probably the largest number of species and varieties of the genus *Pinus* are to be found here—represented, as a rule, by a good group of each species, and a few plants of each form—than in any other garden in existence. The only conspicuous absentees are many of the long-leaved Mexican species which, unfortunately, are too tender to withstand the cold of the Kew winters. They, however, thrive in the extreme south-west of England, and especially near some of the lakes of northern Italy.

The Scotch or Wild Pine (*P. sylvestris*) is a very widely-distributed plant, and stretches from northern and central Europe through the Siberian forest-region as far as the Amoor River. Practical Scotch foresters seem to agree that in a given time this Pine produces more timber than any other tree known to them. I do not know whether any experiments on a sufficiently large scale have been made to test the value of Cobbett's statements about the "worthless and villanous Scotch Fir." He says: "I will show that the country would have been worth a hundred million of pounds sterling more than it now is, if this sort of tree (the Locust) had, during the last forty years, been cultivated instead of the villanous race of Firs." In any case the Scotch Fir is a handsome tree, with its tall, erect trunk clothed with bark of a warm, red tint. Several curious varieties are growing well at Kew, notably the variety *Aurea*, which, at the present time, is most conspicuous on account of the bright golden color of its leaves; when growth commences the yellow disappears, and during the summer and autumn months—indeed, until the winter again arrives—the trees of this variety are hardly distinguishable from the ordinary type. In *P. sylvestris argentea* the upper halves of the young shoots are creamy white. A form called *Globosa* is a compact-growing bush with short, glaucous leaves, and so like the New Mexican *P. edulis* in general aspect that the two have frequently been mistaken for each other by Conifer-loving visitors.

The Austrian Pine (*P. Austriaca*) is a fast-growing tree with rigid, sharp-pointed, blackish-green leaves densely clothing the branches. As a nurse or shelter-tree or for forming screens it is an excellent Pine, but the timber is inferior to that of *P. sylvestris*. Of this there is a golden form, which is very effective on some soils. Some authorities make *P. Austriaca* a variety of the Corsican Pine, *P. Laricio*, of which a remarkably fine specimen—interesting, also, from an historical standpoint—grows near the principal entrance to the gardens on Kew Green. The Corsican Pine is a very fast grower, and has attracted the attention of foresters of late years, and where the Larch has failed on account of disease, it has been recommended as the best substitute. It is often, however, difficult to transplant. *P. Laricio pygmaea* is a dense, compact, dwarf form, apparently never exceeding a man's height.

The Aleppo Pine (*P. Halepensis*), a native of the Mediterranean region is not a handsome tree, but is interesting as having claims—according to some commentators—to be the Pine or Fir of Scripture. Amongst rocks on the Mediterranean shores it thrives where scarcely any other tree can grow, and often forms highly picturesque objects. In Britain it is useless either for timber or landscape purposes.

Of the Stone Pine (*Pinus Pinea*) many fine specimens exist at Kew. Those who have learned of the quite recent disappearance of "Ravenna's immemorial wood," a forest of Stone Pines whose praises were sung by the classical Latin poets, may well feel surprised that the succession of cold winters which destroyed the famous Ravenna forest spared the Kew plants, so much further north. Not many years ago the eatable seeds yielded a large revenue to the Italian province.

Pinus Cembra, the Arole of the high Swiss regions, is a handsome, slow-growing Pine, with deep-green leaves and elongated pyramidal outline. According to Dr. Christ, in his "Flore de la Suisse et ses Origines," the Arole will ere long disappear from Switzerland unless specially protected and planted. Self-sown seedlings, except in one or two of the almost impenetrable forests of central Valais, are very rarely seen; the mountain black squirrels eat the cones before they ripen, and what escape the squirrels are eagerly collected by the peasants for food. The cones ripen the third year, and

the large seeds take a year or more to germinate. In the Swiss nurseries, to protect the seed-beds from mice, it is necessary to drive stout planks about fifteen inches into the ground, leaving as much above the surface; a fine wire-net is then fastened across. In gardens the Siberian form has a distinctive name, but neither in habit nor in cone is there—as far as the fine series of trees at Kew enables one to judge—any difference between plants from that and other outlying regions and those raised from Swiss seed.

The Mountain Pine (*P. montana*) embraces a large series of slightly varying forms, differing widely in habit and general aspect according to the conditions under which it finds itself. It is a native of sub-alpine regions of central Europe, and is also found in the Pyrenees on both the Spanish and French sides. On rocky, bare ground this Pine lends itself to good purpose for the landscape-gardener. As a rule the species makes a dwarf, densely-branched, more or less procumbent, bush, but the form *Uncinata* has a tendency to make a neat pyramid. In the bottom of the *Cirque de Gavarnie*, in the Pyrenees, along the stream fed by the Cascade, I noted some years ago a number of trees of this variety, varying from three to ten feet or more, imitating in habit very markedly the Arole of Switzerland. The same habit is also to be seen in the Kew specimens of *P. uncinata*.

Certainly one of the most important of all the European Pines is *P. Pinaster* of the Mediterranean region. It is a handsome pyramidal tree, with light green leaves, from eight to twelve inches in length, and yellowish cones densely clustered around the base of the current year's shoots. Perhaps no other Pine has become more widely distributed over the earth's surface. It is very common in South Africa, and has become naturalized in many countries. The previously almost worthless Landes of western France have, by the agency of this tree, been totally changed; the continuous invasion of the sand dunes has been arrested, and almost the whole population of a considerable district kept employed in collecting the valuable, resinous products. The tree thrives well enough at Kew; and it is useful as a sea-side tree, as it will thrive in shifting sands. The timber, however, is of little value; it is soft and soon decays. *P. Pyrenaica* is a somewhat rare species, not interesting except from a botanical standpoint. A figure and full synonymy are given by Dr. Masters in the *Gardeners' Chronicle* for September 8th, 1888.

All the previous species belong to the group with two leaves in a sheath; the only European Pine which has five leaves to a sheath is *P. Peuce*, from Macedonia. This last-named tree is a handsome, symmetrical species, evidently allied to the Himalayan *P. excelsa*, but with shorter, differently-formed leaves, and almost sessile (not very long-stalked) cones. Both fruit freely enough at Kew, but *P. Peuce* has not been long enough in the country to allow of any statements being made as to its full size under cultivation. By some botanists it is regarded as a geographical form of *P. excelsa*, the nearest habitat of which is in Afghanistan, a distance of more than 2,200 miles from the Macedonian forests of *P. Peuce*.

Kew.

George Nicholson.

New or Little Known Plants.

Portlandia pterosperma.*

AMONG the many novelties collected by Dr. Edward Palmer, during the last season, in the region about Guaymas upon the eastern side of the Gulf of California, is a *Portlandia* which promises to be a valuable acquisition if it can be secured for cultivation. This genus belongs to the *Rubiaceæ*, an order which supplies such ornamental shrubs as the Gardenias, Bouvardias, Rondeletias, etc., and received its name in honor of the Duchess of Portland, who in the last century was a friend and patron of Botany and made a fine collection of rare and valuable trees and shrubs for the adornment of her grounds at Bulstrode.

The first species described, *P. grandiflora*, is a native of Jamaica; was introduced into England in 1775, and was figured in the *Botanical Magazine* (t. 286) in 1795. It is there spoken of as a beautiful stove plant, not of difficult growth, and readily disposed to flower, blooming when not more than a foot high, its flowers uncommonly large, showy and fragrant. Seven other species have since been added, from the West Indies and Mexico, of which the *P. platantha* was also figured in the *Botanical Magazine* (t. 4534) in 1850. This is a similar shrub, with dark-green

*PORTLANDIA PTEROSPERMA, Watson, *Proc. Amer. Acad.* xxiv, 52.

and glossy evergreen leaves, and very large funnel-shaped white flowers, "flowering in a very dwarf state and almost always in blossom."

The present species, as it is found growing in the deep cañons of the mountains about Guaymas, is a shrub or small tree, from two feet to ten feet in height. The foliage differs from that of other species in being rather thin and deciduous, instead of leathery and evergreen. The flowers are numerous upon the young, slender branches, a pair appearing at nearly every node. They are pure white and exceedingly fragrant, funnelform in shape, and nearly three inches in length. The triangular lobes of the limb are

beauty and fragrance of the flowers, and the free-blooming habit of the plant make it very desirable as an addition to our green-houses, and it will probably prove to be hardy in the Gulf States or even farther north. S. W.

Cultural Department.

Notes on Primulas.

THE result of the special Primula Exhibition and Conference held in London in 1887 has been to bring under the notice of horticulturists generally a large number of pretty and interesting alpine species which previously were almost unknown, except to botanists. It also roused an interest in

Fig. 105.—*Portlandia pterosperma*.—See page 208.

folded edge to edge in the bud so that it is strongly angled before opening.

Normally, as in most of the allied genera, the parts of the flower should be in fives, but most of the flowers in the specimens examined have them all in sixes, which may be a constant character of the species. In not a few of the related genera, however, the number of the corolla-lobes, stamens, etc., varies from five to six and sometimes to four, so that the variation in this case cannot be considered of any very special importance.

The plant fruits freely, and seeds were obtained, but these have failed to germinate. The surest and quickest mode of propagation would doubtless be by cuttings. The size,

many of the commoner species and races, especially in the Polyanthus section and in the Auriculas. The origin of the last-named race has, since then, been the subject of several very interesting papers. Dr. Kerner, whose investigations on this point are based on personal observation, and who, therefore, is entitled to be heard with respect on the origin of the Auricula, has arrived at views something like the following:

About the year 1570 Clusius left Vienna to settle in Frankfort-on-the-Main; he began an active correspondence with noblemen and others upon botanical matters, and in this way was continually receiving living specimens from the Tyrol, Styria, Corinthia, Bavaria, etc.; a few years later he bewails his want of success in taming these alpine Primulas, especially the "Blanc Speik" (*P. glutinosa*), and the only two he really succeeded with were *P. Auricula* and *P. pubescens*. With this

latter plant Dr. Kerner experimented, and found it to be a hybrid between *P. Auricula* and *P. hirsuta*—exactly what one would expect to find on a study of the plant as we know it at the present time. About 1582 Clusius began to distribute these two plants to his friends, and in the year 1664 several forms of *P. pubescens* were known with different colored flowers, and these spread shortly after to England, Germany, Holland, etc. The true *P. Auricula*, as is well known, is not prolific in varieties, and as the other is known to succeed in almost any position, it was naturally much sought after until the varieties increased to something like a thousand or more. This *P. pubescens* will, no doubt, do very well for the origin of the alpine Auricula, but it does not account for the abundance of meal and the abnormally large bracts of the show kinds now in cultivation. We must look somewhere else for indications of this characteristic form, and *P. Palinuri* is the only species that is likely to help us. Just lately, however, another plant has been found wild in upper Styria, namely, *P. Göblii*. It was described by Kerner in 1875, and is said to be a hybrid between *P. Auricula* and *P. villosa*, which is very likely. Here we get meal in profusion, the large bracts and the dark-colored, pasty flowers of an inferior show Auricula. The perfection of the present times has been the result of selection to a large extent, and it will be many years before the investigations now proceeding will give us any real clue, and this only, on the one hand, by reversions and, on the other, by working with *P. pubescens*, about the parentage of which we are now quite certain.

To show what the conference has done for this genus one has only to glance at the number of species and varieties recently introduced, and the number of people interesting themselves in their cultivation. Hardly an English garden nowadays but is rich in Primulas of some kind, and not the least beautiful and interesting are the gold-laced Polyanthus, which are once more coming into favor with us. Including species, hybrids and varieties there are, exclusive of Auriculas and the Polyanthus forms, no less than 150 different kinds of Primrose in cultivation. A few years ago it would have been hard to find a third of these in this country.

America has helped to swell the number, and few species introduced of late years equal the charming *P. Rusbyi* found by Greene on the summit of Mount Wrightson, and described in the *Bulletin Torrey Club*, viii, 122. *P. suffrutescens*, *P. Parryi*, *P. mistassinica*, *P. angustifolia* and *P. Cusickiana* are all in cultivation now, adding much to the beauty and interest of our rock-gardens and marsh-beds. The greatest number in flower at present are, of course, European species and hybrids, to which *P. Auricula*, in some way or other, has contributed largely. Amongst the most distinct are *P. Christii*, *P. venusta*, *P. Escheri*, *P. Kerneri*, *P. discolor*, *P. Alpina*, etc., some have the flower of one and some of the other parent, but all are worth including in a collection and are easily managed with ordinary care. *P. Balbisii* deserves special notice. It is somewhat like *P. Auricula*, but the leaves are smaller, rounder and less mealy, and the flowers deep-golden yellow. The Marginata varieties are now at their best; they add immensely to the interest of the rock garden and never fail to produce their flowers in the greatest profusion. It is characteristically called the silver-edged Primrose, from the margins being covered with meal, giving quite a character to the leaves. The plants have been likened to miniature, stunted, stone Pines, to which their long, bare stems have really a resemblance. The varieties are Grandiflora, Densiflora, Cœrulea, etc., varying in color from clear lilac to purple. They are quite hardy, and affect exposed rather than sheltered spots. *P. minima* is one of the little gems, but a most difficult plant to manage even when under full control in pots. It is found on the highest mountains of Switzerland, almost to the limits of perpetual snow, forming large sheets of rose and white flowers. It also has given rise to numerous hybrids, most of which are in cultivation, many far exceeding it in beauty, notably *P. Forsteri* and *P. Pseudo-Forsteri*, which produce larger flowers and usually bloom twice a year, namely, in spring and again in autumn. They both are more robust and easier to manage than the type. To this class also belong *P. glutinosa*, *P. Huteri*, *P. biflora*, and others of equal beauty. *P. Allionii* and *P. Ayrolensis* are two dwarf species with large, pretty, pink flowers, also quite hardy and amenable to ordinary treatment.

The Himalayas, give us a great wealth of beauty in this class of plants, amongst the most notable being: *P. Sikkinensis*, *P. Stuartii*, *P. purpurea*, *P. obtusifolia*, *P. Reidii*, *P. rosea*, *P. involucrata*, *P. prolifera*, *P. petiolaris* and others, varying in color from yellow to rose and purple and all perfectly hardy in our climate. *P. denticulata*, *P. erosa* and *P. capitata*

are among the most beautiful of our spring flowers, the former especially, with its large, lilac balls, is very interesting. They stand our rough weather very well, continuing in flower for a considerable time. Some of these, however, like *P. Sikkinensis*, *P. capitata*, etc., are best treated as biennials, and, as they ripen seed freely, no difficulty will be experienced in keeping the stock up. The best of the Himalayan species have yet to be introduced, namely, *P. Elwesii*, *P. Gambelliana*, *P. Kingii*, etc. These are said to be the cream of Indian Primroses and although we have already had seeds we have failed to raise the plants. The most interesting discovery of recent years, however, has been made by Delavay in the mountains of Yun-nan, western China. He discovered no less than sixteen new species, and, although some few were closely allied to Himalayan types, they are distinct enough for specific rank, and will, undoubtedly, add much interest to this class of plants when they can be introduced to our gardens.

Kew, April 6th.

D. Dewar.

The Muskmelon.

IN its delicious and refreshing qualities, the Muskmelon at its best is scarcely surpassed by any fruit of any clime. Though essentially a tropical fruit, its development is so rapid that it may be successfully grown in comparatively northern latitudes, provided the summer's sun shines for a few weeks with something like tropical intensity. But its foliage is injured by very slight frosts, and it cannot even endure the chilly winds of autumn if these are long continued.

The Muskmelon is emphatically a fruit for the home garden. It does not endure long transportation well, and its flavor deteriorates soon after being picked. Indeed, in quality it is quite capricious. If pickled a little before ripe, or if left a little too long before using, it is quite unpalatable, and sometimes even nauseous, and if the foliage of the plant is not in a healthy condition, the flavor of the fruit will usually be quite inferior.

A light, somewhat sandy, fertile soil, and a sunny exposure, sheltered from north winds, best suits this Melon. It may be grown well on a naturally heavy soil that is well drained, and that has been lightened somewhat by sand or coal ashes, and which contains abundance of humus from decayed barnyard manure. But it is useless to attempt Melon culture on a poorly-drained, clayey soil, without a favorable exposure. In the climate of the Northern States it is essential that the plants be started quite early, in order that the fruiting season may be prolonged as much as possible. As they cannot, however, endure the slightest frost in spring, it is well to plant the seeds on inverted sods in the cold frame the latter part of April. Cover the soil in the frame with sods, neatly fitted together, the grass side down. Then with a sharp lawn-edger or sod-cutter, cut these sods into pieces about four inches square, and on each of these place about five seeds. Now cover with about three-fourths of an inch of fine loam, and give a good watering. Keep the sash on, except on bright, warm days, watering as often as is needed. In about a month the plants will have formed their first rough leaves, and may be transplanted to the garden. If the weather is dry, give one very thorough watering at the time of transplanting. It is understood that the little pots are to be taken out of the frame and planted out without disturbing the roots of the plants more than is necessary. When the plants are started in this way, they are not apt to be troubled much by insects, but if the seed is planted in the open ground, the hills must be protected with boxes covered with mosquito netting.

The varieties of the Muskmelon are readily divisible into two classes, namely, the green-fleshed and orange-fleshed. The former have softer, sweeter and more juicy flesh, while the latter are firmer and more highly flavored. Each class has its advocates, but I think the latter are generally preferred. As a rule, the smaller the fruits produced by a variety the higher the quality, and when the seed of any variety is pure, its quality can be fairly judged by the color of the flesh and the size of the fruit, without much regard to the particular name the seedsman has seen fit to give it. And yet we cannot get along without the name. In my own experience, the Emerald Gem, Miller's Cream Nutmeg, Casaba, Surprise and Christiana rank very high in quality among the orange-fleshed Muskmelons. Among the green-fleshed, the New Orange Cream, Queen and Baltimore Nutmeg have proved very good. Livingston's Perfection, which I first tested last season, is a happy combination of the orange and green-fleshed Muskmelon, a union seldom met with. The rich, yellow flesh unites to a very considerable extent the juiciness and sweetness of the one class with the high flavor of the other, and in quality it is very difficult to surpass.

The finest Muskmelon I have ever tasted, quality alone considered, is the Algiers Cantaloupe of the French catalogues. The fruit is of large size, with flesh of remarkable thickness, very firm in texture and of surpassing flavor. Unfortunately it ripens so late that it is not certain of maturing in the Northern States. I am now experimenting with this variety as a parent for crossing with our best early sorts, from which I hope to be able to increase the firmness and thickness of the flesh, and to heighten its flavor.

The suggestions offered in relation to the culture of the Muskmelon apply as well to the Watermelon.

Experiment Station, Madison, Wis.

A Few Early Cucumbers.

CUCUMBERS are acceptable to most people, and those grown on the vines in the home garden have a special excellence of flavor. To obtain them earlier than can be

May. I find a box eighteen inches square the best protection; this has a glass cover to be kept on in cool weather, and removed as the sun-heat is more or less strong. In this way a few hills, say ten or a dozen, can be brought forward in advance of the crop planted in the ground.

There is nothing that gives more satisfaction for an early cucumber than the White Spine, under some of its names. This is large enough, early, tender, and of good shape. For a later crop the Para is excellent; it is a profuse bearer and is fully equal to any of the cucumbers for the table, though it cannot be called early; neither can the Green Pickling. Cucumbers need manure under the plant in the hill and a rich soil besides to do their best.

The White Spine can be grown in a space of one yard for a hill, if cramped for room, leaving five plants in a hill. I put wood-ashes and bone-dust in the hill, mixed with the soil. A pint in each hill will hurry them on rapidly. In my

The Gardens of Levens Hall.—See page 206.

done from seeds planted in the open ground, plant now in boxes containing about three inches of earth, lay six or eight seeds in a group three inches apart, over them sift enough fine dirt to cover one-half inch deep. I use soil from the hot-beds for this purpose. This being used continually from year to year, and mixed with the manure in the bed each year, becomes, in time, specially adapted to such work, being full of plant-food, and does not pack under repeated waterings, as ordinary soil will.

In the absence of such a source of supply, sand and loam, mixed, and having some chemical plant-food in it, will do. Set the box in a sunny window and when the seeds break ground, let the windows down from the top, or carry the box outside, in a sunny, warm, sheltered spot for a while each day. Return them early in the afternoon to the house. After they are well up transfer them to hills in the garden placing some protection over them. This can be done in the early part of

locality the first of July is early for the first specimen grown with this treatment, and this is about two weeks ahead of planting in open ground. When sliced, kept in cold water for an hour, and dropped into sharp vinegar, they will not disturb the weakest digestion. A cucumber kept a while on ice is much better than one fresh from the vine.

W. H. Bull.

West Springfield, Mass.

Orchid Notes.

Oncidium ampliatum majus was first discovered about fifty years ago in Costa Rica, and afterwards in other localities in Central America, where it enjoys a maximum temperature of about 85° Fahr. It is still often to be met with in collections, though not so frequently as formerly, owing to the introduction of larger-flowered and, according to some, prettier species. *Oncidium ampliatum majus* may, even in these days, be reckoned among the very finest representatives of

the genus. It is similar in character to the type, but has much larger flowers, and presents a finer appearance in every way. There are several fine specimens here which have been in flower for over a month, and they will last until the middle of May. There is no other *Oncidium* flowering at the present time which can compete with it in attractiveness, and this fact renders it particularly valuable for decoration and also for exhibition purposes at this time of the year. Before this *Oncidium* came in flower the Orchid-houses were made resplendent by the gorgeous-flowered *O. tigrinum*, a native of Mexico, and *O. splendidum*—which is, botanically speaking, only a fine variety of *O. tigrinum*, but which comes from Guatemala instead of Mexico, where it was first discovered about 1862. The subject of the present note possesses an advantage which can hardly fail to be appreciated by cultivators, namely, that of being easily managed. Large plants generally do well when grown in either pans or baskets, which must, however, be well drained with clean crocks. A compost of good, fibrous loam with a little sphagnum mixed is most suitable for it. Most Orchids like plenty of water during the growing season, but this is an exception. This distinction is due to the large pseudo-bulbs which are well provided with moisture absorbed by the roots from the atmosphere. At no time should much water be given, except in very hot weather, when evaporation goes on rapidly, and then more than usual may be given with advantage. This species, having large, leathery, dark green leaves—like some *Cattleyas* or *Lælias*, but much handsomer—will bear a greater amount of sun-heat than could, with safety, be allowed to thinner-leaved kinds. Small plants should be grown in baskets or pans and suspended near the roof, so as to obtain as much light as possible.

In general appearance this is a very handsome *Oncidium*. Its large, ovoid, compressed bulbs are of a bright green when young, and heavily spotted and blotched with purple. As they become older the skin becomes shrivelled and blackish-purple. The leaves are large and very beautiful—indeed, they form one of the chief beauties of the plant, with their dark-green, glossy surfaces. From the base of the pseudo-bulbs, a panicle of bright golden flowers arises for a length of eighteen inches or more. One plant now in flower here has six such panicles, each bearing from forty to fifty large flowers, which present a solid yellow mass, the monotony of which is most agreeably broken by means of the numerous reddish-brown spots and blotches on the sepals and the base of the petals, as well as on the crest of the lip. The under surface of the flowers—especially the lip—is covered with a peculiar white bloom, which is quite characteristic. Sprays of flowers will remain in good condition for a long time in a room, if placed in fresh water. The base of the stem should be occasionally cut, so as to let fresh cells absorb the water.

St. Albans, England, March 30th, 1889.

J. Weathers.

Cattleya Lawrenceana.—A splendid example of this lovely *Cattleya* now forms a very conspicuous object in the collection of Mr. Hicks Arnold, of New York. Though a comparative small plant with but thirteen bulbs, three of these have borne, in the aggregate, eighteen rich and very striking rosy-purple blossoms, and on one spike alone nine flowers were counted. Its appearance at this season will make it a great favorite with all lovers of this gorgeous family; but it is to be regretted that such a fine *Cattleya* is not more plentiful. But as it comes from the Roraima Mountains, in British Guiana, and can only be collected at the cost of great hardship, it will probably remain a rarity for some time. In habit *C. Lawrenceana* is most distinct, having pseudo-bulbs of a reddish hue and foliage of a stout and very leathery texture. In its native home it has been seen with eleven flowers on one spike, and we hope this number will be soon attained on cultivated plants. They enjoy a few degrees warmer temperature than most of this genus, and the atmosphere should be kept charged with moisture while they are growing. Baskets have been found preferable for this species, and if suspended in a position close to the light, in a mixture of fibrous peat with a little sphagnum, it will produce its handsome blossoms freely. Among other noteworthy plants seen in this collection was the curious green and black flowered *Calogyne pandurata*, a beautiful specimen carrying a spike with a dozen flowers; a *Cypripedium grande*, remarkable for its vigorous growth and striking blooms; an *Oncidium Marshallianum* with a many-flowered panicle of bright yellow and rich brown blossoms, and an *Odontoglossum citrosimum album* bearing a dense cluster of large, pure white flowers. The *Cypripediums* in this collection are growing very rapidly, and a fine show of them is shortly expected.

Summit, N. J.

A. Dimmock.

Rose "Souvenir de Wootton."—This is a hybrid Tea Rose, and was named after the country-seat of Geo. W. Childs, Esq., at Bryn Mawr, Pennsylvania. It is a seedling from the well-known Tea Rose, *Bon Silene*, fertilized by the hybrid Rose, *Louis Van Houtte*. It was raised by John Cook, of Baltimore, and was sent out in the spring of 1888, but its merits as a winter-blooming rose were but little known until this season, when it has proved to be a very free and continuous bloomer and of rank, vigorous growth. The color is crimson, flushed with carmine, and the blooms are very large, frequently measuring six inches across. The petals are short, which gives it a somewhat flat appearance; but, while it lacks something in gracefulness, it is a very showy rose and of exquisite fragrance. The foliage is large and beautiful. It will doubtless prove to be a very useful and popular winter-flowering rose. Of its qualities as an out-door bedding variety very little is known; the coming summer will afford opportunity to test it.

Philadelphia.

Robt. Craig.

This latest American addition to the hybrid Teas seems to be a Rose of much promise, combining the colors of both parents in a very pleasing shade, somewhat similar to that of *Papa Gontier*. As exhibited at the recent show of the Pennsylvania Horticultural Society in Philadelphia, the flowers were of fair size and substance, and in form somewhat like "*American Beauty*," though apparently not quite so double. The color appears to good advantage under artificial light, and this will help it to win a place in popular favor. The foliage of *Wootton* is large, handsome and of good texture, and, what is very important to the grower, is said to be proof against the attacks of "black spot." The plant is of vigorous habit, and also very floriferous, and it is expected by the introducer to prove so valuable an acquisition as to displace *American Beauty* in popularity. Of course, a more extended trial will be necessary to justify these hopes, though many prominent growers have already expressed favorable opinions in regard to this Rose; and, for the credit of a variety of distinctly American origin, it is to be hoped that their confidence may not be misplaced.

Holmesburg, Pa.

W. H. Taplin.

The Spring-Garden.

THE man who plants a spring-garden, even in this New England climate, where the springs are proverbially and almost unexceptionally cold, uncertain and unsatisfactory, provides a richer store of pleasure for himself and his friends than can be obtained from a garden of any other sort. There is no delight to be derived from flowers which equals that which the earliest harbingers of spring afford when they open amidst melting snows, after a long, cold, northern winter. The humblest *Crocus* or *Squill* or *Snow-drop* is more and means more than all the splendors which the suns of summer call into existence. The person who has not a spring-garden, or who does not cultivate at least a few of the hardy plants which flower in the very early spring, knows but little yet of the true pleasures of gardening. These thoughts come to me year after year. Every year the pleasure is keener, as every year the familiar faces of these humble flowers rise up to remind us that the long winter has ended. As I write the earliest flowers have already passed away—the *Snow-drops*, the dwarf, reticulated *Iris* and the early *Crocuses*. But many more plants are already in flower, and the long procession which may be made to grace our northern gardens has hardly commenced to move yet. The most beautiful flower by far just now is that humble plant which the great Swiss botanist, Boissier, brought back from the western Tmolus, in Asia Minor, and dedicated to the companion of many of his journeys, the *Chionodoxa Lucilia*. The generic name derived from Greek words, meaning the glory of the snow, indicates its vernal habits. It is, perhaps, the most beautiful plant of its class of recent introduction, with its compact habit and short racemes of large, intensely blue flowers shaded into white towards the centre. This charming plant is perfectly hardy and in habit it resembles some of the early *Squills*. These, too, are at their best, and whether they are planted in beds or as edgings in the grass, they are always among the brightest and most attractive of the hardy, spring flowers. Their small size adapts them for planting singly among the crevices of the rockery, and when they are freely used in this way the effect which they produce is excellent.

The spring *Snowflake* (*Leucoium vernum*) is also at its best just now, and its nodding white bells, handsomely marked with green at the ends of the perianth-segments, are among the most attractive features of the spring-garden. But this plant, although a native of central Europe, is not entirely hardy here, or rather, perhaps, the bulbs do not last many years, so

that unless new plantations are made they gradually disappear. But the plant well repays the trouble and expense of occasional renewal. Some of the early varieties of the single Daffodil (*Narcissus Pseudo-Narcissus*) are already out, in the warmest pockets of the rockery, and show what the family will do after another week or two of warmer suns. The lovely Bloodroot (*Sanguinaria*) has sent up its one-flowered scapes, and the white star-shaped flowers are just opening in advance of the large heart-shaped and deeply-lobed leaves, which make a fine show all summer long. This is one of the most satisfactory of all our native flowers to bring into the garden. The round-leaved Violet (*Viola rotundifolia*) has just opened its yellow flowers here for the first time. It is a rare northern plant, with stem-leaves of the shape indicated by its name, an interesting species to botanists, and one which, should it take kindly to captivity, will prove a good addition to garden plants. The various Hepaticas, double blue, double purple and double white, are in full bloom, as are the less showy, but not less attractive, single varieties. The Hepatica lends itself to doubling better than most flowers, and some of the intensely double, deep-colored sorts are among the most beautiful objects imaginable in the rock-garden in April.

A few early-blooming shrubs harmonize just now with these humbler plants. The most conspicuous of these is the ever-green Japanese Andromeda (*A. Japonica*), near relative of our Allegheny *A. floribunda*, but of looser habit, with broader and looser panicles of handsome white flowers. These are rarely seen to advantage in this climate, as they appear before the cold weather is over, and so are generally destroyed just as they are opening. This year the exceptionally mild winter has favored them, and they are just now in great beauty. Much better, too, this year, than I remember it here is *Daphne mezereum* its leafless branches being completely smothered with its fragrant rose-colored flowers. It is an excellent hardy shrub, of neat and compact habit. The flowers are always abundant and always early, and they are succeeded by handsome scarlet berries. The Cornelian Cherry, the *Cornus mascula* of Europe, is at its best, too, covered with sheets of golden bloom. It is an admirable hardy shrub or shrub-like tree not too often seen in this country, although it should find a place wherever spring flowers are valued. It never fails to bloom profusely, and is beautiful, too, later in the season, when its ample foliage appears, and when its branches are covered with the scarlet, cherry-like fruit.

Boston, April 18th.

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

VIII.—GERMINATION.

THE sprouting of the seed is a special example of growth under favorable conditions. The supply of building materials is of precisely the right kind and of sufficient amount to insure rapid development. Under the head of "Growth" the principal facts have been already considered by us, so that we can now confine ourselves to those features which are peculiar to the seed itself.

The food in the seed, whether it exists as oil or as starch, is in a form adapted to preservation. Hence this food remains of good quality long after the vitality of the germ may have been lost.

The conversion of this solid food into forms which can be utilized by the germ, is effected by one or more of the nitrogenous, inorganic ferments, which we have already examined briefly in a preceding paper. The most important part is played by that which is known as diastase, an enzyme or ferment, which changes starch into a substance which readily goes over into the form of sugar. In oily seeds there is apparently a complete change in a good portion of the oil, by which starch is produced, and this is then consumed as the food of the germ. In the newer parts of such seeds, and in the paths of transfer, starch can usually be detected by appropriate tests without any difficulty.

In all these changes during germination, there is an absorption of water. Without enough water to insure perfect solubility of the solid food, the process of germination goes on only slowly and irregularly. But in point of fact, the amount of water furnished to a seed must (except in the case of aquatics) be so given to it as not to exclude free access of air; that is, the oxygen of the air must have free access to the soaked seed. But, even with these absolutely necessary conditions, the seed will fail to germinate unless another is afforded—namely, a certain temperature. This is very different for different seeds, as might be expected from what we have already seen as regards growth in general. A few sorts will

begin to sprout at the temperature of thawing ice, but for all of our ordinary plants in general cultivation (except certain members of the Cress family) the temperature must be not far from 60° to 90° Fahrenheit.

The three conditions are, therefore, water, oxygen and warmth. Can we hasten germination by modifying the favorable conditions in any way—that is, by making them more favorable? Various chemical agents have been employed for this purpose, notably those which can yield to the seeds oxygen in its active form, as ozone, but the experiments have not been practically successful.

Attention should be called to the interesting fact that some seeds appear to take their own time for beginning to sprout. While many seeds germinate speedily, and whenever favorable conditions are present, there are many which do not start until definite periods of rest have elapsed. The seeds of many of our forest-trees are of this sort, and in their case it is not difficult to see that the refusal to start at once, even when all the necessary conditions are afforded, has something to do with the protection of the plantlet against beginning its development at an unpropitious season. It is, in short, a conservative faculty.

Whether light affects germination to any appreciable extent is a question which has been attacked in an experimental manner, but as yet with inconclusive results. There are some seeds whose sprouting appears to be plainly hindered by exposure to bright light, while there are many others which are as plainly indifferent. Much can be learned by an attentive examination of the manner in which seeds are self-sown in nature. Some seeds are scattered by nature on the surface of good soil, and there remain uncovered. Here, on the very surface, they will germinate freely and produce good plants. The practical side of this and allied questions is presented in a trustworthy manner by a competent authority* on the raising of plants from seed in a paper wherein directions are plainly given for treating seeds from the period of their ripening to the time of sowing, and the proper conditions are insisted upon in a clear manner. In that interesting paper the directions follow almost exactly the teachings of nature, so far, at least, as it would seem possible they could be adapted to the exigencies of tree-planting on a large scale.

When the germ develops, there is speedily seen a definite assumption of form and direction of parts; the stem rights itself, and the root descends in search of moisture and mineral matters. At this earliest period of growth the seedling requires great care at the hand of the cultivator. Proper conditions of light must be afforded, in order that the work of assimilation may be adequate to the needs of the young plant; but, on the other hand, care must be taken to avoid exposure to too intense a light under artificial conditions. Other conditions, such as temperature, moisture, require the greatest attention.

The practical solution of these difficult questions must be sought in horticultural and arboricultural treatises, but the underlying principles of successful practice are to be found in the accepted statements of modern physiological botany.

There are also certain other practical difficulties which follow the cultivator from the moment he places the seed in the soil. The plants under his care are liable to fall a prey to disease. The study of plant-diseases belongs to what is termed vegetable pathology, a subject which can be alluded to here only in the most general terms. We refer to the matter only that our examinations of the functions of healthy plants may be supplemented by a glance at the same functions when they are disturbed by disease. Many of these diseases are caused by the invasion of other organisms, which may be collectively termed fungi (including under that term all the so-called microbes or bacteria in the widest sense). The discussion in this journal of these invasions as applied to special cases has been entrusted to one who has made very extensive contributions to many parts of the field, and therefore only the briefest general statement is necessary at present.

With respect to attacks of fungi on ripening and germinating seeds, it is merely requisite to say at this point that these fungal organisms are unable to exist unless they find food which has been prepared by other organisms. They can take this prepared food, even from the very tissues of the organisms which they attack, destroying not merely the supply of nutriment, but the organisms themselves. Reserving for the next paper a fuller treatment of this subject, we may turn for a moment to a consideration of a single question, namely, as to whether it is possible to kill the fungi which invade seeds, without killing the germs of the seeds. Attempts have been

*The Propagation of Trees and Shrubs from Seed. By Jackson Dawson, of the Arnold Arboretum of Harvard University.

made to destroy such fungi by subjecting the dry seeds to high temperatures, and to the action of strong solutions of poisons. Among the many liquids which have been employed with partial success in a few cases may be mentioned solutions of blue vitriol or sulphate of copper.

Our Forestry Exhibit at Paris.

To the Editor of GARDEN AND FOREST:

Sir.—Some account of the Forestry Exhibit lately sent to the Paris Exposition by the Forestry Division of the Department of Agriculture may be of interest to your readers.

It is the first ever prepared in this country for such a purpose, in so far as it is confined to forestry as an art, and leaves out the display of manufactures which depend on forest-products. The main object in view in preparing this exhibit has been to be instructive to European students of American forest-conditions, forest-growth, forest-products and forest-utilization, and many novel features in the method of arrangement of the exhibit have been introduced to attain this object.

To give an idea of the forest-areas still existing a large wall-map, twelve by seventeen feet, has been prepared, showing for each state the ratio of forest-land to total area by different shades of green color. This is all the knowledge we can really claim to have in regard to our forest area, since the statistics gathered by the census are no longer true, and a stamp in the shape of a tree has been used to indicate on the map the localities of densest growth.

Great care has been bestowed on the forest botanical exhibit. Out of the 420 or 430 arborescent species forming our forest-wealth, 120 species have been selected which appear to form more or less the important staples of our timber supply, or which for some special reason seem desirable objects for our future forestry. The wood specimens are about nine inches in height and two inches in breadth, representing a cut from centre to periphery of varying width, with a slanting cut at the top of centre, and showing the bark, the upper third oiled and varnished, the lower dressed in the raw. The woods that belong to the same genus, or to several genera closely connected, are mounted together on one panel, and the panel is surrounded by glass-covered boxes containing specimens of branch and fruit of the species contained in the group. By the side of each block of wood is a label showing the botanical name of the species with English and French equivalent, a small map showing its field of distribution, and below it the description of the tree and its wood as given in Professor Sargent's account of the Jessup collection of woods.

There are thirteen such groups or panels. The Pines are represented by twenty-two species—fifty-four northern, six southern, eleven Rocky Mountain and Pacific species. The other conifers fill two panels with twenty-four numbers. The ten most important Oaks fill another panel, and Hickory, with Walnut, Chestnut, Beach and Hornbeam, another.

The Massachusetts Society for the Promotion of Agriculture, which is the trustee of a fund bequeathed by the younger Michaux, a French botanist, for the purpose of encouraging the study of trees in the United States, placed one hundred dollars at the disposal of Mr. Fernow for the purpose of acknowledging by an exhibit their recognition of the generosity of this man. A most fitting exhibit seemed to be the work of this botanist in 240 colored plates illustrating the American forest-flora, grouped twelve in a swinging frame, headed by a steel engraving of Michaux and a French inscription relating the circumstance of the appearance of this exhibit.

Professor Rothrock, lecturer under the Michaux fund, of which one-half was contributed by the American Philosophical Society, obtained permission to loan for photographic enlargement, some of the many fine lantern slides of characteristic tree-growth which he has collected. These were supplemented by photographs from Mr. Henry Brooks, of Boston, and from other sources. Especially noteworthy are the contributions of Mr. Taber, of San Francisco. His California trees, on plates fourteen by twenty inches, are magnificent representations. Altogether some fifty characteristic photographs are in this collection.

A frame of veneer sections shows the gross anatomy of some of our important woods, and a series of magnificent photo-micrographs in swinging frames, executed by Mr. Thomas W. Smillie, photographer of the National Museum, from sections of Mr. Z. L. Zabriskie, illustrates the anatomical structure of twenty species enlarged 100 times in radial, tangential and

transverse section. This is a kind of exhibit probably never before presented to the public, and highly interesting.

The sub-section of Forest-culture contains first, a collection of tree seeds of 100 species in glass bottles. These will convey to the European forester, who is accustomed to handle not more than twenty species, an idea of the variety and also the difficulty in the selection, proper identification and handling of our wealth of valuable trees and their products.

The second number is the model of a tree-planting machine invented by Thomas A. Stratton and lately patented, although it has been tested for two years in western Nebraska. The machine is drawn by five horses, or by a locomotive, and is capable, in one motion, of plowing the ground and planting from 20,000 to 30,000 seedlings in a day. One man to drive and one man to feed have set 15,272 Ash seedlings in nine hours.

The third number represents a collection of sections of fifty trees, planted and grown in different localities of the country, five sections from each tree—a small forest reduced to shipping dimensions. The sections came from the Arnold Arboretum, of Massachusetts, the Agricultural Colleges of Michigan and Illinois and the well-known Farlington Plantation, in Kansas. The sections were taken from the base and every three feet of each tree up to twelve feet, and mounted in frames, so that the five sections in the frame represent a twelve-foot pole, showing on their face the rate of growth in the different parts of the tree. The annual rings are marked with the year of their growth, and a centimeter measure is pasted across the face of each section for ready reference. The amount of information which may be readily read from these living books on tree-growth is remarkable, and would fill many pages.

In the section of Forest-utilization attention is first claimed by the huge slab of Redwood, framed in a frame seven by twelve feet. A series of photographic views, in a Redwood frame, shows the different stages in lumbering these giant trees. A collection of the tools used in lumbering, arranged as a frame surrounding photographic methods of lumbering as practiced in the northwest and in the south, will give to the Europeans an idea of the art of lumbering, which is truly and specifically an American development. The model of a lumbering sleigh, and of a steam logger, which makes its own ice-road, getting into every corner of the woods, completes this phase of our working of the forest.

Numerous large-sized slabs of our economically important woods show the result of the lumbering; especially a fine plank of the White Pine, a monster plank of Cypress, a slab of the Tulip Poplar six feet wide, Black Walnut, Birch, Cherry, Oak, and panels of curled woods of the southern Pines, Maples, etc., give some idea of our wood material.

It is unfortunate that Mr. Fernow had so little time and such a scanty supply of money at his disposal. But when it is considered that the collection had to be made in four months and for \$600, and that it is to be displayed in the limited space of sixteen by twenty-two feet, it will be admitted that the collection is remarkably well fitted for to give instruction to the European forester.

New York.

E. T. Lander.

The Home of Shortia.

To the EDITOR OF GARDEN AND FOREST:

Sir.—I lately made a collecting trip to the region of Shortia, and found the route from Highlands, North Carolina, an interesting one. It passes through quite extensive thickets of *Rhododendron Vaseyi*, easily distinguished, even at this early season (March 25th) by their very large flower-buds, with black-tipped scales. A fine group of Carolina Hemlocks was also passed. We camped the first night at the White Water Falls, which alone are worth a considerable journey to see. The Jocassee Valley, our destination, is at the mouth of White Water Creek, or rather at the junction of White Water and Devil Fork. I wished to see if Shortia was growing as high up in the mountains as these Falls, which are at least 1,000 feet above Jocassee. No Shortia was found, however, until we reached the valley, which has an altitude of about 1,200 feet, and here it grows by the acre. Every little brooklet is lined with it. Most of these little water-courses are in deep, narrow gorges, where the sun hardly penetrates, except during the middle of the day. All of these steep banks are literally covered with Shortia. What is comforting to the botanist is that it can hardly be exterminated. It is on land too steep to be cultivated, and there in such abundance that no amount of collecting can ever affect it very seriously. Our party took away bushels of it, and no one could tell that a plant had been disturbed, so thickly is it growing. No idea of the beauty of

this plant can be formed until it has been seen in its native home. The mass of glossy green and white once seen can never be forgotten.

The home of *Shortia* is a strange mixture of north and south. As a rule it grows under the shade of tall Kalmias and Rhododendrons. Hemlock Spruce and White Pine, of splendid dimensions, are very common, while just a few rods distant grows *Pinus mitis*, *Pinus pungens* and *Pinus rigida*. The old cotton stalks in neighboring fields show that the valley is warm enough for so tender a plant.

I found *Stuartia pentagyna* quite common, and recognized it by the remains of last year's fruit, which were still clinging to it.

Vaccinium arboreum is common in the valley; some plants, true to their name, being quite little trees. In some specimens the leaves were still persistent and quite green.

The list of plants found in flower is not large. Of course, *Epigaea repens* was in full bloom. In one place *Polygala paucifolia* showed its bright purple blossoms, contrasting beautifully with the white ones of *Shortia*. *Trillium sessile* is common, but was hardly open. *Stellaria pubera* was very common and well out, and so were *Tiarella cordifolia*, *Saxifraga leucanthemifolia*, and several species of *Viola*, including *V. rotundifolia* and *V. pedata*. On the Pine ridges we found *Chrysogonum Virginianum* and *Erigeron bellidifolium*, and the Amelanchier was covered with bloom. One of the prettiest things was *Smilax laurifolia*, which is common here, its mass of glossy evergreen leaves and abundant dark fruit making it very ornamental. I wondered if it had ever been cultivated.

Jocassee has been settled many years, and contains some good farms. There are no hotels nor stores, and the visitor must either go prepared to camp out or find quarters at farm houses. The nearest railroad station is Seneca, South Carolina, distant about twenty-five miles. There are good roads to Seneca, also fair mountain roads between Highlands and Jocassee. To see *Shortia* in blossom and in its glory one must get there about the 20th of March, usually, not later than March 25th.

After leaving Jocassee we crossed over into Georgia, hoping to find *Shortia* on the Chatuga River and its branches, but were disappointed. It seems to be confined to the one locality, the head waters of Keowee.

Highlands, N. C.

Frank E. Boynton.

The Newtown Pippin.

To the Editor of GARDEN AND FOREST:

Sir.—I had just eaten a Newtown Pippin when I sat down to read GARDEN AND FOREST, in which you quote a writer in the *Saturday Review* who says:

"We cannot admit that the very best American apple ever possesses a title of the flavor of good English fruit."

A man writes confidently about what he knows, and here I find many people judge a fruit more by its appearance than its flavor; but let at least one who puts flavor first say that an American Newtown Pippin is the best apple in the world.

If your people can only grow enough of it, and grow it well, the rest of the world will have to be very active, indeed, to beat you in apples. They have first to raise a kind to equal it. We have good apples here, and there are good apples in France (though not quite equal to ours, I think). But there is nothing with the splendid high flavor and lasting quality of the Newtown Pippin. I am writing this on the 6th of March, and there are Newtown Pippins here in London, still, after their long voyage and long keeping, of high quality. Our own eating apples have disappeared long ago. There may be a few, often flavorless, in private collections, but in Covent Garden one sees nothing of them. I often wonder when reading your excellent rural journals that I do not find anything about the Newtown, and, so far as I have been able to judge, Americans generally do not value it fairly. They tell me they have better apples, but better would be too good for this poor world.

Garden Office, London.

W. Robinson.

A Nursery of Hardy Perennial Plants.

To the Editor of GARDEN AND FOREST:

Sir.—Even at this early season a visit to the nurseries built up and conducted for many years near Passaic, New Jersey, by Woolson & Co., and now in charge of H. Meyers, is instructive as well as interesting. Many of the Christmas Roses are still in bloom. Some of the rarer Tulips are now open, and near them are at least fifty varieties of the choice hybrid Narcissus. Under the trees are colonies of Dog-tooth Violets, *Erythronium albidum* and *E. Americanum*, with Trilliums, Hepaticas,

English Primroses and Cowslips in great masses on every side; while if rarer flowers are sought, one can find the wonderfully deep blue of *Gentiana excisa*, which appears a little earlier than the better known *G. acaulis*, the almost equally intense blue of *Lithospermum prostratum*, or the rich yellow of *Potentilla Pyrenaica*. Another plant to be seen now, not new, but rare in gardens, is *Isopyrum biternatum*, which resembles its relative, *Thalictrum anemonoides*, in foliage, while the smaller pinkish-white flowers are much more abundant. Among the early Phloxes in bloom are *P. bifida*, from the cliffs of the Missouri River, and Douglas' Phlox, from the Cascade Mountains. But I did not set out to make a catalogue of the plants in flower. The collection numbers more than 2,000 species and varieties of hardy, herbaceous plants, and among them are most of the meritorious plants of this class which are now known to succeed well in cultivation. The spring-garden has not been overlooked in making this selection, and the display of bloom in April and May is always attractive.

What I do wish to say is, that this establishment illustrates in a striking way the growth of the interest in hardy perennials as garden-plants in this country. Many years ago a catalogue of hardy perennials was added to their nursery list, by Hoopes Brothers & Thomas, but here was established the first nursery in the country devoted to these plants alone. Mr. Woolson was for many years engaged with Dr. Thurber on *The American Agriculturist*, and both of them took delight in examining and identifying the specimens sent to the office from all parts of the country, and by a system of exchanges they gathered in time a considerable collection. At last the exchanges reached such proportions that two small green-houses were erected to help propagate the plants demanded, and in 1878 the sale of plants began, and the first catalogue was issued. This catalogue, like those which have followed, had the benefit of Dr. Thurber's revision, and they have been distinguished for botanical accuracy as well as for neatness, compactness and instructive comment. From this modest beginning the business has grown, as the taste for hardy flowers has become more general, until now landscape-gardeners and others, having large places to provide for, send orders here for plants by the thousand. But this is no longer the only place where hardy perennial plants are grown in quantity. Other nurserymen have felt the need of adding a department of this kind to their business, so that it will hardly be denied that the development of this demand for hardy plants is one of the most striking incidents in the current history of ornamental gardening in this country.

The soil and exposure of this place is admirably adapted to the class of plants grown. From a plateau of light, sandy loam the ground slopes gradually to a low, marshy hollow, in which aquatic plants will flourish. Beyond this rises a wooded slope, in which have been naturalized many shy or shade-loving plants like Trailing Arbutus, *Pixidantha* and Twin-flower. Almost any variety of soil—sand, clay or peat—can be found somewhere on the eight acres now devoted to the business, and almost any plant that will live in this climate can be made at home here. It is safe to say that a great proportion of the hardy perennials which have been introduced to American planters during the last ten years have been put on the market through the medium of this house. Among these, besides many foreign plants, have been a large number of native plants which are sufficiently showy or interesting to commend themselves to planters. Indeed, some of our native plants which but a few years ago were rarely seen in cultivation are now propagated here in large quantities. Of the lance-leaved *Coreopsis*, for instance, and the Missouri Evening Primrose the sales were last year as large as of any other plants. Many American plants, however, can be gathered wild more cheaply than they can be grown, which is the case with the Dog-tooth Violets, the *Cypripediums* and, indeed, all the native Orchids and Ferns, and collectors send such plants here from all parts of the country.

There are many native plants well worth a place in gardens which have never yet been introduced. No doubt numbers of the alpine and sub-alpine plants of the Rocky Mountains of Colorado and of the Blue Mountains of Oregon, for example, which are likely to prove hardy, will be interesting additions to our rock-gardens. The growing desire for such plants will stimulate the zeal of collectors, and it is gratifying to know that the material needed for all soils and situations is increasing every year. Certain it is that of herbaceous perennials, of perennials partly woody, of low shrubs and woody climbers, the available selection in this country is much richer than it was when Dr. Thurber and Mr. Woolson began to make a specialty of these plants.

Passaic, N. J.

S.

Notes.

The great gold medal of the Royal Horticultural Society was recently bestowed upon Baron Ferdinand von Müller in recognition of his services in the investigation of the flora of Australia.

Mr. E. W. Reasoner states, in the *Florida Dispatch*, that *Exochorda grandiflora* does remarkably well in that State, as does *Spiræa Cantoniensis* and some other *Spiræas* which are not quite hardy in the Middle States.

A correspondent of *The Garden* (London) recently spoke of a spot in Dunrobin Castle Gardens, Scotland, where, about the first of March, two acres of the common Snow-drop could be seen in full bloom under the ancient trees.

Our readers will remember that the first issue of GARDEN AND FOREST contained a photographic picture of the new Chrysanthemum, Mrs. Alpheus Hardy. The first illustration that we have seen of it in a foreign journal appears in *The Garden* for April 6th, a fine wood-cut of a single flower.

Mr. Baker describes in a recent issue of the *Gardeners' Chronicle* a new species of Snowdrop, *Galanthus Fosteri*, brought from the neighborhood of Amasia, in Asia Minor. "So far as the flowers go," Mr. Baker remarks, "it looks most like the larger forms of *G. Elwesii*, but the leaves are broad and bright green, like those of *G. latifolius*."

Le Moniteur d'Horticulture reproduces from *Hygiène Pratique* this simple method of testing the quality of a pear: Write a name with pen and ink upon the dry skin of the fruit. If the ink is quickly absorbed, leaving clear, sharp lines, the quality of the fruit is good; if the skin does not absorb the ink quickly, and the lines are blotted, the quality is inferior.

Mr. D. Dewar, whose interesting notes on Primulas appear on another page of this issue, is now in charge of the herbaceous and alpine plant department at Kew. It will be remembered that the list of cultivated Primulas, which formed the most important part of the printed report of the Primula Conference, held by the Royal Horticultural Society in 1887, was prepared by Mr. Dewar.

Mr. John N. Gerard, of Elizabeth, New Jersey, sends us a blooming plant of *Androsace coronopifolia*, a hardy Russian biennial, its small white flowers, with a yellow centre, borne on slender scapes. A colony of this little plant is an attractive feature in the rocky or on the margin of the herbaceous border. It will come up from seed year after year if it finds itself in a congenial position, so that there are new plants to bloom every spring.

A healthy, well-flowered example of *Shortia galacifolia* was shown by Mr. H. J. Elwes at a recent exhibition of the Royal Horticultural Society, and, as a matter of course, was awarded a first-class certificate. An English correspondent writes that "The interesting account of this plant which appeared in GARDEN AND FOREST in December last has called the attention of English growers of alpinists to it, and consequently living plants of it are already in several collections here. It does not appear to have ever been in English gardens until now, and Mr. Elwes' plant is the first flowering example of it ever seen alive in Europe.

We have heard with much pain of the untimely death of Mr. J. A. McKenzie, who was associated with Messrs. David Yates & Co., of Philadelphia, in charge of the department of landscape-gardening in their business. Mr. McKenzie was the eldest son of Major Alexander McKenzie, the eminent landscape-gardener, of England, and during his brief sojourn of a single year in this country he gained a wide reputation for ability in his profession, and made a friend of everyone he met by his modest and manly bearing. Of an article from his pen which appeared in a recent number of *Building* we shall take occasion to speak hereafter.

Hideous floral designs are produced in every country, but only in our own, perhaps, could one be created which should reveal so grotesque an attempt at humor with so utter a disregard for the claims of art on the one hand and of proper reverence for death on the other. It was designed, according to the *American Florist*, for the funeral of a railroad employee and represented a limited coupon ticket. The ticket, which was five or six feet in length, rested against a column on which was placed a ticket-stamp, and behind stood the Angel of Death in the act of stamping in the date of limit. The coupons bore the names of the different roads upon which the dead man had been employed, with corresponding dates, and at the top were the words "Limited to October 9th, 1888"—the day of his demise.

At the Massachusetts Agricultural College Experiment Station pollen was taken from a Carnation flower of a magenta color, and after being kept in a dry place for five days, was applied to the stigmatic surfaces of a yellow flower. From twenty-seven seeds obtained by this crossing, nineteen plants were grown, all but one of which produced double flowers. Five of them bore yellow flowers of various lighter and deeper shades, eight bore magenta flowers, four bore scarlet flowers, and two white-striped flowers. In another trial the pollen used was taken from a flower of the same variety—in this case a yellow-striped one—and the seedlings all showed yellow-striped flowers, although they varied somewhat in shade. This seems to indicate that for the production of varieties distinct in color, cross-fertilization is a necessity.

The excessive accumulation of garden varieties of favorite plants is illustrated by the fact that a recently-published German catalogue, devoted entirely to Zonal and Ivy-leaved Geraniums, contains 291 entries. It likewise gives amusing proof of the difficulty of finding names for so many varieties. In addition to the many "Glorias" and "Queens" and "Marvels" of one thing and another, we find plants named for a multitude of botanists, horticulturists and lady clients; then the names of living artists are lavishly drawn upon; celebrities of all kinds follow in curious conjunction, such as General Gordon, Tausaint L'Ouverture, Walter Scott, Count Herbert Bismarck, Leonidas, The Cid, De Lesseps, M. Eiffel and Horace Greeley—General Boulanger, by the way, being unaccountably absent; and at last the tradesman's ingenuity has been driven to such expedients as Nemesis, Electric Light, Divine Comedy, Walküre, Red Sea and Centaur.

The first flower-show ever held in Detroit was opened on April 2d, and continued for three days. The display is said to have been most excellent, and it is pleasing to know that the enterprise was commercially most successful. It was organized by Mr. Brearley, proprietor of the *Detroit Journal*, assisted by twenty ladies connected with as many charitable institutions. As a result of this novel yet sensible plan, 4,000 tickets of admission were sold the first day at a price of twenty-five cents each, and more than 19,000 on the succeeding days. The exhibition was held in a large rink, and each of the charities represented had its own booth for the sale of flowers. Most of the plants were effectively grouped in large masses of allied sorts, and the florists who signified their intention of showing decorative arrangements were consulted with regard to the prevailing color they would select, and rooms were furnished for them in a harmonious way.

Thousands of people are now visiting every day the Public Garden in Boston to enjoy the spring flowers which are lavishly displayed there. The great show will come a little later, when the Tulips are blooming. At present the feature is the Hyacinths, which have been brought forward under glass and are now plunged in full bloom into beds previously carpeted with Daisies or with Pansies. Thousands of Hyacinths are used in this way, and this fact will serve to illustrate the expensive manner in which this garden is carried on. The flowers last a few days only, and then the plants, which were first imported from Europe, then potted, then stored away for the winter, then brought forward under glass, then carted to the garden and plunged into beds, are to be thrown away. The sight of all these masses of Hyacinths is a beautiful one no doubt, but the result is hardly commensurate with the expenditure of labor and money. There are certain beds in which very dark blue Hyacinths are alternated with *Narcissus Pseudo-Narcissus*. The combination of colors in these beds is admirable, and the effect which these flowers together produce is as fine as anything of the kind which can be seen. A bed in which the same yellow-flowered *Narcissus* is mingled with a pale pink-flowered Hyacinth is almost as unsuccessful as the others are successful. It is pleasant to note that some of the superfluous flower-beds have quietly disappeared from the garden, that there are fewer of the horticultural curiosities scattered about, and that the garden generally gives promise of greater simplicity of decoration. There is a pile of rocks in a conspicuous place, however, thickly planted with garden Tulips (the garden Tulip is a flower of the parterre, if it is anything), which is calculated to give a shock to the stoutest heart. But perhaps it is an object lesson, intended to illustrate how not to make a rockery, and how not to plant Tulips. That Mr. Doogue knows how to plant Tulips the beds near the Commonwealth Avenue entrance and along the central walk will, if they are as good as they have been in recent years, abundantly demonstrate. Bostonians will have much to enjoy in the garden during the next two or three weeks.

The Artistic Aspect of Trees.—VII.

WE spoke not long ago of the Lombardy Poplar and the Weeping Willow as trees which, on account of their peculiar form, are exceptionally conspicuous, and therefore must be placed with care if a good general effect is to be heightened by their presence. The Purple Beech is a tree of normal shape and texture, but its eccentric color puts it in the same category with trees of eccentric shape. Rightly used, it may be a feature of extreme beauty; wrongly used, it may deform an otherwise beautiful landscape. It should never look as though mere chance had determined its position, for everyone knows that it is not a natural species but a mere variety, originally produced, indeed, by one of Nature's spontaneous accidents, but carefully perpetuated by the hand of man. It should never be planted in a wood, on a rough hill-side, in a picturesque glen, or in any other place in which it is desired to simulate a purely natural effect. Its place is in ornamental grounds near a house or in the more carefully tended portions of a public park or pleasure-garden. Here it may stand in isolation or be grouped with other trees of an appropriate character. Nothing, of course, groups so well with it as Beeches of the normal hue—either the European Beech, with its beautiful dark green, glossy foliage or the American Beech, with its lighter foliage, paler bark and more graceful ramifications. Failing these, its associates should be trees which will repeat its own lines in a general way, like the Horse-chestnut or the Scarlet Maple, or which will gently contrast with those lines, like the Sugar Maple with its more elliptically-shaped head. To group it with the broken, picturesque outline of a White Pine, or the hard, conical shape of a Spruce, would be to ruin its effect. And, as a general rule, it looks better standing apart from all other trees, for a well-grown specimen is as beautifully symmetrical in form as it is peculiar in color. If, however, it is grouped with other trees as much attention should be paid to the shades of green as to the forms of its neighbors. In shape the Negundo, for example, would be a good tree to group with the Purple Beech; but the light green

of its leaves contrasts unpleasantly with the vivid tint that this Beech sometimes assumes. It may be added that it varies much in tint, as may be read in the fact that it is sometimes called the Purple and sometimes the Copper Beech. Those shades which approach most nearly to brown are the most desirable as being less eccentric and conspicuous than the brighter purples; but in our climate, fortunately, the hot sun of summer often turns a tree that has been too vivid in the spring months to a beautifully modulated coppery color. The Purple Beech has sometimes been recommended as a street-tree, and has more than once been planted as an avenue-tree in American country-places. But it is not well adapted for either of these purposes. What we want in the city is as much of Nature's verdure as can be obtained; and to line a street with purple trees is to defeat this object. Not eccentric but normal color is the thing to be secured in systematic street-planting, although, of course, in a small park or the grounds of a villa a well-placed Purple Beech is an interesting object, and if the arrangement of such a spot is formal or semi-architectural, its presence is doubly appropriate. In a country avenue the Purple Beech is likewise out of place. Here we have, indeed, an abundance of green tones in the surrounding landscape, but a whole avenue of a purple color cannot but disturb the restfulness and harmony of even the widest and most varied park. Anything that is eccentric, whether in color or in form, should be sparingly used—should merely accent and enliven a scene, not be so often repeated as to dominate or confuse the general effect. A vast bed of purple *Coleus* could not agreeably take the place of a lawn, nor can a long double row of purple trees agreeably form an avenue.

The common White Birch of Europe, like the Paper or Canoe Birch, which is less frequently planted, is a peculiar tree in both form and color. The color of its leaves, indeed, is green, but the brilliant whitish hue of its bark which, as its foliage is not dense, appears even in the head, added to its slender outline and drooping habit, makes it extremely conspicuous. No tree is more generally seen in our parks and country-places, and none, perhaps, has been such a source of sorrow to the landscape-gardener. Early associations have made our little Gray Birch dear to all lovers of Nature in our Eastern and Middle States, where it grows abundantly in the woods and copses, and, combined with the White Pine, often gives the landscape a distinctive look. The fact that it is peculiar, and is graceful and pretty rather than beautiful in a more serious sense, has tended to make the similar and more easily-procured European Birch very popular. It is easily grown and flourishes in a variety of situations. No tree, therefore, has been more frequently introduced into private grounds by proprietors who think they can improve upon an artist's first arrangement. But, charming though the Gray Birch is when growing wild, and when judiciously planted, a single Birch of this character unwisely placed can work the greatest injury to a landscape. Its weakly pliant form and shining trunk make the smallest specimen conspicuous against a background of other trees, and may disturb the majestic repose and dignity of a dozen great Oaks or Beeches. Nor, as most generally placed by the amateur—especially when the cut-leaved garden variety is chosen—in isolation on a lawn, can it often have a good effect. It is too delicate, fragile, nerveless a tree to look well by itself, and its outline, although graceful, is seldom really beautiful. This, unlike the Purple Beech, is a tree for the edge of a natural-looking wood, for a rocky glen, or a tangled hill-side. A familiar wild tree in many countries, it looks out of place if posed as a garden specimen by itself, while its form shows to the best advantage when several individuals grow near together in association with such trees as Nature herself commonly groups about it. With Pines, Hemlocks, Tupelos and Scrub Oaks in the woods along the Massachusetts coast, the Gray Birch composes most beautiful pictures; and it is pictures such as these that the

landscape-gardener should study when striving to make the best use of the material at his disposal.

A new edition of the "Manual of the Botany of the Northern United States" is in press, and will appear early in the autumn. It has been prepared by Mr. Sereno Watson, with the assistance of Professor John M. Coulter. The Willows have been elaborated by Mr. M. S. Bebb; the Carices by Professor Bailey, and the Ferns by Professor Eaton—the best authorities in the United States upon these difficult plants. The field covered by the new edition is enlarged to embrace the territory as far west as the one-hundredth meridian, older editions having covered the Northern States east of the Mississippi River only; and the *Hepaticæ* from the pen of Professor Underwood are to be added. "Gray's Manual" is one of the best books of its class that was ever written, and for forty years it has been the constant guide and companion of every man and woman who have successfully studied the flora of eastern North America. No popular flora was ever cast in a better mould, or has had a more widespread and lasting influence. Twenty years have passed, however, since the last edition appeared, and a new one to include all the additions which have been made in recent years to our flora, and all the changes in nomenclature and grouping made necessary by recent investigations has long been greatly needed. Professor Gray, up to the very end, expected to publish a new edition of the Manual, but the time never came when he could turn his hand to it without neglecting more important duties, and the task has fallen upon his associate and successor.

The following is the substance of a dispatch dated April 21st, from Holyoke, Massachusetts, and published in the Boston *Herald* on the following morning: A fire which destroyed a large amount of valuable woodland property started from some embers emptied among the brush on the outskirts of this city at four o'clock this afternoon. The wind was blowing a furious gale, and fanned the embers into flames, which were communicated to the woods near by. The wind carried the fire from tree to tree. Farmers turned out to fight the flames, but for hours their efforts were unavailing. Thousands of acres of valuable timber were burned before the fire was got under control. It had laid waste a territory four miles long and 100 to 400 yards wide.

A dispatch in the same issue of the *Herald* from Pittsfield, Massachusetts, states that "two forest-fires are now raging, one in the west part of the town, north of the Valentine summer place, which is doing considerable damage and threatening several dwellings. Another great forest-fire is burning furiously in the north part of the town. This covers a very large area of territory, and is sweeping on toward the east with great fury, taking the timber in its course and threatening a whole settlement with destruction." A dispatch from North Adams of the same date, states that "extensive forest-fires have been raging in this vicinity for the past few days, destroying large quantities of valuable timber, also thousands of cords of wood which had been cut and piled during the winter."

Announcements similar to these appear almost daily at this season of the year in the press of the country. They emphasize what we have so often insisted upon—that it is in the early spring, before the appearance of the new leaves, that there is the greatest danger from forest-fires, and that it is useless to expect that such fires will diminish in number and in violence until the time and the method of setting brush-fires upon farms are regulated by law, and some responsible officer is appointed in each town to decide when such fires can be set with safety to the community. It seems preposterous that any man should be allowed to set a fire on his land without restriction and without regard to the lives and property of his neighbors.

Many lives and many millions of property are sacrificed

every year in the United States in this way, but the men who set the fires and allow them to escape to the land of other people are not responsible or cannot be made responsible for the damage they cause. The number of such fires can, however, be greatly restricted, and the Forestry Associations, Forestry Commissioners and similar bodies who are looking about for some object upon which to centre their efforts will find here a good cause. Prevention is the only cure for forest-fires, and the most efficient way to prevent them will be found in limiting the right of individuals to set brush-fires. A brush-fire in a wooded district on a dry spring day, with a high wind blowing, is a much more dangerous thing to the community than a nitro-glycerine factory. Yet no farmer would ever claim the right to manufacture nitro-glycerine on his premises, or consider that his liberties were invaded if the community in which he lived objected to his making it. It is through the establishment of some supervision over the setting of brush-fires more than by any other one thing that the interests of forestry can be advanced and the protection of rural property increased in the Eastern and Northern States.

Some Old American Country-Seats.

II.—THE LYMAN PLACE IN WALTHAM.

BEYOND Cambridge and Somerville and about seven miles from Boston Common rises a range of irregular and sometimes rocky hills, from whose summits one may see on the west Wachusett and on the east the ocean. At the southern end of this highland two considerable brooks issue from the hills and, joining their waters, flow as one stream across about a mile of smoother country to Charles River. Between the western brook and the foot of the rocks is a warm slope having a southern exposure, and here one of the colonists of 1634, by name John Livermore, built his house and cleared the land for a farm. Other Livermores—namely, Nathaniel, Samuel and Elijah—in turn succeeded to the property; of whom Samuel came to most honor, for he married four times, and served his fellow-townsmen as their clerk, assessor and captain of the company, and also as deacon of the church, which was built about 1722 "within twenty rods of Nathaniel Livermore's dwelling." Elijah Livermore became the founder of a town in Maine, and sold the farm to Mr. Jonas Dix, of the class of 1769 at Harvard College, who brought his bride to the Livermore homestead, and there lived the quiet life of a schoolmaster and selectman until his death in 1796.

It would be very interesting to know what was the condition of the neighborhood at this time, whether the sheltering hills behind the farm were wooded or no, and what sort of a channel the Chester brook ran in. The place must have been decidedly attractive in some way, for its next owner, Theodore Lyman, a merchant of Boston, bought it with the express intention of making it a country-seat, and forthwith built a mansion which was valued by the assessors of 1798 at the vast sum of eight thousand dollars! This substantial house he placed not upon the highland, where the popular taste of to-day would set it, but upon the flat, and from one to two hundred feet south of the southernmost rocks. Here it was sufficiently high above the brook, which flowed in front about 400 feet away, while behind it space was obtained for a well-sheltered garden. The east wing was built close to a little knoll, which, with the trees upon it, helped to make the house appear firmly and comfortably planted. The west wing also had its supporting trees. The smooth lawn before the house was made with material dug from beside the brook, which was then induced, by the help of a low dam, to flow more quietly and broadly. Plainly, English books on landscape-gardening, like Repton's or Whately's, had made part of this American gentleman's reading—the low setting of the house and the serpentine curves given to the grass-edged shore of the stream furnish proof of this.

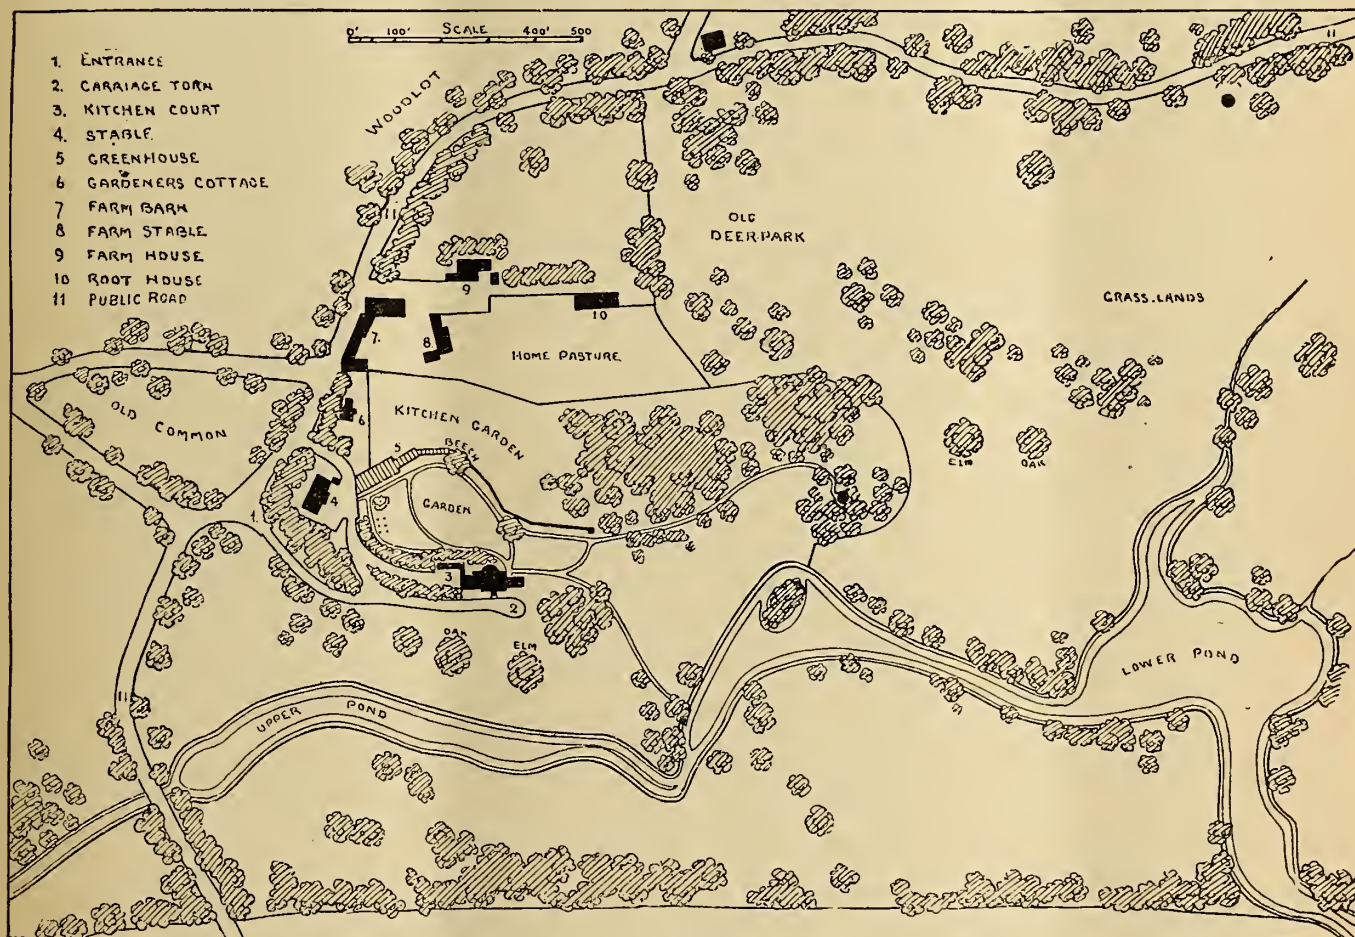

At first, the approach road entered the estate from the south-east and crossed the brook on a stone bridge of three arches, but in after years a new entrance was made in the position shown upon our plan, and then the older way was discontinued, with the unfortunate effect of bringing the driveway to a sudden ending at the house-door. No other important alterations of the original plan have been attempted since the designer himself made this change. To be sure, the second Lyman, probably in haste to provide shade in certain parts, planted many Norway Spruces, but these his son is now

gradually removing, to the great improvement of the general scene; for the deciduous forest trees which these quick-growing conifers hid from sight have now attained a handsome stature and, leaning forward or hanging from the steep banks behind the house and from the knolls, compose a harmonious and striking scene, which the cone-shaped Spruces at present confuse and obscure. A few of the native trees are uncommonly large; for instance, an Oak and an Elm, which stand alone in the grass-field east of the pleasure-ground; and, just before the house, a fine swamp White Oak, which was, doubtless, an aboriginal inhabitant of the Chester Brook Valley—its horizontal branches spread 100 feet. Here, too, is an English Elm of uncommonly wide-spread habit, its many large limbs supported by a trunk which measures fifteen and a quarter feet in circumference.

scenery of the estate—the gentle slopes of grass-land, in the hollow of which lie the ponds, the wide stretches of moist meadow, the occasional passages along the stream where Elms or Willows overhang the water, the sheltering banks and knolls clothed with dense woods or dotted, as in the remote parts, with dark Junipers and outcrops of rock. The landscape is more appropriate to human use and occupation, and at the same time it is more beautiful than was the original natural scene. The meadows are more meadow-like than they were, the stream reflects more sky, the trees are nobler trees, and they stand in ordered masses, not in uniformly dense array. Here is abundant proof that if Nature is helped and not forced she will make for us scenery which shall grow to more and more loveliness and character as the years pass.

Boston.

Charles Eliot.

Sketch Plan of the Lyman Place.

But the most remarkable tree upon the place—a Purple Beech (see page 221)—stands in the garden behind the house. This little level space is curiously irregular in ground-plan. It is bounded on the north by a short range of glass-houses and by a high brick wall, which curves in and out in order to avoid the ledges of the rocky bank behind it. This old wall is trained all over with Peach and Pear trees, an ancient hedge of Box accompanies it at some six feet from its base, and many forest trees rise behind it. The garden-ground is all one slightly varied level of soft grass, with a few trees of chosen kinds near the edges, a few Rhododendrons and Roses, and one giant White Pine, which seems to guard the open end of the ground where the simple but picturesque enclosure expands into the still simpler ground outside. With its soft shadows at all hours of the day, its sheltered quietness, its intricacy in one part and its open network in another part, this is a charming spot—a scene which would be lovely enough without its crowning glory, the guarded Purple Beech. The tree stands close against the brick wall; the circumference of its embossed and tortuous trunk is more than thirteen feet, and its branches extend eighty-five feet. This is a large Beech to be only ninety years old, and it is just possible that Mr. Dix may have planted it and the great Elm before the house; but their stature is more probably to be accounted for by the good soil and shelter.

Many photographs, and we have room for but one, could only partially illustrate the beauty and variety of the larger

Native Shrubs of California.—I.

Nuttallia cerasiformis, belonging to the alliance of the Cherries and Plums, botanically something between the two, with strong points of divergence from both, is perhaps our earliest shrub to put forth leaves and flowers. Before the end of January, if the winter be mild, he who rambles by brooklets among the hills may catch a breath of fresh, delightful fragrance, and so be notified that *Nuttallia* is already coming into bloom. Its nodding clusters of green and white, partly concealed by half-grown leaves, make little show, and the shrub is commonly of humble growth, although occasionally appearing in the dimensions of a Hazel-bush. It must, nevertheless, be a favorite wherever it is known, on account of the sweet odor of its flowers—not heavy and surfeiting like that of the wild Plums and Cherries, but most agreeable and refreshing, something to be compared to the flavor of Almonds. No other flowers have such a smell; and I well remember how, in my earlier walks in California, botanizing one April day in the northern Sierra, at the base of Mount Shasta, where half the thickets were white and red with the bloom of Dogwood and Redbud, and the rocky margins of the noisy mountain-streams were set full of the broad leaves and pink corymbs of the great Saxifrage (*S. peltata*), all so attractive to the eye, I wondered and wondered which of the many new beauties it was that gave forth such unwonted and peculiar fragrance, until at length I

broke off a twig of the little Cherry-like bush, which was then new to me, and found that, in its modest reserve, to be the source of all the sweetness with which the air was laden.

In the Foreign Correspondence of GARDEN AND FOREST I have lately read with some interest the remark that while in France the handsome fruits of *Nuttallia* are its chief attraction, in England it bears no fruit. May not this possibly be explained by reference to the diœcious character of the shrub? Have they in England, perchance, only the staminate flowers? Much the same thing may be noted in some parts of California. About Berkeley, for example, I have never found the fruits, nor even any bushes with pistillate flowers; but on the opposite side of San Francisco Bay, in Marin and San Francisco Counties, there are plenty of pistillate-flowered specimens, and the fruits are produced in abundance. There is much more diœcism in California plants and shrubs of the Rosaceous and Pomaceous families than the authors of our books of botany have known.

Owing to inattention to this matter our common wild Blackberry, or Bramble, has been published by botanists under at least three different names, as if there were three species. The oldest of these is *Rubus vitifolius*. The type so named is merely the pistillate shrub, and its flowers are commonly but one-third as large as those of the staminate plants, and their petals are rounded. These, growing as they do among the staminate shrubs, the flowers of which latter are not only thrice as large, but have narrow and elongated petals, look as if they might indeed be of a distinct species. The fine figure in Hooker's "Flora Boreali-Americana," under the name of *Rubus macropetalus*, represents simply the staminate or sterile condition of what has commonly been called *Rubus ursinus*, of which the prior name, and the one to be retained, is *R. vitifolius*.

I ought here to add that in *Nuttallia*, also, the staminate plant produces rather larger flowers than the pistillate.

Oakland, Cal.

Edward L. Greene.

[*Nuttallia cerasiformis* was on the 22d of April in full bloom in the Arnold Arboretum, where it has been growing for several years with a slight protection in winter. It is a handsome and desirable shrub in cultivation, and the first in the Arboretum collection to put out its leaves. The strong perfume described by our correspondent is not noticed in the flowers of the cultivated plant, which are, however, delicately and faintly fragrant.—Ed.]

Foreign Correspondence.

London Letter.

THE most popular hardy flower in England now is the Daffodil. It is grown in every garden; thousands of bushels of its flowers are distributed daily by the costermonger and flower-dealer, and everyone admires it. And yet we are told by Mr. J. G. Baker, the botanist who has paid greatest attention to Narcissi, that twelve years ago these plants were unknown except by a few specialists and as wild flowers in the woods and fields. Mr. Burbidge, whose writings on the Daffodils have done so much to call attention to them as beautiful garden-plants, added yet another contribution to the literature of the Narcissi in the form of a paper which he read at the last meeting of the Royal Horticultural Society. He told us that the Daffodil was cultivated and valued for its medicinal properties a thousand years before Christ. Dean Herbert, the champion of the whole order *Amaryllidaceæ*, grew and crossed many species and varieties of Narcissi sixty years ago; in fact, he was the first breeder of these plants. After him came Leeds and Backhouse, both noted breeders of Daffodils, and the raisers of some of the best of those grown in gardens now. All the forms cultivated are varieties of or crosses from the following six species, the only true species recognized by botanists—namely, *N. poeticus*, *N. Pseudo-Narcissus*, *N. triandrus*, *N. Tazetta*, *N. Bulbocodium* and *N. Jonquilla*. Mr. Burbidge believes that any careful breeder could obtain from these six species all the many kinds of Daffodil now known in gardens. The life-cycle of a Narcissus is from two to five years. The seeds should be sown in boxes as soon as ripe, and they germinate in the November or December following. The one-year-old bulbs are the size of Wheat-grains, two-year-olds that of Marrow peas, three-year-olds either flower, or if of the large-bulbed kinds, are the size of Hazel-nuts. Others flower in the fourth year, others in the fifth, but they are not at their best till a year or two after this. Mr. Burbidge is of opinion that crude manure of any kind whatsoever is harmful to Daffodils, and recommends the use of burnt-earth, wood-ashes and road-scrappings instead of the strong manures generally used for these plants. Indeed, Mr. Burbidge went so far as to con-

demn the use of manure for all kinds of bulbous plants, but on what grounds he did not state. Certainly good manure, such as cow-dung or horse-droppings, has always proved a safe and vigor-giving help to many bulbs under cultivation. I have in my mind just now several large specimens of *Eucharis*, which have been under my eye ten years, and these have always been watered with liquid cow-manure when the flower-scapes begun to develop, which occurs usually about three times a year. These plants are perfectly healthy, and they bloom well. Of course there are many other cases, equally convincing of the fitness of good manure for bulb-culture. What would the Dutch growers of bulbs do without manure in their poor, sandy soil?

Mr. Englehart, who is well known as an amateur grower of the Daffodil, also read a paper on the breeding of these plants. He recommended certain crosses with a view to finally obtaining larger flowers of greater substance and earlier to expand than those we now have. He did not think that the scarlet Daffodil would ever be obtained, notwithstanding Mr. Burbidge's belief that by careful breeding it would come. We do not want a scarlet Daffodil no more than we want a blue Rose or a blue Chrysanthemum.

There was a grand display of all kinds of Daffodils to illustrate Mr. Burbidge's paper. There was also a charming exhibition of rare and beautiful Orchids. One of our oldest and most esteemed horticulturists said to me, as we stood in front of the superb collection sent by Baron Schrœder, "Can one wonder at what foolish people call the 'Orchid mania' when looking at plants like these? Orchids are Nature's richest gifts to the garden. They have no equals in form, in color, in fragrance and in variety." I disputed the claim of superiority in fragrance, for no Orchid surpasses, and only very few approach, the Violet and the Rose in sweetness. I am afraid, too, that a collection such as was shown by Baron Schrœder is quite beyond the reach of all save a very few. They were of the choicest and rarest, and they were perfect examples of good culture. The Dendrobiums comprised large specimens full of flower of the following: *D. nobile*, *D. nobile Cooksoni*, *D. nobile nobilitus*, *D. nobile album*, *D. micans*, *D. splendidissimum*, *D. Ainsworthii*, *D. Luchianum*, *D. euosmum*, *D. aggregatum* and *D. Brymerianum*. It would be impossible for me to convey any idea in words of the beauty of these plants. And this is true of *Cattleya Lawrenceana*, a richly-colored variety, with twenty-one expanded flowers; *C. speciosissima Schrœderiana*, a large-flowered variety, with pure white sepals and petals, and the broad lip rich crimson, with white veins and a tinge of yellow in the throat. Mr. Sander sent beautiful plants of the white variety of *Trichopilia suavis*, *Oncidium bifolium*, a graceful little Orchid, with arching spikes of bright yellow flowers not unlike those of *O. varicosum*; *Dendrobium marmoratum*, a mauve-tinted form of the old and beautiful *D. transparens*. A fine example of *Maxillaria Sanderiana*, whose large flowers are colored like the white Tigridia (*T. Pavonia alba*), was exhibited by Mr. Tautz, who also sent a plant in flower of a very dark-colored variety of *Miltonia vexillaria*, the flowers being a deep purplish-rose, with a white eye.

From Low & Co., of Clapton, came a spike of *Phalænopsis Schilleriana*, var. *alba*, in which the flowers are large and pure snow-white, save a few yellow dots on the lateral lobes of the labellum. Kew sent a collection of Indian *Arisæmas* in flower; *Godwinia gigas*, with an enormous, boat-shaped spathe, two feet long; *Epidendrum bicornutum*, with eight spikes of flowers; a collection of species of *Primula*; *Columnea Kalbreyeri*, with large, sickle-shaped leaves, olive-green above, purple beneath, and numerous large, tubular yellow flowers; *Rudgea macrophylla*, a large-leaved stove-plant with a large, round head of white fleshy flowers.

Forsythia suspensa (Fortunei) is the most beautiful hardy shrub in flower here now. It has very few equals among hardy, spring-flowering shrubs, its long, wand-like branches being thickly set with hanging, bright yellow, bell-like flowers. It is an excellent plant for training against a house-side, a specimen in such a position at Kew being now a large sheet of bright yellow which catches the eye a mile away. In the shrubberies it is equally at home. It may also be grown for early forcing for the conservatory. *F. viridissima*, the only other species, is a greatly inferior plant, but, unfortunately, it is sometimes sold by nurserymen as *F. Fortunei*. There are two forms of *F. suspensa*; one in which the flowers have the corolla-lobes twisted and the pistil twice as long as the stamens; the other in which the lobes are shorter, not twisted, and the pistil is hidden beneath the stamens. I read lately, in a book on Japan, that next to the "Mumè" (*Prunus Mumè*), which is the most universal favorite spring-flowering tree in Japan, is this *Forsythia*, called "Rengyo" by the Japanese, and

The Purple Beech of the Lyman Place.

cultivated by them in every available corner. It was introduced from Japan to Europe, but is really Chinese, as also is the Mumè and many other plants of supposed Japanese origin, but which were obtained originally by the Japanese from China.

The funeral of the late Duchess of Cambridge, which has taken place at Kew to-day, has been exceptional for the magnificence and variety of the floral wreaths and crosses sent. There must have been close upon two hundred of these, some of them of gigantic size, and mostly composed of the choicest white flowers. Of those which appeared to attract greatest attention were the following: A wreath five feet in diameter, and eighteen inches across the coil, was made up of rich masses of *Odontoglossum crispum*, *Stephanotis*, *Gardenia*, *Eucharis*, etc. This wreath alone contained ten guineas' worth of flowers. A heart three feet across, and made up of *Calla* Lilies, *Eucharis*, *Lilac* and *Gardenia*, with a miniature cross of *Mignonette* fixed in the centre and upon this a tiny wreath of *Forget-me-nots*. A small cross of *Violets* with single flowers of *Stephanotis* dotted all over it. A circle of *Beaumontia grandiflora*, the flowers of which remained fresh when most other flowers were more or less drooping. An

anchor, with cross composed entirely of rich yellow Tea-roses on a ground of *Violets* and *Ivy* leaves. A broad circle of pure white *Lilac*, with a knot composed of *Gardenia*. A large harp made up of rich white flowers, the strings formed of single lines of *Violets*. There were also many of the German style of wreath, in which the leaves of *Cycas* and similar plants form the principal feature. I never saw so wonderful a collection of beautiful flowers as were arranged in the chapel where the remains of the Duchess rested. Taking a rough estimate of their commercial value, I should say there were about \$3,500 worth of flowers there. It has been stated lately in so-called fashionable papers that flowers at funerals were not the fashion. There were evidences at this funeral that flowers are more used than ever. *W. Watson.*

April 18.

The Purple Beech.

THE large Purple Beech at Waltham, of which an illustration appears upon this page is no doubt one of the finest individuals of this variety planted in the United States. Downing, who was familiar with the Lyman Place, does not, however, mention it in his "Landscape Gardening," written forty or fifty years ago; and it is probable that the specimen which was growing at that time at Throgg's Neck, in Westchester County, and which Downing declared was the finest in the United States, is now, if still alive, much larger than the Waltham tree, which has lost a good deal from overcrowding and from the garden-wall built close to the trunk, which has destroyed the lower branches. There is no tree which demands more room for free development than the Beech; and a Beech, standing on a lawn or in a garden, on which there are no lower branches to sweep down to the turf has lost a large part of the characteristic beauty which makes it valuable. The stem of the Beech, it is true, especially of the American species, has great beauty and a charm peculiar to itself, but it is in the wood

or in the forest that this beauty should be seen and admired; and Beeches should not be planted in ornamental grounds where light and space cannot be afforded them for full and unchecked growth in every direction.

The Purple Beech is a tree of much interest, apart from its undoubted value for ornamental planting—a subject which has already been fully discussed on another page. It is one of the few examples among trees where an abnormal bud-variety has retained its character for more than a century, through hundreds of thousands of individuals, all sprung from a single branch* (discovered towards the

*Schübeler, in his *Viridarium Norvegicum*, contrary to the generally accepted theory of the origin of the Purple Beech, states that the parent tree from which all Purple Beeches have come was found between the years 1760 and 1770 near Sondershausen, in the Scandinavian peninsula; and that when he wrote a few years ago it was still in existence. The Beech nowhere occurs more commonly or grows to finer development than around the shores of the Baltic, which are often clothed with splendid Beech forests down to the water's edge. An example figured by Schübeler as standing in 1873 near Gradval was 22½ metres in height with a girth of over three metres, and showed a thick and almost perfectly symmetrical head, the branches diverging at about a metre and a half above the ground.

middle of the last century upon a tree in a German forest), either directly from grafts, and now sometimes by seeds; for the plants raised from the seed of a purple-leaved tree preserve more or less constantly this character to a greater or less degree. The seed from certain trees yield more purple-leaved seedlings than those from other trees, although the proportion of the purple-leaved seedlings from the same tree vary in different years, and among purple-leaved seedlings there is always a great variety of shades of color. In other words, a race of purple-leaved Beeches is gradually becoming "fixed;" and if it was not in practice more convenient and satisfactory to propagate the best varieties of this tree by grafting it would doubtless be perfectly possible, at the end of a few generations, to raise from seed Beeches with leaves of almost any shade of purple with as much certainty as different races of the Cabbage are obtained from seed. There is no reason to doubt, therefore, that the variety will be as permanent as the type from which it originated.

It would be interesting to know if there are large or very fine specimens of the Purple Beech in the neighborhood of this city or of Philadelphia.

Cultural Department.

Brussels Sprouts and Savoys.

MANY people object to Cabbage and even to Savoys—Cauliflower they have found uncertain in our climate, and hard to grow without the aid of glass. For a delicate form of Cabbage, Brussels Sprouts are to be commended. They require a rich soil, and if success is expected they must be abundantly fed. The seed should be started early, and the plants should receive the same treatment as Cabbages, but the Sprouts last all summer, and should be placed where they can have the whole ground for the season. The plants grow with a large, loose, Cabbage-like top and a tall stalk below, over which little Cabbage-like heads form, which can be gathered all summer and until the hard frost of the north may destroy them. In Virginia they usually endure the winter, and furnish an abundance of greens when planted late in summer. Boiled in clean water and dressed with cream, the little heads make a good substitute for Cauliflower. The plants grow tall and top-heavy, and in small gardens it will pay well to stake and tie them up.

Most people who consider Cabbage an essentially coarse food are unacquainted with the Savoy class. Even the Savoys which have been crossed and increased in size and coarseness, like the Drumhead Savoy, are still far superior to the ordinary Flat Dutch and Drumheads. And now we have a variety known as the Netted Savoy, which combines fair size with the highest quality. We never miss Cauliflowers while we have good Netted Savoys. The difficulty in growing all late summer Cabbages is the ravenous green caterpillars which eat them so greedily. Pyrethrum powder will destroy the worms if constantly and thoroughly used, but the maulauders come so rapidly that if the application is not made almost daily it is useless, and with good pyrethrum at seventy-five cents per pound, it will not take long to spend the value of the Cabbages. I generally succeed in raising good crops of Cabbage without pyrethrum by stimulating the growth of the plants during summer with occasional top-dressings of nitrate of soda and frequent, shallow cultivation.

W. F. Massey.

How We Rid Our Vines of the Mealy-Bug.

WITH the exception of Phylloxera this is the worst pest the Grape-grower has to contend with. When I took charge of these gardens I found that two vineries were badly infested, and the vines were also in very bad condition, and most of the bunches of grapes were full of the bug. I had been told it was impossible to clear vines of the bug, but I determined to try what could be done with those in one house. A few of the bunches were not affected, and by tying pieces of wadding around the stalks of these the fruit was kept clear until it was ripe. When the fruit had been consumed the laterals were shortened back, and the spurs, which were only nine inches apart on either side of the rods, were thinned out to about eighteen inches apart. The vines were then heavily syringed with warm water in which one ounce of soft-soap and one tablespoonful of paraffin per gallon were mixed, taking care to keep it well stirred. This operation was repeated several times until the leaves had fallen, and it reduced the numbers of the

insects considerably. As soon as possible after the fall of the leaf the vines were pruned, the loose bark pulled off, and the crevices and spurs scraped with a knife; the glass, woodwork and iron trellis thoroughly washed with hot water and soft-soap, and the wood and iron painted all over with paraffin. Finally the houses were filled with fumes of sulphur, and the walls were scraped and then dressed with hot lime-wash in which some sulphur and carbolic acid had been mixed. The top soil was taken off the border to the depth of three inches, the vines were scrubbed with hot water and soft-soap at the rate of nine ounces to the gallon, and were painted over with a mixture of gas-tar and stiff blue clay, the latter being dried and rubbed into a powder before being well mixed with the tar, the whole forming a stiff paste, with which the vines were coated all over, care being taken not to injure the buds. Some fresh loam was put on the border, and we thought that the last of the mealy-bugs was killed. Meanwhile steps were taken to assist the roots by renewing the outside border, which had got into a very bad state. The vines having started gently on January 5th, all went well, and no traces of bug were found, but as the sap began to rise the coating of clay and tar expanded, and on examining the vines, just as the buds were breaking, three or four young bugs were discovered—a proof that not as yet were all killed. As a last resource a gallon of boiling water was procured, and into which was put five wine-glasses full of paraffin, five of carbolic acid, and half a pound of soft-soap; this was carefully applied all over the rods, with the exception of the growing buds, and decided the fruit in our favor, as we have not had a bug on the vines since that time. This last application may appear to be too strong to be safely applied generally, and I have no doubt it would have injured the vines had they not have been partially protected by the previous application of clay and tar, which formed a hard coating all over them.—W. H. Divers, in *Gardeners' Chronicle*.

Orchid Notes.

Among the many select *Cypripediums* now in bloom at the United States Nurseries, *C. Wallisii superbum* deserves mention for its rarity and beauty. It belongs to the section *Selenipedia*, and is a variety of *C. caudatum Wallisii*. It is supposed to have been imported from Ecuador by the collector whose name it bears, and so far as known there are but three plants in existence. The flowers are somewhat larger than those of *C. caudatum*, of a soft lemon color, veined and marbled with delicate green. The dorsal sepal is hood-shaped, seven inches long by three inches wide at the base, and the lower sepal is similar, although slightly darker. The lip, which is of unusual size, is veined with a deeper color than the sepals—pure white within and mottled on the edge with crimson. The petals are more than twenty inches long, of a crimson tint, except at the base, where they are of a pale yellow. Two or three flowers are borne on a scape eighteen inches long and well above the long, deep green leaves.

C. Schraderea is another rare Orchid belonging to the same section of this genus, a hybrid between *C. caudatum* and *C. Sedeni*, and raised by the Messrs. Veitch & Sons. It inherits the "tails" of *C. caudatum*, while in color it approaches *C. Sedeni*, although superior to the latter plant in this respect. The dorsal sepal is whitish, suffused with rosy pink and slightly veined with green, while the lower sepals are of a pale rose color. The twisted petals are pink, with veins of deeper shade, while the lip is a pale carmine; the lobes white, spotted with purple.

C. bellatulum is another recent introduction, which has been already described in GARDEN AND FOREST. It belongs to the *Eucypripedia*; the flowers are three inches in diameter with brownish-purple spots showing to advantage on a ground of pale lemon-yellow. The scape is very short, scarcely holding the single flowers above the remarkably large and slightly mottled leaves.

C. Druryi superbum, *C. Rabellini*, *C. hirsutissimum*, *C. Day-anum*, choice varieties of *C. barbatum*, *C. Sedeni candidum*, a pure white variety of *C. niveum* and many other choice specimens of the genus are now in flower.

Short Hills, N. J.

H. A. Bunyard.

Orchid-growers in America will be interested in the fact that Mr. F. Sander has succeeded in getting from Madagascar "a splendid consignment of living plants of *Phajus tuberculatus* and *P. Humblotii*," two of the most beautiful of all Orchids. In England these two species are extremely rare, almost all the plants previously obtained and distributed by Mr. Sander and others having died. They are not easily kept in health, but when successfully managed and flowered they are really gorgeous Orchids. The genus *Catasetum* is getting a great

deal more attention from Orchid-growers here than formerly. This is due partly to the attractiveness of several of the most recently introduced species, and also to the extraordinary interest which attaches to the flower-structure of the whole genus. Mr. R. A. Rolfe, of Kew, recently read a paper before the Linnæan Society on the sexual forms of *Catasetum*, supplementing the researches of Schomburgk and Darwin on the same subject. Mr. Rolfe has succeeded in matching males and females of no less than fourteen species. Lindley appears to have suspected that not only would the so-called genera *Myanthus* and *Monacanthus* prove to be sexual forms of *Catasetum*, but that *Cynoches* also would ultimately prove to be another "sport" of that genus. A drawing of a *Catasetum* which flowered at Kew last year, and bore a spike of female flowers (*Monacanthus*) on one side, and a spike of male flowers ("true" *Catasetum*) on the other side of the same pseudo-bulb, was shown by Mr. Rolfe, and caused a little excitement among the Fellows of the Linnæan Society. He also exhibited a drawing of *C. Bungerothii*, showing one female and two male flowers on the same spike. This particular plant flowered with M. Linden, of Brussels, and is the only known instance of this *Catasetum* having produced other than male flowers.

Kew.

W. Watson.

three and a half to four inches across, the sepals and petals being pure white, the crest of the lip yellow and marked with a few crimson stripes. It is a deciduous species, and during its growing period should be placed where light and much moisture is available. After its bulbs are well matured it can be placed in temperature a few degrees cooler, to enable the newly-made bulbs to ripen well before commencing to bloom. A fine specimen of this plant is now flowering with Mr. J. Wallace, at Paterson, New Jersey.

Summit, N.J.

A. Dimmock.

The Common Primrose (*Primula acaulis*), which grows wild and abundantly in England and Scotland, has been a favorite with American planters for generations, and I have seen it taking care of itself in old-fashioned gardens for years as far north as Bangor, Maine. I never knew it, however, to establish itself outside of the rich soil and limited competition of the garden where it was given a place by man, until the past season, when I was shown a locality in Massachusetts where it had taken possession of a piece of pasture along the sides of a brook, and among scattered clumps of the Barberry and other shrubs. In this heavy, clayey soil it was perfectly at home, and thousands of vigorous plants were disputing successfully with grasses and weeds for a chance to live. This

The Lyman Place, Waltham, Massachusetts.—See page 218.

Dendrobium nobile, variety.—There is now in bloom in Sander & Co's Orchid Nursery at Summit, New Jersey, an extraordinary variety of this old and well-known species. The plant was imported last year, and is of robust habit, with pseudo-bulbs measuring nearly two feet in length, and from which a dozen large and very rich-colored blossoms have appeared. Each individual flower measures fully four inches in diameter and is well shaped, both sepals and petals being very broad and of a rich, amethyst-purple, the petals being one inch across. The most distinctive character of this variety is that the two lower sepals are furnished with a broad, deep maroon stripe extending their entire length. The lip, also, is very large and highly colored. The plant has bloomed for the first time in this country, and it proves to be a valuable addition to the already existing varieties now in cultivation. Its nearest ally is the variety known as *Dendrobium nobile Cooksonii*, the same rich maroon color appearing in that variety on the basilar half of the petals.

Chysis bractescens.—The lovely, wax-like blossoms of this fine Orchid have now made their appearance. It is an easy-growing species, and thrives well on blocks or in baskets. Its flowers are produced on short stems, four to six together, with the young growth, and they remain about four weeks in good condition on the plant. Each flower measures from

spot, in spring, when these beautiful blossoms are like a brilliant carpet of crimson and yellow, covering many square rods with their bloom, and peeping out of the half-shaded nooks among the wild undergrowth, is a sight to be long remembered by anyone who knows and loves this old Primrose. This is the only case, as far as I know, in which the English Primrose has become really established and capable of propagating itself permanently, so far north, and it is hoped that this hardy strain of these wholly delightful blossoms may hereafter provide us with a race of these Primroses which will be really hardy throughout a considerable part of the Northern States.

Cambridge, Mass.

F. L. Temple.

Tuberose.—Two years ago last fall we had an experience which, I believe, may prove as valuable to others as it did to us. Early in summer a fine lot of Tuberose bulbs were planted in an open frame in a warm, sunny situation. They grew splendidly, but, unfortunately, did not flower as early as expected. The cold, frosty nights of fall came on them just as they were beginning to expand a flower here and there. To allow them to perish by frost seemed a sin and a serious loss; and yet we could not house them for want of room. On each side of the frame, therefore, hot-bed sashes were stood on edge, and on top of them others were laid, which formed a

roof, thereby enclosing the plants in quite a respectable green-house. During the day, under the influence of the sun, the inside temperature of this improvised house generally ran up to about 80°, sometimes even higher, and although the nights were sometimes pretty cool, a nice temperature was maintained until next morning. Every plant perfected all its flowers—the most of them being as fine as could be desired. Those who have bulbs on hand need not be deterred from planting them out-doors because the season is getting late.

Milwaukee, Wis.

James Currie.

The Perpetual Carnation seems to have been overlooked as a bedding or border plant for the garden. Strong plants from cold-frames in five-inch or six-inch pots are preferable. They should be planted as early as the first of May in a sunny position, and in deep, rich soil. They should be firmly set in the ground, and a neat stake should be placed in each plant, to which the flower-stems should be loosely tied as they grow. In making a selection those varieties with long flower-stalks should be chosen, especially for cutting during the very hot weather. The following will be found among the most desirable: E. G. Hill and Portia, scarlet; Century, May Queen and Charles Henderson, carmine or rose; Hinzes' White and Silver Spray, white; Buttercup and Columbia, buff and yellow; Crimson King, Black Knight and Orient, crimson; Chester Pride, Petunia and Star of the West, variegated.

Pearl River, N. Y.

John Thorpe.

Notes from a Northern Spring-Garden.

NO plant, among those which have opened their blossoms during the present week, is more showy in flower than the very old-fashioned *Adonis vernalis*, which was seen more frequently in gardens a century ago than in those of the present day. This species of *Adonis* rises only a few inches above the surface of the ground; the leaves are produced mainly near the summit of the stems, and are finely cut into narrow, slender divisions. Each stem is now surmounted with a Ranunculus-like flower, two or three inches across, with ten to twenty narrow petals of a clear, yellow color. These flowers, when a great mass of the plants are grown together, make a display of color which in bright sunshine is almost indescribably brilliant. They close during the night and in dull weather. This *Adonis* grows best in deep, rich and rather moist soil. It is slow in establishing itself, and several years are required to obtain all the beauty it is capable of giving at this season of the year. It should never be disturbed when once fairly established, and should be allowed to spread and to obtain as strong a hold on the ground as possible.

The European Dog-tooth Violet (*Erythronium Dens-canis*), which is now in bloom, flowers here several days earlier than our common native species. The flowers are large, having been greatly improved by selection and by long cultivation, and they show considerable variety of color from almost red through rose and pink to white. It is an attractive and perfectly hardy plant, thriving in the shade of trees and in more exposed situations, and it is a capital subject to naturalize by a wild wood-walk or along the margins of shrubbery. The Dog-tooth Violet is grown in immense quantities by the Dutch bulb-farmers, and the bulbs, which should be planted in the autumn, can be imported very cheaply. In speaking of very old-fashioned flowers the Grape Hyacinth (*Muscari botryoides*) should not be forgotten. This, like most of the old familiar bulbous plants of gardens, is a native of Europe, and has been in cultivation for centuries. The short, compact racemes of dark blue, globular flowers, resembling, fancifully, miniature grapes (whence the popular name), are familiar sights at this season of the year in old country gardens, whence this plant has occasionally escaped into neighboring woods and fields, so that it may in time become fairly naturalized. There is a variety with pure white flowers, and others with flowers of pale blue and of flesh color, but none of these are equal to the old and more familiar type. This, like the Dog-tooth Violet, is an excellent plant to naturalize in our New England woods and fields.

Corydalis solida, or, as it is more generally known, *Corydalis bulbosa*, seems destined to become a troublesome weed in the rock-garden, springing up everywhere and spreading rapidly. It is now covered with its short racemes of rather dull purple flowers. It is the earliest of the genus to flower here, and certainly requires no care, except to keep it within reasonable bounds. More attractive is its American relative, *Dicentra Cucullaria*, with its finely-divided, pale green leaves and slender racemes of graceful, white flowers tipped with canary-yellow. It is well established here at last (for it is rather impatient of cultivation, and adapts itself slowly to changed con-

ditions), and is now beautifully in bloom. And so is the Pasque Flower (*Anemone Pulsatilla*), with its great, solitary flower, the mass of golden stamens making a fine contrast with the violet-purple sepals. The finely-divided, silky, glaucous foliage is attractive as well as the very showy flowers, and so are the large heads of fruit, which resemble those of a Clematis. It well deserves a place in every garden. *Primula rosea* (see page 141 of vol. i.) improves on longer acquaintance, and I can only say of it again what I said a year ago, that "it would not be easy to find among early flowering hardy plants a more striking and beautiful object than a mass of this Primrose." The Twin-leaf (*Jeffersonia diphylla*), so named from its curiously-divided leaves, is in flower fully two weeks earlier than usual. It is always attractive, even after its large, pure white, but very fugacious, petals have fallen. It is a native of western woods, is very easily cultivated, and may be increased by division or from seed, which is freely produced and germinates quickly. I wish that this and scores of other little-known North American wild flowers could be more often seen in American gardens. It is because they are American, I believe, that we see so little of them in this country, except in their native haunts.

Very showy now are the flowers of the European *Orobuchus vernus*. It is, as I wrote a year ago, "one of the hardiest and in every way most satisfactory of the early flowering, herbaceous plants." It forms a compact, bushy mass of foliage less than a foot high, now completely covered with nodding, pea-shaped flowers, purple and blue when they first open, but later turning deep blue. This little Veitch will thrive in any good garden soil, and will reappear year after year, but without spreading and without care beyond an occasional division of the roots, to insure vigorous growth—a practice which greatly benefits all herbaceous plants, especially those of vigorous growth and strong digestion.

I invite the attention of all persons interested in spring-gardening to *Magnolia stellata*, or, as it is sometimes known in American collections, *Magnolia Halleana*, so named by Parsons, who first cultivated it in this country, it having been one of Dr. Hall's early introductions from Japan. This *Magnolia* is suitable for the smallest garden or the tiniest lawn. Here in this country it is a low shrub, not yet more than three or four feet high, although in the forests of Japan it is said to become sometimes a small tree; it is perfectly hardy, and it is the earliest of all the *Magnolias* to flower, its pure white, deliciously-fragrant flowers appearing here fully a week earlier than those of *Magnolia conspicua*, formerly the earliest of the *Magnolias*. The flowers of *M. stellata* are pure white, three inches in diameter, with petals which are at first spreading, giving to the flowers a star-like appearance; but later becoming quite reflexed. It is a good plant for the door-yards of city houses, for the rock-garden, or for any situation where spring-flowers are esteemed.

The Allegheny *Andromeda floribunda* and its near relative from Japan, *A. Japonica*, are now flowering here side by side, and the plants afford a good opportunity for comparison from the garden point of view. The panicles on the American species are smaller, more rigid, and are upright; the flowers are whiter and more leathery, and are more than half the size of those of the Japanese species; the leaves are smaller, more rigid, and much darker green; the habit is more compact and less pleasing. On the whole, the Japanese plant, with its broad, drooping panicles of large flowers; its freer and more rapid growth and more graceful habit, is the more attractive garden ornament of the two species. Here at the north, however, it will never be as valuable as its American relative, as the flowers appear so early that it is only in an exceptional season like the present that they are seen to advantage. Did it appear every year as it does just now, *Andromeda Japonica* would be one of the best evergreen shrubs known. It is just now by far the most attractive shrub in this garden. Perhaps some of the readers of GARDEN AND FOREST who have had an opportunity to watch this plant in a better climate for it than that of New England, will make public the results of their observations.

It is interesting to read in an English journal that the "Glory of the Snow," as *Chionodoxa Lucilia* (mentioned in my last letter) is now called in England, is spreading in gardens in that country from self-sown seed, and that it can be naturalized in the grass. When this plant is more common and better known it will, I believe, be one of the most popular, as it is one of the most beautiful, of spring-flowering plants.

The difficulties of gardening in this climate and the variations of the New England climate in April may be well illustrated by the fact that on Saturday of last week the thermometer marked 84° in the shade. Easter Sunday was nearly as

hot, and buds of *Magnolia conspicua*, which were completely closed on the morning of that day, had, by the middle of the afternoon, burst into full bloom. Tuesday night ice was formed in tubs and pails more than half an inch thick. But, strange to say, the flowers of none of the herbaceous or bulbous plants have suffered. The flowers of the Forsythias, almost fully expanded, of the Magnolias and of the Sweet Almond are uninjured, while those of Rhododendron Early Gem, growing in a low, damp situation, which were fully out on Monday, were frozen stiff, and are, of course, entirely ruined.

Boston, April 24th.

C.

Principles of Physiological Botany, as Applied to Horticulture and Forestry.

XIX.—DISTURBANCE OF FUNCTION. CERTAIN PLANT-DISEASES. INJURIES AND THEIR REPAIR.

AS stated in a previous paper, the diseases of plants belong to the province of vegetable pathology instead of vegetable physiology, and they are referred to in this series merely because we can sometimes learn something of the functions of a healthy organ by watching its behavior when it is affected by some disturbing cause. Even if we do not know what the disturbing cause may happen to be (much less remove it), we may still gain further insight into the action of an organ or an organism which has come under its influence.

Before considering this subject, attention should first be directed to what are called monstrosities. Everyone is familiar with the commonest forms of monstrosities, such as four and five-leaved Clover, consolidated shoots of Asparagus, green Roses, and the like. These variations of number, of union of parts, of accidental division, and changes in color, throw much light on the laws which govern structure, but they do not usually aid us in the examination of the office of organs which are abnormally developed. There are, however, some strange modifications of structure which follow the attacks of insects, for instance, in the case of the so-called gall-insects. The slight injury inflicted and the subsequent irritation caused by these insects give rise to variously-shaped excrescences, which are characterized in numerous instances by an increase in the amount of astringent matters, tannin, gallic acid, and the like, collected in the neighboring cells. In fact, as everyone knows, the amount of such astringent matter in the galls on a species of Oak is so great that they become a matter of commercial importance. The symmetrical outgrowths on the stems of some Willows are doubtless familiar to all.

For an interesting account of the relations which exist between certain insects and enlarged organs of some species of tropical plants, the reader is referred to the work mentioned in the foot-note.* From Mr. Belt's statements it appears that some of the Acacias of Nicaragua have enlarged appendages (stipules) at the bases of their leaves, which secrete large amounts of saccharine matter for the nourishment of ants. The insects are completely satisfied with this store of food which is provided by the plant, and they do not attack the leaves. These ants serve as a well-fed garrison to defend the plant from the attacks of leaf-cutting ants. Other cases quite as remarkable as this have been noted in the tropics. In all of them some organ is excited to the exercise of a function not commonly associated with it. But such cases are to be regarded as modifications which have probably arisen by slow adaptations through a series of generations, and hence are not to be properly regarded as disturbances of function.

Certain fungi, notably the so-called rusts, smuts and mildews, are exceedingly destructive to the cells and contents of cells of many plants. Besides being destructive to the contents of cells, certain fungi may give rise to extraordinary distortions of form of the host-plant. Among such may be mentioned the familiar cases of that which causes the outgrowths on our common Cedar, and that which produces the diseased state of the grain of Rye (known as "ergot"). But with these invasions of fungi we are now to deal only in the most general manner.

For the purpose of our present examination, these fungi of all grades may be regarded as parasitic, subsisting on living tissues and their living contents. Many of them act also on the same matters in dead plants, and some act only on non-living matter, but the latter may now be left out of account. A parasitic fungus is unable to utilize inorganic matter. It must have organic matter in some form, and this it obtains from the contents of the living cells of its victim. Throughout the organism the threads of the fungus make their way, frequently sending out invading filaments which grow but a short

distance from the path of the main threads. All of these are engaged in consuming and appropriating the organic matters accumulated by the host-plant. In some cases, the blight sweeps through a plant with great rapidity, while in others the invasion is insidious, and the progress through the attacked plant is, on the whole, rather gradual. In some manner, either by separated cells formed after the manner of buds, or by what are known as spores of sexual origin, these invading plants are disseminated in some instances with frightful rapidity. These spores are frequently very much more resistant to destructive agents than are the invading threads, and hence the problem of destroying the fungus, as one might say, of an herb, "root, and stem, and leaf, and seed," is very difficult and disheartening. But the arduous labors of the cryptogamic botanists have suggested some efficient remedies for a very few cases, and others will doubtless follow. To see what remedies against fungi can be expected to accomplish, a few words must be devoted to the conditions requisite to the growth of some of these fungi. They require precisely the conditions necessary to the rapid growth of vegetable cells in general, namely, moisture, food, plenty of oxygen, and a certain temperature.

When a fungus has fairly invaded the tissues of a plant, there is very little hope of resisting its further advance. In a few instances, experiments have shown that much may be done towards warding off invasion and preventing the fungus from getting a foot-hold. Thus, the fungus which is known as the "Downy Mildew" of the grape-vine, has been successfully combated in certain localities by the use of solutions of salts of copper sprinkled at intervals on the leaves. But it should be acknowledged that in some other instances the solutions have failed. In a few cases, also, the same remedies have been more or less efficacious when applied to the forming fruit of the Grape threatened by the fungus which produces the so-called "black rot." But it has been well said that the results in these instances are conflicting, and cannot be regarded as conclusive.†

In experiments in France, the solutions known as *Bordeaux mixture* (consisting of six kilograms of sulphate of copper in 100 litres of water and eight kilograms of lime in thirty litres of water) and *Eau celeste* (consisting of one kilogram of sulphate of copper and two litres of ammonia in 200 litres of water) have given excellent results in diminishing the ravages of mildew.

In some cases, such as that of the fungus causing the so-called "black-knot" of Plums, the only treatment suggested with confidence is the complete destruction of affected trees, thus lessening the spread of the malady.

Certain fungi are very destructive when they attack non-living wood, causing rapid decay. These invasions are frequent in the case of some of our cultivated trees, and forest trees which have their wood exposed by injury. In not a few cases the resinous matters which impregnate the wood or which are poured out after a mechanical injury, exert a true antiseptic and preservative power. As a general thing, Nature heals all wounds where this is possible by the formation of the tissue known as cork. Even when the leaves fall in autumn, it can be seen that by an anticipatory development of cork at the twig, the wound which would otherwise be an open one is already, at the fall of the leaf, a healed scar.

George Lincoln Goodale.

Periodical Literature.

Mr. Frederick Boyle is an English author and amateur cultivator of Orchids, whose enthusiasm for the latter branch of his activity expressed itself last winter in two charming articles in *Longman's Magazine*, which were duly noted in these pages. Now he writes again on the same subject in the March number of the same periodical, the title of his chapter being "Cool Orchids." Nothing could be more desultory than his treatment, or more lively than his style. He passes at a bound from Orchids in their suburban glass-frames to Orchids in their native habitats, and lays a tribute of glowing words now on the far-off tomb of some fever-stricken collector and now on the head of some favorite *Odontoglossum* or *Cypripedium*. But all his paragraphs are entertaining, and some of them are instructive. His main object is to impress upon the impecunious amateur that Orchids of many sorts are easily within his reach. "I should like," he says, "to publish it in capitals—that nine in ten of those suburban householders who read this paper may grow the loveliest of Orchids if they can find courage to try;" and then he explains how little courage is really needed. "The plain truth is that no class of plants can be cultivated so easily, as none is so

* Belt's Naturalist in Nicaragua.

† Professor F. L. Scribner's Communication in Bulletin of the Commissioner of Agriculture, 1888.

certain to repay the trouble, as the Cool Orchids. . . . We have at least a hundred genera which will flourish anywhere, if the frost be excluded; and as for species, a list of two thousand would not exhaust them, probably. . . . But a reasonable man may content himself with the great classes of *Odontoglossum*, *Oncidium*, *Cypripedium* and *Lycaste*; among the varieties of these, which no one has ventured to calculate, perhaps, he may spend a happy existence." *Odontoglossum* stand first, Mr. Boyle declares, having the great merit of bursting into flower at any season as they may chance to ripen. "It is their instinct to flower in spring, but they are not pedantic about it in the least. Some tiny detail overlooked here and there, absolutely unimportant to health, will retard inflorescence. It might very well happen that the owner of a dozen pots had one blooming every month successively. And that would mean two spikes open, for, with care, most *Odontoglossum*s last above four weeks." *Lycaste* is likewise strongly recommended. Mr. Boyle speaks of that genus as he protests "without prejudice," and, as we think, very sensibly, saying that the flower of the most common species, *L. Skinneri* "is stiff, heavy and poor in color. But there are tremendous exceptions. In the first place, *L. Skinneri alba*, the pure white variety, begs all description. Its great flower seems to be sculptured in the snowiest of transparent marble. That stolid pretentious air which offends one—offends me, at least—in the colored examples, becomes virginal dignity in this case." How vast is the difference in the estimation which collectors put upon varieties of this plant is shown by the fact that "plants of the same size range from three shillings and six pence to thirty-five guineas."

With regard to *Cypripedium*s Mr. Boyle states a fact that will probably be new to American readers. *C. spectabile*, he says, grows "like any water-weed in the bogs of New Jersey where it is frozen hard, roots and all, for several months of the year." But transplanted to England, "very few survive the season . . . even if protected." The fine specimens seen at English flower shows in the spring "are imported in a dry state." It is the damp of the English winter that they cannot bear, and the same thing is true of Canadian and Siberian species. "I saw in Russia, and brought home a magnificent species, tall and stately, bearing a great golden flower which is not known in 'the trade'; but they all rotted gradually. Therefore I do not recommend these temperate varieties which the inexperienced are apt to think so easy. At the same cost others may be brought which, coming from the highlands of hot countries, are used to a moderate damp in winter." At the end of his article Mr. Boyle sums up the requisites for the cultivation of good Cool Orchids: "These plants ask nothing in return for the measureless enjoyment they give but light, shade from the summer sun, protection from the winter frost, moisture—and brains."

Turning now to those parts of his article which speak of the difficulties attendant upon the importation of South American Orchids, we find them bristling with striking anecdotes, familiar doubtless to the practiced amateur, but causing the novice to wonder, with Mr. Boyle himself, how Orchids can possibly be as cheap as they are. Accounts of the difficult and dangerous journeys of the collectors who are sent out by the great English Orchid firms read like paragraphs from Jules Verne's novels rather than sober statements of enterprises undertaken for commercial reasons; and the list of the men who have perished by accident or disease is long and pitiful reading. Even after the Orchids have been found, secured and brought down to the coast they must be transported by water to a port where a European steamer can be had, and the attendant dangers are then as great to the plants as to their guardian. And when the port is finally reached it may very well be that the collector "has to wait days in that sweltering atmosphere for the Royal Mail steamer; and when it comes in his troubles do not cease, for the stowage of the precious cargo is vastly important. On deck it will almost certainly be injured by salt water. In the hold it will ferment. Amidships it is apt to be baked by the engine-fire. Whilst writing I learn that Mr. Sander has lost 267 cases by this latter mishap, as is supposed. So utterly hopeless is their condition that he will not go to the expense of overhauling them." And in this case the charge for freight alone from South America had been £750. Mr. Roetzl, a famous and experienced collector, we are also told, once took special pains with a "unique shipment" of *Masdevallia Schlimii*. "It contained 27,000 plants of this species, representing at that time a fortune. Among the 27,000 two little bits survived when the cases were opened." As for the difficulties attendant upon actual collecting Mr. Boyle says that the Roraima Mountain is getting to be regarded as "quite easy travel for the Orchid-hunter nowadays. If I mention that

the canoe-work on this route demands thirty-two portages, thirty-two loadings and unloadings of the cargo, the reader can judge what a 'difficult' road must be." And to secure *Odontoglossum Hallii* alone the "ardent explorer must march in the bed of a torrent and on the face of a precipice alternately for an uncertain period of time, with a river to cross about every day; and he has to bring back his loaded mules or Indians over the same pathless waste."

Correspondence.

How a City Gained a Park.

To the Editor of GARDEN AND FOREST:

Sir.—The city of Bridgeport is spreading rapidly into the country, and fortunately the suburbs are in many cases provided with shaded streets and open gardens. But the distinctive name of "The Park City" has been given to it, not for its rural surroundings, but on account of the two parks of strikingly different characters which it now possesses.

The one, Seaside Park, secured by the wisdom and generosity of various citizens, lying along the Sound shore, where it curves with a particularly beautiful line, has long been enjoyed as a fashionable resort by the rich, and as a blessed breathing place by the poor; and it has before it a future hardly realized by those who do not know that it is but the starting-point of a system of seaside boulevards which will extend uninterruptedly from Bridgeport to South Norwalk, if the present design is carried out.

The other, Beardsley Park, lying several miles distant on the east side of the town, is the gift of one public-spirited man on the condition that the city improve it for the people, making yearly appropriations to that end.

The appropriations are comparatively small, and progress, therefore, necessarily slow, but already about fifty acres are improved to a degree that invites the attention of the public to this new possession. The gift comprises many acres more of charmingly undulating land, and as the work continues all these will be included.

There is a pretty story about the inspiration of this gift, which should be more widely known. It seems that the good man who gave this park to Bridgeport had been for some time impressed by the need of such a health-giving resort in that portion of the town, and for that class of people who could not drive to the delightful but remote "Seaside."

He had been vaguely intending to give such a park to the city as a sort of monument or memorial—at all events, to give it. But one hot summer day, a holiday, going into town from his farm, he saw a poor woman and some little children enter a field and establish themselves under a tree, apparently for a picnic. Knowing the owner of the field, and seeing him at that moment approach, the good man determined to remain and see the result of the owner's visit. As he anticipated, the little picnic party was ejected, though doing no harm at the time, and as they went sadly away the vaguely benevolent intentions of the spectator were instantly crystalized into a purpose which was acted upon at once. The result of that day's disappointment to the mother and her children was that the beautiful Beardsley Park is open freely and perpetually to them, and to all who, like them, long for the peace and pastoral beauty which "restore the soul" and give to the poor as well as to the rich the sense of sharing in the general beneficence of the bountiful seasons as they pass. All that can be done to make Beardsley Park comfortable and delightful for just this class is being done slowly and well, while here, also, the fine, solid roads will for ages invite those who ride or drive to enjoy this exquisite rural park which so happily places a wide barrier just here between the onward march of the city and one of the loveliest of inland views.

Elizabeth Bullard.

Bridgeport, Conn.

To the Editor of GARDEN AND FOREST:

Sir.—In Vol. I., page 107, of GARDEN AND FOREST, I gave the dates of the first appearance of *Hepatica triloba* in the same locality in the woods of Newton, Massachusetts, during the last twenty-six years; the first blossoms being, as it would seem, a fair criterion of the atmospheric conditions attending the early months of these different years. This year the first flowers were picked, on the same spot, on the 17th of March, and were fairly in blossom and were not forced into bloom by removal to a warm room. I again transcribe from my memorandum the dates for the last ten years:

March	2d,	1880.	April	15th,	1885.
April	3d,	1881.	March	18th,	1886.
March	5th,	1882.	March	21st,	1887.
April	1st,	1883.	March	23d,	1888.
April	13th,	1884.	March	17th,	1889.

The spring of 1880 was the earliest and warmest for the twenty-seven years.
Chestnut Hill, Mass.

D. D. Slade.

An Orchid Nursery.

To the EDITOR OF GARDEN AND FOREST:

Sir.—A few weeks ago your London correspondent wrote that the position held by the Orchid family would be the most remarkable feature in the history of English horticulture in the nineteenth century. It cannot be said that in this country "the cultivation of Orchids has developed into almost a passion," or that millions of pounds are invested in them here. It is true, however, that there are a few collections in the United States which take rank among the foremost in the world for size and completeness, and several more which, although not so large, would be noteworthy in any country for careful selection and skillful cultivation. That there is a growing interest in these plants is proved by the fact that the number of buyers has doubled in the past three years. This does not mean that the sales have been doubled in amount, for the new purchasers take plants in moderate quantities. But, after all, it means that more new collections are started every year, and there is good reason to believe that the demand for these plants is steadily increasing.

That this is the faith of enterprising dealers is proved by the fact that F. Sander & Co., whose great nurseries at St. Albans, England, are devoted to Orchids alone, have established a branch nursery at Summit, New Jersey, to meet the present and prospective requirements of their business in this country. Agents of this firm have been sent here for several years in the season of auction sales, and three years ago Mr. I. Forstermann came here as a resident representative of the house, and it is under his direction that the branch nurseries are now being built. These nurseries, as I learned on a visit to Summit last week, are finely located, and are planned to consist ultimately of eight growing-houses, each 150 feet long by twenty-one wide, with lean-tos attached, and all connected with a central show-house. One of these houses is already built in the most substantial manner, with heavy concrete walls and the best selected yellow pine throughout. The house stands on sloping ground, and the earth has been excavated from the alleys only and left three feet deep under the side and central stages. This earth under the staging is covered with forest-leaves, and it is expected that the evaporation of moisture from the damp earth and leaves will furnish an atmosphere which will approach in quality the air in the natural habitat of the plants. The water-pipes, are not placed below the staging, but under the walks which are made of yellow pine strips. One small pipe runs along the back of each side-table and above it, and behind this is a line of ventilators set so closely as to be almost continuous for the purpose of cooling the house in summer. There are many features in the construction and arrangement of this house which I have not observed before, and which seem to add much to its beauty, convenience and practical effectiveness, but the space you grant will not admit of further detail in this matter.

The principal purpose of this establishment will be to furnish a place for the reception of plants as they are imported, where they may be grown on until they become established and in flowering condition. When a buyer has a skillful gardener he will not hesitate to take Orchids from the case and to care for them from the time of their arrival. But a long sea-voyage is a strain upon the vitality of the plants, and some species always suffer seriously. Comparatively few gardeners in the United States have sufficient experience to warrant success in taking charge of Orchids when in an enfeebled condition; and when plants are lost dissatisfaction must follow. If, however, the plants are taken directly from the ship and placed under the expert treatment which they will receive at these nurseries, a large proportion of them can be safely carried over this period of danger, while under less favorable conditions they might perish. Beginners should never attempt to grow freshly-imported Orchids, and it will be found in every way more satisfactory for them to see the plants they buy in flower, or at least giving promise of flower. Another purpose of these nurseries will be to furnish something like a training-school where young men who wish to learn the niceties of Orchid culture can receive practical instruction, and the young gardeners who come here to assist will be prepared to supply the skilled labor which is now difficult to obtain in this country. Of course rare plants will be propagated here, and in time efforts will be made to produce new varieties by hybridizing.

Nearly all the Orchids in the nurseries at present are recent

importations, and are just as they came from the woods. There are a few specimen plants, however, that would be notable in any collection. One of these is a *Cattleya Skinneri* four feet across, with enormous bulbs and the promise of 500 flowers. Near it is one of the largest plants of *Saccolabium guttatum*, filling a basket three feet square, and a specimen of the white *Lalia anceps* nearly as large. Passing by a remarkable specimen of *Cypripedium grande atratum* and a good *Cattleya citrina*, one of the most interesting plants is a large *Calogyne Forstermanni*, which was discovered in Borneo by Mr. Forstermann. In its home, as many as thirty flowers are sometimes borne on a single erect spike, after the style of *Odontoglossum crispum*. They are of purest white, with a yellow throat. The plant, however, has never yet bloomed in cultivation. It does not bear transportation well, and no specimen has yet been brought up to a strength sufficient for the production of flowers, although the plant here shows promise of bloom.

Inasmuch as Messrs. Sander & Co. have as many as twenty collectors in the East Indies, in Africa, in South America and Mexico the nurseries can be filled with plants as quickly as they are built, and there is little doubt that the market will take them all. There is an erroneous notion that all Orchids are expensive, for many of the very best of them, when estimated for their beauty and ease of culture, are really cheap. Flowering plants of such admirable species as *Cattleya Trianae*, *C. Mossia*, *Dendrobium Wardianum*, *D. nobile*, *Cypripedium insigne*, *Oncidium varicosum*, and many more can be had for a dollar or two each, while there are varieties of the same species which would cost hundreds of dollars. This does not imply that the expensive ones are necessarily the most beautiful, but it illustrates the fact that there are two classes of Orchid-growers. The one class cultivates them for their beauty only, and such a taste can be gratified without any extravagant expenditure. But when one collects Orchids with a similar purpose to that which controls a collector of coins, or of rare books or prints, the diversion becomes a most expensive one. No one will find fault with a collector of the second class who has the means to indulge his fancy in this direction. But I wish there were more of the first class, who grow Orchids as they grow other plants, simply for their beauty and fragrance, and who do not find their highest value in the fact that no one else is able to get plants like them.

Summit, N. J.

S.

Recent Plant Portraits.

Botanical Magazine:

LILIU NEPALENSE, *t.* 7043; a well-marked species, discovered more than fifty years ago in the high mountains of Nepaul, but only very recently introduced into cultivation. The flowers, which appear either singly or in corymbs of three to five, are "four or five inches long, greenish-yellow outside, yellow within, flushed, except in the upper third, with purplish-black."

SARCOCHILUS LUNIFERUS, *t.* 7044.

STUARTIA PSEUDO-CAMELLIA, *t.* 7045; a handsome-flowered, hardy shrub, the Japanese representative of a genus quite widely distributed in our south Atlantic States, where ten species occur. The Japanese plant was introduced into the United States many years ago by Mr. Thomas Hogg, and is now not infrequently seen in American gardens.

OPUNTIA POLYCANTHA, *t.* 7046; this, it seems, is Haworth's (Suppl. Pl. Succulent, p. 82) earlier name for *O. Missouriensis*, the dwarf and horribly armed species familiar to all travelers over the northern plains towards the upper Missouri and the Saskatchewan.

CHIRONIA PEDUNCULARIS, *t.* 7047.

EREMOSTACHYS LACINIATA, *t.* 7048; a noble perennial Labiate from the Levant and the Caucasus, long known in gardens, having been introduced into England by Philip Miller as early as 1731.

DELPHINIUM ZALIL, *t.* 7049; a plant of economic value. This is one of the most interesting discoveries of the Afghan Delimitation Commission. The botanist of the Commission, Dr. Archibison, thus refers to it: "This plant forms a great portion of the herbage of the rolling downs of the Badghis; in the vicinity of Gubron it was in great abundance, and when in blossom gave a wondrous golden hue to the pastures. The flowers are collected largely for exportation, chiefly to Persia, for dyeing silk; they are also exported from Herat, through Afghanistan to northern India, to be employed as a dye as well as to be used in medicine." It is a showy plant when its bright yellow flowers, borne in spikes ten inches long, are expanded.

IRIS BARNUMI, *t.* 7050; a handsome, purple-flowered species, introduced into cultivation by Professor Foster, who

received it from Mrs. Barnum, of the American Mission at Kharput, in Armenia.

CALLANDRA OPPOSITIFOLIA, *f.* 7051; a native of the mountains of Oregon and northern California—a neat but not very showy-flowered species.

Notes.

The annual congress of the German Pomological Society will be held this year at Stuttgart, between the 22d and the 30th of September.

A horticultural and a botanical congress will both be held in Paris during the month of August, this year, in connection with the International Exhibition. An agricultural congress will be held during the month of July.

After the meeting of the Pennsylvania State Forestry Association, at Westchester, on the 26th of April, a Chester County Forestry Association was organized, with the Honorable Washington Townsend as President, and Professor J. P. Welsh as Secretary.

A new edition of Mr. Robinson's popular "English Flower Garden" has just been issued by Murray, of London. It contains more than 1,400 pictures, illustrating many beautiful English gardens, as well as nearly all the plants that are hardy in the kingdom.

The parasitic insects which have been imported from Australia to prey upon the cottony cushion-scale, the most serious enemy of the Orange in California, are already multiplying rapidly in Los Angeles, and sweep the scale before them, as has been the experience in Australia. Mr. Koebele, the agent of the government, has brought to California a large supply of these predaceous beetles, and will distribute them wherever the scale is troublesome.

The legend of St. Patrick and his expulsion of all vermin from the Emerald Isle probably gave rise to the ancient belief that Irish oak-wood was superior to all other kinds, having a sort of sacred character and being proof against the ravages of insects. The venerable Bede declared that this wood "hath a virtue against poison," and so great was its renown that even at the end of the last century it was imported by the King of Portugal after the great earthquake at Lisbon to share in the construction of his new church. The original rafters of Westminster Hall were of Irish oak.

An English horticultural journal states that a small box of Lilies-of-the-Valley was recently sent from England to Pietermaritzburg, in South Africa, the plants being packed in a tin box, and each root enveloped first in damp moss and then in tin-foil. "The roots were all tightly packed at one end of the box, the other end being left vacant to admit of growth being made. The crowns were just bursting their first foliar envelope, and by the time the parcel reached its destination—a journey of twenty-four days—the buds were just breaking into bloom, and the plants were in a perfectly healthy condition."

In 1887 a spot disease was observed on Cucumbers near Geneva, New York, which almost ruined the crop. Professor Arthur pronounces it a parasitic fungus similar to one which has been disfiguring Peaches in Indiana, detracting from their beauty and hindering their growth. The Cucumber spot did not appear at Geneva in 1888, although it seems an aggressive fungus. It has been named *Cladosporium cucumerium*. The fungus on Peaches has only been recorded before as occurring in southern Austria, where it was named *C. carpophilum*. No remedies for either disease have yet been tried so far as known, but both of them threaten to become dangerous pests.

The pea-weevil (*Bruchus pisi*) and the bean-weevil (*Bruchus fabæ*) can be destroyed by putting the Peas or Beans into a pail and covering them with water; if the water is warmed to about blood-heat all the better, but this is not necessary as cold water will answer. If the seed remain in the water from eight to twelve hours every weevil will be destroyed, as the cavity containing the insect is soon filled by the water absorbed by the seed and the weevil is drowned. This simple remedy, which is recommended by Professor J. W. Clark, of the Agricultural College of Missouri, is not only effective, but does no injury to the seed, and if the seed is not soaked until the day before planting it will germinate more readily than before.

Speaking of the great popularity of *Cobæa scandens*, the *Revue Horticole* says that it seems somewhat strange that until recently no variety of it had been raised. A novelty is, however, now offered in the shape of a white-flowered variety, which differs from the type not only in the color of the blossoms

but in the paler green of the leaves and the purplish hue of the stems, which passes into whitish in the young shoots. "Although these differences may not be considered very important, they are sufficiently so to be appreciated when the two forms are growing close together, as we recently saw them at Paris, planted alternately and entirely covering a wall with their abundant foliage, prettily relieved by the white and violet-colored flowers. The white-flowered *Cobæa* being as vigorous and hardy as the type, the same details of culture are applicable to both forms."

Few persons imagine how many different substances have been used of late years in the making of paper. Rags, of course, still furnish the bulk of our paper, but large quantities are also made of wood, straw and Esparto-grass (*Stipa tenacissima*); and in various parts of the world successful experiments have been made with a multitude of materials that have not yet been brought into general use. In France paper has been manufactured out of leaves which are cut, pressed into blocks, and then steeped in lime-water to reduce them to pulp. In Ireland the Mallow, the Hop-vine, the Yellow Iris, and even the Red Clover have furnished paper pulp, and in Scotland the stems of the Hollyhock, peat, bracken, flags and rushes of several kinds. Sea-weed and tan have also been used in Europe, and in the East, Ramie Pine-apple fibre, Bamboo stalks and the refuse of Sugar-cane.

Professor W. A. Henry, writing in *Agricultural Science* of some weeds that are becoming troublesome in Wisconsin, says: "On the great plateau along the eastern flank of the Rocky Mountains grows *Solanum rostratum*, a homely, harmless sort of plant. The naturalist knows it to be the original food-plant of the Colorado potato-beetle (*Doryphora lineata*). In the year 1872 or thereabouts the beetle, coming across the uncultivated strip of eastern Colorado and western Kansas, found a new food-plant in the common cultivated potato, and spread with marvelous rapidity over the country. *Solanum rostratum* also comes into the fields to conquer, and has spread on cultivated lands in Texas and Missouri, where, with greatly increased size, it proves a troublesome weed. Last summer Mr. L. H. Pammel, one of our agricultural graduates, now professor of botany in Iowa Agricultural College, found this plant growing at Watertown, in this State. It is following up the potato-beetle. Will it spread over as large an area as its old acquaintance?"

Nothing could have been more effective or in better taste than the floral decorations of the Metropolitan Opera House as arranged for the great Centennial ball and banquet last week. The walls of the lobbies and lower staircases were entirely concealed by plants so that they presented the aspect of verdant bowers, yet a certain architectural dignity was preserved by the systematic employment of tall, upright Junipers intermixed with the lower plants. On the face of the arch leading from the main lobby into the house the dates 1789-1889 were emblazoned in red upon a quiet green ground, but, with this exception, scarcely any cut flowers were used; and the growing ones were beautifully massed in contrasting groups. The corners were filled with pyramidal banks of pink Hydrangeas, and against the piers stood enormous tall clumps of white Lilies with masses of red Geraniums or Azaleas around their base. In other spots great Azalea bushes rose from a foundation of white Spiræas, or yellow Cytisus from banks of yellow-centred bush Daisies; and the beauty of the individual plants was as conspicuous as the tasteful richness of the general effect. In the supper room again there were no set pieces, but Azaleas, Spiræas, and other growing plants adorned the tables at intervals. The arrangement of the chandeliers in this temporary structure was especially pretty. They were formed as round baskets filled with Palms and Pine branches, apparently growing, and with streamers of Ivy, amid which rose gracefully curving stem-like supports bearing the electric lights. Few plants were used in the ball-room as space was precious, but the corners of the stage opposite the Presidential boxes were banked with pink Hydrangeas and other plants of an harmonious character, while long festoons of green hung from the proscenium arch. Of course, the finest display was when the house was arranged for the dinner on Tuesday; then the vast room was encircled with tall, green plants, and the tables were profusely yet most tastefully adorned, flowers of a single hue, or at most of two contrasting hues, being exclusively used on each of the different tables. Mr. Klunder has long been famous for his skill in floral decoration, but his success in this instance will add a conspicuous new leaf to his laurels.

MR. JOHN D. LYMAN, a popular writer about forestry in the press of northern New England, argues in a recent article published in the *Mirror*, of Manchester, New Hampshire, in favor of thinning the young Pine forests of that state. Mr. Lyman's arguments, like those of many other American writers upon forestry, are not based upon experiment; and in this particular case he falls back, in order to enforce his views, upon the statements of various local authorities and a number of English writers upon agriculture. Thinning a young Pine forest may or may not be a good thing to do, from a commercial point of view. There is no doubt that the trees will grow much more rapidly if they are judiciously thinned than if they are left to fight among themselves for light and nourishment. But who knows what the ratio of income will be under the two systems, or whether there is any money in helping Nature in the case of a forest of White Pines. The finest Pines which ever tossed their tops to the wind grew without any assistance from man; and man has yet to show that he can improve upon such trees. Perhaps he can, if money is not an object; but it is a serious object in the case of a crop which requires a century in which to reach maturity and which has such a low money value in comparison with the time required for its production. A rule of modern forestry, now almost universally adopted, is not to spend money on a crop for the mere purpose of hastening its maturity. Time is less important than money when the interest account is carried through so many years. Forests in Europe are rarely thinned, therefore, until the thinnings are of sufficient value to pay all the cost of the operation. Young White Pines have no value, unfortunately, until they are from twenty-five to thirty years old, and cannot be disposed of. This will be found the one disadvantage in this tree, in other respects one of the most valuable of all trees for general forest-planting.

But let us see where Mr. Lyman's thinning of the New Hampshire Pine forests, if it is carried out on any large scale, is going to lead to. It is not probable that a forest of young, self-sown Pines, which generally stand very close together, could be properly thinned for less than five dollars an acre. Compound interest at four per cent, will double this five dollars in a little less than eighteen years. In something under 150 years, when the Pine forest should have attained its maximum value, the five dollars will be \$144. If the thinning is applied to a hundred thousand acres, as it might well be in New Hampshire, this operation would mean an expenditure upon the crop at the time of maturity of more than fourteen million dollars.

But who knows whether this expenditure will be justified by larger returns from the soil, or how can Mr. Lyman verify the statement he will probably make in reply to this criticism that if the young forest is properly thinned it will reach maturity in half the time that the trees, unassisted by man, would have grown to the same size. Granting that the trees of the thinned forest will be ready for the axe in seventy-five years, there will still be an interest account against them of more than forty dollars an acre, and forty dollars an acre for pine-stumpage is a very large price—larger than any one seriously believes that it will be at any time during the next seventy-five years. The danger, too, of fire and of other accidents is not diminished by thinning.

Now, we neither acknowledge nor deny the value of thinning. It may be a good thing, and it may be a very foolish one from the point of view of economy; and forestry means the economical management of forests. What is needed now in this country are facts upon which to base systems; and facts of this sort can only be reached by long years of experiments, which only governments or corporate bodies like universities can inaugurate with any hope of that they will be persisted in till sound conclusions are reached. We have had enough of the vague statements, based upon personal opinion or the results of European experiments, which pass muster in this country as profound knowledge of forestry, and the sooner we get down to practical work the better it will be for us. It requires the term spanned by the lives of several generations of men to find out anything really reliable about a tree or about a forest, and, from present appearances, ours will pretty much all have disappeared before we get ready to set about learning what is the best way to take care of them.

Great interest is felt in Minneapolis in the new park schemes for the improvement of that city; and the advocates of the plans proposed by Mr. Cleveland have succeeded in arousing so much enthusiasm about them that these plans, with some unimportant modifications, are to be realized. Mr. Cleveland, in an address presented to the members of the Board of Trade, cited the benefit derived by the people of this city from the establishment of Central Park as an argument for city parks—an argument so convincing that we reproduce it for the benefit of those persons in other cities who are trying to impress upon their fellow-citizens the necessity of securing public parks in the midst of all urban populations before the increase in the value of city land makes it impossible to do so:

"The whole expenditure," he said, "for the purchase of land, construction of park, interest on bonds and maintenance for twenty-five years was \$44,000,000. The amount levied in taxes during the same period was \$110,000,000 so far in excess of the average value of city property, that after deducting from it the whole cost of the park, together with all the revenue that could have accrued from taxes at the ordinary rates, there remained the sum of \$17,000,000 to be credited to the park as clear profit. I wish to emphasize this statement, and have it clearly understood, for it is a matter of dollars and cents which cannot be gainsaid or evaded by those who raise the cry that we cannot afford to be sentimental. In the language of the gentleman from whose report I gather these figures, 'the most convincing arguments that can be deduced from theories are weak and impotent compared with the invaluable logic of these figures. They prove beyond the possibility of cavil the

necessity of securing at once all the park lands we may ever want.'

"I tremble," continued Mr. Cleveland, "when I think that this great gift, which is put right down before us, may be lost. In the possession of this area no other city could compete with us. In Chicago they would give millions of dollars to get it, and they are now constructing a forty-mile drive at great expense, which will give them access to an area something like it."

Recent Botanical Discoveries in China.—II.

Rhododendron.—Upwards of sixty species of this genus are enumerated in the seventh part of the "Index," which is just passing through the press, and fifty of them are comparatively recent discoveries. This number is considerably in excess of the total number described in Hooker's "Flora of British India," but it may suffer some reduction when the different forms are better known; and it includes the section *Azalea*, which finds its maximum development in eastern Asia. A very large proportion of the true *Rhododendrons* were discovered by the Abbé Delavay in the mountains of Yun-Nan, but all the mountainous regions of China yet explored have yielded their peculiar species. Taken as a whole, the new Chinese species are by no means so gorgeously beautiful as the Himalayan, though many of them are highly ornamental. *R. aucubafolium* has long, smooth, dark-green leaves and small, snow-white flowers, with very long, exserted stamens. It also resembles the common *Aucula* in having thick, straight, smooth branches. *R. Augustinii* is a densely-branched shrub, with crooked branches, coriaceous leaves, two to three inches long, lepidote beneath, and white or purple flowers, about the size of those of *R. Indicum*. *R. auriculatum* is a robust, large-flowered species, having large leaves, rusty-hairy beneath and slightly auricled at the base. *R. Bureaui* is another very robust species, the thick branches of which, as well as the stout petioles, under surface of the leaves and bracts, are clothed with a dense, rusty, felt-like tomentum, and the rosy or purple spotted flowers, of medium size, are borne in very crowded clusters. *R. decorum* has deflexed leaves, and is altogether so like the American *R. Catawbiense* that if it had been found in America instead of on the mountains of Yun-Nan it would probably have been referred without hesitation to that species. *R. Delavayi* is one of the showiest of the Yun-Nan species, strongly resembling the Indian *R. Campbellii*. *R. lacteum*, a very large-leaved species, has loosely corymbose, milk-white flowers of medium size, and the leaves are glossy above, and very thickly covered with rusty scales beneath. *R. Faberi* is one of the very few Chinese species having a large foliaceous calyx, and *R. bullatum* belongs to the same group. The former has flat coriaceous leaves, smooth above, and densely rusty-tomentose beneath. *R. stamineum* and *R. pitiosporæfolium* are closely allied species or varieties of one species, characterized by smooth, deflected leaves and small, narrow-lobed white or pink flowers on long, slender pedicels, and very long exserted stamens and style.

Baumontia breviflora.—A handsome species of the small, showy genus *Baumontia*, from the island of Hainan, differing from the other species in the manner indicated in the specific name. It is, of course, a warm-house plant. The Rev. B. C. Henry, of the American mission, discovered it, and he describes it as a magnificent vine, climbing over rocks and trees; flowers white and fragrant. Hooker's *Icones Plantarum*, t. 1582.

Rehmannia glutinosa, syn. *R. Chinensis*.—A very handsome plant, is figured as variety *Angulata* of this species in Hooker's *Icones Plantarum*, t. 1589. It differs so materially from the plant figured in the *Botanical Register*, t. 1960, and in the *Botanical Magazine*, t. 3653, that without connecting links one would regard it as a different species. Dr. Henry collected it at Ichang, and describes the flowers as red, with orange and scarlet markings. Commonly cultivated in China, where there are many varieties, recalling in their coloring the American genus *Salpiglossis*.

Trapella Sinensis.—This is a highly curious floating aquatic plant, mentioned here on that account only. It is the type of a new genus of anomalous structure, referred to the *Pedaliaceæ*. In foliage it bears a strong likeness to *Trapa*, but there the resemblance ceases. The small flowers have a funnel-shaped corolla, and the narrow seed-vessels are furnished with usually three long, rigid, hooked appendages, something in the way, though very different from the appendages to the fruit of *Martynia*, and other members of the same order. It is figured in Hooker's *Icones Plantarum*, t. 1595, and in the *Annals of Botany*, ii., t. 5 to 8. A native of Ichang and other parts of China and Japan.

Rubus Henryi.—The genus *Rubus* is represented in China by at least fifty well-marked species, the majority belonging to the simple-leaved section, to which the present species belongs. A tall, climbing shrub, with deeply three-lobed thick leaves, glabrous above, and clothed with a white tomentum below; flowers small, red, in terminal racemes. Received from Dr. Henry, Ichang, and figured in Hooker's *Icones Plantarum*, t. 1705. Certainly one of the most distinct of the genus.

Petrocosmea Sinensis.—A new genus of the *Cyrtandrea*, limited, so far as we know at present, to this species. An elegant little plant, in habit resembling a Violet. Dr. Henry found it growing on the surface of the rock in the bottom of a small cave near Ichang, with the leaves closely pressed against the rock. It has violet or blue flowers, and is figured in Hooker's *Icones Plantarum*, t. 1716. Several other members of the same natural order from China are figured in this work. Thus *Didissandra sesquifolia* (t. 1797), a remarkable species, from Mount Omei, Szechuen, with large flowers and very unequal leaves. *Hemibaea Henryi* (t. 1798), the type of a new genus, of which two other species are described. *Didymocarpus stenanthos* (t. 1799), a modest plant from Mount Omei. These plants are indeed all of them somewhat humble members of an order rich in showy plants.

Primula.—The mountains of Yun-Nan have yielded such a harvest of new species of this genus as nobody could have anticipated. It is not merely the number of new species, but the great diversity of types—among them two or three absolutely different from anything previously known. Altogether we have evidence of between forty and fifty species of *Primula* in China. Foremost among these novelties is *P. Delavayi*, the flowers of which are solitary on radical scapes, and appear before the long-stalked, cordate-rotundate leaves. Corolla deep purple, large, funnel-shaped, with fringed lobes. It differs from all other described species, too, in having large, flat seeds. Discovered in the mountains of Yun-Nan at an elevation of about 15,000 feet. *P. vinciflora* resembles *P. Elwesiana* from the Himalayan Mountains, and the large, solitary scapose flowers bear a striking likeness to those of a Vinca. *P. incisa*, a small-flowered, umbellate species, has small pinnate leaves on slender petioles very much like those of some of the small Potentillas. *P. nutans* has almost capitate flowers with the lilac-purple corollas directed downwards. *P. blattariformis* and *P. malvacea* are also very curious species; the former having racemes of flowers fifteen to eighteen inches long; the latter having whorled flowers with an usually large calyx. *P. bella* is a beautiful little plant, and the smallest from the Chinese region, but not so small as some of the miniature Himalayan species. Many of the others are equally as attractive as those named. Indeed, one might say that all of them are pretty.

Lindera fragrans.—An elegant shrubby Laurel from three to five feet high, with slender branches, narrow leaves and axillary clusters of small, fragrant flowers. From the neighborhood of Ishang, and figured in Hooker's *Icones Plantarum*, t. 1788.

Lonerila peperomiaefolia.—A pretty species, having fleshy, strongly-nerved, ovate, long-stalked leaves, a scapose inflorescence and loosely cymose flowers about an inch in diameter. A native of the province of Ishang figured in Hooker's *Icones Plantarum*, t. 1814.

Hemslaya Chinensis.—A new genus of *Cucurbitaceæ*, a very slender climber of elegant habit with pedately-divided leaves and dioecious flowers. The male flowers are very singularly formed, the almost free petals being recurved on the pedicel like an umbrella or parachute. The clavate seed-vessels are borne in clusters, and open at the top by means of a small lid, giving egress to the numerous winged seeds. A native of the provinces of Hupeh and Szechuen; figured in Hooker's *Icones Plantarum*, t. 1822.

Emmenopterys Henryi.—This is an ornamental tree, thirty to forty feet high, from the Patung district in the province of Hupeh, belonging to the tribe *Cinchoneæ* of the *Rubiaceæ*—a tribe that is almost wholly American. In this, as in *Mussaenda*, which belongs to a different tribe of the same natural order, the most conspicuous part of the inflorescence is the foliar development of one of the calyx-lobes of some of the outer flowers of the clusters, such as occurs in the South American genera, *Calycophyllum*, *Monadelphanthus* and others, and in the recently-discovered Malayan genus, *Craegbia*. A similar, though quite different ornamental appendage to the inflorescence, is found in the Indian genera, *Hymenopogon* and *Hymenodictyon*, belonging to the tribe *Cinchoneæ*. Here, instead of a foliar development of one of the calyx-lobes, some of the bracts of the inflorescence enlarge and color in a similar manner. The broadly funnel-shaped, al-

most campanulate flowers of *Emmenopterys* are yellow dotted and about an inch across, while the leafy expansions of the calyx are white, and persist until the fruit ripens and falls. Dr. Henry does not give particulars of the habitat of this tree, so that we are unable to judge its constitution; but in a general note relating to the plants from the Patung district, he states that most of them come from a range of mountains 6,000 to 7,000 feet above sea-level, along which virgin forest extends for many miles. *Emmenopterys* is figured in Hooker's *Icones Plantarum*, t. 1823.

Kew.

W. Botting Hemsley.

Horticulture in California.

THE gardens of this State are superb this year, as the winter was very mild, warm and moist, and the fifteen Rose-fairs soon to be held in different parts of the State will be unusually interesting. The orchards look well, and the fruit crop will be twenty per cent. greater than it was last year. Only the Apricots will show a shortage, owing to the heavy rains which fell when they were in blossom. The Apricot fails to fertilize well under such conditions.

I lately visited the "Northern Citrus Belt" of this State. It is, broadly speaking, the old gold-bearing belt of the Sierra foot-hills, in which nearly all of the famous old placer camps of 1849-53 were situated. In all this region Orange seedlings of great size and vigor are to be found, but commercial plantations have been established at only a few points. The most important of these is Oroville, on the Feather River, the county seat of Butte County, and sheltered on the north by a high plain, which rises to the great pine-clad volcanic wall of Table Mountain. There are several colonies here, and some two thousand acres of young Orange-trees are already planted. In the gardens of the beautiful little town are many trees of fifteen or twenty years of age, and the orange crop is already of considerable commercial value. The town holds an annual Citrus fair, late in December, in a large tent in the court-yard pitched over a number of well-grown Orange-trees in full bearing.

There is a manifest desire here to plant more native trees and shrubs. The beautiful *Romneya Coulteri*, so long a success abroad, has been, to some extent, re-discovered by Californians. It is now in great demand, but good plants cannot be obtained at the nurseries. A gentleman of Alameda lately sent a man to the mountains of San Diego County to dig up roots, and obtained in this way a good stock for his own garden.

In new fruits the Loquat (*Mespilus Japonica*) has become fairly naturalized. One farmer in Alameda County is able to sell \$100 worth of Loquats annually from two long rows planted originally for an avenue. The Loquat here presents several distinct types, one, apparently, the result of long selection, and well worth grafting. Many of the Loquats are not worth fruiting, but this better type has an undoubted future as a market fruit. The true Carob-tree is bearing here, in Alameda County. Unfortunately the trees were planted on low land, and grew too much to leaves, so that as yet the crop is but light. The Japanese Persimmons are slowly falling in public favor. For a few years producers made money shipping them, but now the large orchards planted ten years ago, when yearling trees cost a dollar apiece, are being cut down.

A curious source of revenue was brought to my notice the other day. Trees grow so fast in this climate, and there are so many old orchards, old gardens and old nurseries that good-sized trees of an immense variety of species are continually being cut down and carted to the wood-pile. A young man conceived the idea of buying up whatever woods appeared valuable and selling them to the carvers and turners in San Francisco. He knew nothing of botany, and the stuff was all sold in "mixed lots," but at high prices. In all he gathered up this winter from farms and gardens, within fifty miles of San Francisco, some seventy-five kinds of woods, none of them indigenous. One Osage Orange trunk was fourteen inches in diameter and eighteen feet long. The wood was a rich orange and brown, deepening to nearly black at the heart. A Pomegranate trunk was four inches through. An African Tamarisk, whose wood is very close-grained and creamy-white, was about the same size. A Japanese Persimmon was a foot through. The wood of this tree is light-colored, with curious black specks and stains, and works in the most charming manner. Among other woods gathered up were Ashes, Maples, *Retinosporas*, *Araucarias*, *Grevillias*, *Acacias*, *Paulownia*, *Cork Oak*, *Persian Walnut*, *Orange*, *Lemon*, *Large-flowered Magnolia* and *Olive*. I notice that the wood-turners call Osage

Orange, Pomegranate and Black Locust-wood all "acacia," that the oak-like woods are all "oak," and the yellow woods all "lemon."

The Japanese Quince fruits so freely here that alert house-keepers are making jelly out of it. The product is better than either apple or the common quince jellies, and would prove very marketable if it could be obtained in sufficient quantities. At present it is rare, and highly prized by the esoteric initiates.
