We are glad to be assured by Prof. Sampson, Astronomer Royal for Scotland, that the damage to instruments due to the explosion of a Suffragette bomb at the Royal Observatory, Edinburgh, on May 21, was happily insignificant. The bomb was placed on the floor below that of the west dome. The floor of the west dome is a heavy one, and thoroughly protected the 24-in. reflector and Cooke photovisual above it. The driving clock for these telescopes was near the bomb, but appears uninjured except in respect to its glass case. On the floor below falling plaster smashed the glass case of the Cooke drum chronograph, which is at present out of use. The disturbance was recorded by the Milne seismograph at 0h. 57·2m. as a small, sharp oscillation of approximately 0·1″ semi-amplitude.

Since 1908 the Somersetshire Archæological and Natural History Society has engaged in excavation work at Glastonbury Abbey, and year by year results of great historical and archæological importance have been secured. Last year, the society, at the request of the Abbey trustees, appointed a special committee to undertake the supervision of the future excavation work, and the researches will proceed systematically. An income of 250*l.* a year is needed to carry out the work efficiently, and the funds hitherto raised by subscriptions and donations are exhausted. The committee now makes a further appeal for money. Subscriptions or donations may be sent to the treasurer of the Glastonbury Abbey Excavation Fund, The Castle, Taunton, Somerset.

At the annual meeting of the Royal Geographical Society on Monday last, in addition to the presentations made to Lady Scott and Mrs. Wilson of the awards voted to their husbands, who died in the Antarctic, and that made to Lieut. Campbell, which are referred to elsewhere, the following awards were made:—The Victoria medal to Col. S. Burrard, Surveyor-General of India; the Murchison award to Major H. D. Pearson, for his work in the Sudan; the Gill memorial to Miss Lowthian Bell (Mesopotamia, &c.); the Cuthbert Peek grant to Dr. Felix Oswald (Armenia); and the Back bequest to Mr. W. S. Barclay (South America). In his anniversary address, Earl Curzon, as president, referred to the momentous events of the past year in polar exploration, and made the interesting announcement that the society expects presently to receive into its charge

Scott's diary and some of Dr. Wilson's beautiful water-colours. He mentioned the important work projected in the Arctic by Amundsen, Stefánsson, and Macmillan, and briefly reviewed geographical work elsewhere. He had naturally a good deal to say on the new establishment of the society at Kensington Gore, viewed with optimism the important bearing which the better conditions under which the society will now work should have on the progress of geographical study in this country, and discussed the new meeting-hall which he clearly expects to see built. At the annual banquet in the evening, Sir E. Grey and Lord Milner, among the speakers, both testified emphatically to the importance of geographical teaching and study, in relation to the maintenance of empire, on their now broadened basis of the bearing of physical conditions upon human activities.

The annual congress of the Royal Institute of Public Health was held in Paris, May 14–19, Prof. W. R. Smith, the principal of the institute, presiding. Important papers on tuberculosis were contributed by Prof. Delépine ("Milk-borne Tuberculosis") and Dr. Lister ("The Future of State Campaigns against Tuberculosis"), who considered that the future of campaigns against the disease was a matter more for the social reformer than for the public health officer. Mr. L. Gaster lectured on artificial illumination, making many useful suggestions on the nature of the illuminant to be employed and its methods of use. Dr. Bertillon arranged an exhibit showing the mortality in a number of trades and employments, contrasting those of Great Britain with those of France and one or two other countries. The members of the congress were most cordially received, and visits were arranged to all the important institutions, municipal and public, factories, and so on. The Harben gold medal of the institute for 1912 was presented to Dr. Roux, of the Pasteur Institute.

This year the Société Helvétique des Sciences Naturelles will hold its meeting at Frauenfeld on September 7–10. Among the lectures announced already the following may be mentioned:—Prof. Grubenmann, of Zurich, "Ueber die Entwicklung der neuern Gesteinslehre"; Prof. Fuhrmann, of Neuchâtel, "Voyage d'études scientifiques dans les Cordillères de Colombie"; Dr. de Quervain, of Zurich, "Die Durchquerung Grönlands durch die schweizerische Expedition und deren Ergebnisse"; Prof. Keller, of Zurich, "Die Tiergeographie des Kaukasus"; Prof. Maillefer, of Lausanne, "Les lois du géotropisme"; Prof. Rikli, of Zurich, "Pflanzengeographische Studien über die Kaukasusländer"; and Prof. Dutoit, of Lausanne, on a subject of physical chemistry. On September 9 the Swiss mathematical, physical, chemical, geological, botanical, and zoological societies will also hold their annual meetings at Frauenfeld. A number of attractive excursions have been arranged for visitors. Persons desiring to attend the meeting of the Swiss Association should communicate with M. A. Schmid, president of the committee, at Frauenfeld.

The Board of Agriculture and Fisheries has issued a circular intimating that numbers of salmon smolts and kelts have been "marked" in various rivers, by means of a wire, or a wire and label, attached to the dorsal fin. Rewards will be paid for the return of these marks, accompanied by the particulars of sex, length, weight, and condition of the fish to which it was attached, and by a few scales taken from the body of the fish behind the gill-cover. The object of these experiments is to trace the migrations of the fish, mainly the length of the period spent in the sea. The object of the removal of the scales is to determine, from a microscopical examination of the latter, the age of the fish and its history as regards sexual maturity and previous spawning acts. Anglers and others interested in the study of the salmon will welcome the instigation of these experiments by the Board. Investigations of a similar kind have been made so far mainly by private persons in this country, but with the resources at the command of the Board very valuable results should be obtained. The investigation is, of course, one which depends for its success upon the cooperation of sportsmen and fishermen, and we cordially recommend that this assistance be rendered.

On May 23 a communication was made to the Hon. Society of Cymmrodorion, by Mr. T. A. Acton and Mr. W. Burton, descriptive of the excavations that have been conducted during the last three years at Holt, near Wrexham. Mr. Acton has discovered the site of a tile and pottery works of the twentieth Roman Legion, and he gave a review of the discoveries of the foundations of buildings for housing the workers and probably the garrison of what must have been practically a frontier post, and also of the excavations of a series of potters' kilns. Thousands of fragments of Roman tiles and pottery have been excavated from the site, and are now in process of classification. Mr. William Burton explained the construction of the kilns, which are fortunately so well preserved that the leading features of the construction of both the circular and rectangular kilns used by the Romans in various parts of the empire are now clearly established; they foreshadow in a remarkable way the main principles of modern kiln construction. Mr. Burton exhibited three models of different types of kilns made from careful measurements of the remains, and these will be deposited ultimately in the British Museum.

The census report of the Nicobar Islands for 1911, just published, gives a good example of the custom of Couvade or "hatching." For some days or even weeks before the wife's confinement, the people in the hut, as a form of sympathetic magic, unloose all the cane and fibre lashings of their spears or vessels. During the first month after the birth of his first child the father is treated as an invalid. On subsequent occasions this lasts only one or two days. He is looked after and fed by his wife, and may not bathe or chew betel. These rules, which are enforced by the Menluanas, or medicine-men, are so irksome that it is believed their observance accounts for a widespread avoidance of maternity among the women.

The classical account of the pagan tribes of the Malay Peninsula by Messrs. Skeat and Blagden is being gradually supplemented by later inquiries among this interesting people; but these investigations only serve to prove the correctness of the earlier record. Mr. L. H. N. Evans now publishes in the Journal of the Federated Malay States Museum, which takes the place of the Perak Museum Notes, an account of the Besisi of Tamboh, Kuala Langat, Selangor. Their advance in culture is illustrated by the fact that they are now able to ride bicycles, which they borrow from the Chinese. Mr. Evans made a considerable ethnographical collection, including specimens of two methods of fire-making—by the saw and drill—which are being replaced by the use of matches and the flint and steel. As an example of culture contact, two ingenious forms of animal traps are now found in use from Nepal and Assam eastward through Indo-China and the Malay Peninsula, and all over the Greater Sunda Islands.

The researches that are being carried out at the present time, with so much patience and minuteness, upon disease-producing parasites, though undertaken primarily with practical aims in view, are helping to accumulate in many cases data of great value from a purely scientific and theoretical point of view. It is becoming, for example, increasingly evident that the pathogenic trypanosomes represent a group of incipient species in process of coming into being, in many cases differentiated physiologically, but not morphologically. From this point of view the human trypanosome generally known as *Trypanosoma rhodesiense* is very interesting. It is possible that it is an old-established species lately discovered; but it is far more probable that it has become but recently differentiated, and that it represents either a race of *T. brucii* that has acquired the power of living in human blood, or a race of *T. gambiense* adapted to transmission by *Glossina morsitans*. The former view has been advocated by Bruce and his colleagues, of the Royal Society's commission working in Nyasaland; but Stephens and Fantham, in a paper in the Annals of Tropical Medicine and Parasitology (vol. vii., No. 1), find it difficult to distinguish between *T. rhodesiense* and *T. gambiense* by means of measurements. The chief distinctive character of *T. rhodesiense* is the presence of the so-called posterior nuclear forms, which are studied by Blacklock in a memoir in the same journal; these forms have been found, however, in other species of trypanosomes, including *T. brucii*.

We have received a report by Prof. E. C. Starks, issued in the Leland Stanford Junior University Publications, on the fishes collected by the second Stanford expedition to Brazil, in which several species are described as new. A report has also reached us on the fishes of certain tanks in Bengal, drawn up by Mr. T. Southwell and Capt. R. B. S. Sewell, and published at Ranchi by the Bihar and Orissa Department of Agriculture.

The March issue of the Proceedings of the Philadelphia Academy contains a report on parasitic worms infesting the animals in the local zoological gardens. The average number of infestations is about forty-five per annum, but in 1910 there was a rise, due to the prevalence of cestodes in birds, while a second rise, owing to nematodes in parrots and perching birds, occurred in the following year. Among mammals Carnivora are much more heavily infested than any other order, monkeys, ungulates, and marsupials making nearly a dead-heat for second place. The new observations confirm previous statements that nematodes are the most common parasites, these being followed by cestodes, flukes, and Acanthocephali, in the order named.

In *The American Museum Journal* for March Mr. Barnum Brown describes, with a good series of photographs, the discovery at Red Deer River, Alberta, of a new crested dinosaur, now named Saurolophus, "the crested saurian." In life this animal was about 32 ft. in length, and stood about 15 ft. in height when erected. Like Tracodon, it was a herb-eater, and unable to defend itself from the contemporary flesh-eating Albertosaurus, except by its power of escaping danger by swimming. Great numbers of these creatures lived in the prehistoric coastal marshes, and in a single quarry on the Red Deer River bones of several hundred individuals, mostly of this kind, have been washed out of the bank. Another set of bones discovered in the same district represents the skeleton of another new dinosaur coming from an older formation, and probably an ancestor of Saurolophus.

The first of a series of studies on the evolution of the teeth of primates, by Dr. L. Bolk, professor of anatomy in the University of Amsterdam, has been published (G. Fischer, Jena, 1913, price 5 marks). A completely new interpretation is given of the relationship between milk and permanent teeth. We have hitherto regarded them as belonging to different epochs of evolution—the milk teeth representing a primary dental outfit, the permanent a secondary acquisition. Prof. Bolk, from a prolonged inquiry into the developmental stages of the teeth of reptiles and mammals, has accumulated evidence to show that both reptiles and mammals have arisen from a stock which was furnished with three rows of teeth, all of which came into use at the same time. In both reptiles and mammals the outer row is represented by vestiges—the so-called pre-lacteal dentition. In reptiles the middle and inner rows persist and come into use together. In the higher or diphyodont mammals the middle rows come into use first, forming the milk dentition, while the inner is delayed in its appearance, and forms the permanent set of teeth. In lower or monophyodont mammals both middle and inner rows of teeth—that is to say, milk and permanent teeth—come into place and use together, forming an apparently linear series. Prof. Bolk's hypothesis promises to simplify our conception of the evolution of mammalian teeth, and explains many facts which were formerly obscure.

Mr. W. Engelmann, Leipzig, has lately issued parts 55, 56, 57, and 58 of "Das Pflanzenreich." This magnificent *regni vegetabilis conspectus* is making rapid progress, though up to the present time only one group (Sphagnaceæ) of cryptogamous plants has been dealt with. Heft 55, by Prof. Engler, begins the account of the Philodendroideæ section of the large family Araceæ by Engler and Krause, and is unusually well and fully illustrated with new figures. Heft 56, by Dr. F. Kranzlin, forms a self-contained monograph of the "Indian shot" family, Cannaceæ, and concludes the treatment of the interesting order Scitaminales, the remaining three families of which (Musaceæ, Zingiberaceæ, Marantaceæ) have already been described by Schumann; in his introduction the author gives an account of the various interpretations which have been put forward of the structure of the outer floral organs in Canna, the sole genus in the family. In Heft 57, Dr. Pax, assisted by Käthe Hoffmann, continues the monograph of the large and difficult family Euphorbiaceæ; in addition to figures of many of the species, there is given a useful table showing the geographical distribution of the genera belonging to the section (Chrozophorinæ) dealt with in this part. Heft 58, by G. Grüning, gives the Stenolobeæ section of the same family.

WE have received a copy of vol. xlviii., No. 8, of the Proceedings of the American Academy of Arts and Sciences, consisting of an extensive memoir by Mr. J. W. Hotson on culture studies of fungi producing bulbils and similar propagative bodies. In this paper the author brings together the scattered references in mycological literature to the occurrence in various fungi of these propagative bodies, which are cell-masses ranging from spore-like structures to large sclerotium-like forms, and indeed shading gradually into these two definite and distinct types (spore and sclerotium) of reproductive body. After describing in detail, with numerous excellent figures on twelve plates, the structure and development of bulbils in the various species examined during his long-continued culture experiments, the author discusses the morphological significance, distribution, and occurrence of bulbils in fungi. He concludes that in most cases, if not in all, these bodies are not to be regarded as abortive spore-fruits (ascocarps), but rather as an auxiliary method of reproduction that has been interpolated in the life-history of certain fungi without definite relation to other methods of reproduction they may possess, or that if they have in reality been derived from some other reproductive body, this was more probably some form of non-sexual spore rather than the primordium of an ascocarp.

THE Memoirs of the Indian Meteorological Department, vol. xxi., part 7, contain an interesting inquiry into the cold weather storms of northern India by Dr. G. T. Walker and Rai Bahadur Hem Raj. It is pointed out that the storms in question, which occur between December and April, are of considerable agricultural importance, and that it is extremely desirable that their origin should be ascertained, the view that these rain-bearing disturbances are generated over the arid districts of Persia and Baluchistan being by no means free from difficulty. An examination of charts recently prepared by the Meteorological Service of Egypt for the years 1906–12 shows that about seven-tenths of the disturbances which affect north-west India in those months are continuations of depressions from southern Europe, but the paths of the depressions vary considerably from year to year. In order to confirm the origin of most of the storms without a large expenditure of labour in preparing charts, Dr. Walker had recourse to statistical methods. He says that if these storms pass over Syria or Asia Minor it is to be expected that severe winters with much precipitation in these areas will tend also to be severe winters in north-west India. "A calculation was accordingly made of the correlation coefficients of the seasonal rainfall in north-west India with those of rainfall in places to the west for which records were available." The evidence shows that the winter seasons in the west of Asia Minor, in Syria, and in Malta have a closer resemblance to those of north-west India than do the winter seasons of Persia and Mesopotamia.

IN his presidential address to the Institution of Mining and Metallurgy, delivered on March 13, a copy of which has just reached us, Mr. Bedford McNeill devoted his attention more particularly to the statistics of production of the more important metals, laying especial stress upon the precious metals. He showed that the production of metals was increasing at a rate quite unexampled in the history of the world, the percentages of increase during the decade ending in 1911 ranging from 29 in the case of lead up to no less than 513 for aluminium, whilst it was 58 for iron and 68 for copper. The metal miner is therefore supplying the world with the metals used in the arts upon an enormously greater scale than ever before. As regards the precious metals, it is shown that within the above-named decade the production of gold has increased by 79 per cent., and that the world's annual output of gold is now more than equal to the total production for the sixty years preceding the year 1700. Mr. McNeill shows that this increase of production is to some small extent counteracted by the remarkable absorption of gold that has been taking place for some years past in India, and to a smaller extent also in Egypt. The production of silver has also undergone an increase, though less than gold, the increase during the decade 1901–11 being 41 per cent.; the actual production of silver during that period was ten times as great as that of gold, though this proportion is one that appears to fluctuate considerably from time to time.

WHEN our knowledge of the mean depth of the oceans was less extensive than it is now, it was supposed that a close approximation along certain lines was given by the velocity of seismic sea-waves. The formula (Lagrange's) used for the purpose was $v=\sqrt{(gh)}$, where v is the mean velocity of the waves and h the mean depth along the line of ocean traversed by them. It was shown, however, by Dr. Davison (*Phil. Mag.*, vol. xliii., 1897, pp. 33–36) that, when the depth is variable, the formula gives too great a depth, and that it should be $v = s \Big/ \int \frac{ds}{\sqrt{(gh)}}$, s being the distance from the epicentre. Prof. Rudski ("Physik der Erde," 1911, p. 340) suggested the formula $v=\frac{1}{s}\int \sqrt{(gh)}ds$. Prof. G. Platania has recently made a comparison of the results given by the three formulæ in the case of the Calabrian earthquake of October 23, 1897, the sea-waves of which were registered by the mareographs at Messina and Catania (*Boll. Soc. Sism. Ital.*, vol. xvi., 1912, pp. 166–174). The actual mean velocity was 102 metres per second, while the values given by Davison's, Rudski's, and Lagrange's formulæ were respectively 109, 114, and 120 metres per second.

VOL. xiii., part 2, of the Proceedings of the Nova Scotian Institute of Science contains an account, by Mr. J. H. L. Johnstone, of measurements of the specific resistance of ice at temperatures between 0° and −19° C., made by a new method, in which the effects of electrolytic polarisation were eliminated. The values obtained agree fairly well with those obtained by Profs. Ayrton and Perry, using a different method, and show that the value of the temperature coefficient is very much higher than that of ordinary electrolytes and decreases in value as the temperature departs from 0°. The same number of the Proceedings also includes an interesting account of the sacred trees of India, by Capt. J. H. Barbour.

WE have received a copy of the reprint of the Carnegie Institution of Washington paper on the magnetic survey work in southern and central Africa carried out in 1908 and 1909 by Prof. Beattie, of the South African College, Cape Town, and Prof. Morrison, of Victoria College, Stellenbosch, who for the time necessary were made officials of the Carnegie Institution. The cost of the work was defrayed by the Carnegie Institution, 2000*l*., the Royal Society, 250*l*., and Sir L. S. Jameson and Sir L. Mitchell, 100*l*. The survey covers the regions between the Zambezi and the Nile, including parts of north-eastern Rhodesia, the Congo, German East Africa, Uganda, Nyasaland, and British East Africa, with further observations in Cape Colony and German South-West Africa. Throughout most of the journey the only means of conveyance was by native carriers, and the history of the expedition reads like a chapter of Livingstone's travels. We offer our congratulations to Profs. Beattie and Morrison on the successful accomplishment of an important and much-needed piece of magnetic survey work.

SEPARATE copies have reached us of a considerable number of papers which have been published by the staff of the Reichsanstalt during the present year. Dr. F. Henning has compared the platinum resistance with the hydrogen thermometer at temperatures between 0° C. and −193° C. He finds that Callendar's formula connecting the two holds only down to −40° C., and proposes another formula, which holds over the whole range. Drs. K. Scheel and W. Heuse have determined by the continuous-flow method the specific heats at constant pressure of helium, hydrogen, nitrogen, oxygen, air, and carbonic oxide, at temperatures down to that of liquid air. The specific heats of helium and hydrogen increase with increase of temperature, the others decrease. In connection with these researches a thermostat suitable for low temperatures has been devised by Dr. Henning. It depends on the passage of a stream of liquid air through a suitable liquid, as, for example, petroleum ether. The air evaporates in the liquid, and the rate of evaporation determines the temperature to which the liquid is cooled. The former papers will be found in the March and April numbers of the *Annalen der Physik*, and the last in the February number of the *Zeitschrift für Instrumentenkunde*.

IT has long been known that the photometry of sources of light widely differing in colour is rendered difficult by the peculiarities of the eye, especially at low illuminations. Until recently this was not of much practical importance, since most of our commercial illuminants yielded continuous spectra and light of substantially the same tint. Now, however, things are changed. A recent communication by Messrs. Broca, Jouast, De la Gorce, and Laporte (*Bull. Soc. Int. des Electriciens*, February, 1913) shows the perplexities likely to be met with in comparing such sources as the mercury-vapour lamp and the new neon tube. The former contains only yellow, blue, and green light, the latter only red and orange rays between 0·585 μ and 0·640 μ. The authors meet with differences of 100 per cent. or more, according to the illumination of the photometer screen. Similar discrepancies are caused by the personal errors of different observers. To these difficulties, due to the colour of the light, must be added those arising from the fact that the light is not a point, but a tube of considerable dimensions, so that the ordinary inverse square law of photometry does not apply. Another interesting observation is that objects illuminated by the neon light appear more sharply defined than in the case of ordinary illuminants. The reason would appear to be that the monochromatic nature of the light avoids the results of chromatic aberration in the eye.

SOME new experiments on the preparation and properties of pure alcohol are described in the Chemical Society's Journal by Mr. R. W. Merriman. The density of the pure alcohol was established for about forty samples as 0·80628 at 0°/4°. It was shown that freshly burnt quicklime prepared from marble is a better drying agent than metallic calcium, which produces no improvement in alcohol dried by lime. In distilling the alcohol from the lime it is necessary to reject the first and last fractions; the latter have a high density, which is attributed to partial dehydration of calcium hydroxide as the temperature of distillation rises from 80° to 100° on the water-bath.

A "NEW Iron Bacterium" is described by Mr. E. M. Mumford in the Transactions of the Chemical Society. It was discovered in the Bridgewater Canal tunnels at Wasley, Lancashire, where the water contains much iron derived from colliery pump water. The new bacterium appears to have a twofold action, an aërobic action whereby it precipitates ferric hydroxide from iron solutions, and an anaërobic action which transforms the ferric hydroxide into bog iron ore with partial reduction of the iron to a ferrous state. It is probable that the deposits of bog ore are due to this organism rather than to the higher bacteria, since the latter have not the facultative power necessary to dehydrate and reduce the ferric hydroxide to bog ore.

THE English Ceramic Society has recently issued the twelfth volume of its Transactions, and is to be congratulated on the good work which it continues to do in furthering the application of scientific methods to so important an industry. Attention may be directed specially to a paper by Mr. A. J. Campbell in which the application of "surface combustion" to pottery practice is suggested, and to a description by Dr. W. R. Ormandy of an "Electrical Process for the Purification of Clays." This consists in partially coagulating the emulsified clay by the addition of electrolytes, and then further purifying the emulsion by passing it through a vessel containing electrodes differing in potential by 60 to 100 volts. The chief impurities are electropositive, and can thus be removed, even when present in very fine particles. The clay-substance is electronegative, and is laid down in the form of a continuous blanket $1\frac{1}{2}$ yards wide and $\frac{1}{4}$ in. thick. It is deposited in a remarkably dry state with only 18 to 20 per cent. of water, and may contain as much as 99·5 per cent. of china-clay substance.

MESSRS. J. AND A. CHURCHILL have nearly ready an English translation of the Italian work, "A Treatise on General and Industrial Organic Chemistry," by Dr. Ettore Molinari. The work of translation has been carried out by Mr. T. H. Pope, of the School of Malting and Brewing of the University of Birmingham.

AN examination of "The Social Guide, 1913," which has now been issued by Messrs. A. and C. Black, at the price of 2s. 6d. net, shows that the editors regard some scientific meetings at least as social events. Attention is directed, for instance, to the meetings of the Royal Society, the Royal Institution, the Royal Geographical Society, and the British Association. The University Extension meetings arranged in the summer by the Universities of Oxford and Cambridge are also referred to, but, speaking generally, the matters of prominence relate to sports and amusements. The subjects are arranged alphabetically, but an index would assist reference greatly.

ERRATUM.—The term $\frac{\Sigma P - P.N}{\frac{N}{2}}$ on p. 279 of NATURE of May 15 should have been $\frac{\Sigma P - P.M}{\frac{N}{2}}$.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR JUNE:—

June 1. 4h. 4m. Venus in conjunction with the Moon (Venus 4° 38′ S.).
,, 12h. 0. Mercury in superior conjunction with the Sun.
4. 0h. 25m. Saturn in conjunction with the Moon (Saturn 6° 22′ S.).
,, 16h. 4m. Mercury in conjunction with the Moon (Mercury 3° 48′ S.).
7. 4h. 40m. Neptune in conjunction with the Moon (Neptune 5° 9′ S.).
19. 14h. 26m. Jupiter in conjunction with the Moon (Jupiter 4° 47′ N.).
June 21. 8h. 8m. Uranus in conjunction with the Moon (Uranus 3° 27′ N.).
,, 13h. 9m. Sun enters Sign of Cancer—summer commences.
22. 6h. 0m. Vesta in conjunction with the Moon (Vesta 0° 31′ N.).
23. 22h. 35m. Mercury in conjunction with Neptune (Mercury 2° 11′ N.).
24. 2h. 0m. Venus at greatest distance from the Sun.
29. 5h. 5m. Mars in conjunction with the Moon (Mars 4° 51′ S.).
30. 7h. 4m. Venus in conjunction with the Moon (Venus 7° 44′ S.).

COMET 1913*a* (SCHAUMASSE).—*Astronomische Nachrichten* No. 4652 contains not only numerous observations of the comet which Mr. Schaumasse discovered, but three sets of elements and ephemerides computed by Kiess and Nicolson, Ebell, and Fayet and Schaumasse. The observations made between May 7 and 11 give the magnitude between 9·5 and 11.

The following parabolic elements are those calculated by the last two observers mentioned above, and they are based on Schaumasse's observations at Nice on May 6, 7, and 8:—

$$T = 1913 \text{ May } 15{\cdot}4222 \text{ M.T. Paris.}$$
$$\left.\begin{aligned}\omega &= 53^\circ\ 32'\ \ 8''\\ \Omega &= 315\ \ 21\ \ \ 7\\ i &= 152\ \ 31\ \ 26\end{aligned}\right\}1913{\cdot}0$$
$$\log q = 0{\cdot}162920$$

Ephemeris for 12*h. M.T. Paris.*

	α (h. m. s.)	δ
May 30	17 45 55	+38 31
June 1	17 15 56	+40 6
,, 3	16 45 33	+41 9
,, 5	16 15 50	+41 35

EFFECTIVE TEMPERATURES OF STARS.—An important communication is published in the *Comptes rendus* of May 5 (vol. clvi., No. 18, p. 1355), by Dr. Charles Nordmann, relative to the effective temperatures of stars. It will be remembered that Dr. Rosenberg published recently (*Astronomische Nachrichten*, No. 4628, p. 360) the results of measures of the effective temperatures of seventy stars based on the determinations of the intensity of the photographic spectra. It will be remembered also that Dr. Nordmann made a like series of measures based, on the other hand, on visual observations. As the two series of measures deal with different regions of the spectrum they may be considered as independent determinations, and Dr. Nordmann here compares the results obtained in cases where the same star has been measured. The following table shows the resulting comparison:—

	Effective temperatures (in absolute degrees)		
	Nordmann λλ 460–630	Rosenberg λλ 400–500	Spectral types (Lockyer)
δ Persei	18500	15500	Algolian
ε ,,	15200	23000	Crucian
β ,, (Algol)	13300	12000	Algolian
α Lyræ (Vega)	12200	22000	Sirian
α Persei	8300	6500	Polarian
α Ursæ Minoris (Polaris)	8200	5200	,,
α Canis Minoris (Procyon)	6800	7000	Procyonian
γ Cygni	5620	5100	Polarian
Sun	5320	4950	Arcturian
α Aurigæ (Capella)	4720	4500	,,
β Andromedæ	3700	2650	Antarian
α Tauri (Aldebaran)	3500	2150	Aldebarian

Dr. Nordmann directs attention to the good agreement of the two series, with one or two exceptions, which he discusses, and points out that if the stars be arranged in the order of ascending temperatures they become hotter and hotter as one passes from the

Aldebarian and Antarian types to helium stars. This, he states, conforms to the thermal classification which Sir Norman Lockyer deduced from his qualitative study of the stellar spectra.

THE WORK OF SIR WILLIAM HUGGINS.—Under this heading, in *The Astrophyical Journal* for April (vol. xxxvii., No. 3) Prof. G. E. Hale takes the opportunity of again cheering up those astronomical observers who possess only a small and limited instrumental equipment, and may conceive the idea that the multiplication of large instruments renders any attempt at research on their part useless. Being the director of an observatory which may be considered the best equipped, contains the largest instruments, and is situated on a nearly ideal mountain site, it may appear that he is only trying to console workers with modest means. But this is not so. Prof. Hale knows the value of both large and small instruments, and there is abundant work for both classes. The reader should look through this article and he will find depicted there the magnificent work of amateurs, in spite of the fact that large instruments were in active employment at the time the work was done. Sir William Huggins he takes as an example of one of "that great English group of amateurs," and he directs attention to the fact that while in 1856 he acquired his first telescope, a 5-in. refractor, in 1858 an 8-in., and in 1870 an 18-in. reflector, such powerful instruments as 15-in. refractors at Pulkowa and Harvard, Lord Rosse's 6-ft. reflector, Lassell's 4-ft. reflector, the Melbourne 4-ft. reflector, &c., did not deter him from securing results of the highest importance.

Prof. Hale concludes in the following terms:—"Every investigator may find useful and inspiring suggestions in the life and example of Sir William Huggins. Their surest message and strongest appeal will be to the amateur with limited instrumental means, and to the man, however situated, who would break new ground."

THE SCOTT EXPEDITION TO THE ANTARCTIC.

THE huge audience which filled the Albert Hall on Wednesday evening, May 21, on the occasion of the Royal Geographical Society's meeting to hear Commander Evans's account of the Scott expedition to the Antarctic, showed no less by its eager plaudits than by its suppression of them at the fitting moments that the public sense of the tragedy of the expedition is not dulled by familiarity. Yet throughout the proceedings there was no false note of sentiment; the president, Lord Curzon, stated, without risk of misunderstanding, that the tribute of the society to the dead had been paid already, and begged any (and there were some) who felt that "this great reception is inconsistent with the feelings of sorrow which affect us all" to "abandon such a reflection," for that he was sure that Scott himself would not have had his companions forgo the reward of their labour. And the story of the expedition was told by Commander Evans very simply; he exhibited the sense of loss which all his collaborators share in a few words only, and by implication rather than by direct statement. Finally, the tribute paid by both president and lecturer to the generosity of the public and to the Government for the provisions made for the dependants of those who are lost showed that any criticism which has been directed against the allowances made from the public funds is without official concurrence.

It was satisfactory to learn that the funds subscribed will admit of the proper publication of the scientific results of the expedition. As regards these results, not a great deal emerged from the lecture which was not already realised by those who have taken interest in this aspect of the work accomplished. Nor was it to be expected that any detail should be given within the compass of a single lecture, though long; for it was long, and a tribute is due to Commander Evans, who so ably sustained the strain of delivering it, and never for a moment allowed the intense interest of the audience to wane. And here a word, though perhaps scarcely appropriate in this place, may be permitted in commendation of the singularly well-chosen organ music which was given before the opening of the proceedings.

But if it is scarcely possible, after hearing the lecture, to add materially to what is already known as to the scientific results of the expedition, it is right at the outset to record the full measure in which the value of those results has clearly been enhanced by photography. Obviously no photographer to any expedition has laboured with a more thorough sense of his duty, or more successfully, than Mr. Ponting. The lecture was delivered with lowered lights and with an accompaniment of lantern slides throughout, and was followed by a few kinematograph films of extraordinary interest. It is impossible to over-praise the beauty of the photographs, nor is it easy to select those of chief scientific interest, though an exquisite series showing new ice at successive stages of formation may be specially mentioned. Of the moving pictures, those of the killer whales were singularly clear, though the motion of creatures of their kind is familiar to many; those which showed seals leaving and entering the water through ice-holes were of even greater interest and value.

Some wonder has been expressed, with the vast area unexplored in the Antarctic region and the many problems awaiting solution in mind, that Scott elected to follow Shackleton's route, or even (and this criticism dates from early Arctic days) that he or anyone else should desire to reach the geographical pole at all. Against this there should be recalled the desire once expressed by a high Antarctic authority, that the south pole should be reached as quickly as possible since, until it should be, explorers would not rest content with work in other directions merely. On this count criticism is scarcely to be directed against Scott's expedition, for it included the largest scientific staff ever taken to the Antarctic, and scientific research certainly played no subordinate part in relation to the journey to the pole. We know already of the devotion with which Scott himself and his lost companions carried their geological specimens to the end of those last dreadful marches. Commander Evans showed how the three weeks during which the ship was held in the pack on the outward voyage were "not wasted," for magnetic observations, soundings, and serial sea temperatures were obtained, while marine biological work of importance was also done. Only the impossibility of finding a suitable base at Cape Crozier prevented the expedition from landing there in order that the embryology of the emperor penguins during winter might be studied. Wilson afterwards made his famous winter expedition thither, and one heard how he recorded the unimaginable temperature of 109° of frost.

Mr. Griffith-Taylor's party, which traversed the Ferrar Glacier, broke new ground, reaching a valley free of snow, containing a fresh-water lake only surface-frozen and full of algæ. Gravels in this limestone region, rich in garnets, "were washed for gold, but only magnetite was found." Commander Evans also paid tribute to Dr. Simpson's work as physicist and meteorologist, which was carried on after his departure by Mr. Wright, who also "made a special study of ice structure and glaciation." Lieut. Campbell's party, in spite of extraordinary hardships, which included wintering away from its base, for which it was not prepared, was very successful in meteorological, magnetic, geological, and surveying work, while the penguins were the object of further study. Commander Evans had time to commend the work of Mr. Griffith-Taylor on the coast of Victoria Land (in geology and surveying), as well as that carried out on the ship, not only in the open ocean, but on the less-known coasts of New Zealand, no more fully than to intimate that each of these departments of the whole great undertaking is worthy of a lecture to itself, which it is to be hoped may be devoted to it.

Finally, reference is due to the results of the determination of the position of the south pole itself, as obtained by Amundsen and by Scott. The latter fixed the exact spot by means of a 4-in. theodolite, "at a point which only differed from Amundsen's reckoning by half a mile," that is to say, "by one scale division on the theodolite, which was graduated to half a minute of arc. Experts in navigation and surveying will always look on this splendidly accurate determination as a fine piece of work, by our own people as well as by the Norwegian explorers."

At the annual meeting of the society on Monday last, in the Theatre, Burlington Gardens, Lady Scott was presented by Earl Curzon with the patron's medal and the special Antarctic medal awarded to her husband in 1904, inclosed in an inscribed silver casket. Mrs. Wilson also received a patron's medal awarded to Dr. E. A. Wilson. To Lieut. Campbell was presented a gold watch as a special award.

THE BRITISH SCIENCE GUILD.

THE seventh annual meeting of the British Science Guild was held at the Mansion House on May 21, the Lord Mayor in the chair. In his opening remarks, the Lord Mayor made sympathetic reference to the aims and work of the guild, which, he said, seeks to further the application of scientific methods to all human endeavour and advocates the adoption of measures for the conservation of natural resources; in other words, its desire is to foster national efficiency. The Right Hon. Sir William Mather was elected president of the guild in succession to Lord Haldane, who has been president since its foundation. The new vice-presidents elected were Lord Sydenham, the Right Hon. the Lord Mayor of London, the Right Hon. Sir John Brunner, Bart., Sir Patrick Manson, and Sir Philip Watts; and other new members added to the executive committee are Mr. Charles Bathurst, M.P., Mr. R. Kaye Gray, Sir Philip Magnus, M.P., and Mr. Robert Mond.

The annual report, which was adopted at the meeting, surveys the activities of the guild in many directions. Reference is made in it to the new Post Office service for the synchronising of clocks—a subject which the guild has done much to promote. Other matters referred to are the final report of the Royal Commission on Tuberculosis, the new horticultural branch of the Board of Agriculture and Fisheries, the conversion of the Sleeping Sickness Bureau into the Tropical Diseases Bureau, the Society for the Promotion of Nature Reserves, and the Royal Commissions and Departmental Committees appointed during the year to deal with subjects with which science has some relationship. All these Commissions and Committees have been announced already in NATURE, but the report of the guild brings them together in a convenient form as a record of official action.

The various committees of the guild continue to do valuable work. The medical and agricultural committees have drawn up a report on the Government's Milk and Dairies Bill. While recognising that the Bill is a very decided advance in the direction of obtaining pure milk, the committees feel that in certain respects stronger and more drastic action should be taken. A note upon the report of the committees appeared in NATURE of May 1 (p. 222).

A report on tide and wave energy, and on the possibility of utilising this form of energy for power purposes, is being drawn up by the committee on the conservation of natural sources of energy; also a report on the utilisation of peat, which occurs in such enormous quantities in some districts in the British Isles and British possessions.

Owing to the declaration of the Government of the intention to bring in a comprehensive scheme to reorganise the educational system of the country, a joint committee of the education committee and the technical education committee, with Sir William Mather as chairman, was appointed to consider the subject. A valuable report has been drafted, which urges that a scientific system of national education demands:—

(1) The duty of local authorities to make such provisions as will promote healthy growth during infancy and throughout school life.

(2) The absolute necessity of manual work and related practical exercises throughout the whole course of school instruction, and also in the training of teachers.

(3) Efficient public elementary schools within the reach of all children, and attendance at school compulsory until the age of fourteen years is reached.

(4) Attendance at continuation schools for at least six hours per week obligatory up to seventeen years of age for all young persons not otherwise receiving suitable education.

(5) Suitable secondary schools available for all who can profit by them and will undertake to complete the full course of instruction.

(6) The institution of school certificates to serve as passports to higher schools or universities, or as testamurs of satisfactory completion of a school course.

(7) Examinations to occupy a secondary place in comparison with school records for the award of certificates, or to qualify for promotion to higher courses of study.

(8) Coordination of technical institutions and faculties of technology in universities in order to prevent overlapping and render specialised types of technological training available to students who have the capacity to profit by them.

(9) Increased grants to universities and other places of higher education for the purposes of ensuring the reduction of fees for all courses and promoting post-graduate research.

(10) The position and condition of service of teachers of every grade to be greatly improved in order to encourage men and women of the highest aptitude and qualifications to devote their lives to the work of teaching and the advancement of knowledge.

(11) Readjustment of the shares of the cost of education borne by the National Exchequer and by local authorities, so that educational progress may be made primarily a national responsibility.

The synchronisation of clocks committee refers to the Government action in connection with the subject, already mentioned. Since the guild took the matter up the Post Office has always viewed the matter sympathetically, and this new departure will, if it be taken up by those exposing public clocks, be of the utmost value. It is hoped that the railway companies, at least in the metropolis, will take advantage of this enterprise on the part of the Postmaster-General. The borough councils have in the past not been very sympathetic, but perhaps, now that the matter will be arranged for them by the Post Office at such a trifling cost, they will adopt a more progressive attitude.

The explosives committee has considered the question of the available sources of nitrates, and the possibility of obtaining them during war; also the feasibility of manufacturing nitrates on a large commercial scale in this country. The committee considers that it is of the utmost importance that nitrates should be manufactured in Great Britain, even if the manufacture is not profitable; it is, however, of opinion that a commercially successful scheme is possible.

In the report of the Canadian committee reference is made to the conservation of natural resources of Canada. A source of great loss to the country is the prevalence of forest fires, and last year the Government spent the sum of 312,500*l*. in protection against this source of loss. The protection of native birds is also referred to. Much useful work has recently been done by the Canadian Waterways Commission, and in connection with this Dr. H. T. Barnes, the hon. secretary of the Canadian committee of the guild, has continued his valuable researches on ice formation in the St. Lawrence. Other subjects dealt with are radium standards, university settlement, prevention of tuberculosis, and free ice for the poor.

Appended to the report are the reports of committees dealing with the Milk and Dairies Bill, the work of the Canadian branch, and on a national system of education. Prof. R. A. Gregory contributes an appendix in which benefactions exceeding 10,000*l*. for the purposes of science and higher education are recorded, and a comparison is made between the incomes of universities and colleges in the United States and that of State-aided universities in Great Britain. From this article it appears that the total receipts of universities in the United States in the year 1910–11 amounted to nearly nineteen million pounds, and the benefactions to four and a half millions. In the same year, the total receipts of those universities and university colleges in Great Britain which participate in the Treasury grant were little more than 600,000*l*. The receipts from fees in England amounted to rather less than 32 per cent. of the total income. The amount received from endowment was about 15 per cent.; the receipts from local authorities 15·6 per cent. The total receipts of all kinds from the Exchequer amounted to 28·5 per cent. of the income.

As regards numbers of students in universities and technological institutions of university standard, comparison is made with Germany. There are twenty-one universities in the German Empire and eleven technical high schools or technical universities having the power to grant degrees. Taking the universities and technical high schools together, the statistics show that in the year 1910–11 they had about 71,000 matriculated students. The total number of full-time day students in the universities and university colleges of England and Wales (including those of Oxford and Cambridge) in 1910–11 was about 17,000, and in Scotland about 7600, in comparison with 55,000 in German universities. In the technical institutions of the United Kingdom, the number of day students in attendance was about 2000, in comparison with 16,000 in the technical high schools of Germany. From other tables given in the article it appears that more than 90 per cent. of the pupils in the State-aided secondary schools of England and Wales are under sixteen years of age, and one-quarter of the pupils are under twelve years of age. More than four-fifths of the pupils have not passed an examination of university matriculation standard when they leave school. Two per cent. of the pupils proceed to universities, and 7 per cent. to technical schools and institutions, medical schools, training colleges for secondary-school teachers, and like places providing special training for professions, trades, or commercial occupations.

RECENT WORK IN ECONOMIC ENTOMOLOGY.

VALUABLE memoirs published by the Entomological Division of the United States Department of Agriculture are constantly reaching us. Of these, Bulletin 110, on "The Spring Grain-Aphis, or Greenbug," by F. M. Webster and W. J. Phillips, is of more than passing interest. The species described—*Toxoptera graminum*, Rondani—has been noticed as seriously destructive to wheat and other cereals in North America—especially in the Middle Western States—during several seasons from 1890. In the eastern hemisphere it has been recorded only from a few localities—Italy, Hungary, Belgium, India, South and East Africa. The bulletin, extended to 150 pages, gives a full account of the insect, its embryology, post-natal development, habits, and natural enemies. An interesting bionomical observation is that south of the 35th parallel the species reproduces itself only by successive generations of virgin females, and even further to the north the sexual generation may be omitted from the life-cycle in mild winters.

Another bulletin which contains welcome original contributions to our knowledge of the life-history of Hemiptera is No. 108, on "Leafhoppers affecting Cereals, Grasses, and Forage Crops," by Prof. Herbert Osborn. H. M. Russell's contribution (No. 118) on the bean thrips (*Heliothrips fasciatus*) is also noteworthy. It is needless to add that these bulletins all deal with practical means for the extermination or control of the pests.

As a contribution to animal parasitology, Bulletin 106, "The Life-history and Bionomics of some North American Ticks," by W. A. Hooker, F. C. Bishopp, and H. P. Wood, is worthy of mention. It forms an excellent introduction to the ticks of pathological importance, giving diagnostic characters of genera and species, and furnishing in each case details of the early stages in the life-history.

From the Canadian Department of Agriculture we have received Dr. C. Gordon Hewitt's Bulletin, No. 10, on the large larch sawfly (*Nematus Erichsonii*). This paper gives, in a handy form, particulars of the prevalence of the insect as a larch-destroyer in Europe and North America. British entomologists are familiar with Dr. Hewitt's work in connection with this insect in the Cumbrian lake district. He finds it still more injurious across the Atlantic, where, he believes, it must be regarded as an introduced species. Naturally he is endeavouring to acclimatise in Canada the ichneumon-fly (*Mesoleius tenthredinis*), which reduced so considerably the sawfly population on the shores of Thirlmere.

Dr. Hewitt has found time also to contribute to *Parasitology* (vol. v., No. 3, 1912), a short account of the larvæ and bionomics of *Fannia canicularis* and *F. scalaris* (better known to most naturalists under the generic name of Homalomyia). These curious spinose maggots have an unpleasant interest as occasional inhabitants of the human intestinal and urinary tracts.

From the Imperial Indian Government's Agricultural Research Station at Pusa has been issued Bulletin No. 28 on "The Cultivation of Lac in the Plains of India," by C. S. Misra, a well-illustrated account of the insect (*Tachardia lacca*), the trees on which it thrives, their culture, the collection of the product, the manufacture of shellac, and its economic uses. The most dangerous enemies of the lac insect appear to be the predaceous caterpillars of four species of moth.

FORESTS AND CLIMATE.

THE very general belief in the influence of forests upon climate, and especially upon rainfall, is discussed by Prof. R. de Courcy Ward in an interesting article in the April number of *The Popular Science Monthly*. The subject is very complicated, and the author points out that we must be careful not to put the cart before the horse; in other words, the forests are the result of the rainfall, and not *vice versâ*.

The various questions involved are discussed in detail, the following being among the points dealt with:—(1) The historical method; (2) why forests should influence climate; (3) influence upon (*a*) temperature, (*b*) humidity and evaporation; (4) the cases frequently cited as showing an influence upon rainfall; (5) recent European studies. Among the authorities quoted, Hellmann has shown that the increase in the rainfall over a forest is accompanied by a lessened fall to leeward—simply a slight difference in distribution. Both Voeikof (Russia) and Hann (the leading authority on climate) believe that the vast tropical forests may increase the amount of rainfall. But as regards our own latitudes the author considers that there is at present no conclusive evidence that forests have a significant effect upon the amount of rain*fall*, as distinguished from the amount of the rain*catch* in the gauge.

There is comparatively little popular interest in the possible influence of forests upon temperature; the forest is a little cooler than the open in summer, and possibly very slightly warmer in winter. Supan sums up the case as follows:—"No one will care to maintain that the system of isotherms would be radically altered if Europe and Asia were one great forest from ocean to ocean." With regard to moisture, the author thinks that the local supply from forests cannot play any considerable part in the great rain-producing processes.

SYSTEMS OF LONG-DISTANCE WIRELESS TELEGRAPHY.

THE Advisory Committee appointed by the Postmaster-General to consider and report on the merits of existing systems of long-distance wireless telegraphy has made its report. The Committee heard evidence in private from representatives of the Marconi, the Telefunken, the Poulsen, the Goldschmidt, and the Galetti interests, and of the Admiralty, and the members visited a number of stations.

The report is strictly limited to practical considerations, and deals with matters of engineering rather than of scientific interest. From the point of view of the building of stations for immediate operation in the Imperial wireless chain, the report is overwhelmingly in favour of the Marconi Company, not only on account of its plant, but also on account of its experience; though the Committee points out that it would be possible for the Government to get together a highly trained staff and erect the stations, using any desirable patents under the provisions of section 29 of the Patents and Designs Act, 1907. The Marconi spark plant was tested by the Committee as to duplex working, and as to automatic transmission at the rate of sixty words per minute, across the Atlantic, a distance of 2300 miles. The Committee found Transatlantic communication practically continuous, though there are periods when the signals become very weak; and there are occasional periods when no signals at all can get through. These weak periods are due to natural causes, and can probably only be overcome by the use of high powers.

The Committee received no evidence supporting the reported transmission from San Francisco to Honolulu (2100 miles) by the Poulsen arc, but witnessed transmission over a relatively short distance at seventy words per minute. The members also saw the Goldschmidt alternator transmit at the rate of sixty words per minute. It is interesting to note that the Marconi Company and the Telefunken Company are both experimenting with generators of continuous waves. The Marconi machine consists essentially of a rapidly rotating contact-maker in a direct-current circuit with special dispositions of other circuits to give continuous oscillations in the antenna. The Telefunken machine is an alternator constructed to give as high a fundamental frequency as may be convenient in the first instance, the frequency being doubled or quadrupled by a polarised transformer method. The Marconi machine was witnessed working across the Atlantic.

SOME FURTHER APPLICATIONS OF THE METHOD OF POSITIVE RAYS.[1]

THE method to which I shall refer this evening is the one I described in a lecture I gave here two years ago. The nature of the method may be understood from the diagram given in Fig. 1. A is a vessel containing the gases at a very low pressure; an electric discharge is sent through these gases, passing from the anode to the kathode C. The positively electrified particles move with great velocity towards the kathode; some of them pass through a small hole in the centre, and emerge on the other side as a fine pencil of positively electrified particles.

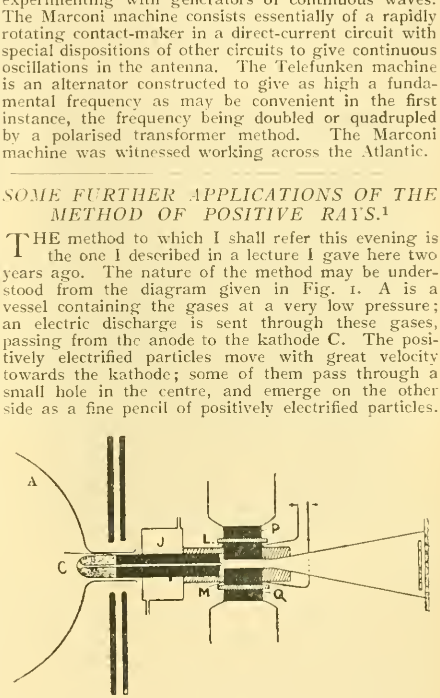

Fig. 1.

This pencil is acted on by electric forces when it passes between the plates L and M, which are connected with the terminals of a battery of storage cells, and by a magnetic force when it passes between P and Q, which are the poles of an electromagnet. In the pencil before it passed under the influence of these forces there might be many kinds of atoms or molecules, some heavy, others light, some moving quickly, others comparatively slowly, but these would all be mixed up together. When they are acted on by the electric and magnetic forces, however, they get sorted out, and instead of travelling along the

[1] Discourse delivered at the Royal Institution on Friday, January 17, by Sir J. J. Thomson, O.M., F.R.S.

same path they branch off into different directions. No two particles will travel along the same path unless they have the same mass as well as the same velocity; so that if we know the path of the particle we can determine both its mass and its velocity. In chemical analyses we are concerned more with the mass than with the velocity, and we naturally ask what is the connection between the paths of particles which have the same mass but move with different velocities. The answer is that all such paths lie on the surface of a cone, and that each kind of particle has its own cone; there is one cone for hydrogen, another for oxygen, and so on. Thus one cone is sacred to hydrogen, and if it exists there must be hydrogen in the vessel; so that if we can detect the different cones produced from the original pencil, we know at once the gases that are in the tube. Now, there are several ways of identifying these cones, but I shall only refer to the one I have used in the experiments I wish to bring before you this evening. These moving electrified particles, when they strike against a photographic plate, make an impression on the plate, and a record of the place where they struck

FIG. 2.

the plate can be obtained. Thus, when a plate is placed in the way of the particles streaming along these cones, the sections of these cones by the plate (parabolas) are recorded on the photograph, hence we can identify these cones by the parabolic curves recorded on the photograph, and these parabolas will tell us what gases are in the vessel.

The first application of the method which I shall bring before you this evening is to detect the rare gases in the atmosphere. Sir James Dewar kindly supplied me with two samples of gases obtained from the residues of liquid air; the samples had been treated so that one might be expected to contain the heavier gases, the other the lighter ones. I will take the heavier gases first. The photograph of these is shown in Fig. 2. When the plate is measured up it shows a faint line corresponding to the atomic weight 128 (xenon), a very strong line corresponding to the atomic weight 82 (krypton), a strong argon line 40 (argon), and the neon line 20. There are no lines unaccounted for, and hence we may conclude that in the atmosphere there are no unknown gases of large atomic weight occurring in quantities comparable with those of xenon or krypton. This result gives an example of the convenience of the method, for a single photograph of the positive rays reveals at a glance the gases in the tube. I now turn to the photograph of the lighter constituents shown in Fig. 3; here we find the lines of helium, of neon (very strong), of argon, and, in addition, there is a line corresponding to an atomic weight 22, which cannot be identified with the line due to any known gas. I thought at first that this line, since its atomic weight is one-half that of CO_2, must be due to a carbonic acid molecule with a double charge of electricity, and on some of the plates a faint line at 44 could be detected. On passing the gas slowly through tubes immersed in liquid air the line at 44 completely disappeared, while the brightness of the one at 22 was not affected.

The origin of this line presents many points of interest; there are no known gaseous compounds of any of the recognised elements which have this molecular weight. Again, if we accept Mendeléef's periodic law, there is no room for a new element

FIG. 3.

with this atomic weight. The fact that this line is bright in the sample when the neon line is extraordinarily bright, and invisible in the other when the neon is comparatively feeble, suggests that it may possibly be a compound of neon and hydrogen, NeH_2, though no direct evidence of the combination of these inert gases has hitherto been found. I have two photographs of the discharge through helium in which there is a strong line, 6, which could be explained by the compound HeH_2, but, as I have never again been able to get these lines, I do not wish to lay much stress on this point. There is, however, the possibility that we may be interpreting Mendeléef's law too rigidly, and that in the neighbourhood of the atomic weight of neon there may be a group of two or more elements with similar properties, just as in another part of the table we have the group iron, nickel, and cobalt. From the relative intensities of the 22 line and the neon line we may conclude that the quantity of the gas giving the 22 line is only a small fraction of the quantity of neon.

Let me direct your attention again to the photograph of the heavier gases in the atmosphere. You will notice that the parabolas corresponding to many of the elements start from points which are all in the same vertical line; this indicates that the atoms or molecules which form these parabolas all carry the same charge. Several of these lines, however, do not follow this rule; you will notice, for example, that the neon line has a prolongation which comes nearer than the normal line to the vertical line drawn through the undeflected spot. Measurement of the photograph shows that the neon line begins at a distance from this vertical line which is only half the normal distance; this shows that some of the neon atoms in the positive rings possess two charges of electricity; the majority of them, however, only possess one. If you examine the argon line you will find that it comes even nearer to the vertical than the neon line; in fact, it begins at a distance from the vertical only one-third of the normal distance; this proves that the argon atom can have as many as three charges of electricity. If now you examine the krypton line you will find that it comes nearer to the vertical line than even the argon; its least distance is one-fourth of the normal distance, showing that the krypton atom may have as many as four charges. The mercury line comes so close to the vertical line that it is only on large photographs that it can be seen that there is in reality an interval; this interval is only one-eighth of the normal interval, showing that mercury may acquire eight positive charges, *i.e.* that it may lose eight corpuscles. The mercury atom when it is on this line must have only the normal charge, *i.e.* it must have regained all but one of the corpuscles it previously lost; if it had retained two positive charges it would have been on the line corresponding to the atomic weight 200/2 or 100; if it had retained 3, or 4, 5, 6, 7, 8 on the lines corresponding to the atomic weights, 200/3, 200/4, 200/5, 200/6, 200/7, 200/8 respectively. All these except the last have been detected on the plate. The lines corresponding to the multiple charges on krypton, argon, and neon have also been detected. It appears, then, that in a vacuum tube a mercury atom, for example, may be ionised in two ways; in the one way the atom loses one corpuscle, in the other it loses eight.

I would suggest that these two types of ionisation may result from the two different types of collision which the atom must experience. The first type is collision with a corpuscle; since the corpuscle is an exceedingly small body moving with a very great velocity, it can pass freely through the atom, and the collision it makes with the atom is really a collision with a corpuscle inside the atom; this may result in the corpuscle it strikes acquiring such a great velocity that it is able to escape from the atom; this type of collision will result in the detachment of a single corpuscle. The second type of collision is when the atom collides with another atom and not with another corpuscle; the result of this collision may be that the atom suffers a sudden change in its velocity. This change is not at first shared by the corpuscles, so that these just after the collision may have a very considerable velocity relative to the atom. If there are several corpuscles which are comparatively loosely attached to the atom, these may all be detached from it and leave it with a positive charge corresponding to the number shaken out. It is this type of collision which we regard as giving the multiply-charged ions, and we see that the magnitude of the charge is a measure of the number of corpuscles in an atom which are readily detachable from it. We have seen that the greater the atomic weight the greater the charge it can acquire, the maximum charge being roughly proportioned to the square root of the atomic weight, hence the heavy elements have a larger number of detachable corpuscles than the lighter ones.

Another application of the method I should like to bring before you is the use of it for the discovery and investigation of a new substance. I have in previous lectures said that sometimes there appeared on the plates a line corresponding to a particle with an atomic weight 3; this must either be a new element or a polymeric modification of hydrogen, represented by H_3. The other possibility that it is a carbon atom with four charges is put out of court by the fact that it frequently occurs when the carbon line is exceedingly faint, and when there is not a trace of a carbon atom with even two charges, though the doubly-charged carbon atom occurs readily under certain conditions. In addition to this, the carbon atom parabola never approaches the vertical near enough to allow of its having four charges. I thought the study of the substance producing this line would be of interest, and I have for some time been working at it, and although the research is by no means completed, I have obtained some results which I should like to bring before you.

At first I was greatly hindered by not knowing the conditions under which the line occurred; although it appeared from time to time on the plates, its appearance was always fortuitous and sometimes for weeks together the plates would not show a trace of the line. The line sometimes appeared, but why it did so was a mystery, and I could not get it when I wanted it. I began an investigation, which proved long and tedious, to find the conditions under which the line appeared. I tried filling the discharge-vessel with all the gases and vapours described in the books on chemistry without success. At last I tried bombarding various substances with kathode rays. Under this treatment the substances give off considerable quantities of gas the greater part of which is hydrogen, carbonic acid, or carbon monoxide. When I came to analyse by the positive rays the gases given off in this way, I found that with a large number of substances these gases contained the substances giving the three lines, so that I was now in a position to get this line whenever I wanted it, and investigate the properties of the gas to which it owes its origin. The question of the gases absorbed and given off by solids is an extremely interesting one, and a considerable number of investigations have been made on it. In all these, so far as I know, the method has been to heat the solid to a high temperature, and then measure and analyse the very considerable amount of gas which is driven off by the heating. So far as I know, no experiments have been made in which the gases were driven off by bombardment with kathode rays. This treatment, however, will cause the emission of gas even when ordinary heating fails to do so.

Belloc, who has recently published[2] some interesting experiments on this subject, after spending about six months in a fruitless attempt to get a piece of iron in a state in which it would no longer give off gas when heated, came to the conclusion that, for practical purposes, a piece of iron must be regarded as an inexhaustible reservoir of gas. There are some interesting features about the emission of gas from a heated solid. If the body is kept for a long time in a vacuum at a high temperature, the emission of gas becomes too small to be detected; if after this treatment the temperature is raised considerably, there will be a further copious emission of gas, which again diminishes as the heating continues. After it has fallen to zero, all that is necessary is to raise the temperature again and you will get a fresh supply of gas; and so far as my experience goes, after you

[2] *Ann. de Chimie et de Physique* [8], xviii., p. 569.

have got all the gas you can out of the solid by heating it, you have only to expose it to kathode rays to get a fresh outburst. This effect of increased temperature in renewing the stream of gas from the solid seems to me to be too large to be accounted for merely by an increase in the rate of diffusion of the absorbed gas from the interior to the surface; it seems to be more analogous to the case of the emission of the water of crystallisation from some salts. There are some salts, for example, copper sulphate, which when heated lose their water of crystallisation in stages; thus, if the temperature is raised to a certain value, some of the water of crystallisation comes off, but the rest remains fixed, and you may keep the salt at this temperature for ever without getting rid of all the water of crystallisation; on raising the temperature, however, fresh water of crystallisation is given off. Something of this kind seems to take place in the case of gases absorbed in metals, and there seem to be indications that there is some kind of chemical combination between the gas and the metal. This absorbed gas may influence the behaviour of the substance. For example, an ordinary carbon filament gives off, when raised to a white heat, large quantities

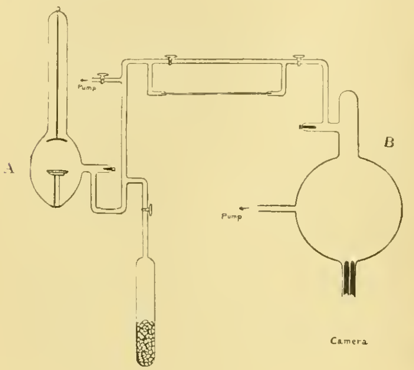

FIG. 4.

of negatively electrified corpuscles; but Pring and Parker[3] have shown that when great precautions are taken to get rid of the absorbed gas, the emission of these corpuscles falls to less than one-millionth of their previous value. It is in the gases given off by certain metals when they are bombarded by kathode rays that I have found an unfailing source of the substance, which I shall denote by X_3, giving the line corresponding to the atomic weight 3. The arrangement I have used for investigating the presence of this gas is shown in Fig. 4. A is a vessel communicating with the bulb B in which the positive rays are produced by two tubes, one of which is a very fine capillary tube, while the other one is five or six millimetres in diameter; taps are inserted so that one or both of these vessels can be closed, and the vessels A and B isolated from each other. A is provided with a curved kathode such as are used for Röntgen ray focus tubes, and the kathode rays focus on the platform on which the substance to be bombarded is placed. (It is not absolutely necessary to focus the kathode rays in this way, but it makes the supply of the gas X_3 more copious.) After the metal or other solid to be examined has been placed on the platform, the taps between A and B being turned so as to cut off the connection between them, A is exhausted until the vacuum is low enough to give the kathode rays; the discharge is then sent through A, and the kathode rays bombard the solid. The result of this is that in a few seconds so much gas, mainly CO_2 and hydrogen, is driven out of it that the pressure gets too high for the kathode rays to be formed, and unless some precautions to lower the pressure were taken the bombardment would stop. To avoid this, a tube containing charcoal cooled by liquid air is connected with A, and this absorbs the CO_2 and enough of the hydrogen to keep the vacuum in the kathode ray state. To see what new gases are given off in consequence of the bombardment, a photograph is taken while the connection between A and B is cut off. After this is finished, and when the bombardment has gone on for about four hours, the tap is turned and a little of the gas from A is allowed to go into B; another photograph is taken, and those lines in the second photograph which are not in the first represent those gases which are liberated by the bombardment, and have escaped being absorbed by the charcoal. I have here a slide (Fig. 5) representing the result of bombarding nickel. There are two photographs, one

α FIG. 5. β

(α) before turning the tap, and the other (β) after; in the second you see the 3 line very distinctly, while it is absent from the first, showing that the gas giving the 3 line has been liberated by the bombardment. I have got similar results to these when, instead of nickel, iron, copper, lead, and zinc have been bombarded. I have tried two specimens of meteorites kindly lent to me from the Mineralogical Museum, Cambridge, and found there the 3 line. Nearly every substance I have tried gives, the first time it is bombarded, the helium line as well as this line due to X_3; if, however, the same substance is bombarded a second time, the helium line is in general absent (occasionally it is still to be detected, though exceedingly faint); and on the third bombardment is invisible in all the substances I have tried except monazite sand, where it is given off in exceedingly large quantities so long as the bombardment continues. It is remarkable that monazite sand, which contains so many elements, gives no trace of the 3 line when bombarded.

I have also obtained the X_3 line and also the helium line when the tube A was replaced by one containing a Wehnelt kathode; with this the current of kathode rays through the tube was much larger than with the other kathode, though the velocity of the rays was

[3] *Phil. Mag.*, xxiii., p. 192.

smaller. The Wehnelt kathode gives the line without placing pieces of metal in the tube, so that in this case nothing is bombarded by the kathode rays but the glass walls of the tube; the strip of metal forming the kathode is, however, bombarded by the positive rays.

The 3 line when present at all continues even though the bombardment is very prolonged. In some cases the bombardment has been prolonged for twenty hours, and at the end of that time the line seemed almost as bright as at the beginning; indeed, I could not feel certain that there was any difference. This might lead one to suspect that X_3 was manufactured from the lead or other metal by the bombardment rather than stored up in it, and this view might be regarded as receiving some support from the fact that very little of the X_3 is liberated by heating. The following experiment is an illustration of this. I took a piece of lead, and instead of bombarding it with kathode rays I placed it in a quartz tube connected with vessel A, and heated the tube to a bright red-heat for several hours. Large quantities of CO, and hydrogen were driven off by this process; this was absorbed by charcoal, and the residual gases, which had accumulated in A, were admitted into the vessel B; the X_3 line and helium line could just be detected, and that was all. I then gave the lead a second heating, raising this time the temperature until the quartz was on the point of softening. The lead was boiling vigorously; the heating was kept up for about three hours. In this time about three-quarters of the lead had boiled away. I then let the gases which had been given off at the second heating into the vessel B, and took another photograph; no trace of the line due to X_3 or helium could be detected. The fraction of the lead which had not been boiled away was now placed in A and bombarded by kathode rays. It now gave the 3 line quite distinctly; the helium line was visible, but faint. By the bombardment with the kathode rays the lead was only just melted, so that the average temperature was much less than when it was heated in the quartz tube. This rather suggests that the X_3 might be due to a kind of dissociation of the metal by the kathode rays, and not to a liberation of a store of that substance. Another experiment shows, however, that for lead, at any rate, this view is not tenable. I took some lead which had just been deposited from a solution of lead acetate by putting a piece of zinc into the solution, and forming the well-known lead-tree. When I bombarded this freshly precipitated lead, I could get no trace of the X_3 line; the helium line, too, was absent. I then tried another experiment. I took a piece of lead and divided it into two parts. The first of these I bombarded by the kathode rays: it gave the X_3 line quite distinctly. The other part I dissolved in boiling nitric acid, getting lead nitrate. The nitrate was heated and converted into oxide, and this was bombarded by the kathode rays: it did not give the X_3 line, showing that the X_3 is not produced by the bombardment, but is something stored up in the lead, which can be detached from it when the lead is dissolved. I have tried several samples of lead; the one which gave the X_3 line most distinctly was a piece of lead from the roof of Trinity College Chapel, several hundred years old. A sample of Kahlbaum's chemically pure lead, which must, I suppose, at no distant date have been subjected to severe ordeals by fire and water, showed the line quite distinctly, though not so well as the older lead. I have tried similar experiments with iron, and found that iron which gave the 3 line very distinctly ceased to do so after it had been dissolved in acid.

As the most obvious explanation of X_3 is that it is H_3, bearing the same relation to hydrogen that ozone does to oxygen, and produced in some way from the hydrogen dissolved in the metal, I tried if I could produce it by charging metals with large quantities of hydrogen, and then seeing if the hydrogen coming from the metal gave any traces of H_3. Thus, for example, I tested the hydrogen given off from hot palladium, but found no trace of X_3. I then charged nickel at a temperature of about 355° C. with hydrogen in the way recommended by Sabatier, but found no increase in the brightness of the X_3 over nickel that had not been deliberately exposed to hydrogen. I tried if the brightness of the line would be increased by adding hydrogen to the bulb A, in which the bombardment took place, but found no effect. I also tried adding oxygen to this bulb, thinking that if it was H_3 it would combine with the oxygen, and thus be eliminated, but no great diminution in the intensity was produced by this treatment. The gas seems quite stable, at least it can be kept for several days without suffering any diminution that can be detected; indeed, when once it has got into a bulb, there is considerable difficulty in getting the bulb free from it. It must be remembered, too, that by the method by which it is produced the gas is subjected all the time to electric discharges which would break it up unless it possesses very great stability. Thus if X_3 is a polymeric modification of hydrogen, it must possess the following properties:—

(1) It must be very stable.

(2) it must resist the action of oxygen.

(3) It must not be decomposed by long-continued exposure to the electric discharge.

These are properties which *a priori* we should scarcely have expected an allotropic modification of hydrogen to possess.

Mendeléef predicted the existence of an element with an atomic weight 3. According to him this element should be intensely electro-negative and possess the properties of fluorine to an exaggerated extent. The gas X_3 can, however, be kept in glass vessels, which we should not expect to be possible if it possessed more than fluorine's power of combining with glass. I prefer to defer expressing any opinion as to the actual nature of the gas until I have had the opportunity of making further experiments upon it. It is only about two months ago that I found how to get the gas with any certainty, and, as the method involves long bombardments, each experiment takes a considerable time. This has prevented me from making several experiments which suggest themselves, and which ought to be made before coming to a final decision. I thought, however, that the investigation, though incomplete, might not be unsuitable for a Friday evening discourse, as the gas, whatever its nature, is certainly one of considerable interest, and its detection illustrates the delicacy of this new method.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Sudbury-Hardyman prize offered for an original dissertation by a graduate member of Emmanuel College under the standing of M.A. has been increased to 40*l*., and divided between G. E. K. Braunholtz, formerly scholar and research student, and R. D. Vernon, research student. Mr. Braunholtz's dissertation was "The Nomina of Italy, peculiar to Gallia Transpadana," and Mr. Vernon's "The Geology and Palæontology of the Warwickshire Coalfield."

THE electors to the Michael Foster research studentship in physiology give notice that there will be an election to the studentship in the year 1913. Candidates are required to send in their applications to the professor of physiology before the end of June, with a statement of the course of research which they propose to undertake.

The Board of Agricultural Studies, in consultation with the president of the Royal Agricultural Society, has nominated C. R. Fay to be the Gilbey lecturer on the history and economics of agriculture.

The General Board of Studies is authorised to appoint a University lecturer in agricultural physiology for a further period of five years from midsummer, 1913. The lecturer will receive an annual stipend of 200*l*., payable out of the agricultural education fund.

Leeds.—Mr. W. A. Millard, formerly assistant lecturer in botany, has been appointed lecturer in agricultural botany.

A series of week-end lectures on modern Germany will commence on May 31, and will be continued on June 6, 7, and 14. Among the lecturers will be Dr. Hiby, managing director of the Otto Coke Oven Co., on industrial and social conditions; Prof. Smithells, on the story of German science; and Mr. J. L. Paton, on modern German education.

Manchester.—The council has made a number of appointments and rearrangements in the department of chemistry consequent on the resignation of Prof. W. H. Perkin on his acceptance of the chair of chemistry at Oxford. Dr. A. Lapworth, F.R.S., has been appointed professor of organic chemistry and Dr. Charles Weizmann has been appointed reader in biochemistry and lecturer in colouring matters. Dr. E. C. Edgar and Dr. F. B. Burt have been made senior lecturers in chemistry. Prof. H. B. Dixon has been reappointed director of the chemical laboratories, to supervise the department as a whole.

Mr. Edward Sandeman has been appointed associate professor of engineering in the University. He will lecture on water supply and irrigation, and will be responsible for the studies of all students specialising in this branch of engineering.

Oxford.—The fourth Halley lecture was delivered in the schools on May 22 by Dr. Louis A. Bauer, director of the department of research in terrestrial magnetism in the Carnegie Institution of Washington, U.S.A. The subject of the lecture was "The Earth's Magnetism." Dr. Bauer paid a tribute to Halley as one of the greatest among early investigators of the variations of the compass. He described the two years' cruise undertaken by Halley in the years 1698–1700, at the cost of William III., for the purpose of making magnetic observations. The expedition which left New York four years ago in the *Carnegie* had followed the same track, but found a great alteration in the magnetic conditions. The magnetic poles were gradually shifting. Though Halley's theory of terrestrial magnetism was not strictly correct, it seems to have been the first definite recognition of the complexity of the problem. This would not be completely solved until the physicists were able to answer the question, What is magnetism?

A valuable lecture on wireless telegraphy has been given before the Ashmolean Society by Mr. W. G. Gill, of the Officers Training Corps and fellow of Merton College.

Entries for the Final Honour School in Natural Science number eighty-nine, distributed as follows:—Physics, ten; chemistry, thirty-two; zoology, two; physiology, eighteen; botany, five; geology, ten; engineering science, twelve.

On May 27 Congregation passed the preambles of two statutes relating to the holders of professorships at present tenable for life, and to which no canonry is annexed. The statutes provide that every such professor shall vacate office within one year of attaining the age of seventy years, and that a scheme of pensions shall be established to apply to professors vacating office under the above conditions. If these statutes are finally adopted in their present form, they will not apply to any of the present holders of professorships, nor, in all probability, to any of their successors for some years to come. It has, however, been widely felt that some steps should now be taken to provide for the eventual establishment of a satisfactory system of retirement and pension, nothing of the kind being at present in existence.

The University of Glasgow has received, under the will of Miss Jeanie Pollock, of Glasgow, the sum of 10,000*l*. for providing a materia medica research lectureship.

Dr. George Barger has been appointed by the Senate of the University of London to the University chair of chemistry tenable at the Royal Holloway College, with the status of appointed teacher.

Dr. S. B. Schryver, biochemist at the Research Institute of the Cancer Hospital, Brompton Road, S.W., has been appointed assistant professor of biochemistry at the Imperial College of Science and Technology.

The board of regents of the University of Nebraska recently voted a general increase in the salaries of deans and professors in the University. *Science* states that the necessary 7000*l*. was obtained from the additional maintenance grant voted by the last legislature.

Dr. L. F. Guttmann, formerly of London University and the College of the City of New York, and for the last four years assistant professor of physical and industrial chemistry at Queen's University, Kingston, Canada, has been appointed associate professor of chemical engineering in this University.

It is now announced that the executors of the late Sir J. Wernher, Bart., have completed the allocation of the 100,000*l*. bequeathed to them to be devoted to charitable and educational purposes. 35,000*l*. has been allotted to charitable and educational purposes in South Africa, and the balance of 65,000*l*. has been distributed over nearly 150 different institutions in this country. Among the grants for scientific and educational purposes may be mentioned: to the Institute of Mining and Metallurgy, 5000*l*.; the Imperial Service College, Windsor (to found a scholarship for Bedfordshire), 2500*l*.; the London School of Tropical Medicine, 1500*l*.; and lesser amounts to the London School of Economics, the Bedford College for Women, and the Working Men's College.

SOCIETIES AND ACADEMIES.

London.

Geological Society, May 7.—Dr. Aubrey Strahan, president, and afterwards Mr. W. Whitaker, in the chair.—M. **Odling**: The Bathonian rocks of the Oxford district. The lithology, palæontology, and stratigraphy of the Bathonian rocks north of Oxford are described, from the evidence afforded by numerous quarries and well-borings and by the Ardley Cutting. The general sequence is given. After a general account of the series, the points of interest in the sections and their relations are described; and it is pointed out that, although no definite zones can be formulated, the different horizons are recognisable by their assemblage of fossils. The chemical and microscopic structures of the rocks are dealt with, and the conditions of deposition and stratigraphical relationship of the different members of the series discussed. Some structures from the Chipping-Norton Limestone are described, and the reasons given for considering them to be annelid-tubes. A list of fossils is appended.—Dr. J. A. **Thomson**: The petrology of the Kalgoorlie Goldfield (Western Australia). The district comprises an area about four miles long by one mile in breadth. Towards the south the auriferous lodes are rich (The Golden Mile), but in the north they are less productive. Most of the junctions are faulted. In "The Golden Mile" the central feature is a broad dyke of quartz-dolerite, forming a prominent ridge flanked by amphibolites and greenstones. The quartz-dolerite is cut by dykes of albite-porphyry. Gold is found in shear-zones, impregnated with sulphides and tellurides, and is most abundant in the lodes in the quartz-dolerite. The sequence of the rocks of Kalgoorlie is discussed. The greenstones, fine amphibolites, and calc-schists are regarded as the old "country-rocks," into which the others are intrusive. The quartz-dolerites, hornblende-dolerites, and pyroxenites are closely related one to the other. Probably the peridotite group is the early basic facies of the quartz-dolerite series, and the porphyries and porphyrites are regarded as being derived from the same magma. The characteristic of this goldfield is the prevalence of albitisation in the auriferous districts. A consideration of the rock-facies developed from the magma suggests that there is in Kalgoorlie an instance of the production of auriferous lodes by rocks belonging to the same class as the pillow-lavas and their diabases and soda-granite-porphyries.

PARIS.

Academy of Sciences, May 19.—M. F. Guyon in the chair.—A. **Haller** and Edouard **Bauer**: Monomethylcamphoroxime, methylcampholenic nitrile, and methylcampholenic acid. By the action of sodium amide and methyl iodide upon camphor, a mixture of monomethylcamphor and dimethylcamphor is obtained. These can be separated by treatment with Crismer's salt (hydroxylamine chlorozincate); dimethylcamphor remains unchanged, and can be separated from monomethylcamphoroxime by fractional distillation.—M. de **Forcrand**: The condition of water in hydrated salts. The determination of the heat of solution of hydrated salts is suggested as the best means of attacking the problem of the condition of the attached water molecules.—M. André **Blondel** was elected a member of the section of free academicians in the place of the late Louis Cailletet.—H. **Godard**: Observations of the comet 1913*a* (Schaumasse) made with the 38-cm. equatorial at the Observatory of Bordeaux. Two positions are given for May 16. The comet appeared as a diffuse nebulosity, without nucleus, of 10·5 magnitude.—J. **Guillaume**: Observations of the Schaumasse comet (1913*a*) made with the equatorial of the Observatory of Lyons. Two positions are given for May 10 and one for May 11. The comet is described as circular, bluish, condensed at the centre; magnitude about 10·5.—Rodolphe **Soreau**: A new approximate formula for the length of the ellipse.—Paul **Lévy**: The integration of functional partial differential equations.—M. **Moulin**: The law of deformation of the flat spiral spring of chronometers.—M. de **Sparre**: Hammering of the water in pipes formed of sections of different diameter.—C. **Tissot**: The influence of electrical oscillations on the conductivity of certain fused metallic salts. A layer of certain fused salts (lead and thallium chlorides, cadmium bromide, silver nitrate, chloride, and bromide) in contact with two metallic plates as electrodes becomes conducting when the E.M.F. exceeds a certain limiting value. If the system is now submitted to electrical oscillations of sufficient intensity, the conductivity immediately disappears.—Carl **Benedicks**: The deduction of Planck's law of distribution of energy by the hypothesis of agglomeration. Planck's law can be deduced without the use of the *quanta* hypothesis.—J. **Chaudier**: The variations of magnetic rotatory power in changes of state.—André **Léauté**: The precautions to be taken in the use of resonance in tests of electric cables intended for use with high voltages.—R. V. **Picou**: Internally excited dynamos.—Camille **Matignon**: The law of volatility in chemical reactions. The law of Berthollet is given in a generalised form. Any system of solids or non-volatile liquids susceptible of giving rise by a new grouping of atoms to a system containing volatile bodies ought to enter into reaction at a suitable temperature. Thus it has been shown that at a very high temperature aluminium will react with magnesia, the magnesium formed being gaseous. The reduction of barium oxide by silicon is another example.—G. **Arrivaut**: Study of the system manganese-silver. Manganese and silver are capable of forming the combination $MnAg_2$; experimental evidence on this is given dealing with the melting-point curves, microscopical structure, electromotive forces, and chemical behaviour of various alloys of the two metals. This conclusion is opposed to that previously arrived at by G. Hindrichs.—Marcel **Gompel** and Victor **Henri**: The quantitative study of the absorption of the ultra-violet rays by the alkaloids of the atropine group. Absorption data are given for atropine, apoatropine, and cocaine.—MM. **Taffanel** and Le **Floch**: The combustion of gaseous mixtures. An examination of the causes of the lag in the inflammation of combustible mixtures of methane. Moisture was found to be without effect in reducing this lag.—J. **Aloy** and Ch. **Rabaut**: Benzoyl cyanhydrins of ketones, amides, and the alcohol acids from which they are derived.—E. E. **Blaise**: The characterisation of the chloro-ketones. The use of the semicarbazones was found to be advantageous for the identification of the chloro-ketones.—Alfred **Guillemard**: Nature of the optimum osmotic pressure in biological processes.—Jean **Daniel**: The relations existing between the age of the dicotyledons and the number of successive layers of their secondary woods. Under certain conditions of growth the number of concentric layers of secondary wood cannot be distinguished, and the number of years of growth cannot be determined by this means.—C. J. **Pitard**: The vegetation of Chouia, Morocco.—M. **Hirtz**: Intensive galvanotherapy with feeble current density.—Louis **Roule**: Contribution to the study of the biology of the salmon.—L. **Bordas**: A case of lateral budding in *Lumbricus herculeus*.—J. **Bounhiol**: The reproduction of the Algerian sardine.—Albert **Berthelot**: Researches on the intestinal flora. The pathogenic action of a microbial association of *Proteus vulgaris* and *Bacillus aminophilus*. A study of the symbiosis of these two organisms *in vitro* leads to the conclusion that the *B. aminophilus* prevented to some extent the growth of Proteus, but experiments *in vivo* with white rats at once showed that the opposite was the case. Proteus alone, even in large doses, is without apparent influence on rats, but in association with the bacillus above-mentioned, enteritis is rapidly produced.—G. **Béchamp**: Concerning *microzyma cretae*. Remarks on a recent communication by Raphaël Dubois.—J. **Lesage**: Epizootic myocarditis of the sheep.—C. **Gerber**: Comparison of the hydrolysing diastases of the latex of *Maclura aurantiaca* with those of *Ficus carica* and of *Broussonetia papyrifera*.—J. **Vallot**: The value and variation of the temperature of the lower portion of the glacier of Mont Blanc.

DYNAMICS OF GOLF.

The Soul of Golf. By P. A. Vaile. Pp. xiii+356. (London: Macmillan and Co., Ltd., 1912.) Price 6s. net.

THIS is a breezy, well-written book, full of valuable hints to the ambitious golfer. Much of the instruction takes the form of attack upon the writings of other exponents, and this makes lively reading. With a great deal of the criticism most golfers who have tried to formulate the principles of the game will agree. But it is not human to be perfect, and Mr. Vaile does not escape falling into pitfalls himself, especially when dealing with the dynamical aspect of things. To the November number of *The Fortnightly Review* he contributed an article on the dynamics of golf, in which he seems to regard himself as a supreme authority. In one respect this article is an improvement on the book, for he accepts in its simplicity Newton's explanation of the swerve of the spinning ball advancing in air, and in one paragraph gives quite a good account of this phenomenon, very much as Tait did years ago. Unfortunately he obscures the explanation in a later paragraph when he says that it is "the continual friction on the lower portion of the ball which gradually forces it up."

Mr. Vaile is merciless in his exposure of looseness of language. Yet in his discussion of the value of furrows cut on the face of iron clubs (a method, by the way, first adopted by Tait), he writes that "marking is frequently done by great deep lines, and, particularly in the mashie, nearly always by lines which run from heel to toe. Now in the great majority of mashie shots, when one is putting on cut one requires lines running in an exactly opposite direction"—that is, if English means anything, from toe to heel! Mr. Vaile, of course, does not mean that, any more than Sir J. J. Thomson means that the golf-ball is spinning like a sleeping top when he says that slicing and pulling are due to rotation about a vertical axis. Sir J. J. Thomson does not say that this is the only spin that exists; but it is the component of spin about the vertical axis which has to do with the phenomena of slicing and pulling. When the ball is rotating about an axis not truly horizontal, there must be a component about a vertical axis. This component, regarded from above, will be either right-handed or left-handed, according to circumstances, producing respectively slicing or pulling. This, obviously, is the meaning to be attached to Sir J. J. Thomson's words. In his article Mr. Vaile says: "Prof. Thomson must now realise that if the axis of spin was the same in each ball"—that is, each sliced or pulled ball—"their conduct on landing would be similar." Can Mr. Vaile not imagine that though the axis of spin may be the same, the direction of rotation about the axis may be either the one way or the other?

Mr. Vaile is to be congratulated upon the clear way in which he describes the conditions under which the so-called "push-shot" with cleek or iron is obtained. But the main feature of this stroke was well understood on the golf-links of St. Andrews and Musselburgh long before the days of Varden or Vaile. The divots of turf which were removed by the club after it hit the ball proved incontestably that this particular stroke of club on ball occurred during the descent of the club. In his article on long driving in *The Badminton Magazine* of March, 1896, the late Prof. Tait shows clearly how underspin is produced. In his figures on p. 370, Tait represents the velocity of the clubhead at impact by the line AB, and remarks that "AB may be made to take any direction we please—*i.e.* the clubhead may be represented as moving in any direction whatever; but it *is quite sufficient for our purpose*[1] to treat it as moving horizontally." Mr. Vaile regards this sentence as meaning that Tait considered every well-driven ball as being projected by a horizontal blow; for he deliberately says that a "fundamental error" of the late Prof. Tait consisted "in regarding the blow of a golf-club as being a force directed in a line parallel with the horizon." This is really very bad. Yet there is a worse case of unpardonable carelessness in Mr. Vaile's reading of the *Badminton* article.

In a footnote on p. 380 of this article Tait, with the honesty of the real investigator, points out the difficulties under which his "laboratory experiments" on the *velocity of projection* of a golf-ball were made, and Mr. Vaile quotes this footnote as if it referred to a totally different experiment described on p. 381. The latter experiment, with one end of a long, untwisted tape "tied to the ball and the other to the ground," was clearly not made in the laboratory at all. The ball was driven into a stiff clay face, not into the 10-inch disc of clay spoken of in the footnote; and the difficulties of aim did not enter into the experiment with the tape. Tait always found the tape twisted in such a way as to show underspin. Mr. Vaile will not believe it. He should therefore try the experiment himself instead of criticising what he has not taken the trouble to understand aright. By this experiment Tait proved to the simplest intellect that underspin was invariably present in

[1] The italics are ours.

a well-struck ball. But before the experiment was thought of Tait had proved to the mind capable of understanding the dynamics of golf that it is not possible to obtain the *distance* of flight and the *time* of flight by balls projected with *permissible* velocities at the *small angles of elevation* which characterise well-driven balls, unless an uplifting force comes into play.

Mr. Vaile is neither fair to Tait nor true to fact. In his chapter x. he says, quite untruly—for the dates can easily be given [2]—that Tait did not take underspin into consideration until after a great drive by which his son Freddie proved that the father's calculations were wrong. He then proceeds to point out what he thinks are errors in Tait's article in *The Badminton Magazine*, which has been already referred to. For example, Tait's remark that "the existence of rotation is manifested at once by the strange effects it produces on the curvature of the path" is branded "as incorrect from a scientific point of view," and "also badly stated." What follows on p. 225 of "The Soul of Golf" shows that our author has not grasped the scientific significance of the problem. He says that it is well known to all golfers that the spin begins to work as the velocity of the ball decreases, and then makes the astounding statement that "it is incorrect to refer to the strange effects it (rotation) produces on the curvature of the path, for it is the rotation itself which produces the curvature."

If this means anything other than Tait meant, it means that the parabola described by a projectile *in vacuo* has no curvature, nor has the path described in air by a ball devoid of rotation. Gravity apparently is not in it! Mr. Vaile fails to see that Tait is comparing the path of a rotating golf-ball with the path it would have had if no rotation had existed. The real dynamic truth is that the underspin begins to work from the very beginning of the drive. The curvature of the path is influenced *from the start*, as witness the upward concavity of the wind-cheater. Not only so, but the underspin exerts its greatest influence at the beginning of the drive when the spin and the velocity are both at their greatest. When Mr. Vaile asserts that it is in the second part of the trajectory that the back-spin is exerting its greatest influence, he is confusing what the eye seems to see with what has been really taking place. The ordinary golfer, indeed, is quite ignorant of what any particular path would have been had there been no spin; also he is badly placed to see the real form of the path, and the initial velocity is too great for him to follow the early details of the flight. Tait's calculated curves bring out the form of the wind-cheater beautifully (see NATURE, June 29, 1893). These calculations are based on the combined effect of gravity and the upward force due to coexistence of translation and spin. Both these motions are present from the beginning, and must dynamically assert themselves from the start. To speak of pace, when there is enough of it, as beating spin, is nonsense. Spin alone has no lifting or swerving power. It must coexist with translational velocity; and the lifting power increases with the amounts of both.[3] The particular instant at which the eye recognises the accumulated effect of the upward lift proves nothing as to the manner in which this lifting force has gone through its successive values. The idea that the spin asserts itself only after the ball has travelled a considerable part of the trajectory is dynamically grotesque and hopelessly erroneous.

The flight of the golf-ball is not a problem which can be solved by intuition; and the man who has not mastered Tait's papers on the path of a rotating spherical projectile is not in a position to criticise Tait's conclusions. If Mr. Vaile will take the trouble to turn up the first of these papers he will find pictured a theoretical curve the gradually increasing curvature of which as the linear speed of the projectile falls off will reveal to him all the essential characteristics of the path of the sliced ball. He may then possibly understand the truth which Tait was wont to impress upon his students year by year, that the direct evidence of our senses is frequently misleading unless controlled and corrected by reason.

There are several other statements in Mr. Vaile's account of the flight of the golf-ball which are scientifically unsound. Thus, on p. 244 he says that the club

"is nearly always moving either upwards or downwards in a curve at the moment it strikes the ball, so that it stands to reason, especially when the club-face is travelling upwards, which is what it does in the great majority of cases, that the blow is never delivered horizontally, but is always struck more or less upward through the ball's centre of mass."

This is deliciously loose, for it means grammatically that when the club-face is travelling either upwards or downwards it strikes the ball upward through the centre of mass. Of course, Mr. Vaile does not mean to say so. What he seems to mean to assert is that in the *great majority of cases* the impulse is through the centre of mass of the ball. If that were so, there could be no underspin, nor, indeed, any spin at all. The great majority of

[2] See, for example, "A Golf Myth: Prof. Tait's Alleged Error," in *Golf Illustrated*, January 1, 1909; or in my "Life and Scientific Work of P. G. Tait," pp. 26-28.

[3] See, for example, Lord Rayleigh, "On the Irregular Flight of a Tennis Ball," *Messenger of Mathematics*, 1877; "Scientific Papers," vol. i.

strokes would be unaccompanied by the phenomena of slicing or pulling or rising above the natural gravitational path. The dynamical condition for the production of underspin is clearly pointed out by Tait in his various articles. The resultant blow must be delivered so as to act in a line which passes beneath the centre of mass. For this purpose the blow need not be horizontal; but a horizontal stroke with a lofted club will produce underspin if the club-face hits the ball below the height of the centre. In this sense loft is an important factor in the production of underspin. In all cases, whether the ball is hit with a downward or a practically horizontal stroke, the production of underspin depends on the existence of a pronounced tangential component of impulse, and this requires that the direction of the blow must be inclined to the face of the club.

Mr. Vaile expresses the same idea when he speaks of the ball being hit with a glancing blow. In his explanation of the manner in which the wind-cheater is produced he is indeed quite sound; and it is a matter of regret that a book so admirable in many respects should be marred, not only by faulty dynamics, but by an inability to follow the dynamical reasoning of a master like Tait. Mr. Vaile sneers at the mathematician and physicist as having gone on utterly fallacious lines. He misquotes, and when he quotes aright he not unfrequently misunderstands. Nevertheless, on the more practical aspects of the game, when he is speaking for himself, and not piling up adjectives of denunciation against the mathematician, Mr. Vaile has done no small service in removing some of the clouds of mystery with which popular writers have obscured the soul of golf.

C. G. KNOTT.

THE AGE OF THE EARTH.

The Age of the Earth. By A. Holmes. Pp. xii+196. (London and New York: Harper and Brothers, 1913.) Price 2*s*. 6*d*. net.

THE question "For how long has it been possible for organic beings to have lived on the earth?" must always be one of supreme interest; and it is good to find a book which states shortly but quite clearly how far we have proceeded towards an answer.

No great weight ought ever to have been given to the argument from the lengthening of the day, because it assumes that the ratio of the polar and equatorial diameters of the earth now is the same as when the earth ceased to be liquid; in spite of the fact that great forces are acting tending to change this ratio. Kelvin's argument from the temperature gradient downwards in the earth's crust ceased to be of value when it was shown that greater conductivity in the interior led to an enormously larger answer; for whether such greater conductivity is or is not probable, it could not be said to be impossible. We are sorry that Mr. Holmes should refer to the work of Mr. Clarence King as if it affected the question. He, following Kelvin, assumed that there could be no greater conductivity inside the earth than in the crust. But all earth-cooling arguments have been set aside by Mr. Strutt's measurement of radium in rocks, and they are now of historical interest only.

Three of the old arguments still hold the field—one from the sun's energy, a second from the amount of salt in the oceans, and the third from observations of rates of erosion and deposit of sediment. To these a fourth is now being added which is likely to have great weight in settling the matter—the increase in the proportion of lead to uranium in rocks as time goes on. Mr. Holmes has himself devoted much time to the laboratory study of radio-active minerals, and of the creation of lead and helium from uranium; in the present state of our knowledge we can suggest no modification of his figures. He ought, however, we think, to be prepared to accept a less age for the earliest sedimentary rocks than 1300 million years.

Consideration of the amount of sodium in the ocean gives less than a quarter of this age, as does also the consideration of the accumulation of carbonate of lime. These two methods of study are on a much less certain basis than the calculation from the rate of accumulation of sediment, which, however, gives about the same age. With this last method Mr. Holmes, as a geologist, is very familiar. The suggestion that erosion used to take place more slowly because all continents were smaller and lower in level than now, would lead to a better agreement between the two methods which he favours. If the average slopes were 60 per cent. of what they are now, we are led to multiply the age by four. On the whole, we feel with Mr. Holmes that the question is in a fair way towards settlement, but, unlike him, we still see a difficulty due to the age of the sun. A person who has not made the calculation will scarcely believe in the liberality with which Kelvin treated his opponents in regard to the argument based on the sun's heat. Assuming that the whole mass of the sun was once scattered through space, and by mere gravitation the stuff came together as we now have it, and considering that it is denser in its central part, the total amount of energy given out as heat cannot be much greater than 25 million times the amount of heat now given out in one year. Kelvin, after making this kind of calculation, said: "It seems, therefore, on the whole, most probable that the sun has not illuminated the earth for 100 million years, and almost certain that he has not done so for 500 million years."

The possibility that the existence of radium in the sun might increase the calculated age has been carefully considered, and it is found that it will not do so; it has no practical effect on the result if the proportion of radium to other substances is taken to be the same as it is on the earth.

It may have been the possibility of a much less radiation from the sun in the past that caused Kelvin to be so generous. But, making every allowance of this kind, it is difficult to imagine a greater age than 100 million years; indeed, it is difficult to imagine so great an age. It seems absolutely necessary to find more energy than mere gravitational energy, and we are very loth to assume that the matter which now forms the sun had once much greater atomic energy than it possesses now. It is curious that the mathematics of a spherical mass of gas, published in NATURE, July 13, 1899, pp. 250 and 252, should lead to a speculation of this very kind; that is, that the mass of gas could not exist unless there was originally some more atomic energy than we find it to possess in the laboratory. Lord Kelvin thought that this conclusion merely meant that such a body would collapse until its stuff ceased to behave as a perfect gas. In these days when the facts of radio-activity are unsettling our beliefs, and it is necessary to get the sun's heat argument into agreement with the others, there is a temptation to let our thoughts linger on the other speculation, although, indeed, it must be quite absurd. And yet we know that the second law of thermodynamics is being evaded somewhere in the universe.

Our thanks are due to Mr. Holmes for this very welcome and interesting little book. J. P.

POPULAR BOTANY AND GARDENING.

(1) *Trees and How They Grow*. By G. Clarke Nuttall. With 15 Autochromes by H. Essenhigh Corke. Pp. xi + 184 + plates. (London: Cassell and Co., Ltd., 1913.) Price 6*s*. net.

(2) *Wild Flowers as They Grow*. Photographed in Colour Direct from Nature by H. Essenhigh Corke. With Descriptive Text by G. Clarke Nuttall. Fifth Series. Pp. viii + 200. (London: Cassell and Co., Ltd., 1913.) Price 5*s*. net.

(3) *Garden Flowers as They Grow*. Photographed in Colour Direct from Nature by H. Essenhigh-Corke. With Descriptive Text by H. H. Thomas. Pp. iii + 197. (London: Cassell and Co., Ltd., 1913.) Price 5*s*. net.

(4) *Garden Work: A Practical Manual of School Gardening*. By William Good. Pp. xvi + 399 + plates. (London: Blackie and Son, Ltd., 1913.) Price 3*s*. 6*d*. net.

(5) *Dahlias*. By George Gordon. Pp. xi + 115 + 8 coloured plates. (London and Edinburgh: T. C. and E. C. Jack.) Price 1*s*. 6*d*. net. (Present-Day Gardening.)

IT is somewhat difficult to know just what to say about the majority of the numerous popular works on botany and gardening that are turned out in such rapid succession in these days —in some cases the writers of such books rival even the most popular of popular novelists in their industry, turning out half-a-dozen or more sizeable books a year. If one is to judge them critically, one is bound to say that these books are, on the whole, rather poor; if inclined to cynicism, one would certainly say that most of them are totally unnecessary; but, after all, one cannot but rejoice at the increasing interest in plant-life and gardening of which this flood of good, bad, and indifferent books may be regarded as the outcome and reflection. One may at least admit that compilers of books of this kind are making fairly good use of improved methods of colour and other illustration processes; that the letterpress, though too often hasty and slipshod, is freer from actual inaccuracies than one might have expected; and that these books are likely to arouse the reader's interest. So much to the good; only, since the writing of such books appears to be fatally easy, let us hope that some few readers may resist the temptation to write books themselves.

(1) This is a readable and interesting account of a number of common trees, with fifteen coloured plates by Mr. Corke, in addition to which the author contributes a large number of remarkably good photographs, including stages in the germination of the seeds and the unfolding of the buds in the majority of the trees dealt with. So much has been done in the letterpress to make the story of these trees attractive that it seems a pity the author did not give, either as introduction or appendix, a general account of the growth of trees and the many interesting biological features (leaf-mosaics, for instance) which they present, and perhaps some account of the ecology of woodlands as developed in Britain—to mention only one or two of the aspects of tree-life not touched upon.

(2) Messrs. Nuttall and Corke are steadily working their way through the British flora; in this volume the former describes, and the latter depicts, a fifth batch of twenty-five native wild flowers. The coloured plates are unusually good, even for

this series; practically all the colours are as true to life as present processes of reproduction can make them, and one can scarcely select any for special praise, though the pictures of butterbur, dwarf thistle, corncockle, and teasel are perhaps among the most pleasing. The line-drawings in the text are still rather too diagrammatic and poorly executed, as in previous volumes. On the other hand, the descriptions show great improvement, the author having incorporated in his accounts the results of quite recent observations on the biology of both flowers and vegetative organs—as an instance of the latter we may mention his account of recent experiments on the biological significance of the water-pitchers of the teasel.

(3) Here the same indefatigable illustrator contributes twenty coloured plates to what is probably the first volume of a companion series of picture-books on garden flowers. It is not easy to see for what class of reader a book of this kind is intended, though the text is pleasingly written, and the pictures nice to look through—one is tempted to suggest that this sort of book is simply meant to be laid on the parlour table for the delectation of the waiting visitor, as a change from the old-fashioned album or book of views. The practical gardener has surely no use for books like this, and the text is not such as to be of much service to the amateur grower. Still, there seems to be a brisk demand for any and every sort of book on botany or gardening that is illustrated in colour and attractively got up in a "suitable-for-presentation" style, and we may leave it at that.

(4) This is another book which scarcely appears to fill a distinct gap in the copious literature of gardening. The author is enthusiastic and practical, but the botanical portions of the book (chapters iii. and iv.) are rather badly in need of revision, and some of the illustrations are poor woodcuts which contrast strangely with the many excellent photographs; some of these cuts (*e.g.* those on pp. 48, 162, 170, 171, 174, 226, and 241) would be well-nigh unrecognisable if not labelled. Since this book is published at a low price, and may come into sufficient demand to make a second edition necessary, it is to be hoped that it will be subjected to considerable revision; apart from the unsatisfactory blocks just referred to, at least half of the illustrations given are neither necessary nor helpful as aids to the comprehension of the letterpress, and might well be omitted, or replaced by more useful pictures. It is only just to add that, apart from the more botanical portions, the text is thoroughly practical and clear, and the book would form a very useful guide to the amateur gardener, as well as to the school-teacher, for whom it is more particularly intended.

One thing that certainly ought to be omitted from a new edition is the preface, the writer of which appears entirely to have overlooked the danger of advising the turning loose of troops of school-children armed with trowels and collecting-tins—what this has to do with school-gardening is hard to see—to help in the extermination of rare plants. It would have been much more to the point to have directed attention to the urgent need for the protection of wild plants against the avarice of collectors old enough to know better, rather than to deplore the fact that the vasculum and fern-trowel are not yet ubiquitous in this country. We have quite enough plant-collectors as it is, though we could do with more students of plant-life in field and garden—that is quite another thing.

(5) The editor of the "Present-Day Gardening" series, which is rapidly becoming an invaluable library in itself, is to be congratulated on having secured for the authorship of the volume on dahlias the president of the National Dahlia Society. Needless to say, Mr. Gordon has succeeded in giving, within comparatively small compass, an immense amount of information of all kinds about these flowers, including an extremely interesting historical chapter and the thoroughly practical hints regarding cultivation that might be expected from a writer of authority upon the subject. The eight coloured plates by Mr. Waltham are well chosen and beautiful. It may seem somewhat ungracious to find fault with such a fine series as this, but the pasteboard binding is very liable to get cracked in use, and one cannot help wishing that more resistant material had been used in covering the books. F. Cavers.

OUR BOOKSHELF.

Wild Life. An Illustrated Monthly. Vol. i., Nos. 1–5. Edited by Douglas English. (London: *Wild Life* Publishing Co., 1913.)

Last summer the members of the Zoological Photographic Club held an exhibition at the offices of the Zoological Society, and the object of this periodical is to continue and extend the work of that exhibition. The first number appeared in January and promised well. Mr. R. B. Lodge wrote of eagles and vultures in Albania, and Mr. Farren, who showed some wonderfully beautiful photographs, described the life of the egrets in the valley of the Guadalquivir, where Mr. Abel Chapman and Mr. Buck have done so much to preserve this species. Mr. Francis Ward had some interesting notes and plates of fishes, living birds, and otters: the photographs were taken in his pond on a method of his own invention.

The editor's paper on the sand-wasp (*Odynerus spinipes*) was welcome as breaking new ground in photography, for of photographs of birds it is possible to get weary, unless they have something new to tell us; and that is by no means always the case, in spite of the editor's extravagant claim (p. 8) that our knowledge of British birds has been doubled in the last decade by photography alone.

We are glad to see that in the four succeeding numbers the art is applied freely to insects and reptiles, as well as to birds and quadrupeds. The March number contains some admirable photos of the three species of British snakes, and also a good paper on the snake-fly and the alder-fly, with illustrations showing a decided improvement on those of the sand-wasps. The April number has a paper with good illustrations of young moles, and the May number is appropriately devoted mainly to the cuckoo. Special mention may be made of Mr. Oliver Pike's "bioscope record" of the performance of a young cuckoo in ejecting from the nest a sedge-warbler older and larger than itself. We wish the editor and his contributors all success in their work, hoping at the same time that, in spite of the beauty of its illustrations, *Wild Life* will not be used by beginners simply as a picture-book.

Photographic Supplement to Stanford's Geological Atlas of Great Britain and Ireland. Arranged and edited by H. B. Woodward, F.R.S., with the cooperation of Miss Hilda D. Sharpe. Pp. 113. (London: Edward Stanford, Ltd., 1913.) Price 4*s*. net.

Two years ago Miss Hilda Sharpe published a field notebook of geological illustrations (see NATURE, vol. lxxxviii., p. 74), and she has now done further service by collecting nearly half the photographs in Mr. H. B. Woodward's volume. Some of the remaining half have been previously published by the Geological Survey, and others are from the series in the care of the British Association. Among the most original and suggestive are Miss Sharpe's own "View from Summit of Caer Caradoc," showing the outweathered cones of Uriconian rock, and Mr. Armstrong's "Escarpment of Millstone Grit, near Leek." Landscapes like these, and the Survey's "Raised Beaches near Strome Ferry," illustrate the geological atlas better than any number of quarry-sections. Among the latter, however, the Jurassic Clay and Limestone at Bromham (No. 68) and the Chalk and Thanet Sand at Crayford (No. 89) are highly characteristic. The Scotch views include the Torridon Sandstone and the mountainous features near Glen Etive; but the wild heart of Skye is unrepresented. Ireland is honoured by one picture, a rather distant view of the Giant's Causeway; but should this very compact basaltic lava be called a dolerite?

We are glad to see Mr. H. Preston's work in England well utilised, as in the cases of the Norwich Crag of Thorpe (No. 97) and the massive limestones of Lincolnshire; but such a book always makes us ask for more. Those who use the atlas will look for further help in realising the country. Can we not have the cirques of Snowdon, the long lakes of Westmoreland, white between their rain-swept hills, the highland border beyond Stirling, or the scarp of the intrusive sheet that fixed the margin of the Roman world? G. A. J. C.

A Dictionary of English and Folk-Names of British Birds. By H. Kirke Swann. Pp. xii+266. (London: Witherby and Co., 1913.) Price 10*s*. net.

THIS book is strictly a dictionary, and on that account less interesting to turn over than Mr. Swainson's "Provincial Names of Birds," published for the English Dialect Society in 1886, which also dealt to some extent with the folklore. Mr. Swann, however, claims to have added some three thousand names to those collected by his predecessor: he has evidently taken great pains, and deserves much credit for a handbook which will always be useful. We will make one critical remark only. If Welsh, Gaelic, Cornish, and Irish names are freely admitted to the list, why not Anglo-Saxon, which are at the roots of our own local names? "Enid," for example, was the English word for a duck till the fifteenth century, but it is not here. Mr. Swann's work begins with Chaucer; but he might well search the Anglo-Saxon vocabularies for addenda to a second edition.

Religious Beliefs of Scientists: Including over 140 hitherto Unpublished Letters on Science and Religion from Eminent Men of Science. By A. H. Tabrum. With an Introduction by Rev. C. L. Drawbridge. New and enlarged edition. Pp. xxi+309. (London: Hunter and Longhurst, 1913.) Price 2*s*. 6*d*. net.

To the second edition of this collection of letters forty new communications, which Mr. Tabrum has received in reply to his questions from workers in science, have been added. Such a compilation of opinions must necessarily be of doubtful value, the questions propounded unavoidably lack precision, and the answers too often turn out to be very general in character. But the volume will be of interest to the class of reader who is anxious to know the opinions of distinguished men on important questions outside their own special fields of knowledge.

The British Empire with its World Setting. By J. B. Reynolds. Pp. viii+200. (London: Adam and Charles Black, 1913.) Price 1*s*. 4*d*.

THE attempt to survey the geography of the British Empire in a little book of this size, at the same time providing an outline sketch of the geography of the rest of the world and upwards of ninety maps, diagrams, and illustrations, more than forty of them being full-page pictures, was bound to lead to very severe compression. The number of place-names on a single page is often far greater than children can be expected reasonably to remember. The book is very attractive in appearance, and the writer's name is a guarantee for accuracy.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

A Plea for Uniformity in Radio-active Nomenclature.

IN a letter to NATURE (vol. lxxvi., p. 661, 1907) Prof. Rutherford advised against an immediate adoption of a permanent system of nomenclature for the radio-elements since the discovery of a new element in the midst of a series would entail the alteration of the names of a possible half-dozen others which follow it. It was considered, however, that the number of products still to be discovered was nearly exhausted, and that when there was a general consensus of opinion that such was the case, chemists and physicists should meet together in order to revise the whole system of nomenclature.

An opposite view was taken by Mr. Norman R. Campbell (NATURE, vol. lxxxiv., p. 203, 1910), who urged the adoption without further delay of a system of nomenclature for the radio-elements which would admit of interpolation, and would explain relationships between objects named. Since this would constitute a permanent system of naming, those names which are acknowledged as temporary might be at once dispensed with without having to wait for an indefinite time in the future when all the elements in a series are assumed to have been discovered.

Little attention, however, seems to have been given to this suggestion. New elements have been discovered since then, and the names assigned to some of them are even more unsystematic than the names previously given to other elements of the same series. As examples of this diversity of naming may be mentioned mesothorium 1, radium C^1, and radium C_1.

It might be urged in defence of the names now in use that no satisfactory system has yet been devised which would provide for the naming of elements yet to be discovered, and would show relationships between elements either in a straight or branched series. The most favoured system of naming the radio-elements seems to be that by which an element is designated by a letter or number following the name of the first of a group of elements. Such a system, however, does not admit of interpolation, and there may thus be good grounds for the delay in adopting a permanent system of nomenclature.

The object of the present note is to direct attention particularly to the diversity and careless use of symbols selected to represent the names of the radio-elements now in use. The lack of uniformity in the use of symbols is illustrated by the following examples, most of which were taken from recent numbers of the *Philosophical Magazine* and the *Physikalische Zeitschrift* :—

Uranium.—U and Ur.

Actinium.—Ac, Act, and Akt.

Radium A.—Ra A, RaA, and Ra-A. The symbols of all other elements designated by a letter are likewise written in one or other of the three ways represented.

Uranium 2.—U 2 (or Ur 2), U_2, U-2, U-two, and U_{II}. A similar diversity is observed in the symbols of all elements which are designated by a number.

Radio-thorium.—Radio-Th, Radioth, Ra Th, Radth, Rad Th, Rad-Th, and Rt.

Mesothorium.—Meso-Th, Mesoth, Mesth, Mes-Th, and Ms.

Radium A, Radium B, and Radium C when considered collectively.—Ra A, Ra B, and Ra C; Ra A, B, and C; RaA+B+C; Ra(A+B+C); A, B and C; A+B+C. The active deposit of other series is likewise referred to in a corresponding variety of ways.

Such a diversity of symbols must be very confusing to the student in radio-activity, and particularly to the future student when referring back to the work of the present day.

No less confusing is the use of duplicate names in the case of several of the elements. Thus the product following radium is sometimes called radium emanation (Ra Em), and sometimes nitron (Nt); that following radium C is called radium D, and also radio-lead; and that following radium E has the duplicate names radium F (Ra F) and polonium (Po). These different names for the same element are often to be found in the same article. In the same way the terms X-ray and Röntgen ray are still used for the same radiation.

In an abstract journal like *Chemical Abstracts*, where only the symbols of the elements are used, it is particularly desirable that each element should be always represented by the same symbol. In the case of some of the radio-elements this is not possible since no standard symbols have yet been decided on. It would thus seem worth while to adopt by general agreement uniform symbols for the radio-elements, even although the names of some of the elements may be considered as only temporary.

Pianoforte Touch.

I HAVE been very much interested in Prof. Bryan's article on pianoforte touch in NATURE of May 8. There is, of course, no question with anyone who is a pianist that dynamic differences of touch produce enormous differences of quality in the tones of a well-made pianoforte. My own observations in the matter do not go very far, but, amongst other things, it has seemed to me that two things are important: (1) the harmonics of a note have always seemed to me to be most prominent when the note has been produced by the least possible "hit" by the fingers, in fact, when the note is practically produced by pressure alone. Pressure alone is, of course, unable to produce a note, and a certain fractional hit is always necessary to give the hammer the necessary momentum.

(2) As a result of (1), it seems worthy of note that variations in quality must be produced by differences in the time the hammer is in contact with the string. Since the sensitive fingers of a trained pianist will be able to produce an infinite variety of pressure and hit from the heaviest arm staccato to the merest "caress" of a key, it is possible to produce very large differences of quality as well as large differences in intensity.

My own experiences with a player-piano have made me well-nigh despair of its capabilities in its present form. In spite of the instinctive control it is certainly possible to obtain with it, its mechanical details seem to me to fall far short of the ideal that a musician can demand. It is, of course, practically impossible to produce a differentiation of intensity between notes of the same chord, and to a musical ear it is this difference of intensity which enables differences in quality to be detected and appreciated. Prof. Bryan seems to have been able to control this differentiation in quality in a solo passage, and if he can produce a mechanical arrangement which can even approximate to the sensitiveness of a pianist's fingers, he will certainly go far to make the piano-player more acceptable to musicians.

I have often endeavoured to make a player-piano play Chopin's First Ballade, but I have never yet succeeded in overcoming the uncompromising self-assertiveness of the mechanism. It seems to me a curious fact that while a piano-player can often play Beethoven acceptably, it fails hopelessly with Chopin, especially in works like the ballades and nocturnes. I have succeeded in getting presentable performances of the sonatas, and I had almost said of the scherzos, but the lack of flexibility of the instrument seems to make it impossible in music where differences in colour are so important as in the ballades and nocturnes.

Although I have no doubt it will be possible to devise a mechanical arrangement which will improve the player in the direction I have mentioned, yet it would seem impossible to make any mechanism sufficiently sensitive to be able to produce effects such as those which can be produced by the fingers, just as it may be possible to produce an aëroplane which is capable of marvellous evolutions, while it never attains the instinctive facility of a bird.

The College, Epsom, May 23.

On the Habitat of Protodrilus and the Occurrence of the Archiannelid, Saccocirrus, on the South Coast of England.

ONE habitat of Protodrilus on the English coast has already been mentioned in NATURE of March 27 (p. 85). This animal, however, has since been found in so many similar localities in the Plymouth district that there can be little doubt that it will be found on other parts of the coast when looked for in suitable situations. Protodrilus has indeed now been taken in numbers in eleven different localities between Salcombe and Looe.

In one of these situations there was found, along with Protodrilus, a species of the interesting genus Saccocirrus, which, as is well known, appears to link up the Archiannelids with the Polychætes. This genus has not apparently been taken outside the Mediterranean region except at Madeira, but, as in the case of Protodrilus, it may very likely be found on other parts of the coast when looked for in suitable places. Hence the following description of the habitat of these animals may induce some of the readers of NATURE to look for them on other parts of our coasts.

In all cases Protodrilus—and in one case Saccocirrus—has been found in gravel just below the high-water mark of neap tides where fresh water runs or percolates into the sea, and in nearly all cases the animals were taken at the lower level of a gravelly beach where the gravel passes into a rocky foreshore. Given these conditions in the Plymouth district, namely fresh water running over or percolating through gravel near the high-water mark of neap tides with rocks at the lower levels, and one is practically certain to find Protodrilus where the gravel meets the rocks, and especially under stones embedded in gravel in the pools at the junction of the gravel and the rocks.

In appearance the species of Protodrilus found near Plymouth, *P. flavocapitatus*, resembles a piece of silk thread about half an inch long, looking brownish-white to creamy-white on a dark background, and having a rosy-coloured portion just behind the head; the body is often curved in a characteristically sinuous manner, and may become rolled up into a close spiral coil if the animal is alarmed. Saccocirrus is very similar to Protodrilus in habits, but is larger, attaining a length of nearly 2 in., and having a correspondingly thicker body, which is opaque-white in colour. This species of Saccocirrus has not yet been determined, but it does not appear to be the same as the *papillocercus* of Bobretzky as revised by U. Pierantoni (*Ann del Mus. Zool. Napoli* (N.S.), vol. ii., No. 18, 1907).

Sub-Red Crag Flint Implements and the Ipswich Skeleton.

THE best reply to Mr. J. Reid Moir's criticism (NATURE, May 22, p. 296) on my paper in the Manchester memoirs discussing his sub-Crag flints will be the paper itself when published. The second part of his letter, dealing with the Ipswich skeleton, reveals so complete a change of ground that it is necessary to comment on it. In his original description (Proceedings of the Prehistoric Society of East Anglia, vol. i., part ii., p. 194) Mr. Moir laid very great stress on the fact that the contracted skeleton was lying partly embedded in glacial sand, and partly in decalcified boulder clay.

In a report (*ibid.*, p. 196) by Mr. W. Whitaker, F.R.S., appears the following:—"The bony cavity of the skull is filled with earth of the same kind as that beneath which the skeleton was found, a brown loam, and the filling is so thorough that a cast of the cavity has been made."

Dr. Arthur Keith, in his description (*ibid.*, p. 203) of the Ipswich skeleton, remarks "that on reaching the museum the bones were exposed by removing from them the overlying boulder clay and leaving them still *in situ*, on the underlying glacial sands," and adds, "There is the further advantage that anyone can now examine the exact relationship of the parts to the strata in which they lie."

Mr. J. Reid Moir now says "that in his opinion the skeleton was either buried in the sand, or else covered by blown sand to a considerable depth." In either case the skeleton, when found, should have lain entirely in sand and the cranial cast in boulder clay would have been impossible. Mr. Moir's present view is hence quite inconsistent with his original description of the occurrence, and, as he cannot have it both ways, he must choose which view he prefers to stand by.

W. H. SUTCLIFFE.

Littleborough, May 27.

Antennæ for Wireless Telegraphy.

I FIND that an iron bedstead with wire mattress on the top (fourth) floor of this house answers quite well as antennæ for the receipt of wireless signals. It is only necessary to connect the receiving apparatus, which includes a Brown relay, between the bedstead and the water-pipe to receive the Admiralty signals loudly, and others from various unidentified stations faintly but quite audibly.

I find also that with the bedstead antennæ it is possible to get the time signals from the Eiffel Tower. As might be expected, the signals are not very loud, but are sufficiently audible to be recognised and read easily.

A. A. CAMPBELL SWINTON.

40 Chester Square, S.W.

Use of a Carbon Filament Lamp to Charge Electroscopes.

I FIND that a very convenient way of charging an ordinary gold-leaf electroscope is to rub the charging rod with the glass bulb of a glowing carbon filament lamp. The leaf system becomes negatively charged. It is quite easy to charge a Braun electrostatic voltmeter to several thousand volts in this way.

There appears to be nothing mysterious in the phenomenon. The glass of the lamp is kept hot and free from moisture by the heat supplied from within, and is therefore always in a suitable state for producing electricity by friction against metals or other substance. It is obvious that the corpuscles shot off from the glowing filament and sticking to the inside of the bulb can have little or no part in the production of such high potentials, for the very greatest speed they could acquire would be that corresponding to the voltage of the supply mains. A glass tube filled with hot mercury can, in fact, be used as successfully as the lamp.

This lamp method of producing electricity by friction is so easy to employ, and, moreover, so certain in action (the degree of electrification can be regulated to a nicety), that it is bound to be of interest to users of electroscopes. R. Whiddington.

Naid or Tubificid?

In Nature for November 16, 1911 (p. 78), I directed attention to the fact that a tiny annelid known as Rhyacodrilus had been found in England, and that it differed in some respects from the specimens recorded for Switzerland. Some difficulty was experienced by the Continental authorities in assigning it a place. Ditlevsen contended that it belonged rather to the Naididæ than to the Tubificidæ, but Michaelsen in his various publications refers it to the latter. In his "Süsswasserfauna Deutschlands" he specially distinguishes those annelids which reproduce by fission from those which form cocoons, and places the Naididæ in the former group, while the Tubificidæ are relegated to the latter. Then he places Rhyacodrilus (=Taupodrilus) among the Tubificidæ, because it is possessed of sexual organs.

Aided by a Government grant for the study of annelid bionomics and economics, I have just been able to make an interesting discovery. Rhyacodrilus is found in our midland streams, and in the summer is possessed of all the organs belonging to the Tubificids. In the winter and spring, however, it adopts the Naid method of reproduction, and forms a chain (Tierkette). It is therefore a link between the two families, and the question arises: To which does it most certainly belong? I favour the Naid association.

Swadlincote, May 16. Hilderic Friend.

WORK OF THE EUGENICS RECORD OFFICE.

PROF. DAVENPORT and his staff of collaborators and "field" workers have shown great activity in the collection of family histories. The two first of a series of quarto memoirs, beautifully printed at the expense of Mr. Rockefeller, and published by the Eugenics Record Office, contain elaborate accounts of the members of two particular stocks whose claim to fame resembles and rivals that of the Jukes. The "Hill Folk," whose relationships with one another and with their common ancestry were investigated by Miss Danielson, comprise more than 700 persons all descended from two particular individuals who settled near a New England town in about the year 1800. Elaborate calculations as to their cost to the town and State for aid as paupers and for maintenance in prisons and institutions reveal the fact that these charges are constantly and rapidly increasing. Feeble-mindedness, alcoholism and the evils which spring from each or both in combination are terribly prevalent among them, and their distribution within the families is clearly shown in the extensive pedigree charts which embellish the memoir.

Although Prof. Davenport does not claim that the material here collected is of a kind suitable for the study of inheritance, it is of interest to note that from it he propounds a theory on the transmission of feeble-mindedness of a kind very different from that suggested by himself and Dr. Weeks in their paper "A First Study in Inheritance of Epilepsy" (Eugenics Record Office, Bulletin No. 4, 1911).

According to his earlier view, feeble-mindedness and epilepsy are both due to the absence of a gametic factor the presence of which is necessary for normal development. They are thus transmitted as a simple recessive character which might appear in either or both of these forms.

The material collected in the memoir under review, when analysed, gives results quite incompatible with this theory, and another and more complex one is consequently suggested. In the latter, which is propounded not as a dogma, but as a tentative hypothesis, different types of feeble-mindedness are taken into consideration, and it is supposed that each depends on the absence of a separate factor. Thus when two feeble-minded persons whose defect is of the same type are mated together, all their children will reproduce it, but where the type of mental defect of one parent is different from that of the other, none of their children need necessarily be feeble-minded at all.

The second memoir deals with a family to which the fictitious name of Nam has been attributed. The origin of the Nams is described as follows:—"In 1760 there lived in the mountains of Western Massachusetts a set of people called Nam, descended from the union of a roving Dutchman, who had wandered there from the Hudson Valley, and an Indian princess. These people were wealthy in land, having inherited it from their Indian ancestors." The family in more recent times is said to be characterised by alcoholism and lack of ambition. As in the case of the Hill Folk, Dr. Davenport has prepared a bill of what they have cost the State. We do not, however, agree with his system of accounting, in which everything is entered on the debit side and nothing on the credit. Even the most valuable of citizens would show up badly in this system. Thus the largest item of the Nams' account, forming two-thirds of the total, is their drink bill of rather more than a million dollars, distributed among 700 of them. If we were to take 700 prosperous professional men in England it would not be an overestimate to suppose that each would have a drink bill of something like 5000 dollars in fifty years, or, combined, their total bill for drink would be more than double the total bill of the Nams for all items. Thus, if nothing is reckoned on the credit side, we could come to the surprising conclusion that the Nams were the less unprofitable of the two.

The other publications of the Eugenics Record Office are their octavo bulletins. Of these, eight have appeared, three dealing with the inheritance of insanity. Special attention may be directed to that of Dr. Cotton, the medical director of the New Jersey State Hospital for the Insane (Bulletin No. 8, 1912). E. H. J. S.

LORD AVEBURY, F.R.S.

LORD AVEBURY, whose death on May 28 we recorded last week with regret, was a many-sided man, one of those gifted men who, without making any very profound advance in science, yet succeeded in making science acceptable and even welcome to the ordinary man. He was a banker by profession, and an antiquary, a politician, a man of science and of letters by inclination. He was born in London on April 30, 1834, the eldest son of Sir John William Lubbock, third baronet. His school was Eton, which, however, he left at a schoolboy age to enter his father's banking business. Throughout his life Lord Avebury, or, as he was for many years better known, Sir John Lubbock—he succeeded his father in 1865—showed a great capacity for steady, plodding work, not only in the City, but in politics, municipal administration, and in scientific and archæological research, and his activities were of the widest.

In 1870 Sir John Lubbock was returned for the borough of Maidstone, and he held this seat for ten years. In 1872 he became vice-chancellor of the University of London, and eight years later he was elected member for that university, and for the next twenty years he represented this seat of learning. He was active as a Parliamentarian, taking an especial interest in questions of education and social reform. He made a particularly good university representative, being a man of learning as well as of affairs. Amongst the many good causes he advocated, perhaps the establishment of bank holidays was the one most widely known and the one which will preserve his name the longest. In 1900 he was raised to the peerage as the first Lord Avebury, and it is characteristic of him that he chose a title intimately connected with archæology.

For many years Lord Avebury was a neighbour of Charles Darwin at Down, Kent, and it may have been their friendship that led to his interest in "Ants, Bees, and Wasps"; "The Senses, Instincts, and Intelligence of Animals"; "The Collembola and Thysanura"; "Flowers, Fruits, and Leaves," and in "The Origin and Metamorphoses of Insects," as five of his most illuminating books are entitled. He and his helpers added materially to our knowledge of the habits and instincts of social and other insects, and to our acquaintance with the activity of many forms of vegetable growth. His work, indeed, did much to pave the way for the great interest now taken in insects, especially at present in relation to the conveyance of disease.

But Lord Avebury by no means confined his attention to biological studies. He was an expert on banking; he was the first president of the Institute of Bankers, president of the London Chamber of Commerce, and for twenty-five years he was secretary of the London Bankers Association and president of the Central Association of Bankers. For five years he was president of the London Chamber of Commerce, and he published important treatises on coins and currency, and on municipal and national trading. His was a very steadying influence on the commercial world. Without having the dominant influence of a Pierpont Morgan, or the great American banker's power of handling a financial crisis, he had an infinite capacity for mastering detail, and a great gift for bearing in mind many things of importance which are apt to be overlooked in the ordinary course of business.

Lord Avebury took much interest in municipal government, and was vice-chairman of the London County Council in 1889 and 1890, and chairman from 1890 to 1892. Nor must it be forgotten that he was principal of the London Working Men's College, and did most admirable work in connection with that institution. His "Hundred Best Books" was the result of a lecture delivered at the college.

Few men have attained eminence in so many subjects, an eminence which would satisfy many a specialist. Part of this eminence was due to a gift of style. An American contemporary once described him as an "elegant British writer on bugs." Even his most strictly scientific monographs were written in an engaging manner, and none more so than his "Origin of Civilisation and the Primitive Condition of Man," which is now in its sixth edition. Perhaps of his scientific works "The Scenery of England" and "The Scenery of Switzerland" are the most enduring. The former is still recommended by the teachers in many a university as a most admirable introduction to the study of geology. He seemed to have an instinct for knowing "what the public wants," and his more popular literary works appealed widely to "the man in the street." "The Pleasures of Life," "The Use of Life," "The Beauties of Nature," sold by the hundreds of thousands—in fact, a quarter of a million of "The Pleasures of Life" have already been disposed of, apart from more than forty foreign editions. These books, though they partake of the nature of reprinted commonplace books, certainly hit the popular taste, and were in their influence wholly healthy and helpful.

In our restricted columns it would be impossible to enumerate the numerous associations over which Lord Avebury presided. He was, indeed, to paraphrase an Elizabethan phrase, "President General to the Age." He was president of the British Association in its jubilee year, and president of the Entomological, Ethnological, Linnean, Statistical, African, and Ray Societies; president of the Anthropological Institute, of the International Institute of Sociology, and of the International Association for Prehistoric Archæology; of the International Association of Zoology, and of the

International Library Association. Here, again, our space forbids us to catalogue his almost inexhaustible list of honours, but we must mention that he was a Commander of the Legion of Honour, and he held the Order Pour le Mérite. He was elected a Fellow of the Royal Society in 1858.

Lord Avebury married firstly Ellen, only child of the Rev. Peter Hordern, and secondly Alice Augusta Laurentia, daughter of the late General A. A. L. Fox-Pitt-Rivers, a granddaughter of the second Baron Stanley of Alderley. He is succeeded by his eldest son, the Hon. J. B. Lubbock, who is a partner in the banking firm of Robarts, Lubbock and Co.

PROF. J. T. NICOLSON.

THE early death of Dr. J. T. Nicolson, professor of mechanical engineering in the Manchester School of Technology and in the University of Manchester, will be much regretted by a wide circle of friends. His health during the past six months had given serious cause for anxiety, but had improved sufficiently to allow him to return to his duties. There followed a sudden relapse, and he died at Macclesfield on May 27 after a brief illness.

Prof. Nicolson was born at Amble, in Northumberland, in 1860, and received his early education at Watson's College, Edinburgh. He was then apprenticed to Hawthorne Leslie and Co., Newcastle-on-Tyne. From there he gained a Whitworth scholarship and entered Edinburgh University, where he graduated in 1889, obtaining the D.Sc. degree some years later. After graduation he spent two years in Charlottenburg, where he investigated the strength of materials under Prof. Martens. After holding the position of assistant-lecturer in engineering in the University of Cambridge, he was appointed in 1892 professor of mechanical engineering in McGill University, Montreal. He took an active part in the equipment of the engineering department and in arranging the courses of instruction for students. During his stay in Montreal he undertook an investigation with Prof. Callendar on the valve-leakage of steam on the surface of cylinders. This important investigation led to the award of the Telford premium to the authors. Prof. Nicolson resigned his professorship in Montreal in 1899 in order to take charge of the engineering department of the School of Technology, Manchester, and was largely responsible for the whole engineering equipment of that institution—an equipment which in variety and extent is even now unsurpassed in this country. When degree courses were instituted in the School of Technology in connection with the University of Manchester he was appointed the first professor of mechanical engineering, a position which he held until his death.

Prof. Nicolson's tenure of the chair at Manchester was marked by several important and extensive investigations. He made detailed experiments on rapid-cutting steels, in which he showed the relations between the cut and speed and the durability. The results of these investigations were published as a report by the Manchester Association of Engineers in 1903, and were well received by the engineering profession. As was characteristic of Prof. Nicolson, he immediately applied the experimental results to the improvement of the design of machine tools.

During the last few years of his life he took up the question of the transfer of heat to boilers. The late Prof. Osborne Reynolds had predicted in 1874 on theoretical grounds that the rate of transfer of heat from a gas or fluid to a solid surface should increase with the velocity of movement. This was confirmed for fluids by the experiments of Dr. Stanton in 1897. Prof. Nicolson, in an elaborate series of experiments, showed that the same result held for gases. He then applied this idea to the design of boilers and condensers, the essential point being that the heated gases were driven at a high speed through the tubes of the boiler, the water circulating in the opposite direction. As a result of an extended trial of a 60-h.p. boiler over sixty days, it was found that the efficiency of such a combination was considerably greater than that of the ordinary boiler. There has been much difference of opinion among engineers as to the practicability of this idea, but Prof. Nicolson himself had the strongest belief in the greater overall efficiency to be obtained by his methods.

The training of Prof. Nicolson fitted him admirably to fill the position of a professor of engineering, for he had not only a wide scientific outlook, but took a keen interest in the practical side of his profession. This is shown by the promptness with which he applied the results of his scientific investigations to the improvement of engineering practice. He was a man with strong opinions on engineering questions, and vigorously supported his position when attacked. His personal integrity, straightforward character, and sympathy with their scientific difficulties endeared him to his colleagues, while his vigorous personality and ability as a teacher made a strong and lasting impression on all his students. Owing to his increasing deafness he was unable in recent years to take that active part in administrative matters for which his wide outlook well fitted him. His premature death is a great loss to science, and will be much regretted by his colleagues both in Manchester and Montreal.

NOTES.

THE home list of honours conferred on the occasion of H.M. the King's birthday on June 3 includes three new Privy Councillors, seven new baronets, and twenty-six knights. The only fellow of the Royal Society in the list is Prof. E. A. Schäfer, professor of physiology in the University of Edinburgh, who has received the honour of knighthood. The same honour has been conferred upon Prof. J. H. Biles, professor of naval architecture in the University of Glasgow. Prof. T. H. Middleton, formerly professor of agriculture in the University of Cambridge, and now assistant secretary, Board of Agriculture and Fisheries, has been appointed a Companion of the Order of the Bath (C.B.). The appointments to the Order of the Indian Empire (C.I.E.) include Major G. K. Walker, professor of sanitary science, Punjab Veterinary College; Mr. L. Mercer, president of the Forest Research Institute and College, Dehra Dun; and Mr. J. H. Lace, Chief Conservator of Forests, Burma.

In opening, on Tuesday, June 3, the new buildings of the medical school at Guy's Hospital, Mr. A. J. Balfour delivered an address in which he pleaded for the endowment of research. In the course of his remarks he said :—Some people unacquainted with the movement of modern science may ask why it is that in 1913 apparatus, buildings, and expenditure of all kinds are required infinitely in excess of what was necessary even fifty years ago. The necessity arises not merely through the growth of the great urban population, but through the inherent progress of science itself. Fifty years ago some branches of science, such as physics, biology, and even some modern parts of chemistry, although studied by those who intended to devote their lives to medicine, had nevertheless an incomparably smaller connection with medicine than exists at the present time. As the connection of other collateral sciences with the science and practice of medicine has become closer, so the apparatus required has greatly increased in cost, so the amount of knowledge required from the teachers and the specialisation of the teachers have grown, until we may sometimes wonder how it is possible for any physician in a great practice even to keep himself abreast of what is being done in his own country and by researchers in all the other countries who are now engaged in happy rivalry for the furtherance of knowledge.

Besides the man of practical intuition and besides the man who can teach, Mr. Balfour added in the address referred to above, we want, if a medical school is to be all that it might be, a man who can investigate, a man who possesses that kind of originality which enables him to point out in what direction the next advance should be made, where progress may be expected, where nature may, under existing conditions, be most easily compelled to yield up her secrets. This man is the researcher. Genius is rare in any country and in any profession. All that organisation can do is to give to those rarely endowed individuals some opportunity by which they can exercise effectively for the common advantage the gifts which God has given them. If a man is going to devote to research hours which might profitably be given to the general practice of his profession, he must have a position of security in which he can feel that he is not sacrificing the interest of those nearest and dearest to him in the pursuit and advancement of new knowledge. The public must assist the great hospitals by a form of endowment which will enable them when they obtain a man with a genius for research to keep him and to use him. There are men who have quite a unique talent for research, who probably would not be very great clinical physicians. Places must be found for such men. This is absolutely necessary if there is to be a true organisation of medical research. The actual sufferings of the moment touch all hearts, but my appeal now is for the future, in favour of having academic lines of research of which the public knows nothing and yet on which depends the real future of the healing art.

The bicentenary of the Imperial Botanic Garden at St. Petersburg, which was founded in 1713 by Peter the Great, will be celebrated this month.

Lord Glenconner has presented 1000*l.* to the Edinburgh Royal Infirmary for the purchase of radium to be used in the work of the institution.

The twenty-fourth conference of the Museums Association is to be held in Hull from July 14 to 18, when Mr. E. Howarth will occupy the chair.

Prof. C. S. Sherrington, F.R.S., has been appointed an additional member of the Departmental Committee on the lighting of factories and workshops.

News has reached us from Mexico of the death, on April 23, at forty-seven years of age, of Prof. L. G. León, general secretary of the Mexico Astronomical Society. His death is deeply regretted by the members of the society, who appreciate highly his activity and work for astronomical science.

On June 11 the Right Hon. the Lord Mayor of London will officially open the Anglo-German Exhibition at the Crystal Palace. The exhibition includes a section on industry, with subsections relating to chemistry, surgical and optical instruments, electricity, and agriculture and forestry, among others.

An excursion to Minehead and district, West Somerset, has been arranged by the Geologists' Association for June 20–24. The directors are Mr. L. Richardson and the president, Dr. J. W. Evans. On the Saturday, June 21, there will be an opportunity to study the classic sections of Upper Keuper, Rhætic, and Lower Lias in the neighbourhood of Watchet.

Announcement is made that Mr. Arthur James has decided, as a memorial to his late brother, Mr. William James, to give the income of a sum of 20,000*l.* for cancer research to the Middlesex Hospital, as being the institution where clinical and pathological researches on the disease are most closely combined.

Prof. A. G. Ruthven, curator of the museum of the University of Michigan, is in charge of an expedition that will sail from New York on June 15 for Colombia, South America. The expedition will make its headquarters near Santa Marta, and will study the fauna from the sea-level to the mountain summits. The party will also include Prof. A. S. Pearse, of Wisconsin, and Mr. F. Gaige.

The autumn meeting of the Iron and Steel Institute will be held in Brussels, from Monday to Thursday, September 1–4. The opening meeting will be held in the hall of the Palais des Académies on Monday, September 1, when a selection of papers will be read and discussed. In the evening a reception will be held by the burgomaster at the Hotel de Ville. It is hoped that his Majesty King Albert will receive the members at the Royal Palace, Brussels, on September 2.

Three Chadwick public lectures, on nature and nurture in mental development, will be given by Dr. F. W. Mott, F.R.S., at the Royal Society of Arts, on Fridays, June 6, 13, and 20. Admission to the lectures is free. Information concerning future Chadwick lectures may be obtained of the secretary, Mrs. Aubrey Richardson, at the offices of the Trust, 8 Dartmouth Street, Westminster.

In February last the Italian Colonial Office appointed a commission to undertake the scientific study of the country of Tripoli. Prof. F. Eredia, of Rome, informs us that the commission has now travelled through the area, and has collected valuable geological, agricultural, botanical, and meteorological data. Meteorological stations have been established by Prof. Eredia in appropriate situations. Temperature and rainfall observations are to be sent from these stations to the Ufficio Centrale di Meteorologia in Rome, and will be published monthly, with the observations received regularly already from the Tripoli Meteorological Observatory.

We are asked to state that the British Fire Prevention Committee, having established a technical library that will be known as the International Fire Library, with a nucleus of more than 2000 books dealing specifically with matters of fire prevention, fire service, and fire loss, is now desirous of directing the attention of authors, public authorities, publishers, and collectors to the fact that a new catalogue is in preparation, and that any books, pamphlets, or reports which they are able to spare for this collection should be addressed as soon as possible to the honorary chief librarian, The International Fire Library, 8 Waterloo Place, Pall Mall, S.W.

The death is announced of Prof. Ernst Kittl, director of the geological and palæontological section of the Imperial Museum of Natural History, Vienna. Born in 1854, Prof. Kittl became custos of the Vienna Museum in 1893, and subsequently succeeded Prof. T. Fuchs as head of his department. He was the author of numerous papers and memoirs on fossils, chiefly Mollusca, and he prepared a valuable guide-book to the geology of the Salzkammergut for the meeting of the International Geological Congress at Vienna in 1903. For many years he was an active member of the Austrian Tourist Club, and from 1889 to 1898 he edited the publications of its natural history section.

The death is announced of Dr. Léon Pervinquière, lecturer on palæontology in the University of Paris. After a brilliant career as student in the University, he spent three years in investigating the geology of central Tunis, and on his return published an exhaustive volume on the region, with the best geological map of Tunis which has hitherto been prepared. At the same time he made a great collection of Tunisian fossils, which he afterwards studied in Paris, and the results of his researches were published in two handsome volumes on the Jurassic and Cretaceous Mollusca. Two years ago Pervinquière accompanied a boundary commission to examine the geology of the frontier between Tunis and Tripoli, and made valuable contributions to our knowledge of the extreme southern part of these countries. His untimely death at the age of forty is a serious loss to geological science.

The death is reported, in his fifty-sixth year, of Prof. W. Hallock, for the last eleven years professor of physics at Columbia University, New York. He graduated at that University in 1879, and then studied at Würzburg, where he was for a short time an assistant in the physical laboratory. Returning to America in 1882, he was successively a physicist on the U.S. Geological Survey, professor of physics at the Corcoran Scientific School, Washington, professor of chemistry at the National College of Pharmacy, and assistant in charge of the Astrophysical Observatory of the Smithsonian Institution. For ten years before his appointment to the full professorship he was associate professor of physics at Columbia. While on the staff of the Geological Survey he conducted the investigation of the subterranean temperatures in the dry well at Wheeling, where the drill went down to 4500 ft. below the surface of the earth. For three years Prof. Hallock was at work in the Yellowstone Cañon, investigating the phenomena of the hot springs and geysers there. Among other subjects that attracted his attention were the effects of pressure on powdered materials, and the thermal expansion of rocks.

An account has reached this country of the experiences of Mr. Frank Wild and his companions in the Antarctic. Mr. Wild led the second party of Dr. Mawson's Australasian Expedition. This party was dispatched by the leader to Sabrina Land or Knox Land; the existence of the former was disproved, while the latter was found to be unapproachable. The party, however, "landed" on a glacier in motion, and established a depôt on the land behind it. Thence the party divided, carrying out surveys east and west; the eastern section carried its work as far as 101° E., and explored inland for fifty miles, to an altitude of 4500 ft., while the western section worked along the coast to effect a junction with the surveys of the German expedition of 1902. Its route also lay at high altitudes. The discovery of the largest known rookery of emperor penguins is recorded. Severe weather conditions were encountered, and it is stated that the same blizzard which proved fatal to Scott held Wild's party prisoners for nine days. The new land was taken possession of in the name of Queen Mary's Land; it is a continuation of the King Edward VII. plateau, and has an upward slope towards the pole, and a coast-line of 350 miles.

A very interesting circular has just been issued by the Department of Mines of Canada, directing attention to the fact that an experimental laboratory for the concentration and treatment of Canadian minerals has been installed by the Department at Ottawa. The laboratory includes both small-scale laboratory apparatus and plant of working size, though, of course, not unduly large, for the practical treatment of bulk samples. The plant is to be operated free of all charges upon Canadian ores, the minimum amount for a laboratory test being 200 lb. of mineral, and for a working test not less than 5 tons. It is true that something of the same kind has been done previously in Australasia, but never upon the same liberal scale, and the intelligent enterprise of the Canadian Government in thus facilitating the development of mining and metallurgical industries in the Dominion cannot be too highly appreciated. It is sincerely to be hoped that the example may be followed elsewhere.

THE summer meeting of the Institution of Naval Architects is to be held in Glasgow on June 23-27. The premises of the Institution of Engineers and Shipbuilders in Scotland have been placed at the disposal of the visitors to Glasgow. Among the papers included in the programme of proceedings may be mentioned:—Dr. S. J. P. Thearle, note on some cases of fatigue in the steel material of steamers; Messrs. G. S. Baker and J. L. Kent, effect of form and size on the resistance of ships; Prof. A. H. Gibson and J. Hannay Thompson, experiments on "suction" or interaction between passing vessels; Mr. A. Cannon, experimental determination of the effect of internal loose water upon the rolling of a ship amongst a regular series of waves; Mr. Lloyd Woollard, effect of water chambers on the rolling of ships; Prof. L. Gümbel, on the criterion for the occurrence of cavitation. The programme also includes a variety of functions, visits to works, and excursions, in addition to the more serious business of the meeting.

MR. A. RADCLYFFE DUGMORE, the pioneer photographer of big game in their native haunts, and the author of "Camera Adventures in the African Wilds" and other works on kindred subjects, delivered, at the Æolian Hall on May 30, the first of two lectures entitled "Stalking Big Game with a Camera." This lecture dealt solely with his experiences in British East Africa, where he succeeded in getting some splendid flashlight photographs of lions creeping up to a "kill" at night, and of hartebeests drinking at a water-hole. He was very fortunate also in securing pictures of rhinoceroses, giraffes, zebras, gazelles, and buffaloes in the open, two of them, showing a large black rhinoceros in the act of charging the photographer, being particularly impressive. So close was the beast at the final click of the shutter that he had to be turned with a rifle bullet; but to Mr. Dugmore's credit be it said that he claims never to have used firearms unless his own life was in danger or unless meat was required for feeding the members of the expedition. Many of the photographs show beautiful spots in the scenery of East Africa, one with a group of Grant's gazelles in the foreground and the snow-clad summit of Kilimanjaro breaking through the clouds in the distance being especially charming. Mr. Dugmore is a clever and practised lecturer, and those who are interested in living animals could not spend a pleasanter hour and a half than by visiting the Æolian Hall this evening, June 5, when the second of the two lectures will be given.

MR. R. E. DENNETT, Deputy Conservator of Forests, Nigeria, a well-known authority on the negroes of West Africa, has reprinted from the Journal of the African Society a paper entitled "A Common Basis of Religion." In our existing knowledge of Bantu culture, derived from writers like Miss Mary Kingsley and Sir A. Ellis, it is startling to find the negro credited with a system of philosophy, including no fewer than 201 parts, each representing an Orisha, or departed spirit. It is said to be based on on elaborate scheme of symbolism, and the order of these symbols represents "to the psychologist what the periodic classification is to the chemist, or perhaps another form of Newland's law of octaves." The exposition, as it stands, is most ingenious, and the writer concludes by stating that by "superimposing the kinetic parts upon the potential in the moral and intellectual categories we note that the soul becomes the home of faith, the mind of idealism, the body of the senses, the will of life." At the same time, it must be remembered that the interpretation largely rests on the verbal analysis of native terms, and it may possibly be held that while our knowledge of Bantu philology scarcely warrants the conclusions, Mr. Dennett may have read between the lines of his authorities more than they may be reasonably admitted to bear.

A RECENT number of the Annals of Tropical Medicine and Parasitology (vol. vii., No. 1) contains a detailed study, by Major Christophers, I.M.S., upon the colour-markings and other variable characters of Anophelinæ, with special reference to the systematic and phylogenetic grouping of the species. The publication of this memoir in a medical journal may cause it to be overlooked by naturalists, to whom it should be of special interest. The author concludes that colour-markings can be utilised, equally with structural characters, in a natural classification of the anophelines and for placing species in groups to which they have affinities. A classification based on colour-marking approximates very closely to one based on scale-structure, but shows the affinities and relation between the groups much more clearly. The tendency of the phylogenetic evolution of the group is towards elaboration of ornament and development of scales; the more scaly an anopheline, the more advanced phylogenetically it would appear to be. Three main subdivisions are recognised; the Proto-anopheles, occuring both in the Old and New Worlds; the Deuteranopheles, chiefly African, South Asian, and Malayan; and the Neoanopheles, a peculiar Australasian type.

THE report of the Philadelphia Zoological Society for 1912-13 records a large increase in receipts over the previous year, this increase being distributed over every month of the year.

THE *Naturwissenschaftliche Wochenschrift* of May 11 (No. 19, Bd. xii.) contains an excellent summary, with bibliography, by Dr. Oberstein, of the fungoid diseases of animals and the bacterial diseases of plants.

WE have to acknowledge the receipt of a copy of the third part of vol. i. of the *Sarawak Museum Journal*, the contents of which include an article by Mr. C. Aurivillius on Bornean longicorn beetles, and a second, by Mr. C. J. Gahan, on those remarkable Indo-Malay coleopterous larvæ commonly termed "trilobites," the adult condition of which is still unknown. Mr. Gahan suggests that the larval stage may be permanently retained in the females.

Extinct North American horses, all referable to the modern genus, form the subject of a paper by Mr. O. P. Hay, published as No. 1969 (vol. xliv., pp. 569–594) of the Proceedings of the U.S. National Museum. Four species are described as new, two of these being based on teeth alone, while each of the other two is represented by the skull. No. 1975 (vol. xliv., pp. 649–654) of the same serial is devoted to the description of a remarkably fine skeleton of a zeuglodont lately set up in the museum. For these primitive whales Mr. J. W. Gidley, the author of the article, revives the extremely inappropriate name Basilosaurus, despite the fact that it was replaced by its sponsor, Sir R. Owen, by Zeuglodon when the mammalian nature of the remains became evident.

We have received reprints of two papers by Mr. W. E. Collinge on the relation of wild birds to forestry and on the destruction and dispersal of weed seeds by wild birds. In the former it is pointed out that but few wild birds are directly hurtful to forests in this country, the majority of species found in or near forests being distinctly beneficial owing to their destruction of insects and small mammals. Attention is directed to the importance of providing nesting-boxes in forests for the insectivorous birds. Merely to protect these birds is not sufficient; their multiplication must also be looked after. In the second paper many interesting details are given as to the frequency with which birds completely destroy even hard fruits and seeds, but there are so many cases in which the seeds pass through the bird's alimentary canal without being injured that the author cannot regard the seed-eating birds as a class as being beneficial—on the whole, they appear to act as distributors of weed seeds to a much larger extent than is generally supposed.

At the commencement of a very interesting article on our present knowledge of the earliest quadrupedal vertebrates (Tetrapoda), Prof. F. Broili points out that the occurrence of remains of land plants in the Lower Silurian of North America and the Upper Silurian of Kellerwald and the Hartz, coupled with their occasional presence in the Lower Devonian, may be taken as strong presumptive evidence of the existence of a contemporary vertebrate land-fauna. The first actual evidence of such an early fauna does not occur, however, until the Upper Devonian, and then only in the shape of the remarkable footprint from Warren County, Pennsylvania, to which O. C. Marsh gave the name Thinopus. Very noteworthy is the fact that this print represents a relatively large animal, vastly superior in point of size to the tiny salamanders of the succeeding Lower Carboniferous epoch, although equalled in this respect by Eosaurus of the Upper Carboniferous of Nova Scotia. Its evidence appears, however, quite indisputable, and we must therefore assume the Tetrapoda to have attained a relatively high degree of development in the Devonian, and thus to have been well represented in the Silurian. This being so, the Carboniferous and Permo-Triassic forms, interesting and in many respects generalised as they are, cannot be regarded as the earliest types, and, consequently, any attempts to formulate the phylogeny of the group must be to a great extent premature. The author has much to say regarding the structure and affinities of labyrinthodonts and anomodonts, but space permits only of the remark that he regards most of these, not even excluding dicynodonts, as amphibious.

We have received three numbers of the *Bollettino* of the Italian Seismological Society, forming a volume of more than 300 pages, and containing notices of the earthquakes recorded in Italy during the first half of the year 1909. The total number of entries is 726, all but seventy of which refer to shocks that originated within the area of Italy. This number, which is much greater than usual, is partly due to the frequency of the after-shocks of the Messina earthquake of December 28, 1908. Dr. Martinelli, the editor of the volume, connects 152 shocks with this great earthquake, but many shocks recorded at Messina and other isolated places, if more fully known, might have to be placed in the same category.

The Commonwealth Meteorologist has recently issued sheet maps showing the mean temperature and mean rainfall of Australia for the separate months and for the year. These maps confirm in the main those published in the "Atlas of Meteorology," so far as regards the south-eastern portion of the larger island; they extend the information over the remainder of the continent, and thus include Tasmania. The earlier maps, based on the *Challenger* results, show temperatures for six alternate months only. The most striking points of difference occur in the annual maps. The annual isotherms in the atlas map sweep southwards between the coasts; the new maps show roughly a sweep to the north. The annual isohyets on the new maps show much greater detail for the north and east coasts, and indicate that parts of the north coast receive more than 60 in. and Geraldton district on the Queensland coast more than 140 in. annually. The new monthly rainfall maps indicate clearly the winter rains in the south and the summer rains in the north.

According to the *résumé* of the communications made to the French Physical Society at the meeting on April 18, a large proportion of the evening was devoted to a discussion of the results of recent determinations of the radiation constants, σ of Stefan's law and c of Wien's and Planck's laws. One of the most recent and most accurate determinations of c is that of Warburg, Leithäuser, Hupka, and Müller, made at the Reichsanstalt, and reported in the April number of the *Annalen der Physik*. According to this determination c has the value 1·437 centimetre-degrees, a number which differs little from the mean of the more modern of the previous determinations. The determinations of σ differ much more seriously from each other. The oldest values lie between 5·0 and 5·5, while almost all the newer values are above 5·5, those of Valentiner and Westphal being 5·58 and 5·54 respectively, while M. Féry has in three sets of experiments obtained values above

6·0. M. Bauer attributes these high values to erroneous determinations of the corrections to be applied to the observations for the reflecting power of lamp black. He gives as the most probable value of σ deduced from his own and other observations $(5{\cdot}60 \pm 0{\cdot}04) \times 10^{-12}$ watt/(degree)^4.

AN interesting account of the survey of the Alaskan boundary, by Mr. J. A. Flemer, appears in *The Engineering Magazine* for May. The northern section of this line follows the 141st meridian. The initial point, determined by telegraphic longitude, is at the crossing of this meridian and the Yukon River. The azimuth of the meridian at this station was determined astronomically, and the line itself is being projected both north and south by two observers, one an American and the other a Canadian. The international projection party is being followed by a triangulation party. The topographical work is being executed by the plane-table method, since the climatic conditions in this part of Alaska have not that extreme character inherent to south-east Alaska, where the photo-topographic surveying method had to be employed. The triangulation party which precedes the topographic party furnishes the latter with the needed geodetic control, based on the field computations. The plane-table sheets are on 1 : 45,000 scale, with a horizontal contour interval of 100 ft., and the topographic details are mapped with the 141st meridian as the median line of a strip four miles wide. The boundary is being marked with aluminium-bronze monuments, the monument-setting party cutting a vista through wooded areas 10 ft. on each side of the meridian.

THE Academy of Natural Sciences of Philadelphia commemorated its centenary in March, 1912, by a number of conferences, of which an account was published in the issue of NATURE for April 11, 1912 (vol. lxxxix., p. 143). On that occasion the academy decided to publish several volumes in commemoration of the centenary, and one of these —an index to the entire series of its Journal and Proceedings, from the first volume issued in 1817 to the close of 1910—recently made its appearance. The index forms a volume of 1433 pages, and consists of a catalogue of the contributions under the names of authors, and a reference to all species, genera, families, &c., described or mentioned in the several volumes, arranged alphabetically. The expense incurred in the preparation and publication of the work has compelled the publication committee to make a charge for it. The price, 3.50 dollars, carriage paid, is less than the cost of production. Copies may be obtained from the editor, Dr. E. J. Nolan, Academy of Natural Sciences, Logan Square, Philadelphia, Pa., U.S.A.

A CLASSIFIED catalogue of second-hand books, journals, and monographs on zoology and other branches of natural science, including works from the library of the late Mr. Robert Shelford, sometime curator of the museum, Sarawak, and afterwards assistant in the Hope Museum of Zoology, Oxford, has been issued by Messrs. Bowes and Bowes, Cambridge, who have the works on sale. Mr. F. Edwards, Marylebone, London, W., has just issued a catalogue of books on ornithology and oology, including copies of the works of John Gould, H. E. Dresser, Lord Lilford, Henry Seebohm, &c.; also a series of native original drawings, in colours, of birds of India and Malaysia.

WE have received the first number of a new periodical, *La Science et la Vie* (April, 1913), the object of which is to popularise science. The principal contributions are :—Time measurements and signals, by M. G. Bigourdan; the construction and life of a big gun, by Lieut.-Col. Picard; the little agents of death (dealing with insect carriers of disease), by M. J. Paul Dupuy; and "Can the onset of old age be retarded?" by Dr. Toulouse. The periodical is profusely illustrated, and is issued at the price of one franc the number. The list of collaborators includes the names of many well-known men of science.

OUR ASTRONOMICAL COLUMN.

PERIODIC SPECTRUM OF 12 CANES VENATICI.—A Kiel telegram, dated May 30, states that Belopolsky has found that the star 12 Canes Venatici exhibits a spectrum that is periodic. Lines appeared on the following dates, April 22, 27·8, May 4, 9, and 22·5, but on seventeen days they have been invisible.

POSITION OF THE AXIS OF MARS.—Prof. Percival Lowell publishes, in the Bulletin No. 56 of the Lowell Observatory, his observations and those of Mr. Slipher of the position of the polar cap of Mars for the determination of the axis of this planet. The observations were made towards the end of the year 1911, but they include others made by Mr. Slipher in 1909. The values of the position of the axis are given in the case of each observer for every alternate year from 1901 to 1909. As regards the results and their accuracy, it is stated at the end of the paper that the mean of all Prof. Lowell's measures for the last fourteen years gives for the tilt of the Martian equator to the Martian ecliptic the value 23·5°, while that obtained by Mr. Slipher for 1909 and 1911 gives precisely the same value. In this publication Prof. Lowell refers to Prof. H. Struve's communication to the Berlin Academy, in which it is stated that the motion of the satellites affords a better determination of the Martian axis than direct measurement of the polar caps. This view is not acceptable to Prof. Lowell, who says, "it seems advisable to here correct a few misapprehensions," and these are contained in the present bulletin.

THE SOLAR ECLIPSE OF APRIL 16–17, 1912.—A communication by M. Simonin to the *Comptes rendus* for April 28 contains the results of the discussion of observations made during the eclipse of the sun on April 16–17 of last year. It will be remembered that the central line extended from Portugal to Russia, and along that line, scattered at various points, a great number of observers noted the times of interior and exterior contacts. In fact, a large amount of material was available for discussion, and this has now been completed. The conclusions may be summed up as follows :—

The right ascension and declination of the moon's centre, published for April 17, 1912, by the *Connaissance des Temps*, and corrected after Newcomb, ought to be increased respectively by 0·63s. and 4·3″. The calculated values of the semi-diameters of the sun and moon at the earth's mean distance give the figures 15′ 59·96″ and 15′ 32·16″. The sun's semi-diameter thus obtained exceeds by 0·33″ the value generally adopted for eclipses, while the moon's semi-diameter is a very little less than the mean of the two values adopted in the calculations of the *Connaissance des Temps*. The discussion also shows that the first exterior contact was in the mean observed six seconds too late, and the last three seconds too early, while the observations of the interior contacts were not affected by any such systematic error.

Details of the calculations will be published later in a memoir.

THE SPECTRUM OF NOVA GEMINORUM NO. 2.—The spectrum of Nova Geminorum No. 2 is the subject of a long communication by Prof. F. Küstner in *Astronomische Nachrichten*, No. 4654. Some time ago Dr. Giebeler, his assistant, published the results of a series of measures he made (*Astronomische Nachrichten*, No. 4582) of the fine sharp absorption lines in the nova spectrum, concluding that they gave an indication of the presence of radio-active elements. This paper contains an investigation by Prof. Küstner of the same and other negatives taken at Bonn of the nova, and the measures he secured and those of Dr. Giebeler are given together. The subject is discussed in considerable detail, and we can only here direct attention to the conclusions to which he has arrived with regard to the origins of 241 lines which are contained in his list. Thus he concludes that there is good evidence for the presence of uranium, titanium, and blue argon—that radium, manganese, and zirconium may be present, but that there is no evidence of the emanation, iron or vanadium. As regards calcium, helium, and magnesium he finds that certainly absorption lines observed corresponded to calcium H and K, probably also *g*, fairly certain He 4471·66, and questionable Mg 4481·34. It may be added that the wave-lengths of the enhanced lines of Lockyer were included in the investigation, and that little evidence was found for lines to be assigned to their origin; thus he rules out the presence of enhanced iron, titanium, and manganese. This paper should be read in connection with that recently published in the Monthly Notices of the R.A.S. by Prof. Newall and Mr. Stratton, who corroborate in the main the enhanced-line spectrum of the nova as first put forward by Sir Norman Lockyer in the case of Nova Persei.

SCIENCE, POLITICS, AND PROGRESS.

WE gave last week an account of the annual meeting of the British Science Guild and a summary of the report adopted at the meeting. We are glad to be able to supplement that article with abridged reports of the speech delivered by Lord Sydenham in proposing "that the best thanks of the British Science Guild be tendered to Viscount Haldane for his services as president since its foundation, and that Sir William Mather be elected to succeed him," and the reply made by Sir William Mather.

By the retirement of Lord Haldane, remarked Lord Sydenham, the guild was about to sustain a very severe loss, for in Lord Haldane they found a great leader and an inspiring power which had been of the utmost value in promoting the progress of the guild. It might be that there was a certain incompatibility between science and politics which the guild must strive in time to remove; or possibly science had not yet been brought to bear upon the delicate process of Cabinet making as it certainly should be. At least the spectacle of a Minister of the Crown who was a whole-hearted believer in the benefits of science and who could proclaim those benefits with knowledge and experience was a rare, if not a unique, phenomenon in this country. In Lord Haldane they had had an educationist who had long ago realised what technical education had done for other countries, and realised the deficiencies of the British Empire and had striven to remove them. And now the pleasant duty had been imposed upon him of proposing the election of his old friend Sir William Mather as their second president. The career of Sir William had been spent in the successful application of science to industry, and not only to processes and machines, but to men. It was in Sir William's great firm that the standard of forty-eight hours a week labour had long been adopted, and it was not an accident that for fifty years no strike had occurred in his business. As a member of Parliament, he was a persistent and consistent advocate of technical education. The guild has before it important national work. He (the speaker) felt confident that in Sir William they would have a most worthy successor to Lord Haldane.

Sir William Mather said he felt the deepest gratitude to the members of the guild for having so cordially elected him as their new president, but when he was first appealed to by Sir Norman Lockyer to take office he had some reluctance in assenting. He, however, had a great interest in the movement, for the British Science Guild claimed to teach the vital importance of using scientific methods in the common things of life. Those of them who were engaged in applying the fruits of scientific research and discovery furnished by the brilliant students of natural science realised the immeasurable debt the country owed to those who, in the long and patient work of laboratory experiment and the solitude of study, revealed the secrets of nature, and declared the scientific laws by which they might be adapted to the uses of man. The producers and manufacturers of the things that were used and consumed by the human race, and were necessary to its higher progress and happiness, had neither the time nor the requisite training to seek in the hidden treasure-house of nature for the sources of higher development. This was the work of the scientific explorer, and the guild embraced men who felt it to be a patriotic duty to encourage both the scientific explorer and the practical expert in the promotion of national prosperity and continual progress. They were beginning to realise in the twentieth century that there were latent forces in human beings as well as in nature that need to be exploited whereby their national welfare might be enhanced. The evils they deplored, the misery and suffering they saw among their fellow-creatures, were all preventable, and education in this matter became the most important thing in the world.

The British Science Guild had made education one of the chief objects of its study in relation to the training of children in their earliest years before the rational faculty became active, and this propaganda would be continued, for by this means only could the nation rise to higher achievements in removing the causes of poverty, misery, and disease, which affected the national progress, notwithstanding the wealth, power, and industrial prosperity which scientific discoveries had yielded to those who had been able to use them. It was not incompatible with individual ambition in the acquisition of wealth and power that the chief aim of the nation should be to encourage and support other means of adding to the contentment and welfare of the whole people. One of the most retrogressive conditions of present-day life in England was the recurring and increasing outbursts of passionate discontent amongst the working classes resulting in incalculable economic loss from strikes and lock-outs, and the deplorable absence of good feeling, sympathetic interest, and even patriotic effort between employer and employee. But did anyone consider that this was a normal or inevitable condition of things? Surely not. It was the result of human forces ignorantly applied and producing woe where the common weal should prevail. Both parties in the struggle usually displayed an equal amount of ignorance, but with a truly educated people all industrial progress should be admittedly dependent on the perfect accord between capital and labour in the pursuit of an end mutually advantageous. The lamentable condition of things had been of late the subject of Parliamentary and Government concern. Admirable means, including the recommendation of the principle of the minimum wage, had been devised and must be continued, but meanwhile the whole nation was being kept in a condition of inefficiency compared with what they knew would be possible were the whole industrial population of employers and employed working together in perfect accord and with the common aim of producing the most perfect products at the minimum of cost and maximum of benefit to both labour and capital. Such accord would, he believed, be found to lie in some system of profit-sharing between employer and employed, which if scientifically applied would most certainly lead to increased efficiency and contentment.

He submitted, therefore, that it would be a proper function of the British Science Guild to study and, if possible, to initiate by some considered recommendations a new order of industrial organisation, based on scientific principles of management, in which full justice would be done to all the interests involved in developing to a condition of maximum efficiency the great resources of the nation.

At the banquet of the British Science Guild, held on Monday, May 26, the following speech was delivered by Sir David Gill, K.C.B., in proposing the toast of the guild:—

I have been asked to propose the toast of the British Science Guild—and I rise to do so with much pleasure, because I feel and know that the objects for which it was founded are most worthy, and because in many directions the guild is doing good and useful work.

The aims and objects of the guild may be summarised in a few words, viz. to bring science and scientific habits of thought to bear upon the problems of everyday life and administration. The guild has no politics in the ordinary sense of the word. It belongs to no political party—its object is to help any party, be it Radical or Conservative, or any department of State, any Parliamentary Committee or individual administration with advice or assistance based on scientific knowledge.

It is sad to think how very few of our leading politicians—how very few, indeed, of our members of Parliament—have any serious knowledge of science; and yet it is upon science, and largely upon science alone, that the whole progress of our modern civilisation depends. I would be the last man in the world to deny the advantages of culture as it was understood 100 years ago. I mean the civilising, the refining, and the elevating influence of literature, art, and philosophy, apart from modern science based on experiment and observation. But it is not by progress in the older directions that we have to look chiefly for the modern betterment of mankind—the betterment of the health, the comfort, the safety, and the convenience of the great body of our fellow-citizens. We must go back to the days of Greece for the sculptures that in the present day we strive to emulate; and the like is true of the architecture of Greece and of our early cathedral builders. We have to go back to Giotte for reverence in painting, to Holbein, Titian, Giorgioni, Rembrandt, and Velasquez for other qualities in art that we cannot equal in the present day. In literature it is the same story—Homer, Virgil, Shakespeare, Dante, and Milton are not of our day, nor have we since seen their like. In philosophy I doubt if we have made much real advance since the days of Plato.

But in science what has not the progress been in recent days? That is a story known to you all, and I need scarcely dwell upon it. Tycho Brahe, Kepler, and Newton have laid the foundation of the fair superstructure of modern dynamical astronomy; and Stokes, Kirchoff, and Bunsen have laid on a no less sure foundation our present-day knowledge of the chemistry of suns and worlds other than our own. Chemistry and physics have advanced with giant strides within the last century, and in the present day we see the dawn of a knowledge of the constitution of the atom.

The invention of the steam engine is, by comparison with the fullness of art in the days of Greece, a thing of yesterday, and so practically is the scientific coordination of the laws of heat and electricity, the invention of the dynamo, and the transformation of energy into light and heat and *vice versâ*. The mythical æther is used to convey our wireless messages around the world, and we can travel on sea and land with a rapidity, comfort, and luxury almost undreamt of by men of only fifty years ago. We can travel, if we so desire, under the sea or over the sea, or we can fly in the air.

Medical science has made marvellous strides. Pain and suffering have been diminished and life has been prolonged. All these are steps in the progress of mankind, in the betterment of the conditions of life, which we owe to science and to science alone. I am aware that there is still a school of men who contend that we are no happier or better for this progress. I need scarcely say that I do not agree with them, but I do not propose to bore you with arguments on so trite a subject; the simple fact remains that if we, in these little islands of ours, do not progress with the times by the aid of science and the cultivation of our manhood, we shall be left behind in the race of progress—a strong man armed will come upon us and our inheritance will another take.

That is absolutely certain; so that whether the men of old were wiser and happier without science is not a question that requires discussion. The simple alternative is whether, in face of the competition of other nations, we of this presently great Empire are to be content to give up our place and power, or whether by the successful cultivation of our manhood and our science, we shall keep our place among the nations. Since science is so important to our existence as a nation, is it not strange that amongst our leading legislators there are so few who have any reasonable acquaintance with science?

I do not speak so much of the ordinary member of Parliament—he, poor man, in the present day, has got very little to do with the government of the country. He may have his convictions, he may have devoted time and knowledge and thought to the preparation of a useful Bill—but the chance of getting it even discussed by the House of Commons is small indeed; he may be thankful if he is not compelled by the crack of the party whip to vote for something that is in total opposition to the principles of his own Bill.

The real government of the country lies thus in the hands of a comparatively small number of men, and too often of men who have been selected for fluency of speech, readiness in debate, and a certain personal magnetism that appeals to the masses, rather than for the qualities of the highest statesmanship and sound scientific knowledge. The politician as a rule has had an eye to politics from an early age, and his reading has gone in the direction of history and political economy, generally to the entire neglect of the more exact departments of science, and, above all, he prefers votes to history, political economy, science, or anything else. The instincts of the man of exact science are indeed opposed to those of the normal party politician. The man of science must be very sure of his grounds before he makes a statement, and must rigidly compare all existing facts with any theory before he declares the probability, or his personal conviction, of its truth. Above all, he must be careful to avoid the influence of preconceived views of his own or the views of his friends before he draws his inferences from observed facts. Where would the party politician be if he based his action on such grounds? He would soon be hounded out of his party, or reduced to slavish submission by the party whip.

So long as we have party government I fear there is no escape from the predicament. The object of the Science Guild is to provide some partial remedy at least for this undesirable state of affairs.

When Ministers have on any particular subject recognised the need of scientific advice they always have the Royal Society to which they may apply, and from that society they can always obtain sound advice on any subject that involves exact science. But it needs some scientific knowledge to know when sound scientific advice is required; and too often Governments do not know when they should ask for such advice, or they may know enough to realise that acceptance of the advice they require might involve expenditure that would not purchase votes or might lead to action that would be unpopular with some of their constituents.

Now it is here that a body like the Science Guild may rightly and does most rightly and properly come in. Unlike the Royal Society, it does not wait to be consulted. As a non-political body, it desires no party advantage from its action. Therefore when a Bill is in course of preparation or discussion in which it is clear that scientific advice has been neglected or not demanded, the Science Guild refers the matter to a competent committee of its own, and tenders advice without solicitation. It does not stump the country to proclaim its views; it leaves to the Government or the member who fathers the Bill the responsibility of adoption or non-adoption of its advice; it leaves to others to use any further pressure that may be required, based upon the views of the Science Guild.

Our guild is yet young, and it takes time before the elector at large can realise the due weight of its views. But no one can question the competence of its committees; the men who compose them are well known for their scientific standing and sound practical common sense; and, as time goes on, Governments will more and more find the importance of listening to the advice so tendered. No man was more sensible of this than was Lord Haldane, who has been our president since the formation of the guild nearly seven years ago. It is with much regret we learn that the pressing duties of his high office have compelled Lord Haldane to resign the presidency of the guild. We are most grateful to him for the services he has rendered, and for the recognition he has given to the value of the work aimed at and done by the guild.

We all, I am sure, are gratified to know that the Rt. Hon. Sir William Mather has consented to fill the chair vacated by Lord Haldane's retirement. He, as we all know, has taken a prominent part in the promotion of technical education throughout the country. He has been an able and active member of the guild, and we all have confidence that in his hands and under his inspiring influence the work of the Science Guild will grow and flourish.

JOINT MEETING OF BRITISH AND FRENCH ELECTRICAL ENGINEERS.

DURING the joint meeting of the British and French Electrical Engineering Institutions, held in Paris on May 21–24, a wide range of subjects was discussed. The greater part of the time was devoted to electric railway traction. The electrical equipment of purely urban and suburban railways has already become almost a mere question of economics and technical detail; the broader engineering and scientific problems are solved. So far, however, the replacement of the steam train by the electric train on main lines has only been limited, and this is a work for which the electrical engineer is making ready. Its consideration cannot be deferred until the improvements in the economy of generating and distributing electrical energy, and converting it into mechanical energy on the train, are such that there can be no other reasonable method than to burn the coal at the pit's mouth instead of the locomotive furnace; for in the meantime the "electrification" of suburban lines must continue, and the railway engineers naturally desire to equip their lines on some system which will lend itself to main line traffic as well as suburban, without extensive alterations being necessary when the second part of the problem is taken in hand. For this reason, the presentation and discussion of six papers on electric railways by French electrical engineers of high repute was particularly well timed.

The chief reason for different methods in dealing with urban railways pure and simple and main line railways may be summed up in two words, viz. distance and locomotives. On an urban or suburban line, the energy required is spread over a comparatively small geographical area; while on a main line the energy has to be transmitted over a considerable distance. Again, the traffic on an urban or suburban line is mainly passenger traffic, while a large proportion of the traffic on a main line is for the conveyance of goods.

In the majority of suburban lines a comparatively low electrical pressure (500 or 600 volts) is carried on the conductor along the track; this means a proportionately large current is required, but the voltage-drop and loss of energy which this entails are not serious on account of the small distance between the power station or substation and the train. Partly to facilitate the conveyance of this high current from the conductor rail to the train, and partly to enable trains to be conveniently subdivisible into lengths corresponding with the density of traffic at various periods of the day, the "multiple-unit" system is employed, in which there are two or more motor-coaches on each train, each taking current from the "live" rail conductor, but all controlled from the cab of the front motor-coach.

On long main lines, on the other hand, it is obviously more economical to transmit the energy to the train in the form of a higher potential and lower current, and this is the more desirable owing to the necessity of using locomotives, at all events for the goods traffic, which entail transmission of the whole of the current to the train at one point or one set of contacts with the live conductor. Therefore, other things being equal, a high-pressure single-phase current, as is being used on the London, Brighton and South Coast Railway, and also to some extent on the Midland Railway, and on several American and German lines, is indicated as the solution to the problem so far as main line traffic only is concerned; it is easy to generate and transmit, and requires only one live conductor, which is overhead. On the other hand, the overhead work introduces complications and expense for suburban traffic in which there are many lines of tracks and many points and crossings, the equipment of a single-phase locomotive costs more and weighs more than that on any other system, and, last but not least, there is a great risk of serious disturbance to telephone and telegraph lines in the neighbourhood due to both electrostatic and electromagnetic induction.

In three-phase working, as used on most of the Italian electric railways, the second of these three disadvantages does not obtain, but the first disadvantage is accentuated owing to the need of two live conductors for each line of track, and the possible effect on the telegraph and telephone lines is the same. The high-tension continuous-current system is growing in favour, therefore, but it suffers from other disadvantages, although it would certainly appear to fulfil most completely the conditions required in a large number of cases. Standardisation is, of course, desirable for railway working, owing to the through traffic from one line to another, and many suburban lines are already equipped on the medium-pressure third-rail system. In the full discussion of the subject in Paris, the relative values of these and other technical points were weighed.

Among the other papers read at the Paris meeting was one by Mr. W. Slingo, engineer-in-chief of the British Post Office, on certain auxiliary apparatus in telephone exchanges. He described a class of apparatus, originally evolved in connection with automatic telephone exchanges, which is now being applied by the Post Office in some of the manual exchanges in London to assist in the distribution of traffic. In ordinary exchange working, when a subscriber removes his telephone from the hook, a lamp corresponding to his number glows, being actuated through a relay, and the operator to which this number is allotted, or one of the operators on either side of her, places a plug in the subscriber's answering jack immediately by the lamp, and makes the necessary connection. In spite of there being three operators who can attend to any subscriber in the busy hours of the day, there is nevertheless a certain amount of time in which each operator is not fully engaged. In the new "Avenue" exchange, an endeavour to level the work of the operators was made by using "ancillary" jacks for each subscriber, multipled over two other sections of the board, so that any one of nine disengaged operators could take any call. In the new system, however, this distributing of the calls to a free operator is made absolutely automatic. The allotment of groups of subscribers to definite operators is discontinued. As soon as a subscriber lifts his telephone from the hook, an automatic switch at the exchange end of his line selects a line leading to any operator who is idle for the moment, the calling lamp at her position glows, and she immediately answers the call.

Two lectures were given on the closing day of the meeting, one, by M. Georges Claude, on the neon light, and the other, by Commandant Ferrié, on the Eiffel Tower time signals. A discharge in a tube of neon gas gives a very pleasant red or orange-red light, which is, however, absolutely devoid of blue rays. M. Claude proposes to combine the use of these tubes with mercury-vapour tubes, and as the latter are rich in blue rays and devoid of red, a more or less white light is obtainable. A difficulty arises in the fact that while the neon tube requires high-tension alternating-current for the luminescent discharge, the mercury-vapour tube requires low-pressure continuous current. It appears, however, that M. Claude uses in his "correcting" tubes both neon and mercury, which, he said, renders them suitable for alternating current (the exact physical explanation of this was not given in the lecture), so that both tubes can be connected to the same circuit. He gave the efficiency of the combination at about 0·8 to 0·9 per candle.

Commandant Ferrié's lecture on the Eiffel Tower time signals was extremely interesting, but as this subject was described in detail in NATURE of March 13, it is unnecessary to do more than mention it briefly now. The time signals at present are sent out twice daily, from 10.44 to 10.49 a.m., and from 11.44 to 11.49 p.m. From July onwards there will be some alteration in the times for sending out these signals and also in the character and sequence of the warning signals. The times for the exact time signals will then be altered to 10 a.m. and midnight. To enable the greatest possible accuracy of observation, a series of 180 short dots regularly spaced at one second less about 1/50 of a second apart are sent out immediately before the ordinary night signals. To facilitate counting, the 60th and 120th dots are omitted. This series of dots is received by the Paris Observatory and other observatories, in each of which the operator listens at the same time to the beats of the master clock or another seconds chronometer. The two sets of beats thus constitute an "acoustic vernier," and during the time that the 180 wireless dots last, three coincidences spaced thirty seconds apart occur between the wireless dots and the beat of the clock. By noting the time indicated by the chronometer at the moment of coincidence, as well as the number of wireless impulses heard before the coincidence occurs, it is possible to calculate the time of the chronometer at the receipt of the first wireless impulse. For instance, if the Greenwich mean time of a coincidence was 23h. 30m. 25s., and the number of the stroke at coincidence was 42, the time of the first beat will have been 23h. 30m. 25s. minus 41 $(1-1/50)$ seconds = 23h. 29m. 44·82s.

PROF. BERGSON ON PSYCHICAL RESEARCH.

PROF. HENRI BERGSON delivered his inaugural address as president of the Society for Psychical Research on Wednesday, May 28, in the Æolian Hall, New Bond Street. At the close of the address, which was delivered in French, and held the close attention of the company for nearly an hour and a half, Mr. A. J. Balfour, a past-president of the society, rose to express the thanks of the hearers, and characterised the address as the most interesting and illuminating one that the society has ever received. When we recall that Mr. Balfour himself, Prof. William James, Lord Rayleigh, the late F. W. H. Myers, and many other distinguished men have held the office of president, we can but feel that M. Bergson has justified both the choice of the society and his reputation as a maker of new thought.

M. Bergson took as his principal theme a study of the nature of the prejudices against the work and methods of the society; in fact, against its very existence—prejudices felt, not by the uninformed and unlearned, but by men of science, keenly desirous to extend the bounds of human knowledge. He attributed the objection to the methods which the experimenters in psychical research were forced to adopt in order to pursue their investigations methods akin to the judicial, the historical, or even to those of the criminal detective, but, since the Renaissance, foreign to the world of natural and experimental science. The great development of mathematical science, based on the recovery of Greek learning, and carried forward by such men as Kepler, Galileo, and Newton, had given to the modern mind the conception of scientific proof drawn from a series of accurate measurements of time, space, and mass which can be repeated at will, so that the man of science of to-day is inclined by his traditions and training to set aside as unworthy of consideration all phenomena which are incapable of treatment by the methods of precision and logical proof. Experimental psychology, however, that can measure rates of fatigue of memory, or persistence of association, has been received into the fold of orthodox natural science, and is making great progress towards a better comprehension of the workings of the human brain.

But readers of M. Bergson's book, especially those acquainted with "Matter and Memory," will recall that M. Bergson looks upon the human brain merely as a means of obtaining recollection, *un organe de rappel,* not as the essential phenomenon of human consciousness or of the life of the mind. Thus by the investigations of modern experimental psychology, we learn more about the instrument of communication between the outer and inner worlds—we do not extend our knowledge of those worlds themselves.

M. Bergson suggested that the function of the brain, and indeed of the recognised senses, is to limit rather than to extend the outlook of the mind. They become the organs of attention to life, picking out and preserving ready for use only those impressions and recollections which will be serviceable to the life of the individual or the species. Everything else is masked and put away where, in normal circumstances, it does not distract the attention of the participant from the things which help him to accomplish his mission in the world. But in certain circumstances, such as illness, shock, approaching dissolution of the partnership between mind and body, the limitation may suddenly disappear, the barrier breaks down—perhaps the reason for its existence is removed—and we get produced the phenomena with which the Society for Psychical Research is accustomed to occupy itself, regardless of mathematical theories concerning the nature of proof.

EXPOSURE OF THERMOMETERS FOR THE DETERMINATION OF AIR TEMPERATURE.

THE report of the Prussian Meteorological Institute for 1911 contains the fourth communication by Prof. G. Hellmann upon the above subject. The observations are discussed at considerable length under three principal heads :—(1) Exposure at a north window (formerly the usual method adopted in Germany) and in a Stevenson screen in a meadow (or field) at Potsdam. This section is accompanied by an interesting set of monthly diagrams showing the mean daily range due to both exposures. (2) Comparison of the Stevenson screen with the aspiration thermometer at Potsdam and Grünberg, in Silesia. (3) Comparison of the true air temperature in a meadow and in the north shade of Potsdam Observatory (about half a metre from the wall).

The following shortened summary gives some of the chief results deduced from the four communications :—

(1) The determination of the temperature near the north wall of a building is practically independent of the nature of the window exposure; the thermometer may even be hung freely, so long as it is not exposed to direct or indirect radiation.

(2) An aspiration thermometer installed near the north wall of a building gives results agreeing very closely with those of the usual window exposure; in the summer half-year the latter gives 0·1°–0·2° (C.) higher readings in the afternoon, while in the winter season the morning and evening observation hours give rather too low readings.

(3) A freely exposed Stevenson screen gives in North Germany too high readings at the afternoon observation throughout the year to the extent of 0·1°–0·2° in winter, and 0·2°–0·4° in summer. At the evening reading also it is 0·1°–0·2° too high in summer, and 0·1° too low in the other seasons; at other hours the differences are very small and of varying sign.

(4) The errors of this screen differ in different climates and with varying conditions of weather.

(5) The true temperature in the shade, on the north side of a building, both as regards absolute amount and daily period, is quite different from that obtained in an open field. At the 2h. p.m. reading the excess of temperature in the field is 0·1° in December and 1·0° in July. These differences increase with duration and intensity of sunshine, and decrease with strong winds.

(6) The true daily means in the north shade of a building and in a meadow differ but little from each other; in winter the meadow daily mean is 0·1°–0·3° the lower of the two.

(7) The hourly readings in the two positions are not comparable, but the daily means derived from the hours 7, 2, 9 by Kämtz's formula exhibit relatively small differences.

(8) The daily oscillation of temperature near the house is about 0·3° in December to 1·6° in June less than in the meadow.

(9) The daily maximum is from 0·1 hour in December to 0·9 hour in June later in the shade of the house than in the meadow, but the time of the occurrence of the minimum is the same in both positions.

HYDROGRAPHY IN ITALY.[1]

THE third annual report on the activities of the Italian Hydrographic Department deals with the year 1911, a period which is stated to have been of particular importance in its history, on account of certain drastic changes which were brought about in the administration of the service, through the passing of a law for the better regulation of the work of collecting and classifying data relating to rivers and their mountain basins, to lagoons and to the sea, and for the systematic study of all streams, their sources and outlets.

This new law assigned to the hydrographic service, in addition to the director, four specialist assistants, and has rendered possible the subdivision of the department into four sections, distinguished as fluvial-hydrographical, maritime-hydrographical, meteorological, and geological.

The report deals with the present and proposed fields of operations, and enumerates the various sub-services to be undertaken. These are as follows :—(*a*) Meteorological; (*b*) aërological; (*c*) telegraphic, for forecasting the weather; (*d*) meteorological, for the city of Venice; (*e*) midday signalling for the port of Venice; (*f*) pluviometric; (*g*) nivometric; (*h*) hydrometric; (*i*) stream measurement; (*l*) flood prediction; (*m*) levelling observations; (*n*) maregraphic; (*o*) maregraphic for the city of Venice; and (*p*) maritime lagoon reclamation. Of these services (*b*), (*d*), (*e*), and (*g*) were only inaugurated in 1912.

Within the limits of a brief notice it is not possible to do more than thus indicate in very general terms the extent of ground covered by the report, and those who desire fuller information or who are interested in any way in the extension and development of hydro-

[1] "Terza Relazione Annuale del Direttore dell' Ufficio Idrografico." By Giovanni Magrini. Pp. 71+plates+maps. (Venice: Carlo Ferrari, 1912.)

graphical research can only be referred to the brochure itself, the seventy pages of which contain much useful and instructive data. Included will be found a number of photographs illustrating various stations, and diagrams showing the method of taking observations. In addition there are four relief maps of the north-eastern portion of Italy (Venice and the adjacent provinces), indicating the scope of operations and their localisation. There is an interesting description of the construction of an experimental tank at Stra.

POSITIVE RAYS OF ELECTRICITY.[1]

The first part of the paper contains a discussion of the evidence afforded by the positive rays as to the nature of the ionisation of the gases in a discharge tube and the properties of atoms. The positive rays consist of:—

(1) Atoms with one positive charge.
(2) Molecules with one positive charge.
(3) Multiply charged atoms.
(4) Atoms with one negative charge.
(5) Molecules with one negative charge.

All the diatomic gaseous elements which have been examined furnish both atoms and molecules with single charges. The proportion of atoms to molecules varies very largely with the conditions of the electric discharge, and evidence is given that the charged atoms and molecules are produced by different processes. It is suggested that the ionisation which gives rise to molecules is due to kathode rays, while the charged atoms are produced by the impact of charged atoms and molecules.

All the elements examined, with the significant exceptions of hydrogen and a substance of atomic weight 3 (X_3), furnish, under certain conditions, atoms with more than one charge. The power of acquiring multiple charges seems to be connected with the atomic weight rather than with the valency or other chemical property of the atom. Thus the atom of mercury, the heaviest atom investigated, can have as many as eight changes, crypton five, argon three, while the lighter atoms, as a rule, have only two. No undoubted case of a doubly-charged *molecule* of an element or compound has yet been discovered.

The negative charge is found on the atoms of some elements, *e.g.* hydrogen, oxygen, carbon, sulphur, chlorine, but not on the atoms of nitrogen, helium, neon, argon, or mercury. It may be regarded as an indication of the chemical activity of the atom, in so far as this depends upon the intensity of the electric field outside the atom. No negatively electrified molecules of compounds have been observed; the only cases of negatively electrified molecules of elements are those of oxygen and carbon, and these only occur when the elements are liberated from special types of compounds.

The second part of the paper deals with the use of these rays as a method of chemical analysis. Several applications of the method are considered. The first of these is to the detection of rare gases in the atmosphere. It is shown that while none of the heavier gases in the atmosphere occurring in quantities comparable with that of xenon have escaped detection, this is not the case with the lighter gases.

"Neon," it is shown, is not a simple gas, but a mixture of two gases, containing a large quantity of a gas of atomic weight about 20, and a much smaller quantity of one with an atomic weight about 22. The "22" gas was first observed in samples of residues of liquid air supplied by Sir James Dewar, and has since been found in every specimen of neon examined, including a specimen supplied by M. Claud, of Paris, and a very carefully purified sample of neon prepared by Mr. Watson. The sample from M. Claud contained a small quantity of a substance with atomic weight 3, the properties of which are discussed later on.

Another application of this method was to the analysis of the gas in a small glass tube in which 30 mg. of radium bromide had been sealed for more than ten years; in addition to helium, the gas contained considerable quantities of "neon" or some element with very nearly the same atomic weight; there was also a trace of argon in the gas, a little more than would have been expected from the volume of air in the tube, although the difference was not very great.

The other application of the method is to the investigation of the properties of a substance for which $m/e=3, X_3$. This gas is given off by most solids when they are bombarded by kathode rays. Reasons are given for concluding that the substance is not the carbon alone with four charges.

The gas has the following properties:—

It can pass through tubes containing red-hot copper oxide, and then over potash without being absorbed.

It is not changed when sparked for a long time with an excess of oxygen, the oxygen being subsequently removed by phosphorus.

It can pass over metallic sodium without being absorbed, nor does it disappear when heated along with sodium vapour.

It is absorbed by charcoal cooled with liquid air, but it can circulate through a glass spiral immersed in liquid air without being condensed.

It combines with mercury vapour when an electric discharge is sent through the mixture; it also combines to some extent with red-hot copper when passed slowly over it. If stored over mercury vapour it seems to diminish, though very slowly. The gas has been detected after it has been stored for several weeks.

The study of the positive-ray photograph indicates that the substance is monatomic, and generally it seems to be similar in its behaviour to the inert gases, although its chemical properties are apparently a little more energetic.

[1] Summary of the Bakerian lecture delivered before the Royal Society on May 22 by Sir J. J. Thomson, O.M., F.R.S.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Dr. Shipley, master of Christ's College, has been reappointed representative of the University on the council of the Marine Biological Association.

On June 3 the Rev. S. A. Donaldson, master of Magdalene College, was re-elected Vice-Chancellor of the University for a second year.

It is proposed to confer the degree of Doctor of Letters, *honoris causâ*, upon Commendatore Giacomo Boni, director of the excavations on the Forum and the Palatine.

The registrary reports that the matriculation this term brings the number of new students for the academic year 1912–13 up to 1200. In the last academic year the numbers were 1156.

Mr. R. Assheton, of Trinity College, and Mr. L. Doncaster, of King's College, have been approved by the general board of studies for the degree of Doctor of Science.

Oxford.—A summer course in advanced practical organic chemistry, with demonstrations, will be held at Queen's College, on August 1–30, by Mr. F. D.

Chattaway, F.R.S. The class is open to students who are not members of the University.

THE new college buildings of Bedford College for Women at Regent's Park, London, N.W., are to be opened by the Queen on July 4, at 3 p.m.

VACATION courses for instrument-makers and glass-blowers will be held at the University of Leyden from August 21 to September 4. Particulars of the courses can be obtained from the director, Prof. H. Kamerlingh Onnes, or the general secretary, Dr. C. A. Crommelin.

THE Commemoration Day proceedings at Livingstone College on June 7 will be the celebration by the college of the Livingstone centenary. The reception of the special delegates and visitors by the principal will be from 3 to 3.30 p.m., and afterwards a number of addresses will be given and an exhibition held.

AT the end of the present academic year Cornell University, N.Y., will lose the services of Prof. H. H. Norris, who has occupied its chair of electrical engineering since 1905, and has been head of the department since 1909. He is resigning in order to undertake editorial work in connection with *The Electrical Railway Journal* and *The Electrical World*.

THE following appointments have been made to the faculty of the new school of technology in connection with Johns Hopkins University, Baltimore:—Prof. C. C. Thomas, of the University of Wisconsin, to the chair of mechanical engineering; Prof. C. J. Tilden, of the University of Michigan, to the chair of civil engineering; and Prof. J. B. Whitehead, hitherto professor of applied electricity in Johns Hopkins University, to the chair of electrical engineering.

AN influentially signed memorial has been sent to Lord Haldane, in his capacity of Chancellor of the University of Bristol, directing attention to the circumstances in which Mr. R. P. Cowl, formerly professor of English literature, was removed from the University of Bristol in 1910. The signatories point out that it appears that a grave injustice may have been committed, and ask for a full investigation of the case. In the first list of signatories there are many distinguished names, including the following men of science:—Prof. W. Ridgeway, Sir Bertram Windle, Profs. R. H. Yapp, J. A. Green, W. M. Travers, P. F. Frankland, Leonard Hill, William Bullock, J. Adams, Gisbert Kapp, F. W. Burstall, W. M. Bayliss, E. W. Hobson, and F. R. Japp.

IT is announced in *Science* that Mrs. G. W. Hooper, of San Francisco, has transferred to the University of California 200,000*l*. for the establishment of an institute of medical research. We learn from the same source that the late Prof. Louis A. Duhring, formerly professor in the University of Pennsylvania, in his will disposes of an estate valued at about 100,000*l*. The will creates a trust fund of 5000*l*., the income of which is to be used for the benefit of the department of cutaneous medicine, and it gives the University of Pennsylvania Hospital 10,000*l*. for the establishment of free beds in which cutaneous, cancerous, and allied diseases shall be treated and studied. After a number of private bequests have been made, the residue of the estate is to be given to the trustees of the University of Pennsylvania, and applied to the treatment of cutaneous diseases and their study.

THE Apprenticeship and Skilled Employment Association has issued its seventh annual report. The work of the association is, among other matters, to watch over the interests of juveniles so far as they are affected by fresh legislation. During the year under review the association has inquired into the hours of employment of van and errand boys, and the conditions of employment of boy clerks in the Civil Service; and representatives of the association have given evidence before the Royal Commission on the Civil Service. It is satisfactory to know that the London County Council has adopted a suggestion made a short time ago by the association that attendance at continuation classes should be made a condition of employment of their laboratory monitors. These lads on leaving the council's service have, as in the past, been referred to the association, and have in almost every case been successfully placed. The report gives further interesting evidence that there is a growing disposition among public bodies to make use of the services of the association in the matter of boys and girls under their supervision.

THE issue of *The Fortnightly Review* for June includes an article on vocational education by Mr. Cloudesley Brereton. The whole spirit of vocational education is, he maintains, that the manual work and crafts with which it deals should not be taught mechanically, or as a mere rule of thumb, but should be used as veritable instruments of culture. In London, vocational education has led, apart from the polytechnic movement and the great extension of trade schools, to the conversion of the higher elementary schools into central schools, to which has been given a definite bias for the preparation of the pupils for an industrial or commercial life; while the work in the infant schools and lower grades of the elementary schools is every day becoming more concrete and constructive. It is to be hoped, Mr. Brereton thinks, that any scheme of national education will immensely enlarge the facilities for vocational education, and be the means of bringing the university into closer touch with the business world and the locality of which it should be the spiritual and intellectual inspiration. One thing is, he says, at least certain: we shall never gain the full confidence of the business world and the working classes until we can show that education is practical, *i.e.* that it has an economic value; while if we are to retain the confidence of those who believe in the spiritual side of education, we must likewise hold fast to its humanistic ideals. Vocational education in the widest sense means the working out of the combination of these ideals.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 29.—Sir Archibald Geikie, K.C.B., president, in the chair.—Prof. A. B. **Macallum**: *Acineta tuberosa*: a study on the action of surface tension in determining the distribution of salts in living matter. In previous investigations it was found that the salts demonstrated microchemically to occur in the living cell were not uniformly diffused but were condensed or "localised" at points in its cytoplasm, or at parts of its surface. Amongst such salts were the compounds of potassium, which are very soluble and are not known to form precipitates in nature. It was concluded that some other force than simple osmotic pressure was concerned in this distribution of the salts, especially in the cases where the condensations were in those portions of the cell surface where, from the deformation observed, it was inferred that a lowering of surface tension was involved. The explanation advanced was that surface tension was the factor primarily concerned in these condensations. Two years ago an investigation of the distribution of potassium salts in *Acineta tuberosa*, a marine Suctorian Protozoan, gave results which appear to place the matter beyond doubt. It would seem, from further investigations, that surface tension not only determines the condensations in the films and elsewhere in the organisms, but also maintains these condensations against the forces of diffusion.—Sir David **Bruce**, Majors D. **Harvey** and A. E. **Hamerton**, and Lady **Bruce**: Morphology of various strains of the trypanosome causing disease in man in Nyasaland. IV., The Mzimba strain.—Helen L. M. **Pixell**: Notes on *Toxoplasma gondii*.—J. C. F. **Fryer**: An investigation by pedigree breeding into the polymorphism of *Papilio polytes*, Linn.—Dr. S. **Russ** and Dr. Helen **Chambers**: The action of radium rays upon the cells of Jensen's rat sarcoma.

Physical Society, May 16.—Prof. C. H. Lees, vice-president, in the chair.—Dr. W. **Makower** and Dr. S. **Russ**: Some experiments to detect β rays from radium A. When an atom of radium A disintegrates an α particle is expelled which carries with it two positive atomic charges. At the same time the radium B atom formed recoils with a single positive charge. To explain this it is necessary to suppose that three negative electrons are expelled during the process. If these are emitted with a high velocity they should appear as β rays capable of detection; or they might consist of a slowly moving δ radiation which would escape such detection. The experiments, made by both methods in the hope of detecting β rays from radium A, failed to reveal any such radiation.—Dr. J. **Robinson**: Dust figures. The ripple formation in Kundt's tube was explained by W. König in 1891. His theory was based on the hydrodynamical forces between two particles in a stream. Certain measurements on dust figures produced by an electric spark have shown that these figures also can be explained in a similar way to the Kundt's tube figures. Cook suggested that viscosity must be introduced in order to account for the formation of ripples. The author shows that it is possible to account for ripple formation without introducing viscous forces at all. In the case of the Kundt's tube figures there is a variation of velocity of the air from a node to an antinode, which produces a variation in the forces, and this causes the powder to lose its uniformity of distribution and to form ripples. The necessary constraints for the ripples are forthcoming without the introduction of viscosity.—Dr. **Haworth**: Vibration galvanometer design. (1) The maximum amount of power available for vibrating the moving system of a vibration galvanometer of the moving-coil type is $V^2/4R$. As the frequency of the instrument is raised the losses increase rapidly, so it is an advantage to be able to increase the useful power input per unit voltage; the resistance of the instrument must be decreased. This can be done in a galvanometer of the Duddell type by leading the current in and out at the bottom bridg and short-circuiting the wires at the top bridge, an it results in an increase of sensibility. (2) Owing to the losses in the moving system increasing at a greater rate than the first power of the frequency, and because the frequency of the system increases at a slower rate than the reciprocal length of the string on account of the mass of the mirror, the flux density must be increased as the frequency increases. As the losses are low at low frequency and the mass of the mirror is not large, then, compared with the mass of the wire, the flux density required is moderate; but at high frequencies the flux density required is large. To obtain this result economically it is convenient to make the depth of the poles small compared with the maximum length of the wires. (3) A combination of (1) and (2) makes a satisfactory instrument with a much flatter voltmeter-sensibility-frequency curve than obtained usually.

Dublin.

Royal Dublin Society, May 20.—Prof. James Wilson in the chair.—W. J. **Hartley**: A violet colouring matter and its production by a certain bacterium. The bacterium was isolated from the water supply of a creamery. The cultural characters resemble those of both *Bacterium violaceus* and *B. ianthinus*, as described by Macé. The colour was best produced on potato. Colour was not produced at 37° C., in the absence of air, or in the absence of more moisture than was sufficient for the growth of the organism. In artificial media colour was produced in the absence of peptone. The colouring matter extracted with alcohol is an amorphous blue-black, solid, without surface reflection. A weighed quantity was dissolved in alcohol, and the absorption spectra were examined optically and photographically at various dilutions. The spectra extended from $\lambda 670$ in the red to $\lambda 227$ in the ultra-violet. At the greatest dilution only one absorption band was observed, starting at $\lambda 6430$, and extending towards, but not further than, $\lambda 5000$; the ultra-violet absorption is general, with no indication of bands. This spectrum differs from that of the dyes, such as Hoffmann's violet, and from the spectra of violet colouring matters extracted from natural sources by Schneider, Moseley, Molisch, Krukenburg, and Lecoq de Boisbaudran. The chemical reactions of the solution resemble those of some natural violet colouring matters. It is an oxygenated substance which, in the presence of light, oxidises substances such as alcohol.—Rev. Henry V. **Gill**: The effect of a low potential electric current on photographic plates. The object of this communication was to describe some results which had been obtained from experiments on photographic plates. There is a great deal of uncertainty concerning the nature of the changes which take place in the sensitive surface of such plates when they are exposed to the action of light and other influences. Many physicists have studied the effect of passing electric sparks over the surface of dry photographic plates. On development a record of the path traversed by the discharge is obtained. The blackening of the plate is in great part due to the luminosity accompanying the discharge, and it is consequently difficult to determine the part played by the current as distinct from the luminosity of the spark. The discharge was non-luminous, and of comparatively low voltage, from 200 to 400 volts. The results obtained show that the effect of such a current on sensitive plates is complicated, and depends to a great extent on the nature of the terminals placed at the surface of the plate, between which the discharge takes place. The ions coming from the positive terminal seem to play the chief part in the reaction. When, for example, copper is employed as positive terminal, a considerable region of the plate surrounding the point of contact is found on development to be blackened; on the other hand, when platinum is used no blackening of the plate is produced. Silver and other metals produce characteristic effects. The effect at the negative terminal is very much less and does not depend on the nature of the terminal.

Paris.

Academy of Sciences, May 26.—M. F. Guyon in the chair.—Emile **Picard**: Concerning the recent meeting of the International Association of Academies. A short account of the subjects discussed at the meeting at St. Petersburg.—Paul **Appell**: The Hermite polynomials $U_{m,n}$ and their analogues connected with spherical functions in hyperspace.—P. **Chofardet**: Observations of the Schaumasse comet, 1913*a*, made at the Observatory of Besançon with the bent equatorial. Positions are given for May 21 and 24. On

May 24 this comet appeared as a circular nebulosity 1·5′ diameter, magnitude between 8 and 9. There was a diffuse nucleus but no tail.—Nicolas **Kryloff**: Some properties of integral equations with non-symmetrical nucleus.—J. **Tamarkine**: The problem of the development of an arbitrary function in a Sturm-Liouville series.—W. F. **Osgood**: An extension of a theorem of Weierstrass and on a restriction of another theorem by the same author.—M. **d'Ocagne**: The general application of the method of aligned points to problems which reduce themselves to solutions of spherical triangles.—Th. **Got**: The equivalence of certain indefinite ternary quadratic forms of the same genus.—L. **Décombe**: The viscosity of the atom. In the absorption of light and in certain abnormal dielectric phenomena an explanation is found in a certain viscosity term, proportional to the velocity, and regarded hitherto as an empirical term. An attempt is made to connect this with the fundamental principles of mechanics.—A. **Tian**: The relation between light energy and photochemical action. An examination of the conditions under which the law of proportionality between photochemical effect and light absorption is verified.—L. **Chaumont**: The theory of apparatus serving for the study of elliptically polarised light.—R. **Fortrat**: The normal magnetic triplet and Preston's rule.—Jacques **Carvallo**: The electrical conductivity of pure ether. An arrangement is described securing the perfect isolation of the electrodes. Under a constant difference of potential of 1144 volts the conductivity diminished slowly for eight days, after which it remained constant. The extremely small residual conductivity observed is attributed to traces of impurities.—Keivin **Burns**: Interference measurements of wave-lengths in the iron spectrum. Employing the methods of Buisson and Fabry, interference measurements of the iron lines have been extended from wave-length 6500 to 8824.—Félix **Bidet**: The displacement limit of monoethylamine by ammonia gas. A study of the influence of temperature and pressure on the equilibrium limit and on the velocity of the reaction.—Georges **Charpy** and André **Cornu**: The separation of graphite in alloys of iron and silicon.—A. **Recoura**: The instability of ferric fluosilicate and its spontaneous transformation into another double fluoride of silicon and iron.—J. B. **Senderens** and J. **Aboulenc**: The ester salts derived from octanol by the method of the authors; observations on the principle of this method. The application of the use of small quantities of sulphuric acid (2 per cent. to 3 per cent.) in the catalytic formation of esters.—Georges **Dupont**: The catalytic hydrogenation of the acetylene γ-glycols in presence of palladium black. Acetylene glycols of the fatty series treated with hydrogen and palladium black are more highly reduced than when platinum black is used. A mixture of a saturated glycol, alcohol, and hydrocarbon is produced. The difference between the two catalytic agents is still more marked with the aromatic acetylenic glycols, platinum giving the saturated glycols only, palladium the hydrocarbons.—A. **Guyot** and J. **Martinet**: The condensation of the primary and secondary aromatic amines with the mesoxalic esters. Synthesis in the indole series.—Jean **Nivière**: The action of α-monochlorohydrin and epichlorohydrin upon the monosodium derivative of glycerol.—Marcel **Lantenois**: Some new properties of carbon tetraiodide and its estimation in presence of iodoform. Carbon tetraiodide reacts with an aqueous solution of silver nitrate giving carbon dioxide, nitric acid, and silver nitrate; iodoform, with the same reagent, gives carbon monoxide, silver iodide, and iodate and nitric acid. When aqueous solution of silver nitrate is allowed to act upon a mixture of iodoform and carbon tetraiodide the proportion of carbon monoxide and dioxide evolved serves accurately to indicate the composition of the mixture.—Henri **Pottevin**: Cholera toxin and antitoxin.—A. **Besredka**: Study of the tubercle bacillus. A description of a good liquid medium for the culture of the tubercle bacillus. The growth after twenty-four hours in this liquid is as abundant as that of an ordinary microbe such as streptococcus. Bovine and human bacilli give distinctive growths in this medium.—Mme. A. **Hufnagel**: A periœsophagian organ observed in two Lepidoptera.—Em. **Bourquelot** and Em. **Verdon**: The use of increasing proportions of glucose in the biochemical synthesis of β-methylglucoside. The influence of the glucoside formed on the arrest of the reaction.

CALCUTTA.

Asiatic Society of Bengal, May 7.—D. **Prain** and I. H. **Burkill**: A synopsis of the Dioscoreas of the Old World, Africa excluded, with descriptions of new species and of varieties. Diagnoses of new species and varieties are given, as well as a key to the genus.—H. M. **Chibber**: Variations in the flowers of *Limnanthemum indicum*, Thwaites. Four hundred and fifty-seven flowers were examined and the variations observed are given in tabular form.—Maude L. **Cleghorn**: Notes on pollination of *Colocasia antiquorum*. The paper records some observations on the pollination of the Indian Kachu, and compares it with the process known in the European cuckoo-pint (*Arum maculatum*).—Jitendra Nath **Rakshit**: Double compounds of mercuric oxide with compounds containing ketonic radical. A compound is described of the formula $C_3H_6O, 3HgO$.

SEEDS OF FLOWERING PLANTS.

Studies in Seeds and Fruits: an Investigation with the Balance. By H. B. Guppy. Pp. xii + 528. (London: Williams and Norgate, 1912.) Price 15*s*. net.

IN this work we find the results of Mr. Guppy's investigations on the seeds of several flowering plants. The investigations seem to have been prompted by a statement by Goebel to the effect that the biology of the ripening fruit has hitherto scarcely received attention, and a further statement by Pfeffer that the means by which the power of resistance to drying is gained and the changes which cause its loss are quite unknown.

Such subjects are investigated as the permeability and impermeability of seeds, their hygroscopicity, shrinking and swelling, their homologies, their dehiscence, the proportions of the different parts of the fruits, the relation between the number of seeds and the size and weight of the fruit, the abortion of ovules and the failure of seeds, seed coloration, the weight of the embryo, the rest period of seeds, and finally "the cosmic adaptation of the seed." It is impossible in the space of a short review to give any adequate ideas of the whole of the author's investigations.

From the beginning his "usual plan of following indications was adopted, forming crude hypotheses as [he] went along, and dropping them as soon as they had lost their usefulness. Many points, of course, remained undetermined," and Mr. Guppy only offers "a contribution to the study of a difficult but highly interesting subject." In the cases investigated it was found that all the ovules begin to respond to fertilisation; but it frequently happened, as in Arenaria, Stellaria, Primula, Scilla, and Iris, that only two-thirds of the original complement of ovules developed into mature seeds. In several legumes a marked constriction results from the abortion of the ovules, the degree of constriction being determined by the number of contiguous failures.

Special stress is laid on seedless fruits, where the fruit develops under the stimulus of pollination but the seeds fail. The author's results, so far as they go, are full of interest, and he fully realises that much more must be determined before it is possible to draw safe generalisations. To some readers the book will appear discursive and perhaps unconvincing, and without doubt the salient features of the work could have been expressed in fewer words; but throughout the book one sees the unprejudiced observer at work, and many of the results obtained are both interesting and important. Its very discursiveness has a kind of charm, and there is an occasional incisiveness which is refreshing, as in the following:—

"Lord Avebury would regard such persistently functionless ovules as carrying us back to the time when . . . all the ovules developed into seeds. Prof. Bower holds a similar view with reference to the abortive ovules in the beak of a fruit of *Anemone nemorosa*. . . It should, however, be pointed out that this would not follow if we accept the standpoint taken by Dr. Goebel . . . that functionless organs in plants are not necessarily the vestiges of former completely developed ones, and that many more primordia are laid down than become functional."

Each chapter is supplied with a full and useful summary, and there is an excellent index. It is refreshing to find that Mr. Guppy is not content with vaguely referring to authorities, but supplies the name of the work and the volume and the page of the authors he refers to. In this last respect, as well as in some others, his methods are worthy of being adopted by more pretentious writers.

ENGINEERING SCIENCE.

Mécanique Appliquée. By Prof. John Perry. Ouvrage traduit sur la Neuvième Edition Anglaise par E. Davaux. Avec des additions et un appendice sur la mécanique des corps déformables by E. Cosserat and F. Cosserat. Tome Premier. L'Energie Mécanique. Pp. vii + 398. (Paris: A. Hermann et Fils, 1913.)

THERE must surely be few text-books about which such conflicting opinions are held as this well-known book on applied mechanics by Prof. John Perry. One of these opinions, favourable to the book, is held by a majority of teachers of engineering science and by almost all engineers. The other, which is equally unfavourable, is confined to a minority of teachers—doubtless the "academic persons" to whom the author so often refers. There must be something fundamental, some conflict of principle, which can produce so wide a difference of opinion between persons equally competent to judge. We are aided in arriving at the nature of this conflict by the fact that engineers outside the colleges are almost universally in its favour; as they are, indeed, of each of the author's text-books relating to engineering subjects. Perhaps a parable may be admitted. We picture two travellers desirous of arriving at the same destination, one of them alert to have all the precise formalities of the journey carefully observed, and the other careless of by-laws, and only careful that he shall arrive at his destination by a road which, while reasonably rapid, shall not absorb his every mental activity until such time as the destination is reached.

Put crudely, it is the old choice between devotion to the "means" and devotion to the "ends." Engineers almost always care more for the latter than for the former, being well aware that their route must ever be subject to other than purely abstract considerations. Unless engineering "instinct" points along some reasonably converging line, nothing will persuade them that the "academic" path is the true one. But this is stated as the point of view of English engineers. How does the matter stand with, let us say, the German and the French? This question is to some extent answered by the interesting fact that, although a German edition of Perry's "Applied Mechanics" was published five years ago, it is only in 1913 that a French translation is appearing.

For this purpose the book has been divided into two volumes, of which the first has now been published with a preface by MM. E. and F. Cosserat. After describing generally the method of the book, the writers of the preface remark: "C'est cette méthode, quelque peu hérétique dans notre pays, qui a été dévelopée avec un très grand talent par M. John Perry dans le livre remarquable que nous présentons aux lecteurs français."

The French mind is logical and is attracted by logical method; their engineering is a far more highly refined product than the English—judged, that is, from the scientific point of view. The Germans are capable of as much precision as the French, but are more desirous of taking high place as capable technicians, and inclined, therefore, to study the methods which successful English engineers have adopted. How successful that study has been there are many instances to show. It has occasionally happened, indeed, that German method has far outreached the English, so that the less sturdy opinion in this country has felt there is cause for pessimism, notwithstanding that such industries are rarely the most productive of income, or the least risky in respect of capital.

Germany is willing to learn from England because she values the "fait accompli." France, looking more to abstract considerations, does not think she has much to learn from English writers, and refrains, therefore, from a zealous study of them. If we take, for example, one of the problems dealt with in this book—that of the proper design of springs—we find English engineers relying chiefly on rule-of-thumb methods, whilst the most carefully refined analysis of the subject appeared in French many years ago. Why, therefore, should the French look to us for guidance? Furthermore, it often happens that English writings on the scientific study of engineering work are unknown abroad. A Swedish engineer recently explained to the writer that, in consequence of the different way in which the bookselling business is managed abroad, English technical books are sold to a very small extent, and that ninety-nine out of a hundred foreigners get the impression that by far the greater progress in science and theoretical engineering comes from Germany. The translation of Prof. Perry's book into French will help to eradicate this impression, and we congratulate ourselves, as well as Prof. Perry, upon this sign of appreciation of English engineering science.

H. E. W.

PALÆOLITHIC MAN AND BRONZE AGE MAN.

Palaeolithic Man and Terramara Settlements in Europe. By Dr. Robert Munro. Pp. xxiii + 507 + 74 plates. (Edinburgh: Oliver and Boyd; London: Gurney and Jackson, 1912.) Price 16*s*. net.

LAST year Dr. Robert Munro founded a lectureship in the University of Edinburgh to popularise the results of research in anthropology and prehistoric archæology, which have recently become so important and interesting. He himself gave the inaugural course, and these lectures have now been published in a copiously illustrated volume, which will be welcomed equally by the general reader and the student. In the first part Dr. Munro summarises our present knowledge of Palæolithic man in Europe, while in the second part he gives a more detailed account of the Terramara settlements of the Po valley in northern Italy, to which he himself has paid special attention. In all cases the readable text is accompanied by ample references to the literature of the subject.

Dr. Munro does well at the outset to emphasise the fact "that the principles and laws which govern the rest of the organic world, past and present, are equally applicable to Man," and he thus begins with an interesting sketch of organic evolution. He points out that man's career was an entirely new departure owing to his superior mental endowments, and he argues that this superiority was primarily due to the attainment of the erect attitude. There are, however, still many difficulties in accepting the latter opinion, and more facts are needed before it can be satisfactorily discussed.

In the admirable review of the discoveries of Palæolithic man and his handiwork, Dr. Munro makes several interesting suggestions, and formulates judgments on some of the subjects of controversy. He accepts the French classification of the successive periods as applicable to England, and concludes that the Chellean is not pre-Glacial, but is referable to the middle of the Pleistocene age. He discusses the human skeleton embedded in ochre found by Buckland in the Paviland cave, Glamorganshire, and points out that it is paralleled by similar burials of a late Palæolithic period in France and Moravia. He considers that the importance of the Engis skull has been exaggerated, and concludes that the Tilbury man cannot be later than the beginning of the Neolithic period. He gives reasons for supposing that the early Neolithic immigrants to western Europe may have lived for some time with the Palæolithic peoples whom they found there.

The description of the Terramara settlements, which occupies nearly 200 pages, forms an exhaustive work of reference on a subject on which Dr. Munro speaks with special authority. More than 100 of these large flat mounds in the valley of the Po have now been examined, and it seems clear that they are all referable to the Bronze age. They are generally quadrangular in shape, and their average superficial area is about seven acres. Implements, seeds and fruits, and bones of the animals used for food are so numerous that a very fair idea of the life of the inhabitants can be obtained, and it is evident that they were occupied with many industries. They made their own bronze implements and ornaments, worked also in bone and terracotta, and must have woven much cloth, judging by the extraordinary variety and abundance of spindle-whorls and loom-weights. Their pottery is especially artistic, and the peculiar horned appendages fixed to the tops of the handles have not been found outside the area of the Terramare and certain districts influenced by the civilisation of their inhabitants.

MATHEMATICAL TEXT-BOOKS.

(1) *Matematica Dilettevole e Curiosa.* By Ing. Italo Ghersi. Pp. viii + 730. (Milano: Ulrico Hoepli, 1913.) Price 9.50 lire.

(2) *New Analytic Geometry.* By Prof. P. F. Smith and Prof. A. S. Gale. Pp. x + 342. (Boston and London: Ginn and Co., n.d.) Price 6*s.* 6*d.*

(3) *Experimental Mensuration: An Elementary Text-Book of Inductive Geometry.* By H. Stanley Redgrove. Pp. xvii + 328. (London: W. Heinemann, 1912.) Price 2*s.* 6*d.* net.

(4) *Geometrical Optics.* By A. S. Percival. Pp. vii + 132. (London: Longmans, Green and Co., 1913.) Price 4*s.* 6*d.* net.

(5) *Problèmes d'Analyse Mathématique.* By Prof. E. Fabry. Pp. 460. (Paris: A. Hermann et Fils, 1913.) Price 12 francs.

(6) *Leçons sur l'Intégration des Equations Différentielles aux Dérivées Partielles.* By Prof. M. V. Volterra. Pp. ii + 83. (Paris: A. Hermann et Fils, 1912.) Price 6 francs.

(1) THIS collection of mathematical paradoxes should be of interest to a large circle of readers. It is remarkably comprehensive, occupying more than seven hundred closely printed pages, is profusely illustrated, and is published at a very reasonable price. Those who are acquainted with Mr. Rouse Ball's work will find much in these pages with which they are already familiar, but there will be very few who will not discover something that is new and surprising. In addition to the standard problems of antiquity—the squaring of the circle, the trisection of an angle, and the duplication of the cube—there are elaborate sections on arithmetic, algebra, geometry, and mechanics. There are problems on shunting, map-making, perpetual motion, trammells, constructions with limited instruments, probability, magic squares, boomerangs, draughts, chess, and many other themes of a popular character. It is, however, impossible to give any detailed account of so miscellaneous a work; enough has, perhaps, been said to show that there is abundant material to while away any number of idle hours.

(2) It is gradually becoming recognised that the practice in elementary text-books of restricting cartesian geometry to straight lines and curves of the second degree gives the student a narrow idea of the power and generality of analytic methods. For ordinary purposes a course of the character set out in the volume before us is, in our view, far more valuable than that given in most English text-books. Intricate properties of conics and systems of conics, homogeneous coordinates, invariants, &c., are omitted, and space is thus obtained for curves of higher degree and the elements of three-dimensional geometry. There is an excellent collection of examples, few of which demand from the student any high degree of analytic skill.

(3) The author gives us, in the present work, a distinctly original text-book on geometry. He is in sympathy with the principles laid down in the circular issued by the Board of Education, and, in addition, contends that this subject loses most of its educational value if it is not united from the first with mensuration and trigonometry. The trigonometrical ratios are accordingly introduced in the second chapter, and applications are made at every convenient opportunity. With the exception of a few of the chief geometrical theorems, which are mainly derived by inductive processes, there is no formal geometry, and practically all

the examples are of a numerical type. In our opinion, a text-book such as this is more useful to the teacher than the student; we are inclined to think that it is too diffuse for the latter, but it contains so much that is suggestive and stimulating that few teachers would not gain from using it to supplement and guide their class-work. A good feature of the book is the inclusion of descriptions of calipers, verniers, diagonal and plain scales, the micrometer screw-gauge, the spherometer, the planimeter and opisometer, methods of measurement of volumes, the construction and use of a scale of chords, and Simpson's method for evaluating areas. There is also an appendix on the use of duodecimals.

(4) The author writes primarily for medical students, but there is no reason why his work should not be equally suitable for any student of elementary physics; very small demands are made on the mathematical capacity of the reader. The fundamental results are established at such length, and so clearly, that they should be intelligible to all. Great importance is attached to the use and meaning of algebraic signs; as soon as this idea is grasped, the formulæ employed assume simple forms. The text-book is purposely practical rather than academic; there is, for example, little mention of the general mathematical theory of systems of lenses or properties of the paths of rays in heterogeneous media. But the author supplies an abundance of excellent illustrations and exercises which will give the student a far better grasp of the principles of the subject than he would gain from an abstract mathematical treatise.

(5) This collection of about 270 problems (many of which contain several parts), selected from recent French examination papers, is divided into twelve sections: integration, multiple integrals, analytic functions and curvilinear integrals, differential equations, plane curves, skew curves and surfaces, asymptotic lines and lines of curvature, ruled surfaces, partial differential equations, geometrical applications of partial differential equations, total differentials, elliptic functions. The statement of the problems occupies one-seventh of the book; the rest is devoted to their solution. Where we have tested them we have found them sufficiently clear and detailed for any student of average ability. We have no hesitation in saying that this collection will be of real value to students and teachers alike; and its utility will be still further increased if the publishers are able to issue the problems in a separate volume.

(6) These lectures, which were published a few years ago, are now re-issued with a few notes and corrections. Pressure of other work has prevented the author from attempting to re-write them in the light of the very considerable progress that has been made in the last six years, but the addition of numerous bibliographical references will enable the reader, if inclined, to see what has been done. In a comparatively small compass the author covers a wide range of theory. In dealing with the bearing of the theory of differential equations upon physical problems, he investigates the elliptic, hyperbolic, and parabolic types with a view to the interpretation and application of the many-valued form of solution and the relation to multiply-connected domains.

OUR BOOKSHELF.

Myths of the Modocs. By Jeremiah Curtin. Pp. xii + 389. (London: Sampson Low, Marston and Co., Ltd., n.d.) Price 12s. 6d. net.

"THE value of Indian myths lies in the fact that they represent the mental labour of men who lived ages before those who recorded their thoughts on papyrus, baked brick, or burnt cylinder" (p. 383). The author has supplied us with a valuable set of documents embodying the floating traditions of the Modocs, whose country lies on the borders of Oregon and California. "Man does not appear in any of these myths" (p. 383). In their non-human and non-moral elements the myths belong to the same stratum as the oldest Irish and Welsh tales, which are generally admitted to be pre-Celtic. In his too brief notes on the myths the author is evidently impressed with their obvious astronomical significance. The first he records "is evidently a sun myth." Mr. Curtin obtained the bulk of his information from "the oldest woman of the Klamath-Modoc tribe of Indians," and from one who, in the prime of his life, was chief of his people.

It is certain that if the witnesses were cross-examined on their astronomical knowledge, the astronomical significance of the myths would have appeared much clearer than it is found in the book. A golden opportunity has been missed. In one case the astronomical key was simply thrown into the author's hand. The myth of the "Star Brothers" ends as follows:

"'You and your brother will no longer be persons; you will be stars, and between summer and winter your people will fight over you.'

"The younger boy was at the edge of the sky when the old man's spirit said: 'You will be a star.' Right away he was one. As soon as the elder boy reached the edge of the sky he became a star too.

"NOTE.—These two stars appear early in the morning toward the end of winter. They are the heralds of spring" (p. 117).

It is practically certain that the author's informant could have pointed out the "Star Brothers." What we have given us is the very basis of the astronomical interpretation of myths and monuments. JOHN GRIFFITH.

A First Book of Rural Science. By J. J. Green. Pp. viii + 146. (London: Macmillan and Co., Ltd., 1913.) Price 1s. 6*d*.

THE teacher who wants to give a rural bias to his school work still has to depend at least as much on his text-book as on his garden for help in his lessons. Amidst the vast number of books on rural science that the nature-study movement has called forth, a few stand out prominently as being eminently adapted to the purpose. Amongst them we have no hesitation in placing this little book. The information is sound, and is clearly and concisely set out; while the order is both logical in method and convenient in practice.

Beginning with seeds, the author follows on with plant growth, plant nutrition, and reproduction. Next he passes to the subject of soils, and then to the relationship between the soil and the crop. Throughout the author displays a vivid knowledge of rural conditions, and he seeks to connect up the child's training with the things that come into the scholar's daily experience. This desirable end is successfully accomplished. New varieties of plants, for example, are now among the common incidents of rural life. The book gives a short but good account of how they are formed. The micro-organisms of the soil have also come in for much attention from agricultural lecturers and others, and here, again, sufficient information is given to enable the student to form an intelligent grasp of the matter. Manures are described in sufficient detail for the purpose, and manurial trials are illustrated. Altogether the book can be cordially recommended both to teachers and students.

Dent's Practical Notebooks of Regional Geography. By Dr. H. Piggott and R. J. Finch. Book ii. Asia. Pp. 64. Book iii. Africa. Pp. 48. (London: J. M. Dent and Sons, Ltd., 1913.) Price 6*d*. net each.

THESE books, and others like them, are a welcome indication that teachers in schools are beginning to understand that children learn more satisfactorily by doing than by listening. The authors are experienced teachers who recognise that with the small amount of time available for geography in ordinary classes every expedient must be tried to select only practical exercises of prime importance. In these little books the practical work is all worth doing, and the instructions given are precise and to the point.

Earthquakes and other Earth Movements. By Prof. John Milne. Sixth edition. Pp. xvi + 388. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1913.)

THE additions and alterations rendered necessary by the knowledge gained since 1903, the date of publication of the fifth edition of his book, are collected by Prof. Milne in an additional appendix of some eleven pages. The chief topics of the appendix are the teleseismic observations which, Prof. Milne says, have already thrown new light upon the homogeneity and rigidity of our world, and have led to the explanation of phenomena in other departments of science.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Ionisation of Gases in the Schumann Region.

IN July last I published a note in the *Physikalische Zeitschrift* (July 13, p. 583) on the ionisation of gases by light and the spectrum of aluminium in the Schumann region. As my views therein expressed have recently been misquoted in print on two occasions, I fear I did not make myself clear. It may be worth while, therefore, to add a word.

It was my object to explain the results of Lenard's volume ionisation experiments by exhibiting the spectrum of his source of light. To this end I published a spectrogram of the aluminium spark in air in the Schumann region. The illustration showed that, though the spectrum contained some strong lines between $\lambda 1850$ and $\lambda 1600$, there was but one group of any strength between $\lambda 1600$ and $\lambda 1250$; this group occurred near $\lambda 1300$. Lenard's data indicated that the rays which produced most of the ionisation lay on the more refrangible side of $\lambda 1600$. I stated, therefore, that the group near $\lambda 1300$ was probably responsible for most of the effect which Lenard observed, because it was the *only* strong group existing in the aluminium spectrum in the region under consideration. This is evidently very different from the opinion ascribed to me by Mr. A. Ll. Hughes (Phil. Trans., vol. ccxii., p. 226): ". . . Lyman concludes that the ionisation of air by light does not take place unless the light contains wave-lengths less than about $\lambda 1300$."

While I am on the subject, I should like to add that the question as to what wave-lengths are responsible for the volume ionisation observed in gases seems to me to be still open. We know that the effect increases with decrease in wave-length in the Schumann region, but that it "sets in about $\lambda 1350$" is not perfectly obvious. Prof. Palmer has been kind enough to test the volume ionisation due to the mercury arc, at my suggestion. He finds a small but perfectly definite effect. This confirms the recent results of Bloch, obtained with an arc in quartz (*C.R.*, vol. clv., p. 1076). I have just concluded a study of the spectrum of the arc, and I have been unable to discover any lines below $\lambda 1400$. The most refrangible line which I have observed through quartz is at $\lambda 1775$. It seems fairly certain, therefore, that some volume ionisation can be produced by light of wave-length longer than $\lambda 1700$.

THEODORE LYMAN.

Jefferson Laboratory, Cambridge, Mass., May 22.

Artificial Hiss.

HAS Lord Rayleigh tried the effect of holding a piece of sheet iron or of compressed charcoal in the small pointed flame of an ordinary foot blowpipe when the air supply is somewhat in excess of the needs of the flame? By adjusting the gas supply, the air pressure, and the position of the iron sheet, sounds can be obtained varying from *f* to *s* or *sh*. The oxy-hydrogen flame, supplied with a slight excess of oxygen, is even better. The air entering a vacuum desiccator through a narrow stopcock gives a fairly good *s* sound.

E. R. MARLE.

Hartley University College, Southampton, May 30.

In reply to the letter in Nature of May 29 (p. 319) under the heading "Artificial Hiss," the following is a suggestion which may be an answer to the question, though not a practical solution to the problem.

A loud hissing noise accompanies the passing of an electric arc across the gap in such a lamp as is used for optical lanterns, &c. Though this hissing noise does as a rule last for only a short time, yet it appears to me quite a simple matter to regulate the carbons so as to prolong the sound. The actual "hiss" sounds much more of a sibilant than an *f*, such as is produced by a current of air or steam being forced under pressure through a small opening.

Charterhouse, June 2. H. L. Kirk.

Red Water.

In Nature of April 4, 1912, Messrs. Mackenzie and Finlay wrote relative to the cause of the occurrence of colouring matter in a sample of water from a crater lake in Uganda, and subsequently in the issues of April 11 and June 6 Messrs. H. Warth and C. Crossland respectively wrote describing the occurrence of similar characteristics in the great salt lake of Sambhar, in Rajputana, also pools at Suez, and near the Rawaya salt lake.

Dr. Gavin McCallum, in a paper read at a meeting of the Geelong Field Naturalists' Club, in March, 1911, entitled "Forms of Life at the Salt-pans," directed attention to this coloration of the water and its blood-red appearance, and described it as being not due to the "colour of the liquid itself, but to the presence in enormous numbers of uniform small round cells. Dr. McCallum also mentions another form as being oval in shape with two cilia or lashes at the narrower end," the cilia and a small portion at the narrower end being colourless. At various times samples of the "red water" have been collected, and kept constantly under microscopical examination both by Dr. McCallum and myself, with the result that we can say the colouring is wholly due to a flagellate organism not unlike *Polytoma uvella*, Müll, as figured in the last edition of the "Encyclopædia Britannica," but as this is given as being a species of Chlamydomonadidæ in the article on Flagellata, and as a similar genus appears in the article on algæ by a different writer, some confusion evidently exists as to both these orders.

The oval form, as mentioned by Dr. McCallum, has two flagella, about one-third longer than the body, which appear to arise from a sort of collar or circular opening at the anterior end; there are two contractile vacuoles near the base of the flagella, and an eye-spot; except the flagella and a small portion at the anterior end, the whole organism is so deeply pigmented with red matter that it is difficult to determine its constituent parts. There are other features, but these it is at present premature to mention. The globular form appears as the brine reaches saturation point, and is a sort of resting stage conditioned by the salinity of the medium in which it lives; this form gives rise to zoospores.

Associated with the flagellate organism is an interesting crustacean, the brine shrimp, very similar to *Artemia salina*, but in all the articles dealing with this crustacean the female is said to carry the eggs underneath the tail, whereas in this shrimp they are carried in sacs on either side, like the egg sacs of the Cyclops. The male, which is much larger than the female, has the usual claspers for holding the female. Dr. McCallum mentions in his article that at 7° to 8° Baume the shrimp sickens and dies; at this stage it becomes the host of the flagellate organism, which absorbs the decaying organic matter in the interior of the shrimp's body, leaving an absolutely hyaline cast skin.

I may mention that during this period of the organism's existence it is nearly always green, the red matter only making its appearance at a later stage. As the brine reaches crystallisation the ensuing salt is of a reddish hue, due, of course, to the pigmented organism, and it is a matter of conjecture as to whether or no each spherical monad does not form the nucleus of each crystal of salt. The salt, upon exposure to the sun, bleaches, but the zoospores contained within the spherical or globular membrane retain their vitality and issue forth in countless numbers of infinitely small green, actively moving flagellate organisms, upon redissolving the salt.

Fred Whitteron.

Geelong, Victoria, March 31.

Phreatoicus in South Africa.

At the beginning of this month I found some isopods in one of the swift-running streams on the top of Table Mountain; they were quite common in and under the moss covering the stones in the bed of the stream, and were very sluggish. On examination they prove to belong to the family Phreatoicidæ. The occurrence in South Africa of a member of this peculiar family, which hitherto has been recorded only from New Zealand, Australia, and Tasmania, is of great interest as bearing on the question of the ancient land connection between the southern continents.

It is a new species, and will shortly be described in the Annals of the South African Museum.

Keppel H. Barnard.

South African Museum, Cape Town,
Cape of Good Hope, May 20.

GEOGRAPHY AND TRAVEL.[1]

(1) THIS work has originated in the desire of its author to make some public statement of indebtedness. It is, as it were, a memorial laid upon an altar. Dr. Cornish, in his researches, has dealt with phenomena that are cosmic rather than humane; yet we now perceive them set against a background, old as that of the cave-dwellers, where accomplishment is due to the fact that man does not live his life alone. Whether their vessel is rolling fifty-six degrees in the Bay of Biscay, or nearing Ceylon in incense-laden air, whether they are walking in the symbolic garden of the Shogun, or in the shattered streets of Kingston, the essential feature is that the travellers are together. The form adopted as a title merely adds emphasis to this impression.

Except for the stirring adventure of the Jamaican earthquake of 1907, these travellers saw little that others have not seen and liberally described. But what they saw they realised as trained observers. "The greatest astronomical

[1] (1) "The Travels of Ellen Cornish." Being the Memoir of a Pilgrim of Science. By Dr. Vaughan Cornish. Pp. xvi+293+plates+maps. (London: W. J. Ham-Smith, 1913.) Price 12*s*. 6*d*. net.
(2) "The Continents and their People: Asia." A Supplementary Geography. By J. F. Chamberlain and A. H. Chamberlain. Pp. ix+198+3 maps. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 3*s*.
(3) "Modern Geography for High Schools." By R. D. Salisbury, H. H. Barrows, and W. S. Tower. Pp. ix+418+vii plates. (New York: Henry Holt and Co., 1913.) Price 1.25 dollars.
(4) "Three Years in the Libyan Desert: Travels, Discoveries, and Excavations of the Menas Expedition." By J. C. Ewald Falls. Translated by Elizabeth Lee. Pp. xii+356+plates. (London: T. Fisher Unwin, n.d.) Price 15*s*. net.

interest of a voyage to the equator is to get the completed view of the Milky Way." The truth of this is memorable, when one thinks of the successive streams of stars and the unfathomable spaces, changing night after night as the vessel swings down across the line. An area of cloud sailed under for twelve days in the North Pacific (p. 90) is shown to have been as large as Australia. It "would form a considerable feature as seen from the moon. Presumably it would appear from there as a great bright patch." At Niagara numerous observations were made on the forms of waves, and one of the fine photographic illustrations is here reproduced (Fig. 1).

Dr. Cornish believes that the redistribution of load through erosion of the highland-axis north of Kingston caused a subsidence which propagated the shocks. He also has some remarks in the next chapter on earth-creep movements on the sides and floor of the Panama Canal.

It was finally Mrs. Cornish who wished, after a trying illness, to revisit Panama, "where things were being done which were worth doing." The book is a slight one, and is in no way a record of research; but none will judge it lightly who can appreciate in scientific work the stimulus of complete companionship.

(2) The "supplementary geography" of Asia is presented by Messrs. Chamberlain in language suitable for an elementary class. Numerous photographs illustrate the human aspects of the subject, and these have evidently been selected so as to leave natural features as much as possible in the background. In fact, the book is in no sense a description of the continent, but it might well be read by pupils who have already become acquainted with the great contrasts of Asiatic structure, from the Arabian desert to the volcanic isles upon the east. This is, perhaps, implied in the subtitle of the book, which conveys very little geographical teaching of the kind now looked for in progressive schools. We can conceive its being

FIG. 1.—Standing wave formed by a hidden rock, Upper Rapid, Niagara. From "The Travels of Ellen Cornish."

On p. 146 an interesting calculation is made as to how long, under modern conditions, it would take a traveller to see the world by daylight, and the "globe-trotter" is humbled when he learns that, by doing 300 miles a day, he would require 136 years to appreciate the earth.

All readers may learn something from the account of the destruction of Kingston, of the cameras carried out from the tottering house, and then put back with a fine perception when the human tragedy of the streets was realised (p. 184), of the later undulations felt upon a grass-lawn, and of the investigation of the causes of the shock when all still lay in ruin.

quite attractive as a gift-book, though twenty lines in cockney from Kipling's "Mandalay" will convey more of Asia than all the mediocre verse that is so freely quoted in its pages.

(3) The essential difference between the compact and detailed geography written by Messrs. Salisbury, Barrows, and Tower and the numerous recent American works on physical geography and physiography lies in the fact that this new book is mainly concerned with human relations to the earth's surface. But the groundwork of physical conditions is well laid. No attempt is made to describe the continents or the oceans, and this duty is probably left to the well-trained teacher and his wall-maps. Features met with on the earth are referred to their causes, and their effect on human enterprise is always kept in view. The United States are naturally selected as a groundwork for the illustration of general principles; but the book will serve admirably elsewhere in showing how teaching may be developed on these lines. "The need of salt," we are told (p. 183), "helped to hold most of the American colonists near the Atlantic coast for a long time." A quantity of salt that would now sell for some 30 cents cost *6l. 10s.* west of the Appalachian Mountains in 1778. The general benefits resulting from the continental ice-invasion are described on p. 265. Soils are adequately dealt with, and the last 150 pages are concerned with such subjects as "the uses and problems of inland waters," irrigation, life in deserts and great forests, and the causes of the distribution of population. The book shows throughout how the problems of man's existence on the earth are fundamentally due to climate and topographic features. It provides, in fact, the kind of geography which every citizen should understand, whether he is developing a local industry or extending the borders of an empire.

(4) The three years spent by Mr. Falls with his cousin, Monsignor Kaufmann, in the Libyan desert were devoted to the discovery and excavation of the early Christian sanctuary of St. Menas. Incidentally, features of the desert and of the soda-lakes are described; but the interest is naturally archæological. The photograph (p. 120) of a Beduin with his gun, seated in the waste of cut stone that represents a lost city of the empire, is one of those impressive scenes that the camera most convincingly records. But behind the camera is needed the artist with the right imaginative perception. The author mentions incidentally that photographs can be taken from a camel-saddle. As a matter of fact, this high seat is ideal for a preliminary survey, and would probably be of service in the African bush, in place of viewing the landscape from occasional ant-hills.

Miss Lee's translation is usually clear and simple; but we have doubts about the "fields" of mica on p. 57, while the account of snake-charming on pp. 303 and 304 is very puzzling. What are we to make of a "happy presentation" of snakes, or of "the Moses rod was only useful on the ground"?

G. A. J. C.

THE BIRMINGHAM MEETING OF THE BRITISH ASSOCIATION.

Arrangements for the Meeting.

THE Birmingham meeting of the British Association next September promises to be a notable one. Already more members have agreed to attend than has been the case at the corresponding period for the last few years, and the secretaries expect that the number both of local and of visiting members and associates together will reach 3000. But size, though an element in rendering the meeting notable, is not of the first importance, and it is the importance of the pronouncements made during the sessions which more than anything else stamps a meeting as of signal value. This may well be the case in Birmingham. The most important statement of the meeting is usually the presidential address, and since as president we are to have the principal of the Birmingham University, we may expect that Sir Oliver Lodge will deliver a notable pronouncement.

As a place of meeting Birmingham enjoys almost, perhaps quite, unrivalled facilities. Not merely is it centrally and accessibly situated, but its main buildings are placed unusually conveniently to one another, to the stations, and to the residential districts. A corridor or a street only intervene, as a rule, between two sections, so that the time often lost in passing from one section-room to another is here gained.

The centre of this system of sections is the reception room. This room serves almost every purpose except the one which its name implies. It is the bureau of information and headquarters of the association for the time being. It serves as the general meeting-ground, post-office, and place of supply of publications. On these accounts the town hall has been chosen, as being close to the railway and tram system.

Radiating from the town hall as a nucleus are the buildings in which the business of the association is transacted. The city council chamber will serve for the meetings of council, of the general committee, and of the committee of recommendations, the last being the financial body that allocates the grants of the association. The University building, Mason College, will contain eight out of the thirteen sections, and in addition there will be here a ladies' room, the Press bureau, the president's room, and the quarters of the permanent officers. Queen's College (no longer appertaining to the University) will lodge the economic section in its examination hall. The small lecture theatre of the Midland Institute will serve for the geographical section, whilst the closing meeting and probably the meetings of delegates will take place in the large theatre. In the Technical School, Suffolk Street, the sections devoted to engineering and chemistry will find their headquarters. Lastly, anthropology has its meeting room in the Temperance Hall, Temple Street, and is therefore the only outlying section.

Among men of science from abroad who have accepted invitations to the meeting are:—Prof.

Svante Arrhenius, of Stockholm; Prof. Reinke, the veteran botanist of Kiel; Prof. Pringsheim, of Breslau, Germany; Prof. Keibel, the embryologist of Freiburg; and M. Lallemand, the geodetic expert from Paris. The list is, however, at present incomplete.

Programme of the Meeting.

The meeting will formally open on Wednesday, September 10, with the presidential address by Sir Oliver Lodge, at 8.30 p.m., in the Central Hall, Corporation Street. The retiring president, Sir Albert Schäfer, is unable to be present owing to an engagement in America. On Thursday, September 11, the work of the thirteen sections opens with the delivery of the several presidential addresses, beginning in most cases at 10 or 11 o'clock. On Thursday afternoon there will be a reception and degree ceremony at the new University buildings, Bournbrook. The Vice-Chancellor will preside, and an opportunity will be given for an inspection of the various University departments (mining, metallurgy, engineering, chemistry, geology, and physics.)

On Thursday evening the Lord Mayor will hold a reception at the New Art Gallery, the Council House, beginning at 8.30. This will give visitors an early opportunity of realising the advance which Birmingham has made in housing and exhibiting its art collections. Also it is hoped that the new Natural History Museum will be available during the evening.

On Friday afternoon, following upon the usual spell of scientific work during the morning, there will be a garden party at Bournville, by the invitation of Messrs. Cadbury Brothers. This, and any other garden parties that may be offered to members, will naturally be limited to a specified number. Applications will be received at the reception room.

On Friday evening the first of the two evening discourses will be given by Sir Henry H. Cunynghame, K.C.B., of the Home Office, on explosions in mines and the means of preventing them, at 8.30 p.m., in the Central Hall, Corporation Street.

On Sunday special services will be arranged at most of the places of worship in Birmingham. The Lord Bishop has consented to preach in the Cathedral Church.

On Monday morning the work of the sections will be resumed, but on Monday evening the local committee will entertain the association to grand opera and to other entertainments mentioned below. On Tuesday, and probably also on the preceding Thursday, there will be a meeting of the Conference of Corresponding Societies in the Midland Institute, at 3 p.m.; and on Tuesday evening the second evening discourse will be given in the Central Hall, at 8.30, by Dr. Smith Woodward, F.R.S., of the British Museum, on missing links among extinct animals, a subject upon which he is one of the foremost authorities. On Wednesday morning the closing meeting will be held in the large theatre of the Midland Institute.

The Handbook.

The custom of the association is to induce the local committee of the place of meeting to publish two handbooks, one for the enlightenment of the visiting member, enlarging upon the history, topography, organisation, and scientific interests of the locality; the other for the enlightenment of the local member, who, in nine cases out of ten, knows little of his or her neighbourhood. The first is *the* handbook. The second is the excursion guide-book. The handbook is a work of reference, a volume of some 500 pages, laborious and expensive to produce. The guide-book is a small pocket affair that can be easily carried and consulted. Both these books are given free to every member or associate on presentation of their tickets at the reception room.

The handbook, under the editorship of Dr. Auden, this year reflects most aspects of municipal activity. The history of local enterprise, and of the chief Birmingham institutions, is dealt with by competent authorities. The existing state of these several bodies is described by others, and if the contributors had enough collective insight the future to which the city is tending, or striving for, might well be prophesied by those who had a sufficiently clear vision of what they wish to attain. In town planning this is more possible than in most other subjects, and as Mr. Neville Chamberlain has undertaken this section we may hope for an important forecast in that direction. Perhaps the sections of the work dealt with most fully will be those treating of economics and of geology; whilst, without any doubt at all, the most novel thing in the handbook will be the geological and topographical maps. These, under the guidance and help of Prof. Lapworth, mark an epoch in map-making.

Sectional Excursions.

The work of the association is not limited to that done in the meeting rooms. Most of the sections devote some time to excursions or visits. The geologists, as a rule, spend a considerable part of their time in field work, and an organised programme for this purpose has been prepared by Dr. T. T. Groom, with the supervision of Prof. Lapworth. The date of the meeting coincides with Prof. Lapworth's retirement from active university service, but it is hoped that both he and his successor, Prof. Boulton, will be able to take part in showing geologists those features of interest in the district which have been made famous by the classic investigations of the University geological staff.

The economic section, probably, will survey some part of the Midland waterways; the agriculturists have many opportunities of interesting their members in the application or the results of agricultural practice; and the engineers, geographers, and those interested in education will find much of historical or of present-day interest in the neighbourhood. But as all these excursions have naturally to be limited, it is hoped that only those members who are really interested in the subject to be studied will join the excursions.

Visits to works, either by appointment or by presentation of membership tickets, have been arranged by the excursions sub-committee. Most of these naturally appeal to engineers—for example, the Daimler works at Coventry, the Milward works at Redditch, the Great Western Locomotive works at Wolverhampton. Others, such as the Bournville works of Messrs. Cadbury, interest a larger number of visitors. Details with regard to facilities for these and other visits may be obtained in the reception room.

General (Saturday) Excursions.

The practice of the association has gradually tended to convert Saturday during the meeting into a day given up to excursions. The excursions sub-committee has planned a number of whole-day trips; whilst for those members who do not wish to give so much time, half-day excursions are available. The general programme of itineraries is as follows: Stratford-upon-Avon, Charlecote Park, and Warwick Castle; Coventry, Stoneleigh Abbey, and Kenilworth Castle; Banbury, Wroxton Abbey, Compton Wynyates, and Broughton Castle; Bromsgrove, Hewell Grange, Grafton Manor, Droitwich, Hanbury Hall, Mere Hall, Westwood, Salwarpe Court, and Hartlebury Castle; Tewkesbury, Deerhurst, Bredon, Woolas Hall, Pershore, Evesham, and Abbey Manor; Worcester; Lichfield and Wall; Sutton Coldfield and Oscott College; the Forest of Arden villages—Solihull, Knowle, Henley, Wootton Wawen, Alcester—and Coughton Court; Malvern, British Camp, and Madresfield Court.

The mayors of the cities and boroughs to be visited are offering a civic welcome to members of the association, and the owners of historic buildings and beautiful estates on the routes of excursions are offering exceptional facilities for inspection on the Saturday.

Entertainments.

The lighter side of the association week has been the subject of careful consideration by the subcommittee appointed for the purpose. For the first time grand opera is to be given. On Monday, September 15, the local committee will entertain the association in the Prince of Wales Theatre, Broad Street; in the new Repertory Theatre, Station Street; and in the Picture House, New Street.

The opera to be performed will probably be Glück's "Orpheus," under the direction of Herr Denhof, and a well-known work by a modern dramatist will be produced at the Repertory Theatre; whilst special kinemacolour and other films, dealing mainly with scientific subjects, will be displayed in the New Street Picture House.

It is a little unfortunate that the Botanical Gardens, Edghaston, cannot be used freely, but those who have an hour to spare will be well advised to go to the gardens by the Harborne motor-'bus. Botanists and zoologists particularly will find much to interest them in the exhibits.

The arrangements for working-men's lectures, and the nature of the topics to be discussed during the visit of the association, will form the subject of later articles.

F. W. G.

MICROSCOPE STANDS.

MORE than a year ago (NATURE, December 21, 1911, p. 245, and January 11, 1912, p. 351), in some articles on microscope stands, we were enabled to give the opinions of several recognised authorities on the various methods adopted to utilise the optical properties of the instrument.

It was shown that, speaking generally, there were two distinctive types, which might be conveniently styled English and Continental. Further, the English type of microscope was thus defined:—

"By the term 'English microscope' is meant the distinctive type of instrument which has been built to embody conveniences for working with modern high-class objectives and condensers, which conveniences cannot be found in combination in any other microscopes than those of British origin. Among them are the following:—(1)* The tripod foot; (2)* a long range of coarse adjustment for the use of low-power objectives; (3)* the body tube fitted with mechanical draw tube to allow for the adjustment of objectives for thickness of cover-glass; (4) the mechanical stage scientifically constructed as a part of the whole instrument; (5) the compound substage with rackwork to focus and screws to render the substage condenser axial with any objective that may be in use; (6)* fine adjustment to substage; (7)* the Wenham binocular body; (8) the various fittings for substage apparatus, eyepieces and objectives of the Royal Microscopical Society's standard gauge; (9)* all the working parts fitted with sprung bearings and controlling screws, so that compensation for wear and tear may be readily effected."

It was pointed out that in no Continental microscope are the fittings marked with an asterisk provided in the manner that is usual in an English one.

The defenders of the Continental model contended that many of the above-named means of adjustment were unnecessary, and held that the greater simplicity of the Continental model was to the advantage of the worker. Among these means of adjustment they named the centering arrangement for the substage and its fine adjustment.

It may be mentioned that the arrangement for oblique illumination and decentering of the iris diaphragm, so common in the Continental model, is of very rare occurrence on the English microscope.

One of the writers pointed out that changes were going on, and that a common ground was being approached. The centering arrangement discarded as useless for the ordinary condenser was really being introduced for an achromatic condenser and the many arrangements for dark field illumination.

Another great step in advance has recently been made. We have received from Messrs. Leitz, a German firm which produces perhaps more microscopes than any other, two models designed with a view to incorporate the most important features of the English and Continental models.

In one the tripod base is well spread, is exceptionally rigid. in the horizontal as well as the vertical position, and allows of free access to the substage. The substage is of the compound type, consisting of rack and pinion focussing adjustment, with centering screws controlling condenser sleeve, which is of the Royal Microscopical Society standard gauge. The stage is of the square fixed type, and may be provided with a detachable mechanical stage. The curved limb allows of additional working space on the stage and incidentally forms a convenient handle for lifting the microscope. The fine adjustment consists of the cam and worm screw continuous motion, originally introduced in the Leitz Continental microscopes, coarse adjustment being by diagonal rack and pinion, and draw-tube with millimeter scale.

The other form is similar, but it is fitted with a mechanical stage forming an integral part of the instrument. The stage is provided with anterior, posterior, and lateral movements of greater range than is generally found in similar models, and is controlled by two milled heads mounted upon one spindle. The stage is also provided with millimeter scales and verniers reading to 1/10 mm. (1/250 inch).

A model on the above lines, but of much larger dimensions and having a wide body-tube, is particularly valuable in photomicrography. It is stated that these new models are made in the firm's London workshop.

But Messrs. Leitz, we now find, are not the only firm which is endeavouring to make stands as complete as possible in the way of adjustment. We have received from Messrs. Angus, the London agents of the Spencer Company of the United States, one of their latest models, which is admirably designed and worked out, and in it we find the English arrangement for the centering of the substage, as well as the German device for oblique illumination.

In these new models furnished by Leitz and Spencer, then, we find the maximum of adjusting power, and on this account they may be considered to be universal instruments, and it should not be forgotten that this universal quality of adjustment need not necessarily be confined to instruments of the largest size. The mechanical stage and the oblique illumination device may be made much lighter than they generally are, and the Spencer model shows how space may be saved by mounting the two screws of the former on a vertical spindle.

One of the great outstanding differences, then, remaining at present between the English and Continental microscopes is the absence of the simple oblique illumination device in the former. Regarding the use of this we are aware there are many different opinions.

NOTES.

It is officially announced that the King has become patron of the Entomological Society of London.

At the meeting of the Chemical Society, held on Thursday, June 5, Prof. Dmitri Petrovitsch Konovaloff, of St. Petersburg, and Prof. Alfred Werner, of Zurich, were elected honorary and foreign members of the Chemical Society.

The annual conversazione of the Royal Society of Arts will be held on Tuesday next, June 17, at the Natural History Museum, South Kensington, and that of the Institution of Electrical Engineers will be held at the same place on Thursday, June 26.

The trustees of the British Museum have agreed to undertake the publication of the natural history results of Capt. Scott's Antarctic expedition. The work of publication will be carried out at the Natural History Museum, South Kensington. It is understood that on the arrival of the *Terra Nova* in this country the collections will be sent in the first place to the Natural History Museum.

The Cannizzaro prize of 10,000 lire, founded by the late Dr. Ludwig Mond, has been awarded by the Reale Accademia dei Lincei, of Rome, to Mr. Frederick Soddy, F.R.S., lecturer in physical chemistry at the University of Glasgow, for his researches in radio-activity. The presentation of the prize took place in the Capitol on June 1, in the presence of his Majesty the King of Italy.

The annual general meeting of the Research Defence Society will be held on Tuesday, June 24, at five o'clock, at the Royal College of Physicians, Pall Mall. The chair will be taken by Sir David Gill, K.C.B., F.R.S., president of the society. The report will be presented by the Hon. Sydney Holland, chairman of committee. Other speakers will be Sir William Osler, regius professor of medicine at Oxford; Bishop Frodsham, sometime Bishop of North Queensland; and Mr. Waldorf Astor, M.P.

The death is announced of Dr. Forbes Winslow in his seventieth year. Dr. Winslow was known as a specialist in lunacy, and founded the British Hospital for Mental Disorders. He was the author of numerous works on mental diseases and kindred subjects, among them being "The History of Lunacy Legislation," "Manual of Lunacy," "The Suggestive Power of Hypnotism," and "The Criminal Responsibility of the Insane." For eight years he was editor of *The Psychological Journal*.

The death is announced, in his sixty-third year, of Mr. W. McMurtrie, the predecessor of Dr. Wiley in the post of chief chemist to the U.S. Department of Agriculture. Mr. McMurtrie had served for some years as assistant chemist before his appointment to that office in 1873. In 1882 he left Washington and became professor of chemistry at the University of Illinois. While holding the latter post he was also chemist to the Illinois State Board of Agriculture. Of late years he had been a consulting chemist in New York. He was the author of monographs on the culture of the beet, the culture of sumac, grape culture in the United States, and wools and other animal fibres.

In a note in the issue of NATURE for May 22 last (vol. xci., p. 300) attention was directed to the formation of an influential committee to endeavour to establish a uniform notation in the theories of potential and elasticity. The committee of organisation has issued an appeal to astronomers, mathematicians, and physicists, asking them to cooperate in this attempt to secure uniformity, and as a beginning solicits answers to the question: "What are the notions and notations in respect of which it is desirable to establish uniformity?" Answers to this inquiry—which may be in English, French, German, or Italian—should be addressed Mr. Arthur Korn, Charlottenburg, Schlüterstrasse 25. As has been stated, discussions on the subject will be arranged to be held at the international congresses of mathematicians in 1916 and 1920, and it is hoped that the final report of the committee will be issued in 1921.

Dr. F. W. Mott, F.R.S., delivered the first of his Chadwick Public Lectures on Friday, June 6, upon the subject of "The Structure and Development of the Brain." In the course of the lecture he described the structure of the brain in relation to its function as the organ of mind, particular attention being directed to the significance of the folds and fissures, first as determining the extent of the surface grey matter, and, secondly, in the formation of a convolutional pattern. Just as faces show similar features and expression by heredity, so the convolutional pattern of the brains of relatives exhibits a similarity in its folds and fissures. The fact that a parallelism exists between arrest of development of the grey matter and feebleness of mind, and between loss of mind and the decay or destruction of the grey matter, tends to prove that the intellecual and moral character of the individual should be regarded as a natural process of organic development—a product of nature and nurture. The subject of Dr. Mott's second lecture to-morrow, June 13, at 5 p.m., at the Royal Society of Arts, is "Inborn Potentialities of the Brain of the Child."

A joint session of the Aristotelian Society, the British Psychological Society, and the Mind Association was held on June 7 and 8 at University College, London, and Crosby Hall, Chelsea. The first meeting consisted of a symposium, "Are Intensity Differences of Sensation Quantitative?" by Dr. C. S. Myers, Prof. Dawes Hicks, Dr. H. J. Watt, and Dr. Wm. Brown, under the chairmanship of Prof. Spearman. Dr. Myers showed that the "all or none" principle is obeyed by all kinds of reflexes and all kinds of sensibility. The type of reaction is therefore the correlate of quality of sensation and the difference of degree—moreness or lessness of the same reaction is the correlate of difference of intensity of sensation. The second and third meetings, presided over by the Hon. B. Russell, were devoted respectively to a discussion on memory and consciousness, opened by Dr. Robinson, and to a symposium, "Can There be Anything Obscure or Implicit in a Mental State?" by Mr. H. Barker, Prof. G. F. Stout, and Prof. R. F. A. Hoernle. Dr. Robinson said that M. Bergson, in his "Matter and Memory," neglected the fact that memory was an assertion, and that he did not do justice to the function of meaning in remembering. Intuition and intelligence must be somehow inclusively related. A vigorous discussion revealed many criticisms opposing this anti-Bergsonian thesis. In the symposium Prof. Stout maintained that within the field of consciousness, whether of mere sense experience or of thought, there are contents which are not separately discerned. The opposing point of view to this was due to a confusion resulting from the fact that the presence of implicit consciousness can only be ascertained by a process of analytic scrutiny rarely present in normal conscious life.

Mr. Ananda Coomaraswamy has issued part iv. of his useful album of Indian sculpture, "Visvakarma." The plates include two representations of the Buddhist Avalokitesvara, the personification of power, preserver of the world and men, from Ceylon; one of the local goddess, Pidári, from Madras, and a set of Nága and Nágini water or snake deities from Ceylon, Ajanta, and southern India. In some cases the reproduction of the photographs is not as clear as might be desired, but they are sufficient to answer the purpose of the publication. The collection will be of much value to students of Indian religion, archæology, and art.

The recent report of the census of the people of the Andaman Islands, taken in 1911, shows a melancholy decrease in the population. Of the Yerawa and Bojigngiji groups, estimated to number 3500 when British occupation began in 1858, only 455 survive. This decrease is attributed by Mr. R. F. Lowis to three causes—increased infant mortality in the case of parents who have come under the influence of civilisation, and to an epidemic of measles; a tendency to infertility as a result of the introduction of syphilis; an increased death-rate among adults, accounted for by the draughty buildings in which the sick are housed, and the use of clothes and blankets in hospitals, which are discarded when the patients resume their jungle life. The savage Jarawas alone, who live isolated from civilisation, seem to be holding their ground, and it is only in this group that any hope remains of the preservation of this remarkable people.

The alleged atrocities in connection with the rubber trade in the Putumayo district of Peru, now the subject of investigation, have directed attention to the Indian tribes of that region. An English explorer, Capt. T. W. Whiffen, whose evidence has been given before the Parliamentary Committee, contributes to vol. xxiv., part i., of *Folk-lore* an interesting account of these races. He was probably the first and the last white man to observe them while they were unaffected by outside influences. These tribes of the Issa-Japara River region do not, as Dr. Martius supposed, furnish an example of culture degeneration. There is no trace of any submerged superior culture; on the countrary, they have not emerged from the condition of the Stone age. While the people to the north smoke cigars and those to the south use pipes, they make a treacly decoction from the leaf which friends lick ceremonially in the tribal palaver, or to ratify a contract. When twins are born, the second, particularly if a girl, is killed; and deformed or sickly children are drowned by the mother. Among the Boro the father practises the couvade. The only social or artistic function is the dance, announced by beat of drum heard at a distance of eight or ten miles. Prisoners are slain and ceremonially eaten by their captors. After death the soul hovers round the hut for a time, and then wanders to the happy hunting-grounds of the Good Spirit. It may be hoped that Capt. Whiffen will publish a detailed account of these people, with a reproduction of the good photographs which he exhibited before the Folk-lore Society.

Those who were present at the fourth International Congress of Genetics at Paris in 1911 will always recall it as a meeting that was very much alive, and evidence of this is to be found in the report which has recently appeared. Some fifty-eight communications made to the congress are printed in this volume of nearly 600 pages. The greater part of them deal with plants, though there are a dozen papers on animals, and several of a general nature. Many of the communcations are of great interest and permanent value, and special mention may be made of Orton on the inheritance of disease resistance in plants, of Lotsy on crosses between different species of Antirrhinum, and of Walther on the inheritance of coat colour in horses. But the whole volume is full of interest and suggestion, and valuable as giving an excellent idea of the scope of genetic research, and of the great activity at present prevailing. Two languages are used throughout—French and English. A French abstract is given with the English papers, while all other papers are in French with an English abstract appended. The volume is beautifully got up and fully illustrated, a pleasant feature being the collection of portraits of workers in this branch of knowledge. It is published by Masson et Cie., and costs 25 francs.

In an address given at the anniversary meeting of the Royal Society of South Africa in March last, the president of the society, Dr. L. Peringuey, dealt with the antiquity of man in South Africa. So far no human remains have been found in South Africa which belong to the Palæolithic period. On the other hand, stone implements of the various European Palæolithic periods of culture abound in South Africa—Chellean, Acheulean, and Mousterian—but there is no evidence that these types followed each other in point of time; all seem to have been in use at the same period. Dr. Peringuey is convinced that there was a direct relationship between the later Palæolithic cultures of Europe and South Africa—the Aurignacian and Solutrean. The problem of determining the degrees of antiquity of the various Palæolithic cultures of South Africa is rendered difficult by the fact that the climate and the fauna of South Africa have altered very little, if at all, during the Pleistocene period, whereas in Europe there have been recurring periods of change. Lately the fossil remains of two extinct antelopes—"gnu- and pallah-like creatures"—have been discovered in the Free State, with large flakes and other implements of a Palæolithic type. Remains of very similar antelopes occur in the Pliocene formations of India and Attica. Molar teeth of a mastodon have also been found in gravels of the Vaal River along with Palæolithic implements. It will be thus apparent that man's presence in South Africa is of great antiquity, although as yet the necessary data have not been gathered for estimating the degree of that antiquity. So far only Europe and certain parts of America have been searched for man's earliest traces; it seems very probable that Dr. Peringuey and his colleagues may soon be in a position to elucidate, by their discoveries in South Africa, some of the problems which are at present puzzling their European colleagues.

Mr. R. S. Pearson, of the Indian Forest Service, has published (Indian Forest Records, vol. iv., part v.) a detailed and valuable report on the utilisation of bamboo for the manufacture of paper pulp. Four species of bamboos (*Bambusa arundinacea, B. polymorpha, Cephalostachyum pergracile, Melocanna bambusoides*) were examined with regard to their suitability for paper-making; the area over which the examination took place was restricted to Lower Burma and the west coast of the Indian peninsula, as both these localities are geographically well suited for import and export purposes, and contain vast areas covered with bamboos. Figures as to yield, &c., were carefully collected; in order to obtain practical proof of the quality and cost of preparing pulp from bamboos about eighty tons of raw material of the four species were converted into pulp, and eventually into paper at Calcutta; and the report is printed on paper made from *B. polymorpha* (the most useful species), both nodes and internodes being used. The report contains very valuable data for estimating the probability of the success of establishing a paper-pulp industry in Burma and India.

The interesting weather maps for May 9–15, published in the first issue of the Meteorological Office charts of the North Atlantic and Mediterranean for June, show a continuation of the type of conditions which had prevailed during the preceding two weeks, affording a noteworthy illustration of an almost stationary cyclonic system over the north-eastern quarter of the Atlantic for nearly three weeks. The high pressure in the north of Europe and western Siberia spread along the arctic circle to Iceland, formed a barrier against the eastward progression of Atlantic disturbances, and held the depression above referred to in practically the same position until nearly the middle of May. The latest reports showed that "a huge area of high barometrical pressure covered nearly the whole of the North Atlantic." Some icebergs were passed in 42° 30′ N. and 49° W. about April 4. Since April 10 (up to the time of going to press, on May 15) ice had not been sighted south of latitude 44° N.

"Forecasting the weather" is the title of an interesting bulletin (No. 42) by Mr. G. S. Bliss (section director), recently issued by the U.S. Weather Bureau. It shows the great advantage enjoyed by the bureau in being able to watch the developments and movements of storm-areas over the entire country between the Atlantic and the Pacific, and from Canada to Mexico and the West Indies, by the receipt of telegrams twice daily containing observations made at the same physical instant of time. The author shows how perfectly the machinery works, and how rapidly the operations are performed, from observation to map-making. In less than two hours the various forecasters are prepared to issue particulars for a day or two in advance for any State or city with nearly as high a degree of accuracy as they can for their own locality. This useful bulletin is accompanied by weather maps and an epitome of the various processes at work in the atmosphere, to assist students in applying to the maps the principles learned in a cursory study of the elements. It is claimed that by mapping the whole northern hemisphere the Weather Bureau is enabled to forecast general conditions for a week or ten days in advance with a creditable degree of accuracy.

It is well known that the distance of the epicentre of a great earthquake is determined by the duration of the first series of preliminary tremors. The relation is not a simple one for all distances, but Mr. G. Negri states (*Anales de la Soc. Cien. Argentina*, vol. lxxv., 1913) that the duration I_1 of the preliminary tremors in minutes and the distance S of the epicentre measured along a great circle in thousands of kilometres are connected by the following relations: if S be equal to or less than 1, $I_1 = 2{\cdot}05.S$, if S lie between 1 and 9, $I_1 = \sqrt{(16834.S)} - 2{\cdot}32$, and if S be greater than 9, $I_1 = (S + 5{\cdot}929)/1{\cdot}463$. Thus the curve which represents these relations consists of three portions which are respectively straight, parabolic, and straight. Mr. Negri suggests that earthquakes which originate at distances represented by the above limits might be termed near, distant, and antipodal.

In the May number of *The American Journal of Science*, Prof. L. P. Wheeler, of Yale, examines the more recent measurements of the refraction and dispersion of metals in the light of the electron theory of dispersion. The experimental data cover silver, copper, gold, nickel, and cobalt, but the accuracy attained is still insufficient to make the comparison satisfactory. It appears, however, from the results available that the number of free electrons in each of these metals must increase with the frequency of the incident radiation slowly and fairly uniformly in the infra red, and more rapidly in the regions for which the metals are transparent. The dispersion due to the free electrons is more important than that due to the bound electrons, especially in the region of short wave-lengths, and the form of the dispersion curve given by theory agrees with that found experimentally in its main features, although the inaccuracies of the experimental results do not permit of any satisfactory comparison of details.

Science Progress for April contains an important article by Dr. J. V. Eyre on the projected revival of the flax industry in England. Dr. Eyre has, on behalf of the Development Commissioners, visited, during the past two years, the principal flax-growing countries of Europe, and made a special study of the methods adopted in cultivating the plant and separating the fibre. The information gathered has been recently presented to the Commissioners in the form of a report, which is summarised in the article now referred to. The inquiry leaves no room for doubt that the climate of this country is well suited to flax, and experiments are in progress as to the possibility of cultivating and separating the fibre at a profit. Taking into account the fact that flax is now worth nearly twice as much as it was ten years ago, and other considerations which are specified in detail, there is strong reason to believe that the judicious revival of the industry by improved methods would be of benefit to British agriculture. During the past year flax was grown in Bedfordshire experimentally as a fibre crop, and useful information gained as to the more difficult operations of harvesting and retting, special tanks being constructed for the latter purpose. It is proposed in the present year to make trials on a larger scale, and for this purpose a society has been formed under conditions of non-profit trading, so as to be eligible for a grant from the Development Commission.

The third of a series of articles on the Panama Canal appears in *Engineering* for June 6, and deals with the lock-gates. The locks are 110 ft. wide, and have a nominal length of 1000 ft.; intermediate gates are provided, together with valves, allowing lengths of chamber of 278·5, 370, 550, 908·5 and 1000 ft. respectively to be employed, an arrangement which will result in a considerable saving of time and water with vessels of short length. The gate leaves are built of flat girder work sheathed with plating, and the whole of the support is given by a pintle at the base and a yoke above; there is no roller path provided. The leaves have a length of nearly 65 ft. and are 7 ft. wide; the largest are 82 ft. high. The largest leaf has a weight of 1,483,700 lb. The material used in the gates is open-hearth steel, having an ultimate tensile strength of 60,000 lb. per sq. in. Under ordinary conditions, the working stresses do not exceed 13,000 lb. per sq. in., and do not exceed 15,000 lb. per sq. in. under extreme conditions.

The city of Edinburgh recently appointed a commission "to visit various cities in England with a view of inspecting self-propelled cars and obtaining further information on the subject." The deputation has issued a report which is commented upon in *Engineering* for June 6, and gives some valuable data as to various installations for running tramcars by petrol, in place of by cable or by electricity. At Morecambe the autocar service was opened eighteen months ago: the line is 1·2 miles long, and passes through a sparsely populated district. The first year's working shows a surplus of receipts over all expenditure. The car seats thirty-seven passengers; its weight unloaded is 8 tons. It is propelled by a 40 h.p. four-cylinder petrol engine, the mileage per gallon of petrol being seven to eight. The average daily run for each car is about seventy miles. The total cost of car is from 985*l*. to 1150*l*. The Leyland Motor Company, which built the cars, gave a five years' guarantee that the costs of working, exclusive of wages, upkeep of car body, and administration expenses, should not exceed $3\frac{1}{4}d$. per car-mile so long as the price of petrol did not exceed 9*d*. per gallon. Birmingham, Coventry, and London were also visited, and as the result of the inquiries, the deputation recommends the introduction experimentally of petrol-driven cars in Edinburgh.

AMONG the latest additions to the "Cambridge Manuals of Science and Literature" are five volumes dealing with scientific subjects. Prof. John Cox, under the title "Beyond the Atom," tells the story of discoveries in radio-activity, and his brief summary of the work of Rutherford, Curie, and many others will prove of interest to students and general readers alike. Dr. Gadow's book on "The Wanderings of Animals" gives the main facts of geographical distribution in a readable form. Prof. Fortescue writes on wireless telegraphy for readers with a general scientific knowledge who desire to know something, not only of the accomplishments of wireless, but also of the means by which they are attained. Mr. O. H. Latter's book on "Bees and Wasps" deals with British species of Hymenoptera in a thoroughly practical manner, and Mr. Clement Reid's "Submerged Forests" gives a simply worded account of a very interesting series of geological researches. The "manuals" are one shilling net each, and at the rate the library grows the student will be able soon to secure at this small cost an authoritative account of every branch of modern scientific research.

OWING to the development of their optical business, Messrs. Newton and Co., 72 Wigmore Street, London, W., are unable to find space for their philosophical and physical apparatus department, and are consequently disposing of their stock at low prices. The catalogue of apparatus for sale is comprehensive, and includes particulars of shop-soiled and second-hand instruments used in the study of physics and chemistry, lanterns and lantern apparatus, and microscopes and accessories.

OUR ASTRONOMICAL COLUMN.

THE VARIATION OF SOLAR RADIATION.—With the permission of the secretary of the Smithsonian Institution, a definite and important statement under the names of Messrs. C. G. Abbot, F. E. Fowle, and L. B. Aldrich is published in the *Astronomische Nachrichten*, No. 4656, with the title "The Variation of the Sun." The observations from which the conclusions are drawn were begun in the year 1902, when preliminary experiments were made at Washington to determine the solar constant of radiation. About 700 determinations of it have now been secured, and they depend on observations made at altitudes ranging from sea-level to 4420 metres. The results, some of which are mentioned in this communication, will be published in detail in the Annals of the Astrophysical Observatory of the Smithsonian Institution (vol. iii.) now in the press, and will probably appear next month. The authors nevertheless publish in this statement some of the more important conclusions, which are as follows:—

(1) The mean value of the solar constant of radiation for the epoch 1905–12 is 1·929 cal. per sq. cm. per min. (2) An increase of 0·07 cal. per sq. cm. per min. in the "solar-constant" accompanies an increase of 100 sun-spot numbers (Wolfer). (3) An irregular variation frequently ranging from more than 0·07 cal. per sq. cm. per min. within an interval of ten days is established by numerous nearly simultaneous measurements at Mount Wilson, California, and Bassour, Algeria. (4) Indications of two wholly independent kinds incline the authors to think that these variations of solar radiation are caused within the sun, and not by interposing meteoric or other matter.

The extreme importance of the conclusions here stated cannot be overrated, and students of solar physics in its broadest sense will await with eagerness the publication of the detailed investigation.

PROMINENCES ASSOCIATED WITH SUN-SPOTS.—The discovery of radial motion in sun-spots by Mr. Evershed revealed the fact that there are two opposite movements in the penumbra of every spot, the gases at the level of the reversing layer flowing outwards away from the umbra, while those at the higher levels of hydrogen and calcium flow inwards. It was thought that a study of the higher solar region, namely that of the prominences, might shed some light on these remarkable motions, and with this object Mrs. Evershed undertook a study of the fine prominence photographs taken at the Kodaikanal Observatory. The results of this investigation are described in the current number of the Monthly Notices of the R.A.S. (vol. lxxiii., No. 6), and they are accompanied by a series of fine reproductions of numerous types of prominences explained in the paper.

Mrs. Evershed states that the investigation suggests more problems than it solves, yet some preliminary conclusions are nevertheless drawn. The most general result seems to indicate that the movements observed in the prominences situated directly above sun-spot groups are of quite a different kind from those in the penumbræ of spots, being intermittent and variable in direction and amount instead of uniform and constant. Reference is also made to the presence of forces other than those of an eruptive and gravitational nature, which is responsible for such a peculiarity as was observed in some rising prominences which moved with an accelerating velocity into space by a force opposed to gravity.

STUDIES IN STELLAR STATISTICS.—The general question of the distribution and motion of stars in space is perhaps the most important problem of the day, and the attention of astronomers has been turned more and more towards it since the initial investigation of Kapteyn in 1904, who determined for the first time the elements of the two star-streams. Space will only allow here of a list of a few of the more recent papers connected with this subject. Mr. F. W. Dyson has contributed to the two last numbers of the Monthly Notices of the R.A.S. (vol lxxiii., Nos. 5 and 6) two important researches on the distribution in space of the stars in Carrington's circumpolar catalogue, discussing in the first the proper motions in a direction perpendicular to the solar motion, and in the second the proper motions in the direction of the solar motion. In the same publication (No. 6) Mr. H. C. Plummer continues his series of papers on stellar motions, the title of this contribution being "A Preliminary Discussion of the Galactic Motions of the Bright Stars of Type I., with Some Additional Material." Mr. C. V. L. Charlier, in the *Meddelanden fran Lunds Astronomiska Observatorium*, series ii., No. 9, publishes the second of his studies in stellar statistics, entitled "The Motion of the Stars," giving an account of an extensive research into the proper motions of Boss's catalogue based on correlation methods.

RECENT OBSERVATIONS OF NOVÆ.—The results of a valuable piece of work are recorded by Prof. E. E. Barnard in *Astronomische Nachrichten*, No. 4655. They relate to the present appearance of many of the novæ which have been discovered from time to time. The following is a very brief digest of some of the notes he gives, but reference should be made to the original paper for further details of each star:—

Nova	Discovered	Max. recorded mag.	Present mag.	Remarks
T Coronæ	1866	2	9	Colourless
Cygni	1876	3–4	15·0	Hazy
Andromedæ	1885	6	Invisible	—
Aurigæ	1891	4·5	14	Ill-defined
Sagittarii	1898	4·7	15	Hazy and ill-defined
Persei	1901	<1·0	12·05	Colourless
Geminorum (1)	1903	8·16	16·3	—
Aquilæ	1905	5	<17	—
Lacertæ	1910	5·0	12·5	Nebula bluish-white
Geminorum (2)	1912	4	8± (fluctuating)	—

With regard to the last nova, Prof. Barnard writes: "On February 8, 1913, with good seeing and at the proper focus the Hα image of Nova Geminorum No. 2 was clearly seen. It was small and sharp and intensely crimson, and was surrounded by a greenish-blue halo some 3″–4″ in diameter. The normal focus, however, was not different from that of an ordinary star."

THE NATIONAL PHYSICAL LABORATORY DURING 1912.

THE annual report of the National Physical Laboratory, Teddington, was presented to the meeting of the general board on April 25, and marks another milestone of steady progress. The birth of the laboratory but some ten years ago is fresh in the minds of most of us, but many may not realise the extent of its development; few institutions can indeed parallel it in rapidity of growth.

As a nation we were late in starting a national laboratory, but we have been unusually quick in making use of the facilities and advantages which it affords. To it from all parts of the Empire come requests for advice and assistance—requests increasingly exacting and ever-widening in scope; the National Physical Laboratory is fast taking its place as the Imperial laboratory. Its staff, formerly fewer than half a dozen, now numbers 150 of all grades; its history recounts an uninterrupted succession of new buildings. Progress such as this bears witness to the labour and devotion which the director, Dr. Glazebrook, has showered on the laboratory, to the loyal cooperation of his staff, and to the wise administration of the Royal Society.

The National Physical Laboratory is steadily gaining in the nation's appreciation; in common fairness the nation should put itself in the position of being able to say that it has provided for the laboratory in such fashion that financial cares need not distract its administrators from their proper sphere. The laboratory should be able to attract and keep on its staff brilliant young men who are keen to work at research for the profit of the nation and the advancement of learning. The men are not wanting; it is for the country to see that their remuneration is commensurate, and that they are adequately housed and equipped for their work.

The laboratory is being increasingly consulted by the different Government Departments. During the year various matters have been carried out for the Admiralty, the War Office, the Foreign Office, the Home Office, the Board of Trade, the Local Government Board, the India Office, &c. Last year the expenditure amounted to more than 32,000*l.*; the Treasury grant was only 7000*l.* The remaining 25,000*l.* had to be raised by payments for work done and by donations.

A new building designed to accommodate the administration offices and the optics division is approaching completion; this will satisfy a most imperative need. Generous donors have supplemented the special Treasury grant of 15,000*l.* for the purpose; these include the 1851 Commissioners (5000*l.*) and a number of the City Companies. But further funds for equipping these and other departments are urgently needed. The new buildings are to be opened by the Right Hon. A. J. Balfour on the day of the annual visitation, Thursday, June 26.

Turning now to the work of the year, its comprehensive nature is at once evident. The National Physical Laboratory is a physical laboratory in the widest sense, and accordingly we find in its yearly record papers on almost every branch of physics and technology. Some forty original communications were published during the year; it is possible now to touch on only a few of these.

Taking first the work on the fundamental electric units, the Lorenz apparatus for the determination of the ohm in absolute measure was completed during the early part of the year, and a large number of experiments have already been carried out by Mr. F. E. Smith. Some idea of the precision attained may be gathered from the fact that the estimated probable error of any single measurement is of the order of two parts in 100,000. The final result of the measurements is not yet available, but it may perhaps be said that the value will probably be somewhat less than has been generally supposed. Comparisons with the resistance-standards of the Bureau of Standards, the Reichsansalt, and the Laboratoire Central d'Electricité have been made during the year, with the result that the English and German values were found to agree within one part in a million; the American value was ten parts in a million greater.

Mr. Campbell has evaluated the ohm in absolute units by two alternating-current methods, remarkable for their ingenuity. The testing of wavemeters is becoming an important feature of the work in the electrical department.

The British Radium Standard, consisting of 21 milligrammes of extremely pure radium-chloride, is now deposited at the laboratory. Dr. G. T. Beilby provided the funds for the purchase of the standard, which has been compared with the international standard at Sèvres, and will shortly be available for standardising radium preparations.

An important paper dealing with the discharge of electricity from carbon at high temperatures was presented to the Royal Society by Dr. Harker and Dr. Kaye. By reason of the conditions and magnitude of the experiments, ionisation currents amounting to several amperes were obtained.

The thermometry division is investigating the thermal conductivities of the various heat insulators used for cold-storage purposes, and for steam-pipe lagging—a piece of work which presents special difficulties and has long been needed. The equipment for testing the thermometers hitherto verified at Kew Observatory has been set up; some idea of the magnitude of this work will be gathered from the fact that more than 33,000 thermometers were tested last year. A research on the viscosity of oils has been completed by Mr. Higgins.

The photometric division has conducted an inquiry into the visibility of ships' lights, and is at present engaged in an investigation of "glare," particularly that produced by motor-car headlights. Intercomparisons of candle-power units have been made with the Bureau of Standards and the Reichsanstalt through the medium of tungsten filament lamps (Mr. Paterson). The agreement of the results is extremely good, and incidentally affords evidence that the photometry of lights of different colours is not of necessity liable to the errors which are commonly attributed to it. Work has been published by the electrotechnics division on the electric strength of ebonite, the compressibility of micanite, the dielectric losses in insulators (Mr. Rayner), and the heating of flexible cords and cables (Mr. Melsom).

Some important researches have been carried out

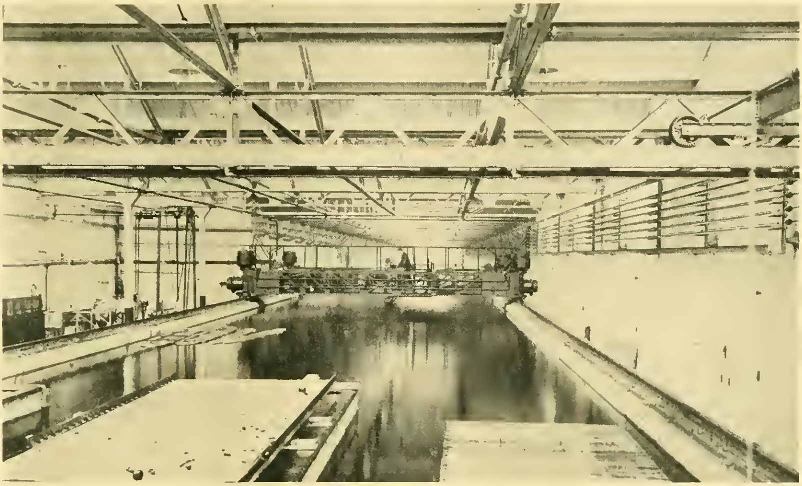

FIG. 1.—The tank and carriage, with model ready for towing.

FIG. 2.—Model being towed—showing waves created.

by Mr. Baker and his colleagues in the Naval Tank. The most noteworthy is that with a series of ship models, each having the same principal dimensions, but with a different distribution of the displacement in a longitudinal direction. The experiments revealed the limits of speed to which various forms can be driven without excessive wave-making, and have also increased the general knowledge of eddy-making at the sterns of ships. An extensive series of experiments has also been carried out on hydro-aëroplane floats. Fig. 1 gives a general view of the tank with a model in place under the carriage by means of which the model is towed. Fig. 2 shows the wave profiles for a model of mercantile form with fairly bluff ends. It is satisfactory to note how very small the loss of water from the tank still continues—a tribute to its design and construction.

In the metallurgical department, Dr. Rosenhain and Mr. Archbutt have published the tenth report of the alloys research committee of the Institution of Mechanical Engineers. The report, which deals with the alloys of zinc and aluminium, contains features of great interest in view of the increasing importance of light alloys in aëronautical and instrument work. Dr. Rosenhain and Mr. Ewen have communicated an important paper on intercrystalline cohesion in metals, while Mr. Humfrey has been working on the effects of strain in iron at high temperatures.

The metrology division has been largely occupied with the arrangements for the reception of the Kew Observatory test work. The behaviour of the silica standard metre has been closely followed, and the value of its expansion-coefficient determined (Mr. Donaldson).

Dr. Stanton and his staff have carried out extremely valuable work in a number of directions, more particularly on wind-pressures (at the Tower Bridge), on the frictional high-speed flow of water and air in pipes, and on the pressure and flow round aëroplane surfaces. The experiments conducted in the 4-ft. wind channel have afforded valuable information to the Royal Aircraft Factory at Farnborough in designing biplanes and dirigible balloons. The Treasury has accordingly authorised the erection of a new 7-ft. channel at the laboratory; this is now approaching completion.

The new experimental road constructed for the Road Board is complete, and abrasion and endurance tests have been begun.

The optical division has been concerned with the testing of photographic shutters, the absorbability of glass for ultra-violet light, and the testing of telescope objectives and trial lenses. The staff took an active part in the organisation and proceedings of the Optical Convention which was held during the year at South Kensington.

This short summary may suffice to give a notion of some of the many fields of activity in which the National Physical Laboratory is working for progress. There are important problems waiting to be taken up; it is in many cases purely a question of "ways and means" which prevents a start being made.

THE ROYAL OBSERVATORY, GREENWICH.

At the annual visitation of the Royal Observatory on June 7, the Astronomer Royal, Dr. F. W. Dyson, F.R.S., presented his annual report. The following extracts indicate the chief items of interest:—

The observatory has ceased to generate its own electric current for lighting and other purposes, and now obtains current from outside. Alternating instead of direct current is now used, and a small supply of direct current is obtained by means of a rotary converter.

In the new magnetic observatory, shortly to be erected, provision is made for the continuation of the long series of Greenwich observations of the variations of the magnetic elements. This series is unique as regards the length of time during which observations have been made on the same site. The care which has been taken to guard the observatory from all artificial electromagnetic disturbances which could affect the accuracy of the observations has preserved the suitability of the site for such work.

Observations of double stars have been made with the 28-in. refractor from a working catalogue containing all known double stars showing appreciable relative motion, and a number of pairs from the catalogues of Hussey and Aitken under 2″ separation. κ Pegasi was observed on five nights, δ Equulei on three nights, 70 Ophiuchi on thirteen nights, and ϵ Hydræ on one night.

The 26-in. refractor, the 30-in. reflector, and the 6-in. Cooke triplet have been in constant use during the year. The new cell for the crown lens was received and mounted in July. The adjustment of the crown and flint lenses for tilt and eccentricity relative to one another was made in August.

During the year 164 plates were taken for determination of stellar parallax, 124 of these being new plates and forty being re-exposures of plates taken six months previously. The programme for each star consists of six photographs. Three photographs taken in the evenings are re-exposed in the mornings about six months later, and are then developed. Three plates are exposed in the mornings, and, after re-exposure six months later, are also developed. For several stars the cycle has been completed and the plates have been measured for three stars. The results obtained are $+0{\cdot}082'' \pm 0{\cdot}017''$, $+0{\cdot}043'' \pm 0{\cdot}009''$, and $-0{\cdot}014'' \pm 0{\cdot}012''$. The star which gave a negative parallax is one with a small proper motion. It is considered that these probable errors are too large, and that one of $\pm 0{\cdot}005''$ should be attainable. The increased constancy in the adjustment of the object glass secured by the new cell, and the use of the rotating sector by which the star observed is reduced to the magnitude 10·5m. to 11·0m. of the comparison stars, are expected to make a considerable improvement.

The 6-in. Cooke triplet which belonged to the late Mr. Franklin Adams has been employed in the determination of the photographic magnitudes of the stars brighter than 9·0m. in the Greenwich astrographic zone. During the year fifty-three photographs of fields compared with the standard polar area have been taken. Fifty-six plates have been measured, completing the eighty-eight necessary for the whole zone. The catalogue of the resulting magnitudes is nearly completed, and will contain 8000 stars.

Fifty-nine photographs of Neptune and satellite, taken in 1909–10, have been measured, and the results published.

At the date of the last report, 152 out of the 206 Franklin-Adams photographs had been counted in the manner then explained. During the year fifty of the remaining plates have been dealt with. The four plates still uncounted have not yet been received from Johannesburg.

The requisite photometric data for the reduction of these counts to statistics based on actual photographic magnitudes are now being obtained at a steady rate. The plan of taking long exposures on a field and a standard polar area has been abandoned, because of the rarity of nights on which the sky is uniform and constant for more than one hour. Instead of this, exposures of 5m. duration are being taken on the central fields of the Franklin-Adams plates and on the standard polar area. The actual procedure consists in giving an exposure of 5m. on a field taken at the same altitude as the pole, two exposures on the pole, and then a second exposure on the field. These will serve to determine standard magnitudes down to the 13th or 14th magnitude on the Harvard photographic scale. With these short exposures it will be possible to make several determinations for each field required. For the fainter stars photographs will be taken with a wide grating and the magnitudes derived by comparison with the diffracted images of the brighter stars. These determinations have the advantage of being independent of the changing transparency of the sky. The star-images are compared with a scale formed by taking a number of different exposures on the same plate—the scale being calibrated by the Harvard standards.

With the astrographic equatorial 176 photographs have been taken on fifty-nine nights. Of these, 154 were for the determination of the photographic magnitudes of the stars in the Greenwich section of the Astrographic Catalogue by the method described in last year's report, and 107 of them were considered satisfactory for the purpose. There are now twenty-nine plates on the working list to be taken to complete the series.

Attention is directed to the determination of the position of the sun's axis which has been carried out by Mr. Maunder. The attempt has been made to utilise as fully as possible the long series of measures of the positions of sun-spots made at Greenwich. Although Carrington's determination proves to be only a few minutes in error, it is desirable that the position of the sun's axis should be obtained with all possible precision, and that the limits of accuracy should be known. A redetermination should be made at each sun-spot cycle.

An apparatus was set up on July 5 for the reception of the wireless time-signals from the Eiffel Tower and Norddeich. The signals have been constantly observed since that date, the morning signals being observed each day (except Sundays). The night signals from the Eiffel Tower have been observed on 128 and the rhythmic signals on eighty-two occasions. The night signals from Norddeich have been observed on 124 occasions. The morning signals from the Eiffel Tower were observed by both Mr. Lewis and Mr. Bowyer on 167 days; there is a mean difference $L-WB=-0{\cdot}066$s. in their times of observation with an accidental discordance of $\pm 0{\cdot}06$s. between the observers. Similarly in the receipt of the Norddeich signals the two observers showed a mean personal difference $L-WB=-0{\cdot}043$s., and a similar accidental discordance. Thus the ordinary signals are observed by either observer with a mean error of less than $\pm 0{\cdot}05$s. The rhythmic signals are apparently received with an error of less than $\pm 0{\cdot}01$s., and the mean discordances between these and the ordinary signals are less than $\pm 0{\cdot}05$s.

As regards the actual difference between the time sent out by the Eiffel Tower and that of the Greenwich 10h. and 1h. signals, from 184 observations Mr. Lewis makes the Eiffel Tower signal 0·256s. late on Greenwich, and Mr. Bowyer from 234 observations makes it 0·313s. late. It is supposed that the difference is mainly due to the difference of personal errors of the standard observers at Paris and Greenwich. The mean discordance after allowing for this constant difference is $\pm 0{\cdot}11$s.

The Norddeich signals are, according to 160 observations of Mr. Lewis, 0·297s. late on the Greenwich time signals, and 0·340s. late according to 229 observations of Mr. Bowyer. Allowing for this there is an accidental discordance of $\pm 0{\cdot}23$s.

The daily comparison of the Eiffel Tower signal affords a useful regular check on the time as determined at Greenwich. At the request of the director of the Paris Observatory, this comparison has, since the installation of the receiving apparatus, been forwarded daily to him as a check on the rate of the clock at Paris. These comparisons are specially serviceable in cloudy weather. In October the Astronomer Royal attended the "Conférence internationale de l'heure" as one of the British delegates, where the further development of the wireless time-service was discussed. The distribution of time in this way is of great value to navigators, and is likely to be of importance in the determination of longitude on land.

ORNITHOLOGICAL NOTES.

THE May number of the New York Zoological Society's Bulletin is devoted to the needs and results of wild-life protection in America, more especially as regards birds. A feature of this issue is a coloured plate representing five species of brilliantly coloured birds—the quezal, the great bird of paradise, the scarlet ibis, the cock-of-the-rock, and the white egret—which are in special danger of extermination in various parts of the world. Altogether, it is estimated that something like one hundred species are in danger owing to the feather trade or on account of their value as food. It is no answer to say that the present comparative abundance of some of these species renders protective measures unnecessary, for it is pointed out that the same argument was used in 1857 in the case of the passenger-pigeon and Wilson's snipe, the former of which is now extinct, save for one survivor in the zoological gardens at Cincinnati. The purchase of Marsh Island as a bird sanctuary by Mrs. Sage is recorded as an important step in the right direction.

In connection with the above may be noticed an article by Mr. B. H. Grove in the May number of *The American Naturalist* on the influence of agricultural development in Wyoming on the bird-fauna, in which it is pointed out that several species are on the increase, while others—notably the quail—have made their first appearance, as new-comers, into this State during the last few years.

The January number of *The Emu* contains the report of a committee of the Royal Australasian Ornithologists' Union appointed to consider the nomenclature of Australian birds and to publish a revised list of names. Although the list which accompanies the report is not based on absolute priority, the committee acknowledges its indebtedness, in its compilation, to the one recently published by Mr. G. M. Mathews, in which that principle is adopted throughout. Trinomialism is rejected.

In an article by Capt. H. Lynes on the drumming of snipe in the May issue of *British Birds*, it is pointed out that the performance is normally connected with the sexual function, but that it may occasionally take place at other seasons, although always within the limits of the breeding area. R. L.

THE AMERICAN PHILOSOPHICAL SOCIETY.

THE annual general meeting of the American Philosophical Society was held in Philadelphia on April 17–19 inclusive. A large number of papers was presented, their general character being of a high order of merit, and it is possible here to refer only to a few of them. The president, Dr. W. W. Keen, was in the chair at most of the meetings.

In a contribution on the flora of Bermuda, Mr.

Stewardson Brown, conservator of the botanical section of the Philadelphia Academy of Natural Sciences, said that more than 1450 separate collections of plants have been made from all parts of the archipelago, with the exception of a few of the smaller islands which are only rocks with but little vegetation. The native species of flowering plants and ferns, exclusive of the endemic forms, number 155, all of which are identical with those existing on the American mainland or the West Indian islands. The fourteen endemic species, four of which have been added through these studies, are all more or less nearly related to those of the south-eastern United States, West Indies, or tropical continental America, and are probably derived from such ancestors by modification during long periods of isolation. It would appear that the greater portion of the native flora has come to Bermuda from the south-west through the agency of ocean currents, hurricane winds, and migratory birds, of which a considerable number of species visit the islands regularly each year.

Prof. George E. Coghill, professor of zoology, Denison University, Granville, Ohio, read a paper on the correlation of structural development and function in the growth of the vertebrate nervous system. Recent studies in comparative neurology have resolved the central nervous system of vertebrates into four longitudinal divisions which are severally functional units. Among lower vertebrates the relative development of these divisions, the somatic sensory, the visceral sensory, the somatic motor, and the visceral motor, has been in a significant manner correlated with the behaviour of the species. Such correlations by the comparative method formed the point of departure for this study on the correlation of the behaviour of embryos with the developing structures in the growth of the nervous system. Some of the more general results of this method of study are (1) the demonstration of the nature of the primary reflex arc of the vertebrate nervous system; (2) the discovery of the adaptive nature of the early reflexes when considered from the phylogenetic point of view; (3) proof that the final common path of the most primitive reflexes is elaborated into the nervous mechanism of locomotion; (4) the explanation of the typical behaviour of a vertebrate upon the basis of demonstrable reflex arcs; (5) a distinctive contribution towards a biological neurology.

Prof. Victor C. Vaughan, professor of hygiene and physiological chemistry in the University of Michigan, dealt with the nature and significance of fever. It has been shown experimentally that fever is due to the digestion of proteins in the blood and in the tissues. Bacteria are living proteins. They get into the body and grow, converting the proteins of man's body into bacterial proteins. After a period of incubation the cells of the body pour out a ferment which digests and destroys the bacteria. In this process fever originates. In itself fever is beneficial: it is a manifestation of the attempt on the part of nature to destroy the invading organism. However, nature may overdo the matter, and fever *per se* become dangerous when it goes much above 105°. Any kind of fever, acute fatal, intermittent, remittent, or continued, may be induced in animals by repeated injections of properly graduated doses of foreign protein.

Prof. Mazÿck P. Ravenel, professor of bacteriology in the University of Wisconsin, described the control of typhoid fever by vaccination. In the United States vaccination against typhoid fever was recommended in 1909. The results were so favourable that it was made compulsory for all officers and enlisted men under forty-five years of age in 1911. The most striking results were obtained during the mobilisation of troops in Texas in 1911. There were 12,801 troops in Texas, all vaccinated. There was only one case of typhoid fever, occurring in a private of the hospital corps, who had not completed his immunisation. The case was mild and resulted in recovery. In 1898 10,759 troops were stationed in Jacksonville, Florida, under very much the same conditions as regards climate, &c. Vaccination was not practised at that time. There were 2693 cases known or believed to be typhoid fever, with 248 deaths. The French troops in Morocco, under most unhygienic surroundings, have entirely escaped typhoid fever where vaccination was practised. In Wisconsin the State Laboratory of Hygiene sends out the vaccine free of charge to all physicians in the State. In more than 3000 vaccinations only two cases of typhoid fever have come to notice; both these cases mild and atypical.

A paper on Guatemala and the highest native American civilisation was read by Prof. Ellsworth Huntington, of Yale University. Among the native civilisations of the western hemisphere that of the Mayas was decidedly the highest. Not only did they develop the arts of architecture and sculpture to a surprisingly high point, but they were the only American race to evolve the art of genuine hieroglyphic writing. To-day the magnificent ruins of the later, decadent Maya period, dating about 1000 A.D., are relatively accessible, as they lie in the dry and well-populated strip which borders the peninsula of Yucatan on the north. The oldest ruins, however, those representing the period of highest development a few centuries after the time of Christ, are located in one of the most inaccessible regions of America. In the last 1500 years, more or less, there must have taken place a change of great magnitude. Three possibilities present themselves. First, the Mayas may have possessed a degree of energy, initiative, and of resistance to fevers much in excess of that of any other known people. Secondly, in their day tropical fevers of the more destructive types may have been unknown in Central America. And thirdly, the climate may have changed. Alluvial terraces and their relation to such ruins as Copan furnish strong independent evidence of climatic pulsations during the past 2000 years.

Prof. W. M. Davis, of Harvard University, discussed Dana's contribution to Darwin's theory of coral reefs, and an account of his paper has already appeared in these columns (February 6, 1913, p. 632.)

Dr. Charles D. Walcott, secretary of the Smithsonian Institution, gave illustrations of a remarkable and ancient fossil fauna discovered by him in the mountains of British Columbia, 2000 ft. above Field, on the Canadian Pacific Railway. The fossils are most beautifully preserved, and include such delicate forms as Medusæ, holothurians, finely preserved marine shells of various kinds, and a variety of crustaceans. Some of the latter are so perfectly preserved that the branchia, legs, and alimentary canal are shown, and even in several forms the liver is so perfect that the ramifications of the tubes through it are reproduced by photography. Altogether more than eighty genera of invertebrate fossils have been found from a bed not more than 5 ft. in thickness. They are all of marine origin, and lived at a period when there were no vertebrates in existence.

The Alleghenian divide and its influence upon freshwater faunas was described by Dr. Arnold E. Ortmann, curator of invertebrate zoology in the Carnegie Museum of Pittsburg. Although it is known that the Allegheny Mountains form a boundary between the aquatic forms inhabiting their western and eastern slopes, particulars about the relations of the two faunas were missing. Dr. Ortmann furnished facts for a number of aquatic forms of life, chiefly the fresh-water mussels, the Pleuroceridæ, and the crayfishes, covering the region from the New York-Pennsylvania State line to the northern boundary of Tennessee. The main results are that the groups mentioned have not been transported overland to any extent, and consequently are apt to furnish evidence as to the former drainage conditions. The Allegheny Mountains have acted most of the time as an effective barrier to the dispersal of fresh-water life, at least since the end of the Cretaceous. The Atlantic side received its fauna from the interior basin—not across the mountains, but around the northern and southern ends. A few instances are known where single species crossed the divide, and these cases are found in two sharply restricted regions.

Progressive evolution among hybrids of Œnothera was discussed by Prof. Bradley M. Davis, of the University of Pennsylvania. Certain cultures of hybrids between *Oenothera biennis* and *O. grandiflora* have presented in the second generation a high degree of progressive advance in flower size and in the size of the leaves and the extent of their crinkling. An hypothesis for such progressive evolution is offered by the Mendelian principle of recombination of factors for large size on the assumption of multiple factors for the dimensions of organs, but this hypothesis also demands the presence in the same culture of groups of plants containing the factors for small size. When in an F_2 generation there is a considerable group of plants with flowers larger than those of the larger parent there should also be expected corresponding groups with flowers as small as, or smaller than, those of the smaller parent. In F_2 generations of about 1000 and 1500 plants respectively there were no groups of plants with flowers as small as, or smaller than, those of *O. biennis*, the small-flowered parent. The cultures as a whole presented a marked advance in flower size. A similar situation was presented by the character of the foliage in certain F_2 generations The leaves throughout the mass of these cultures were much larger than those of the parents and generally much more crinkled. It is difficult to explain the results on strict Mendelian principles of segregation. Admitting the complexity of the situation when such an extreme cross is made as that between *O. biennis* and *O. grandiflora*, there still appears to Dr. Davis sufficient reason in the data at hand to present the problems as material for reflection on the Mendelian theory of the stability of factors and the principles of their distribution unchanged in the organisation of gametes.

Attention was given to the subdivision of the United States into climatic areas more or less susceptible of quantitative definition by Prof. Burton E. Livingston, professor of plant physiology in Johns Hopkins University, in a paper on climatic areas of the United States as related to plant growth. From a thorough study of the climatic data which are at hand, it appears that any two systems of isoclimatic lines, one system representing the geographical distribution of temperature conditions and the other representing that of moisture conditions, have a strong tendency to cross each other, thus dividing the country into climatic areas, each one capable of quantitative description.

Dr. William Duane, late of the Curie Radium Laboratory, University of Paris, referred to some unsolved problems in radio-activity (illustrated). He discussed such questions as: How can atoms which are physically and chemically similar to each other yet be so different that some of them will disappear immediately and others not for a long time? The explanation of this probably lies in the internal structure of the atom and not in external causes, for external conditions have no known effect upon the phenomenon. The second unsolved problem to which attention was directed was connected with the rays given off by the substances during their transformations. The third problem had to do with the γ rays. He asked: Is the γ ray a wave form spreading out as sound waves do from their source, or is it of corpuscular nature resembling the sparks projected from an exploding rocket? The fact that the β ray, which the γ ray is capable of producing, does not depend upon the distance from the source of the γ ray to the point at which the β ray is produced seems to indicate that the latter hypothesis is correct.

Dr. Edward C. Pickering, director of the Harvard College Observatory, introduced the subject of the determination of visual stellar magnitudes by photography. Ordinary photographic plates are most sensitive to blue light, while the yellow rays are those that effect the eye most strongly. Accordingly, blue stars appear brighter and red stars fainter in a photograph than to the eye. Isochromatic plates are, however, manufactured which are very sensitive to yellow light. If a yellow screen is interposed, the blue light is cut off and red stars appear even brighter, relatively, than they do to the eye. By using a thin yellow screen which cuts off only a portion of the blue rays it is possible to obtain plates having the same colour index as the eye. To fulfil this condition several blue and several red stars have been selected near the north pole. Photographs are then taken with different screens until one is found which gives images of the same relative brightness as the naked eye. With the 16-in. Metcalf telescope at Harvard, stars as faint as the twelfth magnitude may be photographed in this way with an exposure of ten minutes. With an exposure of two hours, stars can be photographed about as faint as they can be seen with a telescope of the same size. On a perfectly clear night a photograph is taken of the north pole with exactly ten minutes' exposure, then similar exposures on four different regions, then a second time on the north pole, on five other regions, and a third time on the north pole. The twelve plates are developed together and various precautions taken to secure uniform results. The magnitudes of numerous stars near the north pole have been measured with great care, and the magnitudes of the stars on the other plates can thus be determined on the same scale.

The spectroscopic detection of the rotation period of Uranus was the subject of a paper by Dr. Percival Lowell and Dr. V. M. Slipher, of the Lowell Observatory, Flagstaff, Arizona. By means of the spectroscope, it is possible to measure the speed of approach or recession of a luminous body; for the lines of the spectrum are shifted toward the violet or red in proportion as the body moves toward or from the observer. Hence, if the image of a rotating planet be so thrown upon the slit of the spectroscope that one end of the slit is illuminated by light from the approaching side of the planet and the other end by light from the receding side, the lines will be tilted through an angle which measures the speed of rotation. In this way, from spectrograms obtained at the Lowell Observatory in 1911, the authors determined the rotation of the planet Uranus about its axis to take place in ten hours and fifty minutes, in a direction opposite to that of the rotation of the planets nearer the sun. Thus, for the first time, an authentic determination of the rotation of this planet has been made by a direct method.

Dr. V. M. Slipher also described the spectrum of the nebula in the Pleiades. Two photographs of the spectrum of the faint nebula near Merope, a bright star in the Pleiades, were obtained in December, 1912, with a slit spectrograph attached to the Lowell 24-in. refractor. The two plates were exposed five and twenty-one hours respectively. They agree in showing a continuous spectrum crossed by the dark lines of hydrogen and helium, the spectrum of the nebula being a true copy of that of the brighter stars of the Pleiades. The light of the nebula is thus shown to be of stellar origin. As it seems improbable that a mass of stars, all of the same spectral type as the Pleiades, should so group themselves behind the Pleiades as to give the appearance of a nebula, the author believes it more probable that the nebula consists of diffused material surrounding the stars and shining by reflected starlight. This is the first successful observation ever published upon the spectrum of this faint nebula.

A symposium on wireless telegraphy and telephony was an important part of the meeting. Among the papers read was one on radiated and received energy, by Dr. Lewis W. Austin, head of the U.S. Naval Radio-Telegraph Laboratory. Mathematical theory indicates that the energy radiated from a radio-telegraphic antenna will produce an electromotive force on a receiving antenna proportional to the current in the sending antenna, to the height of the sending antenna, to the height of the receiving antenna, inversely proportional to the wave-length, and inversely proportional to the distance between the two antennas. Since the loudness of signal is proportional to the square of the current in the receiving antenna, the signal falls off as the square of the distance between the two. This law has been verified by the experiments made by the United States Navy Department between the new high-power station at Arlington and several other stations situated in and near Washington. Observations at distances above 100 miles show that in addition to the diminution in intensity of signal with the distance, there is in an absorption either in the atmosphere or ground, such that at a distance of 1000 miles over salt water, with a wave-length of 1000 meters, the received current is only approximately 1/25; that is, the received signals are reduced to 1/600 of what they would have been had there been no absorption. The absorption decreases as the wave-length is increased, so that for communication over great distances, long waves 4000 to 7000 metres in length are used, while for short distances of a few hundred miles short waves are better, since they are radiated more energetically. These facts apply to daylight communication only, which is in general regular, night ranges, though greater than day, being freakish and uncertain. The absorption over land is much greater than over water, especially for the shorter wave-lengths. In recent tests between the Arlington station and the scout cruiser *Salem*, on its voyage to Gibraltar and return, messages were received from Arlington in the day-time on the *Salem* up to a distance of 2100 nautical miles, and at night as far as Gibraltar. A comparison was also made of the action of two types of sending sets, one being the regular spark-sending set and the other a set in which the waves are produced from an electric arc. It has been claimed that the continuous waves emitted by the arc are less absorbed than the broken-up trains of waves produced by the spark. Up to 1000 miles no difference in the absorption was observed, but at 2000 miles the observations indicated that the received arc energy was relatively four times greater than that of the spark.

During the meeting Sir A. J. Evans, Sir Joseph Larmor, and Dr. Schuster were elected foreign members of the society.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—Prof. W. S. Boulton, professor of geology at University College, Cardiff, has been appointed to succeed Prof. C. Lapworth, F.R.S., who is retiring at the close of the present session. Before his appointment to University College, Cardiff, Prof. Boulton had been assistant lecturer in geology at Mason College, under Prof. Lapworth.

Dr. O. J. Kauffmann has been appointed successor to Prof. A. Carter, as joint professor of medicine, and the chair of surgery, vacated by Prof. G. Barling, on his election as Vice-Chancellor, has been filled by the election of Mr. W. P. Haslam.

Dr. T. Stacey Wilson has been invited to deliver the Ingleby Lectures for 1914.

Dr. P. T. Hughes is to represent the University at the International Congress of Neurology and Psychiatry at Ghent.

Leeds.—At the request of the Development Commissioners, the University has undertaken the preliminary arrangements for an investigation in flax growing and in the methods of retting which would be suitable for a central rettery. Selby has been chosen as the chief place of experiment, and 120 acres of land have been sown with various selected types of seed. Negotiations are in progress for the establishment of a central rettery where the whole crop may be treated. The Treasury has sanctioned a grant from the Development Fund to cover the cost of the preliminary steps. The question of the subsequent control and direction of the experimental station is still being considered by the Development Commissioners.

Oxford.—The annual report of the delegates of the Oxford Museum, which was presented to Convocation on June 10, is a lengthy document occupying thirty-two pages of the *University Gazette*. It includes separate reports of the museum departments, prepared by the regius professor of medicine, the professors of pathology, physiology, human anatomy, comparative anatomy, zoology, experimental philosophy, physics, engineering science, chemistry, geology, rural economy, and mineralogy, by the curator of the Pitt-Rivers Museum, and the reader in pharmacology. The introductory matter records the resignation of Prof. Odling, and the election of Prof. Perkin to the vacant chair of chemistry, together with the appointment of Mr. J. A. Gunn to the newly established readership in pharmacology. The reports of the several professors give evidence of much activity in both teaching and research; in most cases they include lists of important additions to the collections of specimens and the stock of apparatus. The longest and most elaborate contribution is that of the Hope professor of zoology (Prof. Poulton), whose account of the work of his department takes up more than half of the whole publication. The events of which he makes special mention are the taking over by his department of the lower portion of the south room of the old Radcliffe Library, and the meeting of the International Congress of Entomologists at Oxford last August. Attention is directed to many valuable additions to the collection, and particularly to the African insects presented by Messrs. K. St. A. Rogers, W. A. Lamborn, J. A. de Gaye, and Dr. G. D. Carpenter. An interesting list of accessions to the Pitt-Rivers collection is given by the curator (Mr. H. Balfour), who makes special mention of stone implements collected in Ashanti by Mr. R. S. Rattray, a former diploma student in the department. Space will not allow mention of the other reports, all of which contain matter of interest.

Dr. T. K. Monro has been appointed professor of practice of medicine in the University of Glasgow, in succession to the late Prof. S. Gemmell.

Mr. P. F. Kendall, junior assistant curator of the zoological museum of the University of Sheffield, has been appointed lecturer in zoology and geology in the South-Eastern Agricultural College at Wye.

The widow of the late Dr. Hervieux, who died six years ago, has given 4000*l.* to found two bursaries for poor students. We learn from the *Revue Scientifique* that Mme. Hervieux has also bequeathed to the Paris Academy of Medicine a bust of her late husband.

Under the auspices of the Edinburgh Mathematical Society, a mathematical colloquium will be held in Edinburgh during the week beginning Monday, August 4, and lasting five days. The following courses of lectures have been arranged:—"The Theory of Relativity and the New Physical Ideas of Space and Time," Prof. A. W. Conway; "Non-Euclidean Geometry and the Foundations of Geometry," Dr. D. M. Y. Sommerville; "Practical Harmonic Analysis and Periodogram Analysis: an Illustration of Mathematical Laboratory Practice," Prof. E. T. Whittaker, F.R.S. Further particulars may be obtained from the honorary secretary of the Edinburgh Mathematical Society, 19 Craighouse Terrace, Edinburgh.

The prospect of early educational legislation has led lately to much discussion and to many speeches by prominent persons on various aspects of the problem of providing an adequate and properly organised system of education. Opening the new buildings on June 6 of the Newcomen's Foundation Domestic Trade School for Girls in London, the President of the Board of Education, Mr. Pease, said that when the history of the past fifty years comes to be written it will show that there has been too great an effort to make individuals read books. The result has been that people too often take their opinions from books, instead of forming them for themselves as the result of their own experience, their own thought, and their own work.—On June 6 and 7 the annual meeting of the Association of Education Committees was held, and resolutions were passed (*a*) declaring that it is imperative that a revision of the incidence of the cost of education as between the national and the local contributions shall precede any further legislation or administrative action which will increase the cost of education; (*b*) expressing the opinion that a new form of State contribution should be substituted for the very unsatisfactory system of grants to local education authorities, and that the Exchequer grants should increase automatically as new and increased responsibilities were put upon local education authorities; (*c*) expressing the opinion that the time has arrived when the strongest possible protest should be offered to local authorities undertaking any further financial obligations until the Government has redeemed its promise of further financial aid. Mr. Pease, who attended the meeting, said it is realised that more money ought to be given by the State in support of education, and that education committees should cooperate one with another with the view of coordinating the whole system of education in the country and making it more perfect.

Commemoration Day at Livingstone College, Leyton, was held on June 7, and formed the centenary celebration of David Livingstone's birth. After a preliminary statement by the principal (Dr. C. T. Harford), the chairman (Bishop Montgomery) addressed the meeting. He emphasised the importance of medical training for missionaries, especially for those who had to go to tropical countries. Sir A. Pearce Gould said that the life of Livingstone was an outstanding contradiction to and repudiation of materialism. He spoke of the value of the college training for all missionary students, and urged the advantage of the course for missionaries on furlough, who would thus be brought into touch with recent medical researches. He referred to Livingstone's skill as a physician, and to his anticipations of modern research. Livingstone clearly saw the close connection between mosquitoes and malaria, and that there was an absence of malaria in the highlands where there were no mosquitoes, but in the lowlands where they swarmed malaria was prevalent. Livingstone recognised that the bite poisoned the blood, and noted that "the germ which enters when the proboscis is inserted to draw blood, the poison germ, is capable of reproducing itself." Livingstone also saw clearly the high importance of quinine in cases of fever. The Rev. W. D. Armstrong, who had been fifteen years on the Congo, spoke of the extreme value of his medical training in the maintenance of his own health whilst he was sampling Congo diseases, and in the valuable work he was able to do for his wife and fellow-missionaries at critical times. He spoke of the frequent call for help from traders, who were often entirely dependent on the missionary for medical help. This relationship had been an efficient means of establishing good relations between traders and missionaries in the troublous times of the rubber controversy. At the conclusion of the meeting the visitors had opportunities of examining the college laboratory for research in tropical diseases and the Livingstone relics which were on exhibition.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 5.—Sir Archibald Geikie, K.C.B., president, in the chair.—Dr. R. **Broom**: The origin of mammals (Croonian Lecture). An endeavour is made to trace the evolution of mammals from Cotylosaurian ancestors through the carnivorous Therapsida.—Dr. E. A. Newell **Arber**: The fossil floras of the Wyre Forest, with special reference to the geology of the coalfield and its relationships to the neighbouring Coal Measure areas.

Zoological Society, May 20.—Prof. E. A. Minchin, F.R.S., vice-president, in the chair.—Dr. R. **Broom**: The South African pseudosuchian reptile Euparkeria and allied genera. Besides giving an account of the very completely known South African form, the author also discussed the structure of the Elgin allied forms, Ornithosuchus and others. The group of pseudosuchians he regarded as an extremely important primitive reptilian order, as there is good reason to believe that not only does it contain the ancestor of the dinosaurs, but also the ancestors of the pterodactyles and birds. Euparkeria and Ornithosuchus are, in structure, almost dinosaurs, and it is held that when the bipedal habit was more fully acquired the few characters not quite dinosaurian would become dinosaurian. Birds are held to have originated from a pseudosuchian which, by a bipedal habit, had acquired a dinosaur-like hind limb, and had then become arboreal in habit and acquired the peculiar power of flight.—E. G. **Boulenger**: Experiments on the metamorphosis of the Mexican axolotl (*Amblystoma tigrinum*). A detailed description was given of the changes that take place in the course of transformation. The author also exhibited a number of specimens in the perfect or amblystome condition. The conclusions arrived at, as a result of his experiments, were that, in accordance with Mlle. de Chauvin's experiments, and contrary to those of Dr. Powers, the axolotl will, with a few exceptions, transform if placed under special conditions which force it to breathe air more frequently than usual; that starvation, irregular feeding, and temperature have no influence on the metamorphosis; that the elimination of oxygen from the water has likewise no bearing on the point, as the animal will not, in the circumstances, rise to the surface and make use of its lungs at more frequent intervals than animals placed under normal conditions.—G. E. **Bullen**: Some cases of blindness in marine fishes. Work hitherto performed, *e.g.* that of Hofer, de Drouin de Bouville, and others, upon the pathology of fishes has been directed largely upon species of fresh-water habitat. The present author has found, in certain specific cases of blindness in marine fishes, pathological conditions similar to those described, and others with slight modifications, in several fresh-water species. The examples dealt with in detail are traumatic corneal opacitis in a conger-eel, corneal opacitis, &c., in a greater weaver, and corneal opacitis and cataract in a pollack. Dr. R. W. **Shufeldt**: The patella in the Phalacrocoracidæ. From a study of the patella in a number of species of this family, the author had found that in adult individuals that bone was composed of the true patella solidly fused with the proximal portion of the cnemial process of the tibiotarsus, which became dissociated from the latter early in the life of the bird. Late in life this fusion obliterated the tendon of the ambiens muscle, which heretofore had been described as passing through the patella and persisting through life.

Royal Meteorological Society, May 21.—Mr. C. J. P Cave, president, in the chair.—E. **Gold**: Determination of the radiation of the air from meteorological observations. The theory of the cooling of the air during the night hours was developed and applied to observations made near the earth's surface and 130 ft. above it, in order to obtain an estimate of the radiating power of the atmosphere. The results obtained show that even on calm, clear nights, when the air at the higher level is warmer than that near the surface, the cooling of the air is affected by convection, and the observations available do not suffice for the determination of the correction to the value of the radiating power necessary on this account.—S. C. **Russell**: Results of monthly and hourly cloud-form frequencies at Epsom, 1903–10. The author had made hourly records of the varieties of cloud observed each day throughout the eight years, and these he has grouped under fifteen forms of cloud. The total number of individual records approximates to 100,000. The cumulus cloud yielded the greatest number of daily values (1622), the stratus coming next (1155). The upper clouds, which include the cirrus, cirro-stratus, and cirro-macula, showed a marked prevalence during the summer with minima during the winter. Morning and evening maxima, with a mid-day decline, are common to all these varieties. The intermediate clouds, which include cirro-cumulus, alto-stratus, alto-cumulus, and cumulo-stratus, are also more prevalent in the summer than in the winter. The lower forms, which include strato-cumulus, nimbus, fracto-nimbus, fracto-cumulus, stratus, and fog, attain their maxima in the winter months, their minimum frequency being in the summer. The clouds of diurnal ascending currents, cumulus and cumulo-nimbus, are independent of any seasonal variation in hourly frequency, the maxima at noon and 3 p.m. respectively, taking place at these hours in every month of the year.

Geological Society, May 28.—Dr. Aubrey Strahan, president, in the chair.—P. G. H. **Boswell**: The age of the Suffolk valleys, with notes on the buried channels of drift. The main watershed of Suffolk follows generally the Chalk Escarpment. Suffolk forms a plateau, dissected by a valley-system which is palmate in form. The strata cut through by the valleys, and the mantle of glacial deposits which more or less covers the whole county, are described briefly. Reasons are given for thinking that the Contorted Drift does not extend far south of the Waveney. The valleys, although they may have been etched earlier, are on direct evidence post-Pliocene in age; but, by analogy with the Waveney and the Norfolk rivers, they may be younger than the Contorted Drift. The Upper Boulder Clay covers much of the plateau, and wraps down into the valleys. The Glacial Sands, &c., below it also appear at times to lie on the valley-slopes. Intense glacial disturbances are found to be situated always on "bluffs" or "spurs" of the plateau, which were in existence before the advent of the valley-glaciers to the action of which the disturbances have been attributed. In each of the main valleys occur one or more buried channels of drift; borings made recently allow these to be described in detail, and the deposits filling them to be discussed. These buried channels were probably eroded by sub-glacial water-streams. The evidence indicates that the pre-Glacial or early Glacial contours of Suffolk were in the main much as they are now.—D. E. **Innes**: The internal structure of Upper Silurian rugose corals from the Grindrod collection, Oxford Museum.

Physical Society, May 30.—Prof. A. Schuster, F.R.S., president, in the chair.—Prof. A. W. **Bickerton**: The origin of new stars. The author gave an account of a theory which he has held for many years. He points out that the energy developed by mutual fall of colliding suns is so great that shearing must ensue. Hence the problem of oblique impact of all suns is taken in two divisions—first, the actually colliding parts that are torn away and coalesce, and, secondly, the parts that escape the collision but are profoundly influenced by it. The impact of meteoric swarms, nebulæ, and sidereal systems may similarly be taken in two parts. The coalesced part is called the third body. The properties of this new body are best studied in the third star resulting from grazing suns. The third star is thermodynamically unstable, and selectively sorts its atoms into ensphering shells. It rotates, and has at its formation a special distribution of its elements. It will produce a new star. Its deduced properties correspond with the three criteria of thermodynamic intensity, complex light curve, and the physical peculiarities shown in each series of the spectrograms of novæ.—Dr. W. H. **Eccles**: Electro-thermal phenomena at the contact of two conductors with a theory of a class of radio-telegraph detectors. The paper deduces mathematically the laws connecting the current and the applied E.M.F. in a circuit containing a light contact of two conductors. When an electric current passes across a light contact of two different substances, heat is liberated or absorbed in accordance with the law of Peltier, heat is generated in accordance with the law of Joule, and, in the regions of the conductors where there is a temperature gradient, heat is liberated or absorbed in accordance with the laws of the Thomson effect. These thermal actions are very noticeable in contacts made of badly conducting natural oxides or sulphides on account of the high resistivity and the large thermoelectric effects in these substances. The low thermal conductivities of these substances exalt the electrical consequences by conserving the heat. The bulk of the wireless telegraphy of the world is carried on by such contacts as these, and the present paper, therefore, constitutes a theory of the action of these detectors.—**J. Walker**: The extraordinary ray resulting from the internal reflection of an extraordinary ray at the surface of a uniaxal crystal. By the principle of least time it is shown that the diameter of the extraordinary wave-surface described round the point of incidence, that is, conjugate to the reflecting surface, is coplanar with the incident and reflected extraordinary rays, and is the median of the triangle formed by these rays and a parallel to the reflecting surface. The direction-cosines of the reflected ray are then obtained in terms of those of the incident ray and the said diameter of the wave-surface.—**S. Butterworth**: The evaluation of certain combinations of the ber, bei, and allied functions.

NEW SOUTH WALES.

Linnean Society, March 26.—Mr. W. W. Froggatt, retiring president, in the chair.—*Annual General Meeting*.—Presidential address: "A Century of Australian Civilisation, from a Zoologist's Point of View." The address was devoted to a consideration of the great changes that have been wrought by the advent of the white man with his domestic animals, in the displacement of the aboriginal population and the original fauna, in the course of a hundred years' civilisation.—*Ordinary Monthly Meeting*.—Mr. W. S. Dun, president, in the chair.—A. H. S. **Lucas**: Notes on Australian marine algæ. No. 1.—H. J. **Carter**: Revision of the Australian species of the subfamilies Cyphaleinæ and Cnodaloninæ (family Tenebrionidæ).

April 30.—Mr. W. S. Dun, president, in the chair.—A. B. **Walkom**: Stratigraphical geology of the Permo-Carboniferous system in the Maitland-Branxton district, with some notes on the Permo-Carboniferous palæogeography in New South Wales. The vertical succession of the formations represented in the area under consideration—Lower Marine Series, Greta Coal Measures, and Upper Marine Series—has been worked out in some detail. Vertical sections of the Lower Marine Series were obtain in three localities, showing a thickness of nearly 4800 ft. In his important monograph on the geology of the Hunter River Coal Measures of New South Wales (1907), Prof. David mapped the outcrop of this series and gave numerous detailed sections of the coal seams developed at many points along the outcrop; but, at this time, very little was known about the development between Branxton and Pokolbin. Additional data now available show that in four localities, as elsewhere, the main Greta seam is split, and that the upper split has been struck in ach case; the lower split seems to be entire at Rothbury, but splits again further north.—A. B. **Walkom**: The geology of the Permo-Carboniferous system in the Glendonbrook district, near Singleton. The Glendonbrook district lies from five to fifteen miles E. by N. from Singleton. Permo-Carboniferous rocks are developed there in a small isolated basin. They consist chiefly of sandstones, conglomerates, and shales belonging to the Lower Marine Series, Greta Coal Measures, and Upper Marine Series. The whole basin is only some three miles in diameter, and is surrounded by rocks of Carboniferous age. Further to the west, nearer Singleton, owing to heavy faulting, rocks belonging to the Upper Coal Measures and Upper Marine Series also appear. All these rocks are described more or less in detail, and their relations to one another discussed. A coal seam about 10 ft. thick occurs in the Greta Coal Measures in the basin mentioned above.—A. B. **Walkom**: Notes on some recently discovered occurrences of the pseudomorph, glendonite. Glendonite, a pseudomorph after glauberite, has been recorded from seven horizons in New South Wales and Tasmania, all, however, in the Upper Marine Series. In this paper, the occurrence of the mineral in rocks of the Lower Marine Series is recorded for the first time, with details of a comparison of crystals from both series.

MENDELISM AND STOCK-BREEDING.

The Principles of Stock-Breeding. By Prof. James Wilson. Pp. vii+146. (London: Vinton and Co., Ltd., 1912.) Price 5*s.* net.

IN this volume Prof. Wilson claims "to deal with the problem of stock-breeding in the light of the Mendelian discovery." The book is addressed to breeders; for the sake of clearness it is shorn of many words common to the writings of the modern exponent of this branch of biological science, and it is clearly designed to stimulate the practical breeder to base the conduct of his business on Mendelian principles.

A book from the pen of Prof. Wilson is sure to command attention, and in this instance he brings abundant enthusiasm to help him in his task, and is full of hope for the future. We are not convinced, however, of the wisdom of the undertaking; neither scientific enthusiasm nor hope appeals forcibly to the practical man; he requires facts on which to base his work. The author himself demonstrates that very few facts applicable to the breeding of domesticated animals are yet to hand, and it seems to us that the time has not yet come when breeders as a whole can reap substantial benefit from the theory of Mendel.

The enthusiastic Mendelian may, perhaps, consider that he has effectively disposed of the opinion of many biologists that Mendelism has not yet been proved to be the main road, has merely been shown to be a side track alongside that road which leads to the solution of the mysteries of heredity and variation. But the practical breeder is aware of this scientific scepticism; he is even more difficult to convince than is the pure theorist, and we doubt if the examples of applied Mendelism which Prof. Wilson gives will serve to stimulate his belief in the practical value of that theory.

There are three main reasons why the application of Mendelism to stock-breeding is rendered difficult: time, cost, and trustworthy data. To-day we have a very meagre allowance of data, and the little we have is rarely trustworthy. In order to gain such data many years must pass, and many wealthy breeders must content themselves with the collection of facts which shall be recorded in great detail. This knowledge must be gained by exceedingly careful observation of the results obtained by breeding on a definite plan and on a large scale, and the records must be designed to embrace the conduct of a number of characters which may in themselves be exceedingly difficult to observe; and when the facts are known they must be applied.

The author gives an instance of such application. "Assume," he says lightly, "that sixty-four heifer calves are got, because this is the smallest number that will split into all the possible cases"; of these, only one can have the characters desired, and these characters can only be fully determined after the animal has grown up. But in order to get such a herd of heifer calves a much larger number must be bred; and suppose this heifer dies before she reaches maturity, or suppose she proves to be sterile! Is this a problem which is likely to attract any but a very rich and a very large breeder? One may grow wheat on an infinitely larger scale at a nominal cost, but the breeding of stock in sufficient numbers is a very different matter, as Raymond Pearl's experiments clearly show. It is true the author adds that "In practice such a number need not necessarily be bred, because from a smaller number the desired stock could eventually be raised." But he does not define what he means by "eventually," and it seems that the element of chance must have a large share in the calculation.

In the early part of the book, Prof. Wilson gives a lucid account of the old theories of stock-breeding. We scarcely think, however, that he does full justice to some of the experimental work done in those days, and cannot agree with some of the deductions he draws from his study of the subject; as, for instance, in the degree of attention paid by the old breeders to the part played by the sire, and, if we understand him aright, in the relation of artificial selection to evolution.

The chapter on the Mendelian theory and animals is another instance of the author's power of exposition. In spite of great difficulties, he has surely made this part of his subject clear to his readers. In doing so he has emphasised the fact that when you can apply Mendel's theory to observed phenomena you may thus obtain valuable knowledge of the forces which act in order to produce those phenomena, and he shows that to this extent you will gain a clearer view of their significance.

But if this is all the help Mendelism will give to breeders there will undoubtedly be much disappointment shown by those who have been led to expect that it will serve as a short cut to the production of improved breeds, and for the modification of special characters; that it will take the place of those laborious methods of selection hitherto practised by the few successful breeders—who are born with an eye for the detection of minute variations, and can afford to fail many times—and thus put success within the reach of all.

In our opinion, much more research and many practical experiments on a large scale are needed before a book on the practical advantages to be derived from Mendelian methods can, with advantage, be presented to breeders, since premature assertion of the utility of a theory tends to alienate the practical man, and to destroy his confidence in the value of science.

THE INDEXING OF CHEMICAL LITERATURE.

General Index to the Chemical News. Vols. i to c. Pp. 712. (London: *Chemical News* Office, 1913.) Price 2*l.*

IN compiling an index of chemical literature on anything like a large scale numberless difficult problems are encountered at the outset. The question as to whether authors and subjects should be divided or not is usually answered in the affirmative and with good reason. The inquirer generally knows whether he wishes to refer to an author's name or to some subject, and it is undoubtedly a help to be able to turn with certainty to one section or the other.

The mere alphabetical arrangement of authors' names would appear to be simple, but the greatest difficulty is often experienced if any effort is to be made to secure that individual authors are to be properly identified with their work.

An index of subjects offers even more problems to be considered. Over an extended period of years, changes of nomenclature are bound to occur, and the same compound is often described under two or even three synonyms. Is the indexer to record the names as they stand, or is he to use the modern name only, and index all older varieties or synonyms under that? In view of the fact that authors rarely know even the rudiments of nomenclature, and seldom consider whether it is correct to write, *e.g.*, caustic soda, sodium hydrate, or sodium hydroxide, it would appear that the only possible thing to do in such a case is to decide on "sodium hydroxide," and index all references to "caustic soda" or "sodium hydrate" under it. With organic compounds the case is much more difficult, but the point has, perhaps, been sufficiently illustrated.

The index under review is one that will be necessary to every reader of the *Chemical News*, and, indeed, will be useful to all chemists, giving, as it does, references to so many subjects, such as university intelligence, &c., which are found in perhaps no other chemical journal.

The advisability of putting authors and subjects together is a matter of opinion, but the searcher after names will turn over with some impatience the 35 pages which separate "Bonz" and "Booth."

The identification of certain authors—for example, "Mr. Brown" and "Dr. Schmidt"—must be difficult, as there are twenty-nine "Browns" and twenty "Schmidts." This, of course, illustrates a common failing of authors of not putting their full names to their papers.

The German "ü" is taken as "u" throughout. This, we believe, is the custom of the British Museum, but to mix up "Mullers" and "Müllers" is, in our opinion, obviously incorrect.

As regards the subjects the list of books reviewed, which occupies the thirty-five pages just mentioned, is very valuable, and so are the collected references to many other matters of general chemical interest, but it is really regrettable that some effort has not been made to avoid duplicate headings; this is the chief fault we have to find with the book. Under "acids" we have "chlorhydric" and "hydrochloric," "cyanhydric" and "hydrocyanic," "naphtholsulphonic" and "naptholic sulpho," "bioxybenzoic," "dioxybenzoic," and "dihydroxybenzoic," with no cross-references from one to the other. Entries are also to be found, again without cross-references, under acid, carbolic, and phenol, aldehyde, anisic, and anis-aldehyde, alizarin, nitro-, and nitralizarin, carbamide and urea, benzalacetophenone and benzylidene acetophenone, benzene, benzine, and benzol, carbon bisulphide, disulphide, and sulphide, and many others.

Cross-references there are indeed, but many are unnecessary; particularly "Amyl-diethacetate, cinn-. See Cinnamyldiethacetate."

In a work of this kind misprints are almost inevitable, but a little more care in the proof-reading might have avoided such mistakes as "alikali earth metals," "alsohols," "eperiments," "methylsalysilic," &c.

J. C. C.

PETROLOGY AND BUILDING STONES.

(1) *The Petrology of the Sedimentary Rocks.* By Dr. F. H. Hatch and R. H. Rastall. With an Appendix on the Systematic Examination of Loose Detrital Sediments by T. Crook. Pp. xiii + 425. (London: George Allen and Co., Ltd., 1913.) Price 7*s.* 6*d.* net.

(2) *Building Stones and Clay-Products: A Handbook for Architects.* By Prof. Heinrich Ries. Pp. xv + 415 + lix plates. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1912.) Price 12*s.* 6*d.* net.

(1) SINCE the days of Sorby much useful work has been done on the less-altered sedimentary rocks—by Hill, Jukes-Browne, and Hume,

for example, on the Cretaceous; Wethered on the Carboniferous; Hutchings on slates and other rocks, Millard Reade and Thomas on the Trias; Cayeaux on many formations, to mention a few only of the workers. Yet, on the whole, the petrological problems of sedimentary rocks have not attracted the attention of geologists with anything like the same force as those presented by the igneous rocks.

The reasons for this partial neglect are not far to seek. Most active, perhaps, has been the influence of the "path of least resistance." It has been much easier to make a brave show for a given expenditure of time and care on the petrology of igneous than on that of sedimentary rocks. Though many sediments, especially when much metamorphosed, may be studied in thin sections, the examination of less compact sediments requires the handling of a considerable bulk of material by somewhat tedious processes, as well as the application of a sound knowledge of the methods of mineral identification. Thus we find the fresher sediments passed over in favour of their most highly altered representatives, which have received a very large share of attention.

It is therefore a matter for congratulation that we have now, for the first time, a book (1) devoted to the petrology of the sedimentary rocks, and, further, that it is a companion to Hatch's "Textbook of Petrology," which has a well-earned reputation for lucidity of treatment.

The book is divided into two parts, the first dealing with the mode of formation and materials of raw sediments (employing this term in its widest sense, to include all but rocks of igneous origin), the second with their metamorphosed equivalents.

In the former the subject-matter is treated on familiar lines under the heads deposition in general, fragmental deposits, chemical deposits, organic deposits. The clastic sediments are graded according to the dimensions of their constituents, *e.g.* boulder and scree deposits, above 100 mm. diameter; gravel, between 2·5 and 100 mm.; sand, between 0·05 and 2·5 mm.; mud and dust, below 0·05 mm.

It seems a little unreasonable to describe the foraminiferal, pteropod, diatom, and radiolarian oozes with the fragmental deposits, while shell and coral formations appear in the organic deposits.

Here and there, as is usual in text-books, difficult ground is lightly tripped over; the explanation of the formation of "iron-pan" is not all that could be desired.

From fresh sediments the authors pass on to what they call the metamorphic derivatives, and follow Van Hise and many modern writers in the assumption that metamorphism must be taken to connote any change in the constitution of any kind of rock, through whatever agency. This is logical, no doubt, but "horse sense" is sometimes better than any amount of logic; by being so precise about the *literal* meaning of the word, its old-fashioned and quite useful significance has been destroyed. By their acceptance of this extended usage of "metamorphism," the authors stultify in a measure their own classification. Why should they trouble to separate the "sediments" from their "metamorphic derivatives" when they must be aware that the former are suffering, from the earliest moments of their formation, those very changes of constitution that produce the so-called metamorphism. There can be no unmetamorphosed rocks if metamorphism is what the authors say it is. However, coming to details, we find this subject treated under the heads contact metamorphism, regional metamorphism, cementation, metasomatism, and weathering. The "zone of cementation" is said to be permanently saturated with water-solutions, but we would point out that cementation may take place in the "zone of weathering," and, indeed, numerous examples are given in the book.

This volume contains little that cannot be obtained by the perusal of the larger general textbooks; none the less, it will be a convenience to students to have the information in this handy form. In a new edition, which we hope will soon be required, we should like to see more illustrations of typical rocks as good as those in the present work; photomicrographs of metasomatic and other structures in limestones and series to illustrate progressive alteration in contact and regional metamorphism are specially to be desired. The value of this volume is greatly enhanced by the admirable appendix on the systematic examination of loose detrital sediments by Mr. Crook.

(2) Prof. Ries is as well known in this country as in the United States for his numerous and valuable works on clays. There is little that is new in his book on building stones and clay-products, but it is well produced, and compiled by an experienced hand; it will doubtless be appreciated by the United States architects, for whom it has been written. The viewpoint throughout is entirely American, as the following extract from the glossary will illustrate: "*Forest-marble*, an argillaceous limestone in which the colouring-matter is so disposed as to resemble forests."

OUR BOOKSHELF.

The Log of H.M.S. Encounter. Australian Station, 1910–1912. By Herbert Wilson. (London: The Westminster Press, 1912.)

IT may be more often than is generally known that a petty officer in his Majesty's Navy keeps a private log; it may be seldom that such a log sees daylight in the form of print; but it is approaching a unique occurrence when such a log is published in book form, and records in considerable detail a complete story of an eclipse expedition.

The particular log to which reference is here made is that of H.M.S. *Encounter*, covering the period 1910–12. In this period, which was her last commission on the Australian station, the total solar eclipse of April, 1911, occurred, and for that event she was placed on special service to assist the British and Australian expeditions; needless to say she did signal service on that occasion.

It may be remembered that Dr. W. J. S. Lockyer and the Rev. Father Cortie, S.J., were in charge of the British parties, while Mr. Baracchi was chief of the Australian contingent. All the parties went to Vavau, one of the islands of the Tonga group, but the British expeditions from England were conveyed from Sydney to their station by H.M.S. *Encounter*.

The author of this book is not only an excellent observer, but, further, he can commit his observations clearly to writing. The account of his experiences at the eclipse station is only one of many incidents which he records in an interesting manner in these pages. To take an example in other fields, he writes:—"We ran into a great storm area—great atmospheric disturbances. There were intermittent downpours of rain, accompanied by great rolls of thunder and most vivid lightning—in fact, a magnificent, typical tropical storm." Being a practical man, he further narrates: "We always take advantage of times like this to wash our dirty clothes in nice soft rain water." Halley's comet was first recorded by him in his entry of March 21 (1910), and he subsequently makes numerous remarks as to its appearance on different occasions.

This log is accompanied by numerous reproductions from photographs taken by his shipmates, and the volume forms not only a valuable memento to those who served through the commission with him, but an interesting survey of a petty officer's life on and off duty.

The Statesman's Year-Book: Statistical and Historical Annual of the States of the World for the Year 1913. Edited by Dr. J. Scott Keltie; assisted by Dr. M. Epstein. Pp. xcvi + 1452 + 10 plates. (London: Macmillan and Co., Ltd., 1913.) Price 10*s*. 6*d*. net.

"THE Statesman's Year-Book" with the present issue reaches its fiftieth year of publication, and by way of signalising this event certain new features are added which not only are appropriate to it, but also enhance the utility of the work. A number of statistics for the British Empire and for the other principal countries are furnished to afford comparison between the conditions of years about 1860 and of the present day. There is a semi-tabular retrospect of recent history. Certain comparisons covering the same period also appear under the individual headings of some of the countries. Map-work also plays an important part; there are maps, side by side, of each continent for the years 1863 and 1913; on some of these (*e.g.* Europe and America) the graphic representation of railway extension is perhaps the most noteworthy feature; from the maps of Africa we have evidence at a glance of the wonderful extension of exploration in the half-century. The year-book always deals exhaustively with the subject of defence, and we now have diagrams illustrating the "growth of displacement, horse-power, and speed of capital battleship types," and the "varying ratio between weight of heaviest gun, its penetrative power, and the protection afforded to ships," during the last fifty years.

It is scarcely necessary to say that the accustomed features of the book are maintained at their usual standard: the Franco-Spanish treaty is dealt with by means of both map and text, and in the same way the recent important extensions of Ontario, Quebec, and Manitoba are indicated. The introductory matter further includes a variety of valuable detail such as the substance of the treaty of Ouchy, a table of cases brought before the Hague tribunal, and material dealing with the naval and land defences of the British Empire. It is clear that in making up this book the problem of space is very carefully watched, and even the important additions mentioned here have not caused the volume to become unwieldy.

Cambridge County Geographics: Lincolnshire. By E. Mansel Sympson. Pp. viii + 193. (Cambridge University Press, 1913.) Price 1*s*. 6*d*.

DR. SYMPSON'S account of Lincolnshire is unusually interesting, and will appeal in many ways to scientific readers. The geology, natural history, climate, and peoples are all dealt with as fully as the limited space allowed. Honourable mention is made, among the distinguished men produced by the county, of Sir Isaac Newton, Sir Joseph Banks, and Sir John Franklin. Altogether the volume well maintains the high standard of the series.

Atlas Notes. By J. C. Chute. Pp. 82. (London: Humphrey Milford, Oxford University Press, n.d.) Price 1*s*.

"THESE notes are intended as a guide to a revision of the subject, for boys who have dabbled in its various departments and who now wish to make good their knowledge of the chief facts contained in a good political and physical atlas," says the author in his preface. If boys are set to study geography in school they should not be allowed "to dabble," but should be encouraged to work methodically and with all the thoroughness the time available permits. In that case the boys would themselves make the notes required for any future revision, which is better than having them already made.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Pianoforte Touch.

I HAVE read Prof. Bryan's piano-player article in NATURE, and wish to congratulate him on seeing so early the wonderful capacity of the pneumatic player. I entirely agree with him. Long ago I have done work like his, though very crudely. Thus I always played with the *feet*, sitting on a pivoted swinging chair, and I constructed an arrangement in which, by means of two strings, I had some control of the touch. It was a partially successful attempt at most. I also fixed up a "dead stop" string operating a brake on the engine, by which pauses could be made at the proper places. I am sure Prof. Bryan's way is immensely superior.

It is very singular that some of the compound touch problems are of a transcendental nature. They cannot be solved by common, rigorous mathematics, but only by my new mathematics. At Prof. Perry's suggestion I made this a feature of one of my books. It was full of compound touch problems insoluble (so I was told) by rigorous mathematics, though the rigorous mathematicians cannot deny the results. It is because their ideas concerning functions are not broad enough. I have also been thinking about the theory, and think it will be more difficult than appears in Prof. Bryan's paper, because his touch variations are secondary to those of the player itself, due to the way the holes are cut and their overlap in the music-rolls. The results are sometimes not good. Another thing, I have considered the piano itself to be a rather imperfect instrument. We get used to its faults; is that any reason they should be made virtues?

I consider the piano-player does for music what the printing press did for books. But while, after reading a book once, you generally never wish to read it again, it is impossible to appreciate elaborate technical compositions without playing them over and over again. So there is something to be said for the playing by children and men even in the most mechanical and unintelligent way.

OLIVER HEAVISIDE.

A Peripheral Effect with X-Radiation.

WHILST repeating the now well-known experiments of Barkla, Laue, and others we have accidentally met with some remarkable effects upon which we should like to invite judgment. By inadvertence the edge of a piece of mica intercepted a direct beam of X-rays, and the recording photographic plate shows pronounced black and white bands along the X-ray shadow of the edge of mica. Further experiments with mica, glass, and metals also gave the effect, the edge of the shadow being bounded by a well-defined black band in the dark portion of the field with a light band in the lighter half.

An extended series of experiments was then made using lead foil cut into thin strips from one to five layers in thickness, mounted on glass, and placed in the direct beam of X-rays; no screen of any kind being employed, as was the case in the preliminary experiments. The distance of the photographic plate, placed behind and parallel to the mounted pieces of lead, was varied from 3 mm. to 5 cm., and that of the anti-kathode to the obstacle from 26 to 450 cm. Under these varied conditions of distance dark and light bands along the edges were obtained on the negative. The X-ray bulb had a fine focus, and exceedingly sharp X-ray shadows were obtained, especially at distances between 200 and 450 cm., a fact to which the observance of these bands is greatly due.

The width of the bands in these lead strip experiments is roughly 0·1 to 0·2 mm., but in the preliminary mica and glass experiments they were much broader, being about 0·5 mm. in width. These bands are distinctly visible under a low-power microscope, whilst under favourable conditions of illumination they are plain without artificial aid, and the same remarks apply to their prints. They are seen also when thrown upon a screen, and these facts seem to preclude the suggestion of their being contrast or optical effects, as was supposed by Haga and Wind in their well-known attempts to demonstrate diffraction. That they are not diffraction effects comparable with those of light is shown by their not varying appreciably in width as the photographic plate is varied behind the mounted strips of lead foil. Nor should these bands be confounded with those which appear upon the portion of the beam reflected from crystalline surfaces (which we also obtained), and have been described by de Broglie and Lindemann; although we are disposed to admit a possible physical connection.

Bands of similar width and appearance have been obtained with other metals, such as iron, zinc, copper, and aluminium, and in one case where an attempt was made to obtain direct refraction the white band appears between the transmitted and the direct beam. The apparent constancy of width and appearance under widely different conditions is a baffling point, arguing *prima facie* an optical or photographic effect. Yet against this is to be set the fact that so far mica and glass have given bands several times as wide as those from metals.

Attempts to vary the bands from metals by passing electric currents through them, and by high temperatures, have given so far negative results, though it may be desirable to mention the fact that in the latter case images of cold wires appear distinctly brighter in the negative. In one experiment, in addition to bands, a remarkable halo appears at a distance of 1·9 cm. from the image of the circular orifice in a metal screen. In another case a black band of approximately equal intensity to the image given by the direct beam appears surrounded by a white area, and in the same position, *i.e.* between the direct and reflected images. The fact that this band is black in the negative shows that the effect cannot be due to absence, in this position, of the generally scattered radiation which may have fogged the plate.

An explanation of grounds of halation, or reflection from the back of the plate, is, we need scarcely say, inconsistent with the accepted theory of X-radiation. The solution to which we may be reduced is that the bands are due to some edge or peripheral condition of the substance depending upon abrupt discontinuity of the media (mica, air), since a mere scratch or break in the surface does not produce the bands. Increase of density along the edges due to surface tension would appear to be of too small an order to account for the phenomenon. A subjective appearance of bands may invalidate some of the cases with metals, but in others (especially that with a halo suggestive of an X-ray spectrum) actuality is beyond doubt.

Radium and the Evolution of the Earth's Crust.

It is now well known that if the proportion of radium in the interior of the earth is the same as that in the surface rocks, the earth ought to be growing hotter, and the temperature gradient of the crust ought to be much higher than we find it. A simple calculation shows that a distribution of radium averaging 2×10^{-14} grams in each gram of rock throughout the earth would suffice to preserve thermal equilibrium. The amounts of radium actually found in the surface rocks are approximately as follows:—

Acid	...	...	3×10^{-12} grams per gram
Intermediate	...	2	" " "
Basic	...	...	1 " " "
Ultrabasic	...	0·5	" " "

In addition to the elements of the uranium family, those of the thorium family must also be considered, for they afford an equally important supply of heat.

Prof. Strutt was the first to indicate the way in which the obvious dilemma might be escaped. In order that the earth should be nearly in thermal equilibrium (*i.e.* not growing hotter, but cooling at the very slow rate allowed by the radio-active elements as they decrease in quantity in accordance with their progressive disintegration), it is necessary to assume that the earth's store of radium is concentrated near the surface. As the following arguments indicate, this conception is less arbitrary than would appear at first sight. The radio-active elements are found most abundantly in the acid rocks, their more basic associates being less embarrassingly rich. The more acid rocks are characteristic of only the outermost zones of the crust, and there are many reasons for believing that with depth the more basic rocks largely predominate. Seismic and other terrestrial phenomena have now provided us with data from which the condition of the earth's interior may be deduced with some confidence. First, there is the crustal zone, rapidly becoming less silicic with depth, having a mean density of 2·8, and an approximate thickness of thirty miles. Within a fairly sharp surface of discontinuity comes what may be called the stony zone. The density is 3·4, and judging from the close analogy presented by meteorites, the material would be of ultra-basic composition. This zone dies out at a depth variously estimated at from 600 to 900 miles. The internal core of the earth is probably largely composed of iron, its density being about 8.

In a number of meteorites, the radium content has been determined by Prof. Strutt and the present writer, and if it may be assumed that they afford a clue to the problem, the heavy metallic core should be completely destitute of radium, and the stony zone should contain only a small proportion, very much less than that of the ultra-basic rocks of the crust.

On the planetesimal hypothesis, the two internal zones find a ready explanation. It is supposed that the earth began as a nebulous knot, and that it has grown up to its present mass by the capture of associated planetesimals. It is very unlikely that as a whole it was ever in a molten condition. Internal heat probably arose largely from the condensation of the mass during the period of its growth. The temperature would slowly rise until the fusion point of certain of the constituents was reached, and the liquid tongues and pockets thus formed would tend to move away from the centre, the lighter and less viscous stony material being squeezed outwards relatively to a network of the heavier and more rigid metallic materials. Once vulcanism had been initiated in this way, the process would continue until a highly metallic nucleus had collected. Surrounding it there would gradually form a thick zone of silicate rocks, the differentiation from the original heterogeneous mixture of stony and metallic constituents being due to the selective fusion of the former. There seems to be little doubt that the radio-active elements would be concentrated in the stony zone. With the establishment of ocean and atmosphere, a new factor in surface differentiation arose, and sedimentary rocks were deposited for the first time. In some way which, as yet, we understand but vaguely, both igneous and denudational differentiation then combined in developing the earth's crust. We now find in the latter all those rocks which hold a maximum content both of silica and of the radio-active elements. The relative concentration of these constituents having taken place at the expense of the zone below, the conjectural paucity of the latter in radium finds a suggestive explanation.

Before the advent of radium, geologists had not recognised the difficulties presented by the peculiar chemical constitution of the earth's crust. Radium did not create this difficulty, but has merely directed attention towards it. Any explanation of the high percentage of silica in the surface rocks will explain equally well their richness in radium.

It can scarcely be said now that radium has given us "a blank cheque on the bank of time." Not only did the discovery of radium destroy the validity of the older thermal arguments, but also it led directly to the elaboration of a new and more refined method. Every radio-active mineral may be regarded as a self-contained hourglass, the radio-active end-products, helium and lead, slowly accumulating at the expense of their ultimate parent, uranium. In the few cases which up to the present have been investigated, periods of enormous duration have been revealed, and the geologist who ten years ago was embarrassed by the shortness of the time allowed to him for the evolution of the earth's crust is now still more embarrassed by the superabundance with which he is confronted. The time scale up to date, as determined by the lead ratio, is as follows:—

Carboniferous	... ...	340 million years
Devonian	... ...	370 "
Ordovician	... ...	430 "
Algonkian	... ...	1000 "
Archæan	... ...	{ 1300 " / 1600 " }

We must not moan over the apparent difficulties with which the geologist has been faced since the advent of radium. Rather should they be welcomed in that they open the way for further advances. If at present some of our ideas are mutually incompatible, the discrepancies do not demand a wholesale rejection of the facts, but simply a re-interpretation of the fundamental hypotheses on which so many of our doctrines seem to hang.

ARTHUR HOLMES.

Imperial College, South Kensington, S.W.

An Amphipod Invasion.

Many specimens of a small amphipod crustacean, *Euthemisto compressa*, Goës, have been forwarded to me by Mr. T. H. Nelson, of Redcar. On May 23 and 24 these were washed ashore in incredible numbers on the coast of Yorkshire, where they lay from Saltburn to Teesmouth—a distance of ten miles—in drifts several inches deep. The pools were alive with the crustaceans, and to the east of Redcar a fisherman was seen raking them into heaps, and wheeling away barrow-loads to put on his garden as manure. In the sea hundreds at a time could be scooped up in one's hands.

Euthemisto compressa is an uncommon British species recorded sparingly from a few localities, but off Redcar it occasionally appears in extraordinary shoals in springtime. Such visitations have occurred previously in the second week of February, 1892, April, 1907, and April 2, 1908. In general the creatures come ashore after a N. or N.E. wind, but on the present occasion a gentle westerly wind had prevailed for a few days. I should be glad to receive information from naturalists or fishermen who may have observed these minute "shrimps" about the same date, on other parts of the coast or in the open sea, so that knowledge may be gained of the full extent and of the provenance of the shoal.

JAMES RITCHIE.

Royal Scottish Museum, Edinburgh.

New Zealand Vegetation.

IN NATURE for April 10 (p. 147), under the title "New Zealand Vegetation," I notice the following sentence:—"The northern rivers and estuaries display a mangrove vegetation—a unique and unexpected occurrence outside of the tropics."

The writer of the article is evidently not aware that mangrove formations are found at intervals all round the coasts of Australia. The species which forms them is *Avicennia officinalis,* L., which occurs in all the Australian States, but not in Tasmania. It reaches its southerly limit in Western Australia in the neighbourhood of Bunbury ($33\frac{1}{2}°$ S.), where the trees reach a height of about 12 ft. On the east coast it is most familiar on the shores of the Parramatta River in Sydney Harbour, which is a little further south than Bunbury, but it occurs so far south as Corner Inlet, on the east side of Wilson's Promontory (39° S.). This southernmost point of the Australian continent is one degree further south than any point on the north coast of the North Island of New Zealand.

W. B. ALEXANDER.

The Western Australian Museum and Art Gallery, Perth, Western Australia, May 10.

I FEAR that in attempting to compress into a few paragraphs a general sketch of the plant communities of New Zealand I inadvertently conveyed the erroneous impression concerning the distribution of the mangrove vegetation in Australasia which Mr. W. B. Alexander has corrected in his interesting note. The sentence which he quotes is perhaps less misleading if read in connection with that immediately preceding it, and containing the statement upon which I wished to lay chief stress in enumerating the main types of New Zealand vegetation—"to find an equal variety a continent extending to the tropics would have to be visited." I was quite aware of the well-known fact that the eastern or Indo-Malayan mangrove flora, well developed on the northern littoral of Australia, extends in an impoverished form along the eastern and western coasts southwards, though it is interesting to note that it actually reaches the most southerly point of the Australian continent. It may be added that Prof. Bews (Annals Natal Museum, ii., 1912, p. 297) has recently described what appears to be the most southerly extension of the mangrove vegetation on the opposite side of the Indian Ocean, in Durban Bay; here, as in the subtropical and warm temperate parts of Australasia, the rich eastern mangrove flora is represented by an interesting though poorly developed outlier consisting of *Avicennia officinalis, Bruguiera gymnorhiza,* and *Rhizophora mucronata.*

F. C.

Anthelia.

IN connection with the correspondence in NATURE on the bright light on dew round the shadow of one's head, the accompanying photograph, which shows the phenomenon on dew on seakale, may be of interest. It was taken here on October 7, 1899, at 8.35 a.m. It shows the shadow of the camera, so that in spite of the irregularity of the leaves the radius of the

bright light is easily measured as nearly 8°. The scale of the photograph is 8·5° to the inch.

T. W. BACKHOUSE.

West Hendon House, Sunderland, June 10.

Antennæ for Wireless Telegraphy.

I WAS interested to see Mr. Campbell Swinton's letter on wireless receiving with his bedstead as an aërial. Many of the more powerful stations are, however, much easier to receive than is generally supposed; for instance, I have been able to read the Eiffel Tower nine o'clock news message with only 12 ft. of No. 18 S.W.G. copper wire stretched across my attic (second floor, about 25 ft. from the ground) using good earth to waterpipes, with usual tuning coils and condensers, bornite-zincite detector, and very sensitive 4000 ohm telephone (H. W. Sullivan), without any relay. Even when the aërial was reduced to 6 ft. of wire the signals were just audible, but very faint.

ARNOLD G. HANSARD.

Limpsfield, Surrey, June 10.

SOME months ago, in endeavouring to reduce the antenna to the smallest possible dimensions, such as by placing a series of wires just over the instruments, I found that by using a bedstead (without wire mattress) signals of "strength 8"—*i.e.* moderately loud—could easily be obtained from Paris *without the aid of a Brown relay*—a costly instrument, reputed to increase the strength of signals five times. The apparatus used was simply the orthodox loose coupling with crystal detector. The bed used is on the second floor of my house, about 20 ft. from the ground, and the gas-pipe below the same floor served as an earth connection.

Under the same conditions Norddeich is usually readable, and sometimes Poldhu and Nauen. That nearer stations are also heard is obvious.

I should be pleased to give a demonstration of reception by means of this same bedstead as the antenna to anyone interested.

Benjamin S. T. Wallace.

Sub-Red Crag Flint Implements and the Ipswich Skeleton.

I would like Mr. Sutcliffe to read p. 199 of vol. i., part ii., Proceedings East Anglian Prehistoric Society, which contains the original description of the discovery of the Ipswich man. I think it would have been better if he had done this before publicly accusing me of inconsistency in regard to this matter.

J. Reid Moir.

THE OXYGEN CONTENT OF THE ATMOSPHERE.[1]

THIS memoir, published under the auspices of the Carnegie Institution of Washington, is of a type with which we are becoming increasingly familiar—a publication, in fact, which, it may be argued, the institution was created largely to undertake. None of the regularly constituted scientific societies would probably charge themselves with the issue of such a work, and it is very unlikely that it would see the light if left to private enterprise. Nevertheless, it is an eminently useful work, and will be welcomed by chemists, meteorologists, and physiologists alike.

The work is divided into two parts. Part i. is wholly concerned with an historical account of the development of the methods for determining oxygen, in which practically everything contained in the literature has been put together and collated, from the days of Scheele and Priestley to those of Regnault and Bunsen, von Jolly and Morley, down to the methods of our own time depending upon purely absorptiometric processes. Naturally there is nothing very original in this section, and it is well-trodden ground to all who are familiar with the development of eudiometry. It is, however, an interesting and useful compilation, and will be of service to those who are concerned with accurate gasometric analysis, especially in relation to the atmosphere, or who desire to know all there is to know relating to its history.

The second and more immediately important part deals with the experimental work of the nutrition laboratory of the Carnegie Institution, Washington, of which Prof. Benedict is the director.

For some time past the nutrition laboratory has been engaged, among other things, in an elaborate inquiry into the nature of respiratory exchange in relation to metabolic processes, and the necessary instrumental equipment has now been brought to a very high degree of precision. After a careful investigation into the merits of the various types of modern absorptiometric apparatus, it was decided that the arrangement devised by Dr. Klas Sondén, of Stockholm, a development of the apparatus originally contrived some years ago by Prof. Pettersson, more fully fulfilled the essential conditions of expedition, convenience and accuracy than any other existing form; and part ii. is practically made up of a description of the Sondén air-analysis apparatus, illustrated by photographs and woodcuts, together with an account of the plan and methods of research to be undertaken by it, with the results which have been obtained up to the date of publication of the report.

The principle of the apparatus is essentially that of the original Pettersson instrument, in which the absorption and determination of the carbon dioxide and oxygen are made, as in the Hempel, Orsat, and Haldane arrangments, by means of caustic potash and alkaline pyrogallate, but with the use of water-jackets and compensating pipettes so as to ensure much greater accuracy of reading.

The plan of the research involved (1) the estimation of the comparative oxygen-content of uncontaminated outdoor air under all conditions as to wind direction and strength, temperature, cloud formation, barometer and weather, including rain, snow, fog and mist; (2) a study of the influence of the temperature of the reagent upon its absorptive power; (3) an examination of the air over the North Atlantic Ocean; (4) on the summit of Pike's Peak; (5) in the crowded streets of Boston and in the subways of New York and Boston.

Such a programme necessitated a very large amount of experimental work and the analysis of many hundred samples of air. In addition, a large volume of work was needed in control and verification, and especially in tracking down and eliminating sources of possible error. Eventually a routine method was established, and from a long series of determinations it would appear that, as regards oxygen content of outdoor air, no material fluctuation could be detected over a period extending from April, 1911, to January, 1912. This constancy was maintained in spite of all possible alteration in weather conditions, barometric or thermometric changes, or changes in humidity, wind direction, and strength; furthermore, the experiments were made before, during, and after the vegetative season. The average result of 212 analyses showed 0·031 per cent. of carbon dioxide and 20·952 per cent (corrected) of oxygen. Hence Dr. Benedict concludes "that air is a physical mixture with the definiteness of composition of a chemical compound." We have, in fact, got back to the position maintained by Cavendish in 1783 and by de Marli in 1787, that is, of the uniform constancy of the composition of normal atmospheric air, so far as regards its oxygen content.

Prof. Benedict further concludes that—

> While the combustion of fuel and the vital processes of men and animals result in a local increase in carbon dioxide and decrease in oxygen on the one hand, and vegetable growth results in a decrease in carbon dioxide and increase in oxygen on the other, the extraordinary rapidity with which the local variations in the composition of the air are equalised is accentuated by the observations on street air, which show but the slightest trace of an oxygen deficit.

[1] "The Composition of the Atmosphere, with Special Reference to its Oxygen Content." By F. G. Benedict. Pp. iii+115. (Washington, D.C.: Carnegie Institution of Washington, 1912.)

The interdependence between the amounts of carbon dioxide and oxygen is so constant that carbon dioxide estimations made in the Sondén apparatus may be taken as an accurate indication of oxygen content. For every 0·01 per cent. increase in atmospheric carbon dioxide, a corresponding decrease in the percentage amount of oxygen may be safely assumed. T. E. T.

THE POTSDAM METEOROLOGICAL AND MAGNETIC OBSERVATORIES.[1]

THE volume referred to below gives a lucid description of the observatories at Potsdam, compiled by Profs. Süring and Schmidt, who are in charge respectively of the meteorological and magnetic departments. A preface by Prof. Hellmann, the director of the Royal Prussian Meteorological Institute, to which the observatories belong, states that the book is primarily intended for the benefit of those studying at or visiting the observatories, the number of visitors being now large. The text describes the buildings and instruments, while reference is made in footnotes to many researches associated with the place. Thirty-one figures supplement the descriptions of buildings and instruments in the text, and a plate gives a ground-plan of the whole site.

The construction of the magnetic observatory began in 1888, and that of the meteorological observatory in 1890, so that the buildings are all modern. The equipment is also modern and exceedingly complete. The site on the Telegraphenberg, a wooded hill on the outskirts of Potsdam, might be criticised by some meteorologists, but it possesses much natural beauty, and the proximity of the astrophysical and geodetic observatories—also situated on the Telegraphenberg—admits of the ready exchange of ideas amongst a number of men of science, each an expert in his own subject. The figure reproduced shows the enclosure devoted to meteorological instruments, especially those recording air and earth temperatures and rainfall. The small building in the corner is devoted to atmospheric electricity. In the background is the main meteorological building, a very large and handsome structure. Its basement contains *inter alia* a physical and chemical laboratory, a photographic dark-room, a workshop, electrical generating apparatus and storage batteries.

Observation enclosure of the meteorological and magnetic observatories at Potsdam.

On the ground-floor are various rooms for meteorological work, including a large room containing the barographs and other recording instruments. Most of the remaining space under the roof serves to provide accommodation for the resident staff and the director of the Meteorological Institute, but it includes a library and a conference chamber. The roof is flat and surmounted by a low and a high tower, the former devoted to optical and cloud-measuring apparatus. The large tower rises to a height of 32 metres above ground-level. A staging on the top of it carries various wind-measuring apparatus, including a Robinson anemometer, the cups of which are 40·8 metres above the ground and surmount all other objects on the Telegraphenberg.

There are two chief magnetic buildings, the larger about 100, the smaller about 150 metres from the meteorological building. The former contains two sets of magnetographs, in a basement maintained at a nearly constant temperature throughout the year; the latter is devoted to absolute observations. In view of electric-tram disturbances in Potsdam—though these are still exceedingly small—a new magnetic observatory

[1] "Meteorologisch-magnetisches Observatorium bei Potsdam." Pp. 67+plates. (Berlin: Behrend and Co., 1912.) Price 3 marks.

was built in 1906 at Seddin, about 12 kilometres south-west of Potsdam. Magnetographs are now in operation there as well as at Potsdam under the Potsdam staff. A description of the Seddin buildings and instruments is thus included.

The volume contains much of interest to all meteorologists and magneticians, and is admirably suited for the purpose for which it was primarily intended. A previous study of it will double the advantages of a visit, while subsequent consultation will recall memories of a most pleasant and profitable experience. C. CHREE.

RECENT SEA-LEVEL VARIATIONS IN JAPAN AND ITALY.[1]

IN a valuable memoir, Prof. Omori deals with the variations in the height of the sea-level at nine mareograph stations in Japan from 1898 (in a few cases from 1894) to 1910, referred to in a note in NATURE of December 26, 1912 (vol. xc., p. 471). They are greatly in excess of any changes that might be due to variations of barometric pressure or air-temperature, and the effects of wind are probably negligible. These variations being allowed for, there remain considerable changes in the mean annual height of the sea-level at all nine stations, the greatest being a decrease in height of 22·7 mm. per year at Ayukama. In the accompanying sketch-map, the shaded areas represent the parts of Japan which are now subsiding, the boundaries inland being determined by interpolation. The figures at the different stations denote the mean annual rise or fall of the sea-level in millimetres per year. It is on the east side, to which the present depressions are chiefly confined, that the greatest depths of ocean lie and the most violent earthquakes originate.

Prof. Omori also compares the variations in the average height of the sea-level in the whole of Japan (the barometric and temperature corrections being made) with the variations in the latitude of Tokyo and Mizusawa for each year from 1895 to 1910. The curves representing both variations show a remarkable correspondence. The average height of the sea-level was greatest in 1899 and 1905–06, and least in 1897 and 1902; the latitude was a maximum about 1899–1900 and in 1906, and a minimum in 1897 and 1902. Corresponding to a variation of 0·1″ in the latitude, there was a change of 40 mm. in the height of the sea-level.

The examination of the records at seventeen mareograph stations in Italy and Austria from 1900–08 shows that in all parts of Italy the height of the sea-level was decreasing by amounts ranging from 10·5 mm. per year in the neighbourhood of Pola and Ancona, to between 4 and 5 mm. per year at Naples and Messina and less than 2 mm. per year at Palermo. In 1908 the mean sea-level reached a well-defined minimum, and Prof. Omori suggests that this may have been a secondary cause of the Messina earthquake at the close of that year.

C. D.

NOTES.

A STATUE of Lord Kelvin, which has been subscribed for mainly by the public of Belfast, is to be unveiled to-day (Thursday) in the Botanic Gardens, Belfast. The Chancellor of the Queen's University, Belfast (the Earl of Shaftesbury, K.P.), will preside, and Sir Joseph Larmor, M.P., F.R.S., will perform the unveiling ceremony, and deliver an address. The statue is the work of Mr. Bruce Joy. Invitations to the ceremony have been issued to the Lord Mayor and Corporation of Belfast, to the Senate and professors of the Queen's University, Belfast, and to a number of leading men of science.—The statue of Lord Kelvin erected by the contributions of his fellow-citizens in Glasgow and the west of Scotland has been placed in position by the side of the new Kelvin Avenue, which traverses the Kelvingrove Park beneath Gilmorehill, close to the University of Glasgow. The statue will be unveiled on October 8 next, by the Right Hon. A. Birrell, Lord Rector of the University, and an address on Kelvin will be subsequently delivered by the Right Hon. A. J. Balfour, Gifford lecturer in the University. —The Kelvin memorial window in Westminster Abbey will be unveiled on July 15.

IT is with deep regret that we have to announce the death, from spleno-medullary leucæmia, of Prof. N. H. Alcock, Joseph Morley Drake professor of physiology in McGill University, Montreal. Prof. Alcock was born in 1871, and received his medical education at Trinity College, Dublin, and Sir Patrick Dun's Hospital. He graduated as B.A. and M.D. in Dublin University in 1896, taking senior moderatorship and gold medal in natural science. He was shortly afterwards appointed demonstrator of anatomy at Victoria University, Manchester. In the following year he was appointed assistant professor of physiology in Dublin University. In 1903 he became demonstrator of physiology at London University, and in the following year he succeeded Dr. Waller as lecturer in physiology in St. Mary's Hospital Medical School, Paddington. In 1909 he obtained the degree of D.Sc. of London University in consideration of his researches on the influence of anæsthetics on nervous phenomena. In 1911 he was appointed to the chair of physiology at McGill University, Montreal. By his early death British science has lost a valuable worker. His experimental work was always most scrupulously verified by every possible control, and he took extraordinary care to reduce experimental error to a minimum. Among his numerous scientific publications were papers concerning "Irish Bats," "The E.M.F. of the Negative Variation of Various Nerves, especially the Vagus," "The Velocity of the Nervous Impulse in Tall and Short Individuals," "The Relations between the Physical, Chemical, and Electrical Properties of the Nerves," "A Text-book of Experimental Physiology" (conjointly with Dr. F. O'B. Ellison), "Accurate Dosage of Chloroform by Means of a Regulating Inhaler," and many others. Prof. Alcock married, in 1905, Norah Lilian Lepard, daughter of Sir John Scott, K.C.M.G., and leaves his widow, one son, and three daughters to mourn his loss.

MR. A. R. HINKS, F.R.S., chief assistant at the Cambridge Observatory, and University lecturer in surveying and cartography, has been appointed assistant secretary of the Royal Geographical Society.

THE new wing of the laboratories of the Rothamsted Experiment Station, Harpenden, will be opened by the Right Hon. W. Runciman, President of the Board of Agriculture, on Friday, June 27, at 3.30 p.m.

THE death is announced, in his sixty-fifth year, of Mr. F. A. Ober, one of the best known of American ornithologists. In the interests of his favourite pursuit he had travelled extensively in South America, Mexico, and the West Indies. In the Lesser Antilles, in particular, he discovered twenty-two new species of birds, and added many types to the collections of the Smithsonian Institution. Mr. Ober wrote largely for the newspaper press, and was the author of forty books.

ON June 5 the faculty of science of the University of Geneva erected a bust to the memory of Pierre Prevost (1751–1839), the Geneva man of science whose name is remembered by Prevost's theory of exchanges. Prof. C. E. Guye presided at the ceremony, and most of the learned societies with which Prevost was associated sent delegates, or addresses of congratulation. M. G. Lippmann represented the Paris Academy of Sciences, and delivered an oration. The Royal Society and the Royal Society of Edinburgh were represented by Dr. W. H. Young, F.R.S., and Mr. Mitchell respectively, who presented addresses in English. The Berlin Royal Academy of Sciences sent a letter of congratulation signed by Prof. Planck.

A TIDAL observatory has recently been constructed by the Ordnance Survey at the foot of the Castle Rock at Dunbar, and is now fitted with a self-recording gauge and other instruments. The main object is to obtain an accurate value for a mean sea-level datum on the open North Sea coast to which the network of geodetic levelling in Great Britain can be very precisely connected. Such an accurate determination is required for the measurement of relative movements of land and sea along our coasts, an object recommended some years ago by the Tidal Commission on Coast Erosion. Incidentally light may be thrown upon slow vertical movements of the earth's crust, periodic coastal movements due to tidal load, and upon the tidal phenomena of the North Sea generally, with their relations to hydrological and meteorological changes taking place in and over the neighbouring oceans. In this country the existing tide-gauges fulfil comparatively rough requirements in harbours not truly representative of open ocean conditions, and there can be no doubt of the importance for scientific purposes of having well-placed observatories on open coasts and capable of being rigorously connected with the network of geodetic levelling.

The Cape Times of May 7 contains an interesting article strongly advocating the founding of a national botanic garden at the Cape. Matters have already gone some distance in this direction, and the Kirstenbosch estate, which is Government property, has been mentioned as an appropriate site. In the interest of South Africa, no less than of scientific botany, it is sincerely to be hoped that this project may be successfully carried through. A view which has been put forward by certain influential people in South Africa is that the garden should be placed under the control of the Agricultural Department rather than that it should be more directly attached to the South African College, and through it to the scientific botanical staff. This view, however, is one which demands, and doubtless will receive, very careful consideration. A botanic garden which is not under scientific direction can have very little value, and it is to be hoped that, in the interests of South Africa generally, this principle will not be lost sight of in determining the nature of the body which is to be responsible for its proper administration. The problems to be solved are mainly scientific, but from their successful solution there may be expected to accrue results of value not only to science but also of great economic importance to the community at large.

A LARGE number of distinguished physiologists, biologists, and medical men have signed a letter addressed to the Home Secretary directing attention to the scientific aspects of the administration of the Mental Deficiency Bill. The signatories desire to secure the continuous prosecution of research into the conditions on which mental deficiency depends, and into the means by which it might be remedied or prevented. They point out that it may be said, in a general way, that the conditions in question must be due either to defective formation and development of the active structures of some portion or portions of the brain, or to defective formation or supply of the fluids by which these structures are surrounded, and by which they are stimulated to activity. For example, one common form of idiocy is consequent upon the absence from the blood of the secretion which should be furnished by the thyroid gland, and may be remedied by the administration of thyroid extract derived from lower animals. The Mental Deficiency Bill will probably bring together many of its subjects into institutions controlled by the State, and supported by the public. It is therefore urged that the facilities for scientific study which such institutions would afford should be fully utilised for the general benefit of the community, and that the duty of so utilising them should be committed to men of science, fully conversant with all that is already known in relation to the subject, and able to point out the directions in which further inquiry should be pursued. It is suggested that the objects in view could scarcely be obtained except by an adequate representation of biological science upon any Commission to which the administration of the law may be entrusted.

In an interesting paper published in the *Biologische Centralblatt* (vol. xxxiii., No. 3), under the title "The Occurrence of Dextro-rotatory Albumins in Organic Nature," Dr. John Beard has developed the idea, published in 1907, that the albumins of cancer and of malignant tumours in general must be dextro-bodies because of the destructive action, ending in liquefaction, of active pancreatic ferments, especially trypsin, upon them. He now shows that asexual generations of animals such as Hydra, Cordylophora, Trichodina, Vorticella, Carchesium, Amœba, Actinosphærium, and Stentor are rapidly killed and digested by pancreatic ferments (trypsin and amylopsin), and hence concludes that such asexual forms are built up of dextro-proteins; on the other hand, sexual generations such as Daphnia, Nauplii, Planaria, Nais, and Melicerta are not in the least affected by these enzymes, and are therefore probably built up of lævo-albumins. In a striking generalisation, Dr. Beard contends that "the micro-organisms, bacilli, &c., of disease are of necessity composed of compounds which are stereochemical antitheses of those making up the normal human body, and that when compared similarly with the pancreatic ferments, the like is true of the ferments by means of which they effect their ends. Only by means of such antithetic or opposite characters of compounds and of ferments produced by them could such disease-inducing organisms bring about their ravages." The natural method of treatment is therefore to employ against them the ferments produced by the organisms, such as mankind, which are their victims, and of these by far the most potent are the pancreatic enzymes, trypsin and amylopsin.

The transference of the Northern Territory of Australia from South Australia to the Commonwealth has been followed by the more active investigation of the country and its resources. Fresh effort is recognised as necessary, for the total population, exclusive of aborigines, has fallen from 4788 in 1891 to 3005 in 1910. An expedition, consisting of Prof. Spencer, Prof. Gilruth (who has since been appointed Administrator of the territory), Prof. Woolnough, and Dr. Breinl (director of the Australian Institute of Tropical Medicine), visited the country in 1911, and their preliminary reports have been published as Nos. 1 and 1*a* of the Bulletin of the Northern Territory. Prof. Woolnough reports that he was much impressed with the mineral wealth of the country, but as the deepest mine is under 400 ft. in depth he recommends that a shaft should be sunk further in order to determine the extension of the deposits in depth. Prof. Gilruth reports on the domestic animals in the territory, and discusses the source of the two prevalent cattle diseases, red water or tick fever, and worm nodules. He concludes that they were introduced from Java in 1872. The red-water fever has spread from the Northern Territory to Queensland. He concludes that under the conditions that have hitherto prevailed the satisfactory development of the country could not be expected, but with a better system of administration and more reasonable land tenure the country possesses unlimited possibilities. Dr. Breinl describes the diseases prevalent amongst both the Europeans and aborigines. He gives full tables of the health statistics available. Malaria is widely spread, and was probably introduced from New Guinea; it is distributed by a mosquito, *Nyssorhynchus annulipes*. Dr. Breinl believes that malaria could be controlled by proper methods. He finds that the white people living under active conditions have good health, and the hæmoglobin content of the blood in children is normal. The population is, however, too small for its evidence to show whether the country can be developed by white labour.

The Museum Journal, of Philadelphia, in its last issue, records the purchase from members of the punitive expedition to Benin of a fine series of brasses and ivory carvings. Of the former class the more important specimens are two bronze heads, said to be portraits, with remarkable head-dresses and a high neck ornament, in one case rising as high as the lower lip. On heads like these the carved ivory tusks, which were apparently objects of veneration, are said to have been placed. A large bronze plaque represents a high official, wearing the same type of necklet, and standing surrounded by his attendants and slaves. Another fine exhibit is a pair of bronze cocks, about life-size, with chiselled feathers and the eyes inlaid with iron.

We have to acknowledge the receipt of No. vi. of Dr. Koningsberger's "Java," which is chiefly devoted to the fauna of the Bouwland.

To the author, Mr. H. Schmidt-Jensen, we are indebted for a copy of a paper, from *Vidensk. Meddel. fra Dansk. naturh. Foren*, vol. lxv., on regeneration in the antennæ in larvæ of a phasmid insect, *Carausius* (*Dixippus*) *morosus*, as the result of both natural and artificial injuries.

No. 2 of the tenth volume of the University of Colorado Studies is devoted to an illustrated synopsis, by Messrs. M. M. Ellis and J. Henderson, of the amphibians and reptiles of Colorado. Despite the varied physical conditions of the country, which in several other groups of animals is correlated with a large and diversified fauna, the species of the groups under review are not remarkably numerous. No new species are recorded.

The existence of a close relationship between the faunas of India and Africa, which was so strongly urged by the late Dr. W. T. Blanford and subsequently by Mr. Lydekker, is emphasised in an article by Mr. Ernst Schwarz on Indian Viverridæ, published in vol. lxxviii., part 11, of *Archiv für Naturgeschichte*.

It is there pointed out that the true civets (Viverra) have closely allied representatives in the two continents, and that the same holds good for several groups of mongooses (Mungos or Herpestes), while the Indo-Malay linsangs (Prionodon) are near relatives of the African Poiana. It is also pointed out in this paper, and in a second by the same author (*op. cit.*, part 12) on the extinct viverroid genera Palhyæna and Ictitherium, that although the Viverridæ are the most primitive type of cat-like Carnivora, and have some representatives (Poiana and Prionodon) approximating to the feline type, while the above-mentioned extinct genera show an equally marked step in the direction of the Hyænidæ, yet that in both instances these resemblances should be regarded in the light rather of convergence than of direct ancestry, the Felidæ having in all probability originated independently from a still earlier stock.

A recent number of *Science* (May 2) contains an account by Dr. C. Gordon Hewitt, entomologist to the Dominion of Canada, of the Imperial Bureau of Entomology. This organisation has grown out of the Entomological Research Committee appointed in 1909 by Lord Crewe, then Secretary of State for the Colonies. The functions of the bureau, which is supplementary to the existing research committee, are to collect and coordinate information relating to the noxious insects of the world, to undertake the authoritative identification of insects of economic importance submitted by the Departments of Agriculture and Public Health throughout the Empire, and to publish a monthly journal giving summaries of all current literature which has a practical bearing on the investigation and control of noxious insects. Mr. Guy A. K. Marshall, the scientific secretary of the research committee, has been constituted director of the bureau and editor of the journal, the first issue of which, under the name of *The Review of Applied Entomology*, appeared in January of this year. It is being published in two parts, devoted respectively to agricultural and to medical and veterinary entomology. Dr. Gordon Hewitt points out that there are no fewer than 1700 periodicals which may contain articles dealing with the subjects of which the bureau takes cognisance, and that entomologists in many remote districts have neither the opportunity of seeing nor the time to consult more than a small proportion of this literature. Hence the establishment of a central organisation for the collection and dissemination of important economic data is likely to be of the highest practical value.

The results of a comprehensive series of trials with varieties of oats are published as Report 29 of the Edinburgh and East of Scotland Agricultural College. The observations extend over the years 1909–12, and indicate marked differences between the varieties, according to weather conditions, altitude, and character of the soil. Of the twenty-six varieties grown at fifty-two centres, eight surpassed the standard potato oat by from 20 to almost 40 per cent. in yield of grain; five others were from 15 to 16 per cent. better, but none of these improved varieties showed itself equal to the standard oat in respect of straw production. On account of early ripening certain varieties are specially suited to late districts, while others failed to ripen at all at the higher centres in the wet season of 1912.

The Bulletin of the Department of Agriculture of Jamaica (vol. ii., No. 6) contains a number of articles on the fungoid diseases of the banana. Amongst these is an account of the Surinam Panama disease (*Leptospora musae*) of the Gros Michel banana. Investigation has shown the fungus to be a parasite on several varieties of Musa, although the plantain is immune against it. Soil disinfection experiments with carbolineum, copper sulphate, and gas water have been made with negative results. Greater success is anticipated from flooding the infected areas, since the fungus is adversely affected by humid conditions. The introduction of immune varieties, such as the Congo and other bananas, is recommended.

The Meteorological Charts of the North Atlantic Ocean for May and June, issued by the U.S. Weather Bureau, contain interesting articles by Mr. R. E. Harris, illustrated by synoptic weather charts and barograms, relating to the unusually heavy storms in that ocean during January last (possibly the stormiest month on record there), and supported by extracts from log-books of a considerable number of vessels. The most severe storm was that of January 7 to 11 inclusive. This depression had two centres at Greenwich noon, January 8, one over New York, while a storm was central near latitude 49° N., longitude 25° W., and was causing winds of force 8 to 12 (Beaufort scale) between the fifteenth and forty-fifth meridians. By noon of January 9 a rapid development in the western storm had occurred, and it was central near latitude 45° N., longitude 48° W. During the night of January 9–10 some remarkably low barometer readings were recorded, the lowest, 26·96 in., being registered by an aneroid at 52° N., 25° 30′ W. This (if really correct) is probably the lowest reading ever made on the North Atlantic. By noon of January 10 the storm was central near 51° 30′ N., 27° W., the lowest barometer being 27·76 in. The log of the ss. *Cedric* showed a continuous rise of 2·8 in. in twenty-five hours and forty minutes (from 27·49 in. to 30·29 in.), which, Mr. Harris observes, probably marks a record north of the thirty-fifth parallel.

Mr. G. H. Knibbs, of the Australian Bureau of Census and Statistics, recently contributed a paper to the *Philosophical Magazine* on climatological physiology. His view is that in "the mechanical and chemico-physical arrangements of the human thermostat actions supervene after about 30° C. is reached which disturb those conditions of thermogenesis and thermolysis which are necessary for the thermostasis of the organism." He analyses a number of experimental results obtained by Prof. W. A. Osborn for losses from the human body by evaporation, and discusses them from the theoretical side. The problem in its simplest form is the same as the problem of the wet-bulb thermometer, and Mr. Knibbs uses the results of Regnault, Stefan, Marvin, and others on the relation of evaporation to temperature, relative humidity, and wind in his discussion. He finds that the change in the loss by evaporation under different conditions is proportional to the product of the absolute temperature and the absolute dryness or saturation deficit, and he makes the interesting suggestion that sufficient observational results should be obtained to give normal values for the constants for different sexes, races, &c. Incidentally the paper emphasises the importance of the wet-bulb temperatures as a climatic factor, especially in tropical or semi-tropical regions. It may be noted that experiments on the effect of different meteorological conditions on the human body are being conducted by Dr. J. R. Milne at Edinburgh, a preliminary account being given in the recently issued Journal of the Scottish Meteorological Society.

The Meteorological Institute of the Netherlands has issued copies of thirteen of the principal magnetic disturbances of the year 1911, as recorded at de Bilt, and the director of the institute, Prof. van Everdingen, intimates that in future it is intended to publish each year copies of the chief disturbances, as indicated on the international lists compiled under his auspices. The time scale adopted is 15 mm. to the hour, and the curves—declination, horizontal force, and vertical force—are very clearly reproduced.

We have received a copy of an address delivered by Dr. Wolfgang Ostwald before the eighty-fourth Versammlung Deutscher Naturforscher on "Die neuere Entwicklung der Kolloidchemie" (pp. 23, T. Steinkopf, Dresden, price 1 mark). Colloid-chemistry is a branch of science which has made striking progress during the past few years, and has now not only a distinct terminology of its own, but a journal, the *Kolloid-Zeitschrift,* to chronicle its advances. The brief review given by Dr. Ostwald of recent development of the science should prove of interest to many workers in the numerous fields of science and industry in which a knowledge of colloids is of importance.

We have received a copy of the *Compte Rendu* of the Geneva Physical and Natural History Society for the year 1912. The society has sixty-eight ordinary and forty-two honorary members, and admits twenty-eight associates free. The *Compte Rendu* extends to more than eighty pages, and contains articles on physics, chemistry, botany, geology, and zoology of considerable interest. Amongst the most important of these articles are Prof. Guye's on the internal friction of metals at high and at low temperatures, and M. Tommasina's surveys of Ritz's theories of the æther and of gravitation.

The June number of *Terrestrial Magnetism and Atmospheric Electricity* contains a list of the determinations of declination made on the magnetic survey ship *Carnegie* during its voyage across the Pacific from Tahiti, Society Islands, to Chile, and thence *viâ* Cape Horn to the Falkland Islands. Comparisons are made between the values obtained and those given on the United States, the German, and the British charts. So far as the latter is concerned, the corrections to be applied to the charted values are in most cases less than one degree, but exceed that amount at nine points off the coast of Chile and Patagonia, where the chart shows the easterly declination too small.

In a paper recently published in the Bulletin of the Imperial Academy of Sciences of St. Petersburg, Prof. P. Walden brings forward additional evidence in favour of the view that the degree of dissociation of a given solute is independent of the nature of the solvent if each solution is at the saturation point. This was demonstrated previously for tetramethylammonium iodide, $N(C_2H_5)_4I$, in fourteen solvents, but is now shown to be true for tetramethylammonium iodide, $N(CH_3)_4I$, in ten solvents ($\alpha = 0{\cdot}666$), for tetrapropylammonium iodide, $N(C_3H_7)_4I$, in five solvents ($\alpha = 0{\cdot}26$), and, finally, for potassium iodide, KI, in three solvents ($\alpha = 0{\cdot}423$).

In the May issue of the Chemical Society's Journal Dr. Scott describes some new methods for the preparation of pure bromine. The first method depends on getting rid of iodate and iodide by boiling potassium bromide with a little potassium metabisulphite and sulphuric acid, then twice adding saturated bromine water and distilling off the bromine, and finally neutralising with potassium carbonate and evaporating to dryness. The bromide was then fused with potassium dichromate in quantity insufficient to decompose any chloride that might be present; the fused mass was decomposed by sulphuric acid with the addition of a little permanganate to decompose organic matter. A quantity of 3250 grams of pure bromine was prepared in this way, together with an additional 185 grams, which should contain all the chlorine, but this was found to amount only to 4 or 5 milligrams. The halogen impurities were separated by extracting the bromine with caustic soda; this appears to provide a very simple and a most effective way of purifying bromine, the chlorine being removed as chloride, and the iodine as iodate. By this method the whole of these halogens can be removed from 10 c.c. of bromine by extracting once with 5 c.c. of normal sodium hydroxide.

OUR ASTRONOMICAL COLUMN.

Observatories and Cities.—Modern astronomical research work, which necessitates the long exposure of photographic plates and the observation of faint stars, is gradually separating old observatories from their historic surroundings and creating new buildings in more favourable situations. The Hamburg Observatory is now settled in its new site in Bergedorf, some distance away from the city, and the new ground is bristling with domes of the latest construction. Berlin Observatory is now on the move, taking up its new position in Neu Babelsberg, not very far from its astrophysical *confrère* at Potsdam. At the present time the question is being considered as to the removal or part removal of the Paris Observatory, as the conditions on the site now occupied are not conducive to the best observational work. Those unfamiliar with the present locality can obtain a good idea of it in relation to Paris from the excellent reproduction of a photograph by M. Baillaud which is given in the current number of *The Observatory* (June, No. 462).

Neptune's Faint Equatorial Belts.—Dr. T. J. J. See publishes in the *Astronomische Nachrichten*, No. 4656, a paper describing some observations he made on the planet Neptune in 1899 and 1900, with the 26-in. refractor of the Naval Observatory at Washington. On some days in those years the air was particularly steady and the mottled appearance of the disc of the planet accidentally attracted his attention. This led him more closely to scrutinise the disc, and he noticed that beaded bands or belts were faintly visible against the brighter body of the planet. The seeing on these occasions was such that 95 Ceti, the most difficult of known double stars, was resolved, and other difficult pairs, such as 85 Pegasi and T Cygni, measured. The bands, he says, were found to be extremely faint, but on a few occasions they came out with more distinctness, and he attaches drawings from which their general character can be inferred. Dr. See refers to Prof. Asaph Hall's observations with the same instrument, which gave the suggestion of suspected mottlings on the planet's surface, and to Prof. S. J. Brown, who noticed an unsymmetrical appearance on the disc. As Dr. See points out, the chief interest attaching to the discovery of these equatorial belts arises from the circumstance that phenomena depending on planetary rotation first noticed on Jupiter, and then on Saturn, and finally on Uranus, are now seen to be common to the most remote member of the solar system. The paper concludes with a brief notice of the discovery of belts on the other major planets.

Variable Stars.—Numerous recent papers deal with the subject of variable stars. Prof. A. A. Nijland, of Utrecht, sends a pamphlet on the light curves of twenty-three Algol stars, and the classification of variables. Two papers in the *Astronomische Nachrichten* (No. 4653, vol. cxciv.) deal respectively with the ellipsoidal variables Sl Tauri and S Antliæ, by Harlow Shapley, and the variability of the pole star by Ant. Pannekoek.

Photometric observations of variables is the subject of Padova's communication to the *Mem. della Soc. dei Spettroscopisti Italiani* (April, disp 4*a*, vol. ii., ser. 2*a*), and he deals with two Algol variables, U Ophiuchi and RZ Cassiopeiæ; two variables of short period, Y Ophiuchi and β Lyræ; five long-period variables, and two irregular variables, RS Cygni and R Scuti. Light curves accompany the observations in most cases. Harlow Shapley contributes a paper on the visual and photographic ranges and the provisional orbits of Y Piscium and RR Draconis to the April number of *The Astrophysical Journal*, while the same journal also contains a second paper by Frederick H. Seares on the Algol variable RR Draconis. Prof. E. C. Pickering refers in Circular 177 of the Harvard College Observatory to the maximum brightness of Algol variables.

Kodaikanal Solar Prominences during 1912.—Bulletins Nos. 29 and 30 of the Kodaikanal Observatory contain a summary of prominence observations made at that observatory during the past year. Previously it was customary to publish detailed lists of prominences, such as those which appeared in the series of bulletins ending with No. 28, but these will now be discontinued and replaced by a *résumé* of the observations issued half-yearly. This *résumé* will include full descriptions of any remarkable phenomena observed or photographed, and, in addition to the summary of the observations at the sun's limb, there will be given the results of a study of the prominences projected on the disc as hydrogen absorption markings. The present two bulletins are written on these lines, and they contain the summarised material for 1912.

THE ALLOTROPY OF IRON.

TWO papers read before the recent meeting of the Iron and Steel Institute, one by Dr. Carpenter on the critical ranges of pure iron, and the other by Dr. Rosenhain and Mr. Humfrey on the tenacity, deformation, and fracture of soft steel at high temperatures, were responsible for a renewal of the discussion upon the allotropic modifications of iron. The present discussion may be regarded as a further contribution to an old controversy, and in order to appreciate its true significance it is necessary to review, somewhat in the manner of a serial story, the incidents of the preceding chapters.

In 1890 Osmond showed that when a piece of steel was allowed to cool from a bright red heat the rate of cooling was not uniform, but that at three points there was an evolution of heat in the steel itself which had the effect of retarding the fall in temperature of the mass. These three arrests Osmond designated as A1, A2, and A3, A1 representing the change taking place at the lowest temperature. In order to distinguish between the evolutions of heat during cooling and the corresponding absorptions of heat during heating, the letters *r* (*refroidissement*) and *c* (*chauffage*) were added, and this nomenclature has been retained, the irregularities in the cooling curve being described as Ar1, Ar2, and Ar3, and those in the heating curve Ac1, Ac2, and Ac3.

It was clearly shown by Osmond that the A1 change was dependent upon the carbon in the steel, whereas the points A2 and A3 were independent of the carbon and equally prominent in the purest steel obtainable. Osmond therefore argued that the thermal changes at A2 and A3 must be due to molecular rearrangement or allotropy in the iron. Iron above the A3 point he described as γ iron, that between the A3 and A2 points β iron, and below the A2 point α iron.

Roberts Austen repeated and confirmed Osmond's experimental work, and accepted his theory of allotropy as being the most probable explanation of the facts. Prof. Arnold, on the other hand, rejected the allotropic theory on the ground that "steel research was, in his opinion, a field of too national an importance to be used lightly as a cantering ground for the hobbies of periodicity and allotropy." After repeating and confirming the work of Osmond and Roberts Austen, Prof. Arnold suggested that the A3 point was due to the influence of hydrogen, and the A2 point to a change from a plastic to a crystalline condition. He contended that these changes had little connection with the phenomena underlying the hardening of steel, but that these were due solely to the carbon, and at a later date he developed a subcarbide theory to explain the changes brought about by hardening, &c. Further investigations, however, by independent metallurgists, tended to confirm Osmond's original views, and within the last few years little has been heard of the controversy between the "carbonists" and the "allotropists."

The two papers which have been responsible for the reopening of the discussion may be briefly summarised as follows:—Prof. Carpenter, following a hypothesis of Benedicks, endeavours to prove that the change at Ar2 is not an independent change, but merely the tail end, or limit of supercooling due to impurities, of Ar3. It may be mentioned that this was Osmond's original explanation, which he abandoned when it was proved that the appearance of magnetism coincided exactly with the point Ar2. Prof. Carpenter argues that if Benedicks's theory is correct pure iron should show the Ar2 change but not the Ac2 change, and he gives a number of heating and cooling curves of the purest iron obtainable in support of his view. Unfortunately, as Prof. Arnold has pointed out, the heating curves actually show the Ac2 change. It is true that they are less strongly marked than the Ar2 changes, but this is only what would be expected.

The changes during heating, as shown by inverse rate curves, extend over a greater range and are therefore less strongly marked than in the cooling curves. This is well shown in the A3 change shown in the curves, and in view of the fact that the Ar2 change is itself very small, it was scarcely to be expected that the Ac2 change would be very easily detected. Moreover, Prof. Carpenter has shown that if the iron, after cooling just below Ar3, is held at that temperature for two and a half hours in order to allow the change from γ to α iron to become complete, and then slowly cooled, the Ar2 change is shown as decidedly as before. He attempts to explain this by assuming that the impurities present are sufficient to prevent actual contact of the γ and α molecules, but the explanation is unsatisfactory, and his results must be regarded rather as proving than disproving the independence of the A2 critical point.

The paper by Dr. Rosenhain and Mr. Humfrey describes a series of experiments admirably conducted with the aid of an ingeniously constructed testing machine, in order to investigate the physical properties of mild steel at high temperatures. It is impossible to describe the experiments in detail, but the results show that the curve representing the tenacity at high temperatures consists of three branches corresponding to the γ, β, and α ranges of iron. Starting at 1100° C., the tenacity increases as the temperature falls, until the Ar3 point is reached, when there is a rapid decrease in tenacity. This is followed by a further increase until Ar2 is reached, when there is another falling off in tenacity. The influence of the rate of strain is discussed, also the influence of varying size of crystals; and photographs are given to illustrate the types of fracture at different temperatures. The authors conclude that they find it difficult to reconcile their results with Benedicks's theory by which β iron is regarded as a solution of γ iron and α iron.

Prof. Arnold's contribution to the discussion when separated from side issues resolves itself into little more than a reassertion of his own theories, which he claims are supported by the two papers in question. The one useful criticism which Prof. Arnold makes has already been referred to, in which he points out that the Ac2 change is observable in Prof. Carpenter's curves.

The criticism of Dr. Rosenhain and Mr. Humfrey's paper is even less helpful. It is claimed that the authors' conclusions are of no value owing to their "erroneously presupposing that they are discussing results obtained from chemically pure iron rather than from their dead mild commercial steel." It is possible that the authors have underestimated the importance of the impurities in their steel and have pushed their conclusions a little too far, but they give full details of the material upon which their experiments have been carried out, and they make no claim that their conclusions are final. Nevertheless, the authors have laid themselves open to some criticism inasmuch as they have chosen for their experiments a steel which, even from a commercial point of view, is of very poor quality.

As a matter of fact, the importance of the discussion has been exaggerated, and the two papers leave the β iron theory very much where it was before. The somewhat ill-defined A2 change and its relation to the physical properties of steel will still attract the attention of men of science who are anxious to discover the truth. Other papers will be read and further discussions will take place, but in the meantime, and until further evidence is forthcoming, those who are wise will refrain from a too dogmatic insistence upon their own particular views.

THE ROYAL SOCIETY CONVERSAZIONE.

THE annual June conversazione of the Royal Society was held in the rooms of the society at Burlington House on June 11. As is usual upon such an occasion, various instruments and objects of scientific interest were exhibited. Most of these have been described already in the account of the May conversazione given in NATURE of May 15 (p. 273). Other exhibits are mentioned below:—

Dr. E. C. Pickering: Colour-blindness, if any, of eminent astronomers. The sensitiveness of the eye to rays of different colours has been tested for numerous astronomers by grouping their estimates of the light of the stars according to their colour, as shown by the class of spectrum. The earliest estimates, those of Ptolemy and Sûfi, show results agreeing closely with those of recent times. Peirce shows a marked sensitiveness to the red, and Seidel to the blue, rays. The latter effect is still more marked in photographic plates.

Prof. Silvanus P. Thompson: Poulsen's telegraphon. The telegraphon of Dr. V. Poulsen, of Copenhagen, is an apparatus which records speech or sound transmitted by telephone, and reproduces it, at any subsequent time, in another telephone. The recording is effected magnetically. In this newest pattern, a thin wire of tungsten steel is caused to run rapidly between the poles of a small electromagnet in the receiving circuit of the telephone; and this electromagnet impresses the corresponding vibrations on the wire by magnetising it in an immense series of minute local spots. The record on the wire is absolutely invisible. On passing the wire again between the poles of a small electromagnet in the circuit of a receiving telephone, the series of minute magnetic spots on the wire sets up, by magneto-electric induction, a corresponding series of electric undulations, causing the telephone to emit a corresponding sound. The sounds so reproduced are faint unless a Brown telephone relay is employed to magnify them.

Mr. R. Inwards: Spiraloid curve apparatus. This is an instrument consisting of a revolving table carrying the paper, and over which a pen is caused by gear-wheels and adjustable cranks to describe an undulating line, and to produce figures resembling the structure of the Diatomaceæ, Radiolaria, and other natural forms.

Mr. C. R. Darling: Experiments with liquid drops and skins. (1) Large drops of liquids may be formed in media of slightly less density, *e.g.* orthotoluidine in water at 18° C. The formation is gradual, and all the stages may be observed by the unaided eye. If two drops of different diameters be made to communicate through a tube, the lesser passes into the greater when both are at the same level; if, however, the lesser drop be lowered, the movement is reversed. A position of equilibrium may be found in which both drops are stationary. (2) Skins of aniline may be formed on suitable frames under water, and made into bubbles filled with water. (3) Skins of various liquids on the surface of water exhibit characteristic movements, depending upon the liquid used.

Dr. T. K. Rose: Recrystallisation of gold on annealing. The specimens exhibited of incompletely annealed gold show that the new crystals make their appearance singly when annealing begins, and that as the temperature is raised or the time prolonged, other crystals are produced round those first formed. Some of the original crystals, which have been distorted by rolling, are completely broken up into the new smaller crystals before recrystallisation begins in other laminæ. The new crystals are soft, and the unaltered laminæ remain hard. Incompletely annealed metal thus consists of alternate strips of hard and soft material.

Prof. C. J. Patten: (1) Model illustrating the topography of the Tuskar Rock and Lighthouse relative to some features in the diurnal migration of certain birds. (2) Studies in the migratory movements of birds at the Tuskar Light-station, illustrated by a series of photographs.

The John Innes Horticultural Institution: Phenomena of plant-breeding. (1) "Maternal" hybrids and actual hybrids in Primula and Nicotiana. (2) Inheritance of double flowers and sex in Tropæolum. (3) Inheritance in *Campanula persicifolia*. (4) Double flowers of various types in Begonia.

Dr. G. D. H. Carpenter: A synepigonic series of *Papilio dardanus* from the parent form *planemoides*. This exhibit represented the first proof by breeding that the form *planemoides* is definitely of the species *Papilio dardanus*.

Dr. H. F. Standing: Photographs of the skeletons of extinct giant lemurs from Madagascar, also casts of skulls of the same. This exhibit showed casts of the skulls and photographs of the mounted skeletons of two species of giant lemur recently exhumed in a subfossil condition at Ampàsambazimba, in the centre of the Island of Madagascar. The smaller animal (*Palaeopropithecus maximus*) shows curious specialisation for an amphibious mode of life. It probably burrowed in the banks of lakes and streams; the peculiar roughened upward extension of the nasal bones no doubt carried some kind of epidermal excrescence, presumably used in burrowing. The larger animal (*Megaladapis grandidieri*) was arboreal in its habits, and its mode of life probably resembled that of the chimpanzee.

Prof. W. M. Flinders Petrie: Egyptian jewellery, 3400 B.C. The pectoral exhibited is of soldered gold inlaid with cut turquoise, lazuli, and carnelian, like the celebrated pectorals of Dahshur, and probably by the same artist. Found with it was a piece of inlaid open work of Senusert II., and a gold shell with soldered wire work of Senusert III. None of this fabric has reached England before. These were found at Gerzeh, forty miles south of Cairo, in a grave in which a plunderer had been killed by a fall of the roof.

REMARKABLE DROUGHT IN THE PHILIPPINES.

THE drought experienced during the eight months, October, 1911–May, 1912, probably the most severe ever observed in the archipelago, has been discussed by the assistant director of the Weather Bureau. At Manila the total rainfall recorded during the period was only 3·73 in., or a monthly average of less than half-an-inch; the driest month was April, with only 0·03 in. The following rainless periods are especially noteworthy: October 24–November 16 (24 days); November 20–December 11 (22 days); March 19–April 12 (25 days); April 14–May 7 (24 days). Deducting the insignificant amount of 0·004 in. (0·1 mm.) on May 8, there would result a rainless period from April 14–May 20 (37 days).

Sr. Coronas shows that, so far as Manila is concerned, the drought was the worst experienced since the establishment of the observatory in 1865. From a cursory inspection of his tables it is seen that for the months October–December, 1911, the rainfall was 14·05 in. below the normal; for the months January–May, 1912, 5·10 in. below, and that the total rainfall for the eight months was 5·56 in. below the absolute minimum recorded for those months during the entire period. In other regions of the archipelago the results cannot be so convincing as those for Manila, as the statistics for the secondary stations cover only a relatively short period. A table of the rainfall at twenty-six selected stations shows that it was without exception less than the normal at every station. The longest dry periods occurred in western Luzon, and the shortest on the eastern coasts of Samar and Mindanao; this was to be expected, as in the former case the dry season is most pronounced, especially from December to March, and in the latter case during the same months the most persistent rains of the whole year occur. An extraordinary period of 165 days without rain occurred at Vigan (western Luzon) between December and May.

Some very high temperatures were recorded in April and May. At Manila a maximum of 100·9° (38·3° C.) occurred on May 19; so high a temperature had not been recorded since May, 1889. It may not be without interest to recall the fact that the drought of the summer of 1911 in this country was followed by a remarkable period of excessive rainfall during the winter six months of 1911–12. This period has been specially discussed by Dr. Mill, and referred to in our columns.

WORK OF THE ROTHAMSTED EXPERIMENTAL STATION.

THE annual report for 1912 of the Rothamsted Experimental Station, which has lately been issued, includes an introduction, the annual report proper, and a supplement giving the year's yields of the various series of plots. The report deals first with the season 1912, its peculiarities, and their effect on the crops, and proceeds to give short abstracts of the work of the various members of the staff.

The central idea of the work of the Rothamsted Experimental Station is the investigation of the relation between plants and the soil in which they grow. Dr. Russell, who has during the year succeeded Mr. Hall as director, is engaged, in conjunction with Messrs. Hutchinson, Golding, Petherbridge, and Goodey, in investigating the effects of partial sterilisation of the soil. His results have now got beyond the theoretical stage. Partial sterilisation is now practised largely in the glasshouses of the Lea valley with good results, and has so impressed the tomato and cucumber growers of that district that they are endeavouring to get established an institute for the investigation of the problems of glasshouse culture—a most encouraging instance of the readiness of practical men to adopt any really sound innovation put before them in a feasible form.

Dr. Miller continues his investigations of the nitrogen content of rainfall and drainage. Dr. Brenchley is studying the possible stimulating effects of poisons on plant growth, and has extended her survey of the weeds of arable land to the eastern counties. Mr. Davis has published the results of a careful series of comparative determinations of potassium by the perchlorate method, which he recommends as accurate and trustworthy. The method is well worth the attention of analysts in these days of dear platinum.

The report on the whole is of great interest as showing the varied methods of attack which are being applied with success to the central problem of the relation of plants to the soil in which they grow. References are given to the original publications, which are for the most part contained in *The Journal of Agricultural Science.*

The report is accompanied by a circular of the society for extending the Rothamsted experiments, which gives details of the financial position of the trust. Subscriptions are invited for the rebuilding of the old laboratory, which must shortly be undertaken, and for the maintenance of the permanent plots, which entails very considerable annual expenditure.

DESIGN AND USE OF SCIENTIFIC INSTRUMENTS IN AERONAUTICS.[1]

AFTER expressing his admiration for the character of Wilbur Wright, his brilliant engineering work, and the scientific method by which he obtained his results, the lecturer considered the resemblance and differences of the manufactured aëroplane and the living bird. The resemblance may be simply the result of copying the bird, or it may be that similar designs have been arrived at independently by birds and men. The wings of both are roughly the same shape: of wide span, and narrow in the direction in which the bird flies; both have concave wings with thick leading edges. In many aëroplanes hollow spars are used like bones and like the quills of the feathers of birds. We copy plants also in this respect, for they too have learnt the economy of material in the use of hollow spars.

These resemblances are remarkable, but there are great differences. The Wright brothers found no biplane bird to copy and did not flap their wings. No flying animal uses a continuously rotating propeller to drive him forward on soaring wings, and it is perhaps scarcely too much to say that if birds only knew how, they would now copy the Wright brothers. Muscular action and the circulation of the blood, however, put supreme difficulties in the way of the development of the continuous rotation of a part of an animal.

Instruments Used in Aëroplanes.

It is important to realise beforehand the difficulties of using instruments on aëroplanes during flight and the errors that may be introduced in the readings. The aëroplane shakes, it does not remain level, and is subject to acceleration in all directions. The instrument should be so designed as not to be affected by any of these disturbances. A vertical acceleration has the same effect as a change in the amount of the downward pull due to gravity; the tilting of the aëroplane changes the direction of the downward pull with regard to the instrument. A lateral or longitudinal acceleration has the effect of altering both the direction and the amount of gravity. But vibration is a greater difficulty still. The hand of an instrument may move so much and so rapidly that it is difficult to estimate the mean reading on the scale, and sometimes it is quite impossible to do so. And this may happen when the quantity which is indicated by the position of the hand only varies slowly and by small amounts. The moving part of an instrument should be well balanced. This reduces the vibration from the shaking of the aëroplane as well as the error caused by its tilting or want of level.

In a compass as ordinarily made, the condition of balance cannot be fulfilled. The magnet rests on a steel point and is horizontal, and its centre of gravity is below the steel point. The force on the north pole acts in a downward direction towards the north, and the force on the south pole in an upward direction towards the south, and the magnet is made to rest in a horizontal position by arranging that the centre of gravity of the magnet is between its south end and its centre. It is below and to one side of the point about which rotation takes place. Hence a sideways movement must start it swinging. The magnet and card in aëroplane and ship compasses are usually surrounded by a liquid, so that any vibration which may be caused by its want of balance is rapidly reduced.

Instruments on aëroplanes should be damped, using the word to damp in the sense of "to dull" or "to abate the motion of." This damping is specially important if it should happen that the rate of vibration of the whole instrument should agree with the natural rate of vibration of the moving part. When this happens with an undamped instrument, the vibration is excessive. Damping is also required in cases where the fluctuations in the quantity to be measured are rapid; it may then be difficult to read the instrument, and the excursions of the hand may indicate a much greater amount of variation of the quantity than really takes place. If the mean reading is required the instrument must be damped, and the damping should be of a particular kind.

The essential features of satisfactory damping are that no force should be applied to the moving part whilst it is at rest, but that as soon as it moves a force should act opposing the movement. Friction at the joint does damp the instrument, but does not fulfil these conditions, and is bad. The force should be small when the movement is slow, and it should increase when the movement becomes more rapid. The most usual method is to immerse the moving part, or a paddle fixed to it, in a liquid more or less viscous, or the paddle can be replaced by a fan in the air. Another method is to damp by the movement of a copper plate between the poles of a magnet. If a Pitot tube is used, the flow of air through the connecting tubes damps the instrument.

Mr. A. Mallock has pointed out that in order to obtain a true mean reading with an instrument the damping force should be proportional to the velocity of movement of its index. When the damping force varies as the square of the velocity there may be no error or there may be a considerable error. Suppose that the quantity to be measured remains at 80 for 2/10 second, and then suddenly increases to 140 and remains at that amount for 1/10 second, and then it goes back to 80 and remains at that amount for 2/10 second, and that this rapid oscillation goes on indefinitely. Suppose also that the instrument is damped by a force which varies as the square of the velocity of the index, and that it is so much damped that the hand appears to remain at rest. The reading of the instrument will be 92 and the true mean in reality is 100, so that we have an error amounting to 8 per cent., by no means a small error. The diagram (Fig. 1) gives the supposed variations of the quantity as it would be recorded on a moving sheet of paper, and gives the true mean and the instrument reading.

In the magnetic method of damping, the force varies as the velocity and the true mean is obtained. With liquid and air damping the force varies as the square of the velocity, unless the movement is extremely slow, when it varies nearly as the velocity.

Speed of Aëroplanes.

The speed of the aëroplane through the air is often measured by a Pitot tube and a manometer.

The principle of the Pitot tube is very simple. If the open end of a tube faces the wind, the air wants to pass down the tube; if the tube is closed at

[1] From the first Wilbur Wright memorial lecture delivered before the Aëronautical Society of Great Britain on May 21, by Mr. Horace Darwin, F.R.S.

the other end the air pressure is increased in the tube, and this increase of pressure is a remarkably accurate means of measuring the velocity of the wind. This method is used in Dines's anemometer, and for measuring the velocity of the air in the wind channel at the National Physical Laboratory. In 1903 Dr. Stanton read a paper before the Institution of Civil Engineers (Proc. Inst. C.E., vol. clvi., p. 78) proving the accuracy of this method of measuring air velocity, and improvements have recently been made which give even more satisfactory results. The delicate measurement of the air pressure necessary for the most refined work is made by the tilting water gauge designed by Prof. A. P. Chattock and Mr. J. D. Fry. This is a laboratory instrument of the highest order of precision, and is far too delicate and accurate to be used on a flying machine. It is a difference of pressure that has to be measured—the increase of pressure in the tube, above the air pressure outside—and a second tube transmits this pressure (the static pressure) to the manometer. It is found by experiment that changes in the size of the opening of the Pitot tube, or the thickness of the tube, or the bevelling of its edge, make little or no difference in the pressure. With the opening of

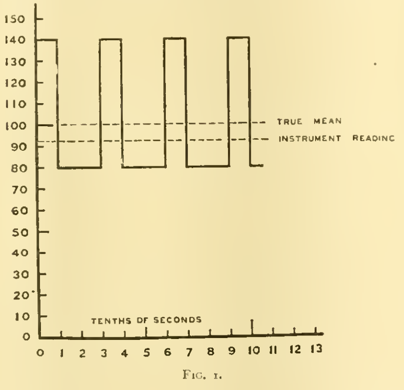

FIG. 1.

the static tube it is different, and its design is important. In the design now adopted at the National Physical Laboratory the pressure obtained is almost exactly what we should expect from theoretical considerations. This is an advantageous simplification, and this form of Pitot tube should be used for all the most refined measurements. But the static tube can be so made that it will give a pressure below the true static pressure, and the Royal Aircraft Factory has made use of this and has increased the manometer readings by 20 per cent. in order to give a more open scale.

The tubes transmitting the pressure can be carried a considerable distance to allow the manometer to be placed in a convenient position for reading; this is often of great importance. If it is found advisable to have a large amount of damping in the manometer it is best to have long tubes of large diameter. This gives the correct form of damping. Short tubes of small diameter will also give a large amount of damping, but in this case the damping force will vary as the square of the velocity of the air in the tube, and the reading will not necessarily be the true mean. For the same reason it is inadvisable to cause damping by throttling the passage of the air by closing a valve, or by means of letting it pass through a small hole in a plate.

If a Pitot tube speed-meter gives the correct speed when flying near the ground level, it will not be correct when flying at a great altitude. The error is caused by the change in the density of the air. As you mount the air becomes less dense because the atmospheric pressure is reduced, and more dense because the temperature falls, and an error of 7 per cent. may be expected at an altitude of 5000 ft.

The simplest form of manometer is a U-tube containing a liquid. The difference of the level of the liquid is then a measure of the difference of the air pressure in the two tubes. For use on an aëroplane this has two drawbacks: the scale is not open enough to read the speed easily and accurately, and tilting of the aëroplane causes an error. Mr. Short, of the Royal Aircraft Factory, has designed a manometer which overcomes both these objections. It is in effect a U-tube manometer; he uses two liquids of different densities, which do not mix, and thus obtains a more open scale. One tube is placed inside the other, and this overcomes the chief error due to the tilting of the aëroplane, leaving only a small secondary error amounting to $1\frac{1}{2}$ per cent. for a displacement of 10° out of the vertical.

If the aëroplane has an upward or downward acceleration or is changing its direction there is an error.

If a Pitot tube is fixed to the tips of the wings of an aëroplane and it is flying in a circle, the speed of the outer wing tip is greater than the speed of the inner wing tip. If these Pitot tubes are joined together by a tube there will be a greater pressure at one end of the tube than at the other, and at first sight we should expect that there would be a flow of air through the tube from the outer to the inner wing tip. But this is not the case, because the aëroplane is moving in a circle and there will be centrifugal force acting on the air in the tube. This will tend to make it flow outwards, and will exactly balance the tendency of the air to flow inwards due to the excess pressure in the Pitot tube on the outer wing tip, and there will be no flow through the tube. If there is a side-slip this statement is only approximately true. For accurate speed measurements at the Royal Aircraft Factory two Pitot tubes are used, one at each wing tip; both are connected to the manometer and the mean speed is given.

An instrument called a yaw-meter was described. It measures the direction in which the air is moving relatively to an aëroplane, and its action depends on the fact that the pressure in a Pitot tube becomes less if it does not directly face the wind. Two Pitot tubes are used, and the indication is independent of the speed of flight.

A method of indicating the speed of ascent or descent was also described.

The Principle of Geometrical Design.

Clerk Maxwell writes:—

"Each solid piece of an instrument is intended to be either fixed or movable, and to have a certain definite shape. It is acted on by its own weight, and other forces, but it ought not to be subjected to unnecessary stresses, for these not only diminish its strength, but (what for scientific purposes may be much more injurious) they alter its figure, and may, by their unexpected changes during the course of an experiment, produce disturbance or confusion in the observations we have to make.

"We have, therefore, to consider the methods of relieving the pieces of an instrument from unnecessary strain, of securing for the fixed parts a determinate position, and of ensuring that the movable parts shall move freely, yet without shake.

"This we may do by attending to the well-known fact in kinematics—'*A rigid body has six degrees of freedom.*'"

Designs in which this principle is carried out may be called geometrical designs. A three-legged table is a geometrical design, and a four-legged table is not. A four-legged table either rocks on two legs, or bends so that all legs touch the floor, and the amount of bending and the pressure of each foot on the floor depends on the stiffness of the table and the evenness of the floor. Every time an ordinary chair is placed in a new position, it takes a new shape. A surface plate is a familiar example of the importance of three supports, and nearly all scientific instruments rest on three feet. Other examples of geometric design were also given.

Good Design and Bad Workmanship.

A most important consideration in a good design is that the instrument shall still work well when the rubbing surfaces get worn or parts get bent, or if the workmanship is not good. With perfect workmanship and a bad design, you may get jamming in the moving pieces and bending of parts which should not bend, and the results obtained will be liable to error and the working unsatisfactory. This consideration brings out most forcibly the advantage of geometrical designs, but also it is a valuable test to all designs. It is a long way from being the only test, but it is always well worth while to consider separately the effects of imperfect workmanship, or the bending of each part and wearing of the rubbing surfaces. Take the case of wear in a wheelbarrow. The axle of the wheel usually consists of two round iron pins running in holes in wooden rails forming the frame of the wheelbarrow. Both the wood and the pins wear; the pin gets smaller but keeps circular, and wears its way into the wood and always fits it properly on the side where pressure is taken. The wheel will work perfectly until either the holes break out of the wood or the pin wears down very small and itself gives way. But sometimes the axle is made differently; an iron rod is fixed to the two wooden rails and passes through a hole bored along the centre of the wheel. With use the iron rod wears on the under side and does not remain circular, the hole in the wheel gets larger; the result is increased friction and a loose and shaky bearing.

The following test was applied to the Rocking Microtome, which has been designed so far as possible on the geometrical method. The iron castings of which it is chiefly made were taken as they left the foundry, were put together with as little work as possible, and it at once cut good sections. This was a severe ordeal, but sections as thin as 0·003 mm. were cut, proving that the instrument still worked with considerable precision.

This test for good design is not the only test, and it may fail. Ball bearings are much used, and when once used for any purpose they continue to be used more and more; this is the best test of a really good mechanical device. All must admire their design, but first-rate workmanship is essential; in this must be included the composition of the steel, the skill in hardening, as well as the accuracy of the figure of the working parts. A ball bearing, however, would be a better thing even than it is at present if it did not require such fine workmanship. It also requires careful mounting, and it is interesting to notice that the recent improvements in ball-bearing design are in the direction of allowing it to work satisfactorily on shafting which may be considerably bent.

The Advantage of Reversing the Parts of a Machine.

An improvement in the design of a machine can often be made by reversing the relative position of two parts of it, or the part that moved can be fixed and the part that was fixed can be made to move. This reversal makes it possible to compare two or more methods, and it is then easy to see which is best. It is advantageous that "the survival of the fittest" should take place early in the life of the machine, and by this means, in fact, it takes place before the design is completed.

In the before-mentioned wheelbarrow it is easy to see which is the best design, and if the designer had deliberately considered whether the iron pins should turn in the wooden rails or whether the iron bar should be fixed, the bad design would never have been made. It is surprising how often this reversal is possible and advantageous, and how difficult it is to realise that it is possible. We are so familiar with a clock in which the frame remains at rest and the hands move that it requires a considerable mental wrench to realise that it is possible and in some cases better that the clock itself should revolve and the hour hand remain at rest. But in recording apparatus it is usual to fix the clockwork in the rotating drum carrying the paper, and to prevent rotation of the hour-hand spindle.

The lecturer concluded:—"I have spoken as a manufacturer of scientific instruments, but my remarks apply equally or even more to the home-made or rather laboratory-made type of instruments. And it is with these that the greatest advances in knowledge have been made. If I could believe that what I have said would be any help to the makers of the wire, cork, and sealing-wax class of instruments, or to the orthodox instrument-maker, I should be glad to think I had done something to advance knowledge."

THE STANDARDISATION OF HYDROMETERS

WE have received from the director of the National Physical Laboratory the following memorandum for publication in NATURE:—

At the present time there appears to be considerable ambiguity as to the bases of standardisation of hydrometers graduated to read directly in specific gravity.

Three different methods have been brought to the notice of the National Physical Laboratory, and it seems desirable to determine which of these three should be considered as standard.

The instruments are in all cases graduated for use in a liquid at a definite temperature—we call this the standard temperature of the instrument—and give the specific gravity of this liquid at some definite temperature, which may or may not be the standard temperature of the instrument, referred to water at the same or at some other temperature.

The following cases have arisen in practice:—

I. (α) The liquid to be tested must be at the standard temperature of the instrument.

(β) The water to which the specific gravity is referred must also be at the standard temperature of the instrument. Thus, if 85° F. be the standard temperature of the instrument[1] the liquid must be at 85° F. when tested, and its specific gravity is referred to water also at 85° F.

II. (α) The liquid to be tested must be at the standard temperature of the instrument.

[1] A more usual value for this temperature of the instrument would be 60° F. or 62° F. The temperature 85° F. is chosen here as an example so as to bring out the differences arising from the various methods of standardisation.

(β) The water to which the specific gravity is referred must be at some other definite temperature, e.g. 60° F., or possibly 4° C., the temperature of maximum density. Thus, if 85° F. as before be the standard temperature of the instrument and 60° F. that of the water, the specific gravity of the liquid at 85° F. is referred to water at 60° F.

III. (α) The liquid to be tested must be at the standard temperature of the instrument.

(β) The graduations are such that they give the value which would be found for the specific gravity of the liquid if it were cooled or heated to some other temperature and referred to water at that[2] temperature. Thus the standard temperature of the instrument might be 85° F. The instrument would then be used at 85° F., but the graduations on the instrument would be such as to give the specific gravity which would be found for the liquid if it were cooled to 60° F., and referred to water at 60° F.

The following table gives the specific gravities of certain sugar solutions, as determined in accordance with these various methods, assuming coefficients of expansion as given in tables issued by the Kaiserliche Normal Eichungs-Kommission of Berlin :—

Solution	I. Specific gravity at 85° F. in terms of water at 85°	II. Specific gravity at 85° F. in terms of water at 60°	III. Specific gravity at 60° F. in terms of water at 60° *
Water ...	1·0000	0·9968	1·0000
Solution A...	1·0496	1·0462	1·0500
,, B...	1·0989	1·0954	1·1000
,, C...	1·1484	1·1447	1·1500

* In this case the liquid to be at 85° when tested, but the instrument is to give its specific gravity when cooled to 60° in terms of water at 60°.

Thus, taking solution C, and supposing in each case the liquid is at 85° F., the instrument will float immersed up to a definite division on the stem. In method I. this division would be marked 1·1484, in method II., 1·1447, and in method III., 1·1500.

Thus there would be a difference of 1·6 degrees of specific gravity between I. and III., and of 5·3 degrees between II. and III., and it is clearly necessary to specify the method of graduation.

There is one obvious objection to the use of method III. In order to graduate an instrument correctly it is necessary to observe its immersion in a liquid at the standard temperature, and then calculate from a knowledge of the coefficient of thermal expansion of the liquid and of its density at some given temperature what its specific gravity at some other temperature will be, and what mark therefore should be put on the stem. No doubt tables could be made up to do this for various liquids and temperatures, but from the point of view of a standardising institution it is preferable that the errors of graduation which have to be determined in the case of instruments sent for test should rest only on observations made during the test and not on a knowledge of the coefficient of expansion of the liquid in which the instrument is to be used.

The instrument is correctly graduated only for a liquid having one definite coefficient of expansion, and cannot be used without error for others.

Of the other two methods, I. and II., method I. has been the usual practice at Kew. The liquid under test and the water to which it is referred are both taken to be at the standard temperature of the instrument, and this, in ordinary practice in England, is about 60°. No. II. has the advantage that the reference temperature of the water is fixed and gives results in agreement with the usual definition of specific gravity, which assumes a fixed temperature for the water.

These notes are circulated with the view of eliciting opinions from makers and users, and also of obtaining information from other countries.

The director of the National Physical Laboratory will be glad to have an expression of opinion from people interested in the subject.

[2] A fourth variation might be added by requiring that in this case the water should not be at the temperature to which the liquid is cooled or heated.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Bristol.—On the nomination of the Society of Merchant Venturers, in the college of which the faculty of engineering of the University is provided and maintained, the council has appointed the Right Hon. Sir William Mather, P.C., a member of the board of that faculty, in succession to the late Sir William H. White, K.C.B.

Cambridge.—The following awards are announced: Harkness Scholarship (geology) for 1913, J. M. Wordie, St. John's College. Frank Smart prizes, J. Line, Emmanuel College (botany); D. J. Gray, King's College (zoology). Wiltshire prize (mineralogy) for 1913, E. V. Appleton, St. John's College; honourable mention, W. E. Evans, St. John's College.

St. Andrews.—The Senatus Academicus has resolved to confer the honorary degree of LL.D. on the following:—Lieut.-Col. Sir Chas. H. Bedford, Dr. George Albert Boulenger, F.R.S., Mr. J. Balfour Browne, K.C., Mr. F. Cornwallis Conybeare, Prof. Herbert J. C. Grierson, and Prof. W. R. Hardie.

The issue of the *London University Gazette* for June 4 gives particulars of the advanced lectures in scientific subjects which have been arranged during the present month for students of the University and others interested. Of those lectures which have still to be delivered may be mentioned a special lecture on the work of the Carnegie Nutrition Laboratory in Boston, to be given in the Physiological Laboratory of the University, South Kensington, on June 20, at 5 p.m., by Prof. F. G. Benedict, director of the Carnegie Laboratory. The admission to the lecture is free, without ticket.

The report of the council for the year 1913 to the members of the City and Guilds of London Institute provides full statistics and particulars of the subscriptions and donations of the great City companies to the institute since its inauguration. The total amount given to the institute during thirty-four years for the purposes of higher education reaches 889,139*l*. Three of the companies—the Goldsmiths', Clothworkers', and Fishmongers'—have each given above 120,000*l*.; eight others have each contributed above 20,000*l*., and other five more than 10,000*l*. The most recent gift is that of the Goldsmiths' Company towards the extension of the City and Guilds (Engineering) College, which is incorporated in the Imperial College of Science and Technology. During the year under review the Goldsmiths' Company supplemented by a further sum of 37,000*l*. its original gift of 50,000*l*., which was commented upon in the last report of the council.

The King Edward VII. British-German Foundation, instituted by Sir Ernest Cassel, decided last year to assist a number of young men of British nationality to prosecute special studies in Germany after the completion of their studies at one of the British universities. The council of the British section of the foundation has just awarded seven studentships with this object in view, and from the list of successful candidates, published in *The Times*, we notice that four of the students will proceed in Germany with scientific research as follows:—Mr. F. H. Smith, Pembroke College, Cambridge, chemical research; Mr. R. S. Wishart, Edinburgh University, chemical research; Mr. A. Cowe, Edinburgh University, neurology and gynæcology; Mr. S. G. Barker, Imperial College of Science and Technology, London University, scientific research in vapour pressures. The studentships are for one year and of the value of 175*l*., and a condition of their tenure is continuous residence in Germany for this period. The cost of these will be defrayed by the German section of the foundation, while the British section is bearing the expense of a limited number of German students who, under a corresponding scheme, will visit this country in the autumn.

In a communication from *The Times* correspondent at Toronto on June 5, it is announced that the report of the Royal Commission on Industrial Training and Technical Education in Canada, instituted three years ago, has now been made public. The report suggests that a fund of 600,000*l*. be provided annually by the Dominion for a period of ten years, and be divided among the provinces on the basis of population for the promotion of higher technical education and industrial training, while for elementary schools teaching manual training and domestic science a grant of 70,000*l*. a year for ten years is recommended. The report also proposes the establishment in each province of a board qualified to carry on industrial training. It advocates the provision of suitable and adequate apparatus and equipment for teaching purposes, the foundation of scholarships for students, the engagement of experts with experience in industrial training, and the creation of central institutions to supplement the work carried on by the provincial and local authorities. Workers in factories whose main task is to attend or to operate machines should, it is suggested, receive instruction which would develop all-round skill and increase their interest beyond the routine of automatic operations. Such training should be provided as will conserve and develop occupations in which skilled handicraft is required. The interests of the rural population should be preserved so far as possible by industrial training and technical education suitable to the needs of its workers. The needs of girls and women for organised instruction and training in housekeeping and home-making under modern industrial conditions should be recognised. The report also recommends that schools for fishermen should be established, and that provision be made for instruction in packing and curing. The distinguishing characteristic of the report is the attention which it gives to the problems of the rural communities.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 12.—Sir Archibald Geikie, K.C.B., president, in the chair.—Commendatore G. **Boni**: Address on recent researches on the Palatine, in relation to geology, ethnology, and physics.—J. G. **Thomson** and D. **Thomson**: The growth and sporulation of the benign and malignant Tertian malarial parasites in the culture tube and in the human host.—Sir David **Bruce**, Majors D. **Harvey** and A. E. **Hamerton**, and Lady **Bruce**: (1) *Plasmodium cephalophi* sp. nov. (2) The trypanosome causing disease in man in Nyasaland. II., Susceptibility of animals to the human strain. (3) Trypanosome diseases of domestic animals in Nyasaland. I., *Trypanosoma simiae* sp. nov. Part ii., The susceptibility of various animals to *Trypanosoma simiae*. (4) Trypanosome diseases of domestic animals in Nyasaland. I., *Trypanosoma simiae* sp. nov. Part iii.

Zoological Society, June 3.—Prof. E. W. MacBride, F.R.S., vice-president, in the chair.—Sir Arthur H. **Church**: Notes on turacin and the turacin-bearers. This paper contains a summary of the chief facts as to the composition, properties, and occurrence of turacin, the soluble crimson pigment of the Musophagidæ. Special stress is laid upon its constancy of composition, the limitation of its occurrence to certain plantain-eaters, and the relation of its spectrum to the spectra of hæmoglobin and chlorophyll. Some current errors concerning turacin are corrected.—Dr. P. Chalmers **Mitchell**: Observations on the anatomy of the shoe-bill (*Balaeniceps rex*). The author showed that Balæniceps and Scopus shared so many anatomical characters, and of these so many occurred also in storks, that if the reasoning generally followed by anatomical ornithologists were adopted, Balæniceps and Scopus must be placed with storks rather than with herons. He submitted, however, that such a method was irrational, unless it were accompanied by a much closer scrutiny of the value of the characters than had hitherto been made or was yet possible, and that for the present Balæniceps must be regarded as the representative of a division equivalent to storks and herons. He thought also that the relation of the Steganopods to these three groups required reconsideration.—T. H. **Withers**: Some Miocene Cirripedes of the genera Hexelasma and Scalpellum from New Zealand. An account is given of the "gigantic Cirripede" of New Zealand, originally described as *Scalpellum aucklandicum*, of which remains have long been known to occur in the Waitemata Beds (Miocene) of Motutapu Island, Auckland Harbour.—Prof. A. **Dendy** and R. W. **Row**: The classification and phylogeny of the Calcareous sponges, with a reference list of all the known species, systematically arranged. This memoir aims at a complete revision of the genera of Calcareous sponges. Fifty recent genera are recognised and diagnosed, and all the described species, amounting to 433, are arranged under these genera. The rejected generic names, which are listed separately, amount to ninety-seven. The fifty accepted genera are grouped in ten families, and Poléjaeff's subdivision into Homocœla and Heterocœla is abandoned.—Surgeon J. C. **Thompson**: Contributions to the anatomy of the Ophidia.—Prof. T. Wingate **Todd**: Observations on Osteomalacia in the zoological collections of Manchester and Cleveland.

Linnean Society, June 5.—Prof. E. B. Poulton, F.R.S., president, in the chair.—Miss L. S. **Gibbs**: A contribution to the flora and plant-formations of Kinabalu and the highlands of British North Borneo.—H. **Scott**: The Histeridæ of the Percy Sladen Expedition to the Seychelles.—Mme. Weber van **Bosse**: Red marine algæ from the Indian Ocean.—J. G. **Needham**: Myrmeleonidæ.—W. L. **Distant**: Rhynchota from the Seychelles. Part I., Heteroptera.—Prof. R. J. Harvey **Gibson**: Mystropetalon, Harv.

Mathematical Society, June 12.—Prof. Love, president, in the chair.—Sir J. **Larmor**: The electromagnetic force on a moving charge in relation to the energy of the field.—Prof. E. **Landau**: Einige Ungleichungen für zweimal differentierbare Funktionen.—G. H. **Hardy** and J. E. **Littlewood**: (1) The fractional part of $n^k\theta$. (2) The trigonometrical series associated with the elliptic θ-functions.—Dr. T. J. I'A. **Bromwich**: Foucault's pendulum.—J. **Hammond**: A certain definite inegral.

Royal Astronomical Society, June 13.—Major E. H. Hills, C.M.G., F.R.S., president, in the chair. F. W. **Dyson** and E. W. **Maunder**: Position of the sun's axis as determined from photographs of the sun from 1874 to 1912, measured at the Royal Observatory, Greenwich. In a previous paper corrections to the position of the axis were deduced from observations of spots crossing the sun's disc; in the present paper the material employed was extended by the consideration of spot groups passing across the further side of the sun. A still more important addition consisted in the observation of the latitudes of spots near the centre of the disc. No change was observed, either with sun-spot cycle or with phase.—A. S. **Eddington**: Preliminary results of observations with the Cookson floating zenith telescope. Mr. Cookson had photographed trails of the same star with reversed positions of the instrument; at Greenwich trails of different stars were taken, a method which brings the trails closer together, and near the centre of the plate. This method considerably reduced the probable error, but there remained discordances, the cause of which was uncertain; there seemed reason to believe that they were atmospheric.—J. A. **Harker**: The origin of solar electricity. A simple apparatus was described with which experiments were made, showing increase of electrical emission in all metals with increasing temperature. The cosmical bearing of the phenomena observed was pointed out.—Prof. E. C. **Pickering**: Some work carried on at the Harvard Observatory, especially the classification of stellar spectra by Miss Cannon. One thousand spectra had been classified by Miss Cannon alone in three years, but with her great experience and by carefully organising the work, Miss Cannon and her staff of assistants were now able to classify 5000 spectra a month. The work to be done was very great; there appeared to be more than 150,000 spectra to be dealt with.—Miss **Cannon**: Classification of spectra of gaseous nebulæ. Many gaseous nebulæ have precisely the character of the spectra of stars of the fifth type.—S. S. **Hough**: Progress of the Cape of Good Hope share in the work of the Astrographic Chart. The catalogue plates were all taken and checked by comparing the overlapping quadrants. Mr. Hough described briefly the other work carried on at the Cape, especially mentioning the high degree of stability of the system of meridian marks used.—Dr. H. N. **Russell**: Studies of stellar evolution, carried on at the Princeton Observatory. Dr. Russell showed diagrams exhibiting the relation between the spectra of stars and their real brightness, that is the brightness which they would have if all were placed at a uniform distance corresponding to a parallax of ten seconds. Interesting relations between colour and brightness were shown by the diagrams.

Cambridge.

Philosophical Society, May 19.—Dr. Shipley, president, in the chair.—Dr. G. F. C. **Searle**: (1) Some methods of measuring the surface tension of soap films. In one method the pressure excess due to a curved soap film is measured by aid of what may be called a "viscosity potentiometer." Air from a gasometer flows through two tubes AB, BC in series. The pressure at A is measured by a manometer; the end C is open to the air. From the junction B a side tube leads to a cup with a horizontal circular rim on which a soap film is placed. On account of the viscosity of the air, there is a fall of pressure along each tube. For a given flow of air, the fall of pressure in either tube is proportional to the length of the tube, and inversely proportional to the fourth power of its internal radius. The excess of the pressure at B over that of the atmosphere causes the film to become part of a sphere. From the distance of the highest point of the film above the plane of the rim and from the radius of the rim, the radius, r, of the film can be computed. (2) A simple method of testing lens systems for aberration. On account of spherical aberration, a lens does not bring to a mathematical point all the rays which have reached it from an object point on its axis. When there is aberration, the emergent beam has at one place a finite minimum cross section called the least circle of aberration; the smaller this circle is the more nearly is the lens free from spherical aberration for the given position of the object point. A metal plate is pierced with three equally spaced circular holes, A, B, C, each about 0·1 cm. in diameter, and the distance AC (measured from centre to centre) is about 2 cm. The holes are illuminated by a flame and their "images" formed by the lens system under test are received upon a very fine ground-glass screen backed by a micrometer scale divided to 0·01 cm.; this scale is viewed by an eyepiece. The examination shows whether the lens is free from spherical aberration or whether it is (1) under-corrected or (2) over-corrected for aberration.—R. D. **Kleeman**: The unstable nature of the ion in a gas. The ions in a gas in thermodynamical equilibrium must at any instant consist of free ions and clusters of various complexities (Proc. Camb. Phil. Soc., vol. xvi., pt. iv., p. 285). In order to obtain some experimental information on the nature of the ions, the ionisation by collision between a gauze and plate was studied, the initial ions being formed outside the space between gauze and plate in a weak field which drew the ions through the gauze. Some of the elementary ions were thus able to form clusters before being seized upon by the strong field producing further ions by collision.—W. A. Douglas **Rudge**: A dust electrical machine. The author has shown that clouds of dust raised by the wind or by artificial means are always strongly charged with electricity, the sign of the charge depending upon the nature of the dust. By a suitable arrangement of apparatus it is possible to get a continuous supply of electricity, by directing a current of air laden with dust through an insulated tube. When the current is passing a stream of sparks, sometimes 6 cm. in length, may be obtained from the tube. Flour, sulphur, road dust, or fine iron filings may be used. The air which escapes from the exit tube of the apparatus is also strongly charged, and if the apparatus is used inside a room the charge may be retained by the air of the room for more than half an hour. The origin of the charge upon the apparatus is probably due to (1) the actual raising of the cloud, (2) friction of the dust against the walls of the tube.—R. **Whiddington**: A mechanical vacuum tube regulator. One of the devices for regulating the speed of kathode rays within a discharge tube is to provide the kathode with a movable glass sheath. The position of the sheath determines the speed of the rays. Experiments are described which show that the inside of the sliding sheath concentrates the cylindrical beam of rays to a fine beam, thus diminishing the effective size of the kathode.

Edinburgh.

Royal Society, May 4.—Sir William Turner, K.C.B., president, in the chair.—Dr. W. S. **Bruce**: The skulls of antarctic seals (Scottish National Antarctic Expedition). The paper contained the measurements of the skulls of the different seals found in the Antarctic, with careful photographs of the skulls in various aspects.—Miss Laura R. **Thornley**: The Bryozoa of the Scottish National Antarctic Expedition. Of the eighty-five species described, three were new to science and six of the remainder had been found in the southern seas for the first time.—W. **Watson**: The compressibility of solutions of certain salts. Dilute solutions of NaOH, KOH, $MgSO_4$, $ZnSO_4$, and Na_2CO_3 were investigated by the electrical-contact method of measuring compressibility. The pressures were from one to one thousand atmospheres, and the temperature was 15° C. Within certain limits the observed compressibilities were found to satisfy Tammann's formula,

$$\frac{1}{v_0}\frac{dv}{dp}=\frac{A}{B+p+\Delta k}\cdot\frac{1}{v_{\Delta k}},$$

where Δk is the internal pressure due to the added salt and A and B are constants.

May 18.—Prof. T. Hudson Beare, vice-president, in the chair.—J. H. Harvey **Pirie**: Deep-sea deposits of the Weddell Sea and South Atlantic Ocean. The *Scotia* collections included three main types, viz. globigerina ooze, diatom ooze, and glacial muds and clays. The latter differs from most blue muds of terrigenous origin mainly in the character of its finest constituents—"rock feons"—and in the irregular size of its coarser components, this being due to its distribution by floating ice. A peculiar feature is the absence of diatoms, although they flourish in the surface waters over it. They seem to be carried off northwards by currents set up by the melting ice to be deposited in the diatom onze band to the north.—F. Gordon **Pearcey**: Foraminifera collected by the *Scotia*. A record of 267 species, including eleven new forms, separated from the deposits. The collection is very rich in arenaceous forms (to which most of the new species belong) from the glacial deposits. It includes also examples of such rare forms as *Verammosphaera fusca*.—Miss Margaret **Moir**: The effect of thermal treatment and the effect of longitudinal strain in inducing a sensitive state in certain magnetic materials. Under certain conditions it was found that longitudinal strain and heating had very similar effects on the manner in which the steels experimented with responded, as regards their induction, to the magnetising force acting on them.

PARIS.

Academy of Sciences, June 2.—M. F. Guyon in the chair.—E. L. **Bouvier**: The genera Pseudibacus and Nisto.—M. de **Forcrand**: The Trouton quotient and the molecular heat of vaporisation of pure bodies boiling at high temperatures. In connection with a modified Trouton formula recently proposed by the author, the experimental methods of determining the latent heat of vaporisation at high temperatures are discussed, and preference is given to the vapour-pressure method, with application of the Clapeyron equation. Experimental data for mercury, cadmium, zinc, bismuth, lead, silver, tin, and copper are compared with those deduced from the Forcrand formula.—M. **Ciamician** was elected a correspondant for the section of chemistry in the place of the late Lecoq de Boisbaudran.—J. **Bosler**: The spectrum of the Schaumasse comet 1913*a*. Three condensations are clearly shown on the spectrographs, the blue band of the Swan spectrum, the cyanogen band (λ 388), and a large band λ 400 to λ 407.—M. **Borrelly**: Observations of the comet 1913*a* (Schaumasse) made at the Observatory of Marseilles with the comet-finder. Positions of the comet and comparison stars are given for May 9, 10, 15, 22, 29, and 30.—M. **Coggia**: Observations of the comet 1913*a* (Schaumasse) made at the Observatory of Marseilles with the Eichens 26-cm. equatorial. Positions for May 26, 27, 28, and 29.—N. **Lusin**: The convergence of Fourier's trigonometrical series.—Paul **Lévy**: The integration of functional partial differential equations.—Jacques **Chapelon**: The numbers of classes of positive binary quadratic forms with negative determinant.—Vasilesco **Karpen**: Hovering flight.—Louis **Roy**: Complement to two recent notes on the movement of indefinite viscous media.—Ernest **Esclangon**: A temperature regulator. The regulator consists of a circular glass tube containing mercury and a volatile liquid supported on a knife edge at the centre of the circle formed by the tube. It is in indifferent equilibrium, and can be rendered extremely sensitive. Curves are given showing the behaviour of this as compared with an ordinary bimetallic regulator.—R. **Détrait**: The slip of liquids on the walls of capillary tubes. The flow of two liquids, petrol and water, was studied in tubes of glass, wetted by both liquids, and sulphur, wetted by the petrol only. H. **Parenty**: The reconstitution photographically of certain invisible details of ancient drawings. Lighting in various ways a *Décollation de Saint Jean Baptiste*, attributed to Rubens, the signature *Rubês* appeared, the first two letters in all the negatives, the last three in one or other of them.—Pierre **Weiss**: The kinetic theory of the paramagnetism of crystals.—G. **Friedel**: The general law of the diffraction of the Röntgen rays by crystals.—A. **Perot**: The movement of the light centres in electric discharges in Geissler tubes.—G. **Malfitano** and Mlle. A. **Moschkoff**: The deflocculation of starch and the solution of glucose.—Edouard **Bauer**: 1-Benzoyl-2-phenyl-Δ_1-*cyclo*pentene. With sodium amide this compound behaves similarly to benzophenone, breaking up partially into 2-phenyl-Δ_1-*cyclo*pentene-1-carboxylic acid and benzene and partially into 1-phenyl-Δ_1-*cyclo*pentene and benzamide.—E. **Léger** and Ferdinand **Roques**: Contribution to the study of carpiline or pilosine.—M. **Chaillol**: Researches on the morphology of the bud in Labiates with subterranean stolons.—E. **Boucherie**: The cytological phenomena and sporogenesis in *Barbula muralis*.—M. **Molliard**: Semi-parasitic *Lepidium sativum* produced experimentally.—D. **Chouchak**: The penetration of different forms of nitrogen in plants; adsorption phenomena.—N. **Patouillard**: A conidiferous Septobasidium.—J. M. **Lahy**: The physical signs of professional superiority in dactylographs.—L. **Bordas**: The gizzard of the Dytiscideæ.—A. **Gruvel**: Fishing for the large Cetaceans on the western coast of Africa. The present rate of destruction is so great that an international control is suggested.—Edouard **Chatton**: Spontaneous septicemia due to the cocobacillus in the cockchafer and silkworm. Auguste **Lumière** and Jean **Chevrotier**: The toxicity of antityphoid vaccines. The vaccines studied proved to be very slightly toxic for the guinea-pig.—M. **Dalloni**: The marine Oligocene and its fauna in Algeria.—Alphonse **Berget**: The exact position of the continental pole of the earth.

June 9.—M. F. Guyon in the chair.—E. **Jungfleisch** and L. **Brunel**: The reactions between water and sulphurous acid at varying temperatures. The formation of hyposulphurous acid. Aqueous solutions containing from 20 per cent. to 21 per cent. of sulphur dioxide were heated to various temperatures. At about 150° C. sulphur and sulphuric acid were formed, an equilibrium being reached in twenty days. A study of the reaction at lower temperatures showed that hyposulphurous acid was formed; this then decomposes into sulphur and sulphuric acid.—Prince Albert de **Monaco**: The twenty-fifth scientific expedition (*Hirondelle II.*). Results obtained in the neighbourhood of the Azores and Madeira in the summer of 1912.—Pierre **Duhem**: An elementary remark on the problem of spherical waves.—Paul **Sabatier** and A. **Mailhe**: The use of calcium carbonate as a catalyser of the organic acids and their anhydrides. A column of precipitated chalk, 15 cm. to 40 cm. long, and maintained at a temperature of 450° C. to 500° C., gives a fair yield of ketones when the vapours of the acids are led over it. Acetic acid and propionic acid give very good yields, but there is an increase in the secondary products as the molecular weight of the acid is higher. Benzoic acid gives no benzophenone, but mixtures of benzoic and fatty acids give fair yields of the mixed fatty-aromatic ketones.—A. de **Gramont** was elected a member of the section of free academicians in succession to the late Alfred Picard.—J. **Guillaume**: Observation of the occultation of a star of the eighth magnitude by Jupiter made at the Observatory of Lyons.—J. **Guillaume**: A curious aspect of the third satellite of Jupiter. Instead of the usual round disc the satellite Ganymede presented a gibbous appearance recalling that of Mars at certain periods. Two illustrations of the satellite are given.—L. **Godeaux**: The classification of the involutions of genus 1 belonging to a surface of genus 1.—A. **Buhl**: Formulæ analogous to the formula of Stokes.—Th. **Got**: The fundamental domains of certain Fuchsian groups.—M. **Schwarz** and M. **Villatte**: The first determination of the difference of longitude by wireless telegraphy in western French Africa. The stations were Kissidougou and Conakry.—A. **Magnan**: Data for the construction of an ideal monoplane based on the flight of birds.—M. **Levavasseur** and M. **Gastambide**: An aëroparachute.—Eugène **Bloch**: The principle of an electrostatic motor. An ordinary quadrant electrometer is modified to serve as a motor.—M. de **Broglie**: The diffraction and reflection of the Röntgen rays.—Jacques **Carvallo**: The electrical conductivity of some pure liquids: ammonia, acetone, ethyl and methyl alcohol. The method used was to seal up the purified liquids in glass tubes furnished with electrodes, and apply a constant electromotive force. The liquid is purified by the action of the current, without, however, any electrolytic phenomena being observable, and the current is noted as a function of the time and voltage.—A. **Tian**: The determination of the order of a photochemical reaction. An attempt to elucidate the effect of absorption on the reaction velocity.—Eugène **Fouard**: A law of tonometry and its consequence as regards the ionic theory.—P. **Leroux**: Magnetic study of the constitution of some antimony alloys. Curves are given for the tin-antimony and lead-antimony alloys.—Daniel **Berthelot** and Henry **Gaudechon**: The photochemical synthesis of a new compound, carbon oxycyanide, by means of ultra-violet light. Mixtures of carbon monoxide and cyanogen are acted upon by ultra-violet light of wave-length less than $0 \cdot 25\mu$, the gases combining in equal volumes. The substance formed is gaseous at about 100° C., and solid at the ordinary temperatures. An analysis, combined with a study of the reactions of this compound, shows that it is carbonyl cyanide, $CO(CN)_2$, analogous with carbonyl chloride.—F. **Bourion** and A. **Deshayes**: The quantitative separation of iron and chromium.—H. **Copaux**: The constitution of the para-molybdates and the para-tungstates.—Léon **Guillet**: The transformation points and the structure of nickel-chrome steels.—Jean **Nivière**: The preparation of diglyceric alcohol.—Marcel **Godchot** and Félix **Taboury**: Some derivatives of β-methyl*cyclo*pentanone. The preparation of the monochloro-derivative and some substances obtained from this are described.—A. **Guilliermond**: New observations on the chondriome of fungi.—D. **Chouchak**: The absorption of different forms of nitrogen by plants; the influence of the medium. The absorption of mineral or organic nitrogen by young wheat plants does not depend immediately upon the living material. It is determined by substances which are contained in the roots and which are not removed by boiling water.—R. **Argaud**: A directly excitable endocardiac region.—Jacques **Mawas**: Action of the traction of the zonule on the general configuration of the human crystalline lens. The possibility of flattening the periphery of the crystalline lens during accommodation.—Em. **Bourquelot** and H. **Hérissey**: The biochemical synthesis with the aid of emulsin of a glucoside isomeric with salacin. β-Salicylglucoside.—L. **Cayeux**: The meaning of mineral gravels included in the Hettangian iron deposits of Burgundy.—Jean **Groth**: The southern border of the Iberian Meseta.—Lucien **Mayet** and Joseph **Mazenot**: The discovery of a prehistoric cave of the Aurignacian age at Brancion (Saone-et-Loire). The cave showed three different archæological levels and a fairly uniform fauna of the middle Quaternary.

CAPE TOWN.

Royal Society of South Africa, April 16.—The president in the chair.—Miss E. L. **Stephens**: A new species of Hæmatoxylon (Leguminosæ-Cæsalpineæ) from Great Namaqualand. The discovery of a South African species of Hæmatoxylin is of particular interest, as the genus has hitherto been represented only by one species—*H. campecheanum*, L., the log-wood tree, a native of Mexico, Central America, the northern parts of South America, and the West Indies. The species here described was found among rocks near Holoog, in Great Namaqualand, by Dr. H. H. W. Pearson, in February, 1909, during the Percy Sladen Memorial Expedition in South-West Africa, 1908–9. It is a shrub, 1–1·5 metres high, and it differs from *H. campecheanum* by its shrubby habit, its more or less pilose and glandular young parts and inflorescence, its smaller leaves, its longer flowered and terminal inflorescence, its bilabiate calyx, and its longer petals and stamens. On a more recent expedition, Dr. Pearson has obtained some wood of this species, which has yielded the characteristic log-wood dye.—G. **Rattray**: Notes on the pollination of some South African Cycads. *Encephalartos Altensteinii*, Lehm., is pollinated by insect agency, the pollen bearer being a weevil belonging to the genus Phlæophagus. Anemophily may still occasionally occur in this species. *E. villosus*, Lehm., from its habitat and cone structure, appears to be exclusively entomophilous. No evidence of entomophily has been found in *Stangeria Katzeri*, Rgl.—R. A. **Dümmer**: A synopsis of the species of Lotononis and of Pleiospora.—T. **Muir**: Note on an overlooked theorem regarding the product of two determinants of different orders.—R. T. A. **Innes**: Note on the Newcomb operators used in the development of the perturbative function.

ORGANIC CHEMISTRY IN MANUFACTURES.

Industrial and Manufacturing Chemistry, Organic. A Practical Treatise. By Dr. Geoffrey Martin. Assisted by Wm. Barbour, T. Beacall, and others. Pp. xx + 726 + plates. (London: Crosby Lockwood and Son, 1913.) Price 21*s.* net.

THE editor of this volume has set himself a rather formidable task. His aim has been "to cover the whole range of subjects," based on organic chemistry, with which the industrial chemist and the manufacturer are usually concerned. In pursuance of this aim the book is arranged with the intention of meeting "the requirements of all business and practical men interested in chemical processes"; and the list of these given includes "manufacturers, consulting chemists, chemical engineers, patent workers, inventors, technical lawyers, students in technical institutions, lecturers on technology, fire insurance inspectors, and others." This is a somewhat motley crew to cater for; but a good attempt has been made to do it, and on the whole a successful one.

The text is divided into twenty-three sections, each dealing with one branch of chemical industry —*e.g.* the sugar industry, the cellulose industry, and so on. With so large a number, even in a work of 700 pages, there could be no such detailed and comprehensive treatment of the subjects as is found in works devoted to only one or two— as, for instance, Lunge's treatise on coal-tar and ammonia. Nevertheless, the volume is not a mere dictionary. Space for detailed discussion and for chemical formulæ, even complicated structural formulæ, is not begrudged (see, for example, the chapter on synthetic dyes); and there are plenty of diagrams and photographs.

A number of experts have collaborated with the editor in the production of the book, and contribute authoritative articles on their special subjects. A very good list of references to the literature of each branch is supplied; this will often be a valuable help to users of the book. Statistics of production, value, imports and exports are given, and frequent references to patents. Furthermore, it is claimed that much of the information respecting the processes is now published for the first time, many descriptions of methods and modern plant having been privately supplied.

As a typical section dealing with well-established manufactures may be instanced that devoted to the fermentation industries. In about 100 pages this gives a good condensed account of enzymes and ferments, and of their applications to the production of wine, beer, alcohol, vinegar, lactic acid, and butyric acid. It includes an article on modern distilling plant, in which the principles of the "continuous" stills are lucidly explained, and illustrated with photographs and lettered diagrams. A subsection of different type is that on the new industry of synthetic rubber. Here the descriptions are largely given by means of chemical formulæ; apparatus is represented by a small form of chlorinating still only. The various methods of obtaining butadiene and its homologues (for example, from butyl alcohol, petroleum, aldehyde, phenol, acetylene, turpentine, starch, or acetone) are explained at some length, together with the processes of polymerising the products to form synthetic rubber.

In addition to the larger industries dealt with— sugar, oils and fats, dyes, explosives, coal-tar products, and so on—there are articles devoted to smaller branches such as inks, glue and albumen, synthetic drugs, and photographic chemicals. The author directs attention to minor industries on account of their potential importance in some cases as the germs of future large undertakings, remarking that they often afford through absence of competition larger profits than those of fully-developed manufactures.

The impression gained on reading through a number of the sections is that a very good outline of the subject is presented, but one that would often want filling up. Looking at the work for a moment from the point of view of a young chemist who contemplates taking up some branch of chemical technology, one may say that the descriptions would serve as an excellent introduction, and the list of books indicated would show him where to supplement his knowledge to any extent he might require.

Very few slips of importance have been noted. There is an error on p. 281, where the composition of "industrial methylated spirit" is given quite wrongly. Such phrases as "the majority of the vinegar" (p. 315), "the great majority of the formaldehyde" (p. 375), "potato manufacturers" (p. 176) are rather slipshod; and it should surely be unnecessary (p. 638) to explain 0·023 as "($\frac{23}{1000}$)." Nor was it really necessary to tell readers four times on the same page (314) that the fusel oils obtainable by Fernbach's fermentation process can be produced at 35*l.* to 45*l.* per ton.

C. S.

THE ANIMALS OF THE ANCIENTS.

Die antike Tierwelt. By Otto Keller. Zweiter Band: Vogel, Reptilien, Fische, Insekten, etc. Pp. xv+618+2 plates. (Leipzig: W. Engelmann, 1913.) Price 17 marks.

EVERYONE interested in the identification of the species of animals known to the ancients should be grateful to Dr. Keller for carrying to completion an exceedingly laborious task, the difficulties and perplexities of which can only be realised fully by those who have essayed investigations of a kindred nature. Exception may indeed be taken to some of his conclusions—as was pointed out in our review of the first volume—but the general results of the work are of the highest value and importance, and form a solid foundation on which superstructures may be laid later.

As the first volume was devoted solely to mammals, all the other groups of animals have had to come in the one now before us. Anything like a detailed review of such a work is manifestly impossible in the space at our disposal, and it must consequently suffice to refer to a few points of special interest. Among such is the statement that the golden pheasant, which was occasionally brought from China to ancient Greece and Rome, was identified, doubtless on account of its rarity, with the mythical phœnix (*phoinix*) of the Egyptians. And this leads to the query whether there is any connection between phœnix and Phœnicopterus (*phoinikopteros*), the name of the flamingo, and between both and Phœnicia—the land of the palm-tree (*phoinix*).

Dr. Keller has, of course, much to tell us about snakes, and it is interesting to note that, in addition to the cobra and the horned viper, he has been able to identify the Æsculapian snake among the species familiar to the ancients. Incidentally it is mentioned that viper (Vipera) is an abbreviated form of *vivipera,* that *aspis* comes from *sepa* (doubtless connected with *seps*), the name of a very poisonous snake; and that *coluber* and *colubra* are derivates from *scolopendra,* a name now assigned to the centipedes. The blind-snake (Typhlops) of the ancients appears to have been the amphisbæna, and not the wormlike species now classed under the former name. Crocodile (or "korkodile") appears to have been used in early days in a more elastic sense than at present, having been applied, with the prefix "land," to the great monitor-lizards, as well as to the animals to which it rightly pertains.

From the section on insects we learn, with regret, that the *melolontha* of Aristotle is neither the cockchafer nor the rose-chafer, but, as demonstrated by the statement that its grubs feed on dung, the dor-beetle, and therefore a near relative of the sacred scarab, of which a full account is given. Did space permit, we would fain quote the author's observations on the pearls and pearl-fisheries of the ancients, particularly the famous pearls of Cleopatra; but as it is, we must refer the reader to the book itself, which is a very mine of etymological and antiquarian information.

R. L.

MOSQUITOES.

The Mosquitoes of North and Central America and the West Indies. By L. O. Howard, H. G. Dyar, and F. Knab. Vol. i., pp. vii+520. Vol. ii., pp. x+150 plates. (Carnegie Institution of Washington, 1912.)

IT is with pleasure that we are able, at last, to announce the appearance of this work. Its publication was expected some few years ago, but, as stated by the authors in their introduction, the material accumulated at this time was by no means complete, and, in order to enhance its value, investigations were continued over a considerably extended period.

Under the title of "A General Consideration of Mosquitoes, Their Habits and Their Relationship to the Human Species" we have in vol. i. a very comprehensive work relating to the subjects under this heading. At the outset, however, we regret to note that the well-known scientific names of two common disease-bearing forms have undergone drastic treatment—*Stegomyia fasciata,* Fabr., being referred to as *Aëdes calopus,* Mg., and *Culex fatigans,* Wied., as *Culex quinquefasciatus,* Say. It is indeed unfortunate that this should be the case with these important species, as much confusion inevitably arises, and it is a question whether, as regards the specific names, the law of priority should be so rigidly adhered to in such circumstances. The validity of the genus Stegomyia is a point for the systematist to decide, but at present its abolition appears to be somewhat premature. The authors direct attention to these changes, and also state that *Anopheles maculipennis* is confined to the Old World, and does not occur in America, the form previously known under this name not being referable to the species, and, in fact, comprising two distinct species, viz. *A. quadrimaculatus* and *A. occidentalis.*

The text very suitably opens with an interesting résumé of the earlier literature and work concerning these insects, and is followed by some eighty pages relating to the morphology of the adult and other stages in the life-cycle. This is entered into in detail, and includes an extensive account of the thoracic structure of the adult; it also contains extracts from numerous workers, and, owing to the limited time available, the portion relating to the internal anatomy has been taken entirely from Stephens and Christophers's work on malaria, &c. The bionomics and natural enemies are next considered, and prove extremely interesting and instructive, much original work having been performed, especially in connection with the former subject. A few pages on technique follow, and we then reach the part dealing with the relation of mosquitoes to man. This, of necessity a somewhat lengthy contribution, covers some 130 pages, and deals successively with the carrying of disease by mosquitoes in general, malaria, yellow fever, dengue, filariasis, suggested relations with other diseases, and the effect of mosquito bites.

Under malaria an account is given of the organisms concerned in its production, and of the demonstration of its carriage; thirty-three species of Anopheles, some of doubtful validity, being cited as transmitters. The general biology of the Anopheline mosquitoes is also satisfactorily dealt with, and the section concludes with reference to the distribution, appearance, and disappearance of the disease. Yellow fever is treated on similar lines, the bionomics of the mosquito, under the name of *Aëdes calopus*, being considered in great detail. As regards filariasis, fourteen species are enumerated, and have apparently been directly incriminated as transmitting agents.

More than one hundred pages are devoted to the consideration of economic loss from mosquitoes, the subject being discussed in relation to disease, real estate, and agriculture. Under this section, too, we find references to the flight and transportation of these flies, and lastly an exhaustive treatise on protective and remedial work in connection with mosquitoes generally. The volume concludes with numerous examples of mosquito control and an extensive bibliography.

Vol. ii. is devoted exclusively to plates. These deal with the structure of the male genital organs of a large number of species, the wings of certain Anophelines, and the earlier stages in the life-cycle. Illustrations are given of numerous species of larvæ, including no fewer than fifty-nine plates relating to their detailed structure. Many of the plates are beautifully executed, and the authors are to be congratulated upon the production of this volume, which points out very clearly the large amount of original work performed.

The work will undoubtedly prove a most valuable addition to the literature of the subject, and will be heartily welcomed by all who are interested in these noxious insects.

TWO FRENCH MATHEMATICAL BOOKS.

(1) *Notions de Mathématiques.* By Prof. A. Sainte-Laguë. Avec Préface de Prof. G. Kœnigs. Pp. vii + 512. (Paris: A. Hermann et Fils, 1913.) Price 7 francs.

(2) *Propriétés Cinématiques Fondamentales des Vibrations.* By M. Guillet. Notes de Dr. M. M. Aubert. Pp. 405. (Paris: Gauthier-Villars, 1913.) Price 16 francs.

(1) THE development of mathematical teaching in this country has been greatly influenced during the last decade by foreign methods. For this, if for no other reason, English teachers will do wisely to watch the evolution of these methods, and this can most easily be done by studying the tendencies of recent text-books.

M. Sainte-Laguë's work on the elements of mathematics is one which will repay such study. Unlike the majority of school-books dealing with this subject, it is not intended for the beginner, but aims at giving a condensed account of results and processes essential to those who have to use mathematics in simple practical applications.

The book is divided into four parts, devoted respectively to arithmetic, algebra, trigonometry, and geometry. Those principles which are continually used in practical applications are kept to the front, and exercises which merely require skill in manipulation are generally excluded. Thus the algebra contains no reference to permutations and combinations, and the binomial and exponential theorems are left to a more advanced stage. On the other hand, the use of logarithms and of the slide rule is explained, and the section on arithmetic contains a valuable chapter on errors and approximate calculations.

It is remarkable that, although the derived function is used and defined, no use is made of the classical notation of the differential and integral calculus. In the section on trigonometry the discussion of the inscribed and circumscribed circles is omitted, and the solution of triangles is compressed into a very few pages. One or two results of spherical trigonometry are included.

The book works throughout in *grades,* instead of degrees; to the English reader this will certainly prove a stumbling-block. The grade has never won recognition outside France, and has not displaced the degree for astronomical purposes.

The section on geometry is the longest in the book. Space geometry is introduced very early. The method of superposition is employed throughout, and the theory of parallels is based on the notion of the motion of translation of a rigid body. Although, according to the best authorities, this may be faulty from the logical point of view, it is probably psychologically sound. There are also chapters on graphical constructions, on plan and elevation, and on contour lines. The work concludes with a section on kinematics. A good set of graduated examples, together with numerical tables and formulæ, will be found at the end.

(2) M. Guillet's book on vibrations is of the nature of a monograph in which the mathematics of "small oscillations" have been collected and classified, with numerous illustrations taken from the theories of light, sound, and electromagnetism.

The whole is a reprint from notes taken by Dr. M. M. Aubert of lectures given in the University of Paris by the author. The first part of the book deals with the theory of simple harmonic motion, free and damped. Several chapters are devoted to the composition of such motions, of plane and elliptically-polarised vibrations, and to phenomena of interference. A number of examples of the calculation of differences of path are given, having special reference to well-known problems of diffraction.

The second part deals with the propagation of waves in elastic solids and fluids. The author establishes the equations of equilibrium and small motion of an elastic solid, and deduces solutions of the problems of flexure and torsion in the simplest cases. He considers the propagation of dilatational and distortional waves in elastic media, and also the vibrations of rods and wires.

The book concludes with a consideration of the elastic-solid theory of the luminiferous æther, the elastic constants being adjusted to give Lord Kelvin's well-known "contractile" æther; certain vectors found are then interpreted in terms of the electromagnetic theory.

A work of this nature, which touches upon a number of different theories, is always liable to fall into the defect of "scrappiness," and it cannot be said that the present volume altogether escapes this reproach; it is, however, both instructive and stimulating, and contains a great deal of valuable information—information which is usually widely scattered, and therefore largely unavailable for the learner. In this sense the book supplies a distinct want. L. N. G. F.

OUR BOOKSHELF.

Abhandlungen und Vorträge zur Geschichte der Naturwissenschaften. By Prof. E. O. von Lippmann. Zweiter Band. Pp. x+491. (Leipzig: Veit and Co., 1913.) Price 8 marks.

PROF. VON LIPPMANN presents in this volume a second collection of the valuable historical studies which he has contributed to *Chemiker-Zeitung* and other periodicals. The articles are thirty-six in number, and, like those published in the former volume, range over the whole history of chemistry. They exhibit the author as a man of wonderfully wide learning and remarkable security of scholarship.

The studies are divided into eight sections upon a chronological basis. The first section contains an analysis, from the point of view of chemical knowledge, of the famous medical papyrus, of the sixteenth centry B.C., discovered by Ebers at Luxor. A second article, on the term "caput mortuum" (=iron oxide), throws interesting light upon the mystical interpretations of chemical phenomena which originated, like the "black art" itself, in Egypt. The second section deals with Greek and Hellenistic chemistry. Here, as is fitting, Plato and Aristotle have the pride of place, the great achievements of Aristotle receiving particularly careful attention. A short note upon Archimedes's method of determining specific gravity leaves the "eureka" story unassailed in principle, but proves that the "crown" of Hiero was really a golden wreath. On the other hand, the author robs that early precursor of Mme. Curie, the alchemist Maria (possibly of the first century A.D.), of the credit of inventing the water-bath ("balneum Mariæ") and Papin of his "digester," showing that the former was known before Aristotle and the latter in the third century A.D. These two destructive articles illustrate very well Prof. von Lippmann's encyclopædic knowledge of the literature of his subject. Among the most interesting of the later articles are those on the chemical names used by Marco Polo, on J. J. Becher's observations anticipatory of Mendel and De Vries, on Jean Rey, on the word "gas," which van Helmont is declared to have adopted from the "chaos" of Paracelsus, and on E. C. Howard, the inventor of the vacuum apparatus for sugar-refining. But the author has touched no subject which he has not adorned.

Mineral and Aërated Waters. By C. Ainsworth Mitchell. Pp. xiii+227. (London: Constable and Co., Ltd., 1913.) Price 8*s*. 6*d*. net.

THE author takes us back to the beginnings of the mineral-water industry by interesting descriptions of natural mineral springs, spas, and holy wells; for it was from the first attempts to copy the actual or supposed healing virtues of such waters that the extensive manufacture of mineral waters began, developed, and expanded into the great industry of to-day. The analyses of the more famous natural waters are given in the first part of the volume, devoted to the history of the subject, and perhaps the most striking feature of this history is the changed aspect of current belief in the efficacy of such waters by the known presence of radio-active substances contained in some of them. The chemical constituents being accurately known, a natural water can be produced in the laboratory, but, as is frequently asserted, without the therapeutic action of the natural product. The author states, however, that "recently bottles of special construction, containing artificial radio-active mineral waters, have been put upon the market in Sweden."

The methods of qualitative and quantitative analysis employed by the chemist are not included, since there is nothing specially applicable to this particular industry in them. The historical account of the apparatus devised for the purpose of aërating natural water by carbon dioxide is an instructive example of the slow and gradual stages required to effect a comparatively simple process. From the first experiment of Bergmann in 1770 the invention and elaboration of apparatus for aërating and bottling has extended, and the latter half of the book is devoted to descriptions of the machines employed to-day. The commercial production of liquid carbon dioxide has simplified the process, and most ingenuity is centred upon the charging and bottling machinery and the gas-tight fastenings. The description of the machinery is somewhat superficial, and is the least effective part of a commendable work. The examination of mineral waters for bacteria and metallic contamination is of special interest in view of the various containers for such waters on the market.

Vorlesungen über allgemeine Histologie. By Prof. Alexander Gurwitsch. Pp. v+345. (Jena: Gustav Fischer, 1913.) Price 11 marks.

Prof. Gurwitsch's work is not a text-book of histology in the ordinary sense. It is arranged in the form of a series of lectures, in which the subject is dealt with not as an end, but as a means to the solution of the wider problems of biology; a good deal of space, for instance, is taken up with a discussion of the meaning of heredity. The lectures, written as they are from a critical and philosophical point of view, are full of interest, and examples are taken from every branch of the kingdom of life to illustrate the subject. The drawings of microscopic appearances which beautify the text are numerous, well selected, and well executed. W. D. H.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

Submerged Valleys and Barrier Reefs.

In a letter on "Dana's Proof of Darwin's Theory of Coral Reefs," published in Nature for April 3, Mr. Cyril Crossland points out that "land valleys which extend beneath the sea are not always proof of subsidence. Such valleys, like coral reefs, may owe their existence to different factors in different cases." He adds that certain harbours on the east coast of Africa "are the high parts of submarine fault valleys," which, although they simulate embayments produced by the general depression and partial submergence of a dissected coastal region, really result from the local depression of fault blocks, and hence cannot be taken as evidence that any coral reefs which may occur near them have been built up during a period of submergence.

There can be no two opinions on this point; but the discussion of fault-block depressions is aside from the problem involved in Dana's proof of Darwin's theory, which is concerned with valleys of erosion. To imply that an argument which involves only such valleys is vitiated because some "land valleys" are due to down-faulting or other causes is unwarranted. If "land valleys" due to faulting were called "troughs" instead of "valleys," their irrelevance would be more apparent.

Some of the harbours on the Red Sea coast, mentioned by Mr. Crossland as due to down-faulting, are regarded by Mr. John Ball as partly submerged valleys of normal erosional origin above sea-level; so he states in a letter which appeared in Nature for May 22. Which of these two opinions is the correct one may be best left to observers on the ground, as neither of the writers here cited adduces detailed evidence to support his conclusion. Mr. Crossland's remarks on the relation of certain coral reefs to abrasion I will not discuss here, because, probably on account of the brevity of his note and the lack of explanatory diagrams, his meaning is not clear to me. But his statement that "land valleys which extend beneath the sea are not always proof of subsidence" calls for comment, because it indicates a misunderstanding of the question at issue.

The embayments considered in my article on "Dana's Proof of Darwin's Theory of Coral Reefs," published in Nature for February 6, were not such as occupy down-faulted troughs, or over-deepened fiords of glacial origin, neither of which indicate subsidence of their region, but only such as occupy valleys of normal erosion; that is, valleys which have been excavated by the ordinary processes of subaërial weathering and washing, and can therefore have originated only on land above sea-level. The peculiar and essential consequence of Darwin's theory, which remained unnoticed by its author, is the invasion of the previously eroded normal valleys of a dissected and subsiding coast by the sea; and the whole point of the long-neglected confirmation of Darwin's theory lies in the evidence that Dana gave to the effect that the drowned valleys of the Pacific islands had been formed by the action of land waters above sea-level before they were drowned, and not by any other process, such as down-faulting or glacial erosion, or by marine erosion, as Darwin apparently thought. Hence, interesting as are the complications which Mr. Crossland mentions, they do not touch the question in discussion, which has to do, not with shore-line embayments of whatever origin, but with embayments of a highly specialised kind, occupying valleys of normal erosion. So far as the evidence of the Admiralty maps and of various recent observers goes, the embayments of the central islands enclosed by barrier reefs in the Pacific are practically all of this highly specialised kind; the occurrence of other kinds of embayments elsewhere is no more relevant to the case than the occurrence of upraised platforms of marine erosion.

The real point raised by Mr. Crossland's letter is the possibility of distinguishing between embayments of different origins. I cannot accept his opinion that embayments which occupy troughs produced by locally down-faulted blocks simulate embayments formed by the submergence of normally eroded valleys, unless in a very rough manner, from which no confusion should arise. Even if the two kinds of embayments do in some superficial manner simulate each other, they can be distinguished readily enough. A normally eroded main valley is joined by branch ravines and side valleys, all systematically related as parts of a valley system; they may have young, mature, or old forms, according to their stage of development. Submergence of a main valley must therefore produce an indented or branching embayment, like the "rias" of north-western Spain or the drowned rivers of Devonshire-Cornwall. A down-faulted trough must at first be bordered by escarpments of simple pattern; the escarpments will gradually be dissected by ravines and valleys, but these cannot be eroded beneath sea-level; hence the arm of the sea that takes possession of such a trough cannot have lateral branches or indentations, unless the sides of the trough as well as the trough block itself suffer depression—that is, unless regional depression takes place. Likewise, a coastal valley may be occupied and over-deepened by a glacier, and invaded by the sea after the glacier withdraws, thus producing a fiord; but a fiord can be easily distinguished from a drowned fault trough or from a ria. Evidently, then, in applying Dana's proof, it is essential to see that glacial fiords and fault troughs are not confused with normal valleys; and it still appears to me that my article of February 6 made it clear that only normal valleys were under consideration.

A few words as to terminology. Various popular terms, like "fish" and "valley," which entered our language in a pre-scientific period, have to-day two meanings; first, their original general meaning, and second, a later acquired and more precisely limited scientific meaning. "Fish" originally meant an animal living in the sea, and included whales and oysters. The latter are still known as shellfish, and a certain kind of whale is still named blackfish; but under the influence of scientific zoology whales are now classed by most persons not with fish but with mammals. So with "valley"; the original meaning of the word is simply an enclosed lowland, more or less elongated, of whatever origin, and this vague meaning is still in common use, as in naming the valley of the Wye, purely the work of normal erosion; the valley of the Ticino, greatly modified by glacial erosion; the valley of the middle Rhine, a fine example of a down-faulted trough; and the valley of California, a broad and relatively shallow down-warp. But "valley" has also been used, since the time of Hutton and Playfair, in the scientifically limited sense for forms of normal erosion under the action of rain and rivers; and when thus used it implies an origin above sea-level, as well as the systematic arrangement of certain significant features, such as slope of stream line, manner of junction of tributary and main valleys, and so on, by which the normal origin of a valley may be easily recognised. The Norwegian term "fiord" (fjord), and the Spanish term "ria," both locally used without scientific definition or implication of origin for the sea-arms that they designate, have in recent years both been given a more limited meaning in scientific geographical literature. It was only, as the context shows, in the scientific sense of a form of normal erosional origin above sea-level that the term "valley" was used in my article; and manifestly it is only to coasts which exhibit branching or indented embayments, such as were shown in the middle block of my diagram, and such as are caused by the submergence of true valleys of erosion, that Dana's proof of Darwin's theory applies.

Uniformity in Radio-active Nomenclature.

IN a letter to NATURE of June 5, Mr. W. H. Ross and Mr. H. J. Creighton point out the present want of uniformity in radio-active nomenclature, and suggest that some definite system should be adopted by all writers on this subject. Every worker in radioactivity recognises the importance of some agreement in regard to this matter. It is difficult, however, for a single individual to suggest a scheme which would be likely to gain universal support. The only international body existing at present which is in a position to deal with such a question conveniently and expeditiously is the International Radium Standards Committee. The constitution of this committee is fortunately very suitable for the consideration of this question, as it comprises about an equal number of physicists and chemists representing five nations. As president of the International Committee, I should be glad to bring the matter to the attention of the other members, and will do so if there is no objection to this proposal. E. RUTHERFORD.

Radio-activity and the Age of the Earth.

MR. HOLMES, in his interesting letter in NATURE of June 19, brings out the embarrassments in which the superabundance of radio-activity in the accessible crust of the earth and the enormous antiquities deducible therefrom have plunged physics. His explanation is that since the earth as a whole cannot be as radioactive as the crust, without liquefying, there cannot be as much radium in it as might be inferred from the samples we can take, and that its "heavy metallic core" must be "completely destitute of radium." This, however, involves the improbability that the heaviest metal of all, uranium, has not gravitated to the "metallic core," and does not explain why this core should be destitute of radio-active substances.

It may be pointed out, therefore, that the whole reasoning rests on an assumption to which alternatives might be considered. It is assumed that the dissociation of uranium has been proceeding always and everywhere at the rate we can now observe on the earth's surface. But it is possible that under the physical conditions obtaining in the interior uranium does not dissociate, or does so much more slowly. It is even possible that it has not always proceeded at this rate in the past. Radio-activity may be an acquired habit of the substances that exhibit it.

There is no scientific objection to the suggestion that the existing "laws of nature" are not immutable but "evolving," beyond the methodological inconvenience that this would greatly complicate our calculations and detract from the exactness of our predictions. But of improbabilities, as of evils, we must always choose the least. F. C. S. SCHILLER.

Corpus Christi College, Oxford, June 23.

Pianoforte Touch.

THREE variables appear to be possible in pianoforte touch, namely:—

(1) The energy of the blow of the hammer.
(2) The duration of contact of hammer with wire.
(3) The resonance of the woodwork.

Of these, (1) will be admitted by everyone; (3) should be in abeyance as much as possible, since it is brought into evidence chiefly when the key is struck too hard—beyond the capacity of the wire for harmonic response. But the mechanism of some pianos (even by first-class makers) is so resonant that a "xylophone" effect is only too easily produced. This effect evidently has its admirers, being cultivated by performers as well as ministered to by piano-makers.

(2) Is assumed by many persons; but the possibility is doubted by others, because the player cannot hold the hammer in contact with the wire. The hammer, as mentioned by Prof. Bryan, is disconnected from the key, so that at the time of striking the wire it is a projectile.

At some point in the mechanism, between the key and the hammer, is an arrangement called the "escapement," which disconnects the key from the hammer when the player's touch is so deep or firm as to cause the risk of blocking; but when his touch is shallow the escapement is scarcely brought into action.

In the upright pianos of fifty years ago the hammer was hinged on to a vertical rod called the "hopper" or "sticker," which pulled it back with a variable force, the escapement being *below*, between the hopper and the key. With a shallow touch in such an instrument it is just possible to avoid bringing the escapement into action, and thus not to hasten the return of the hammer, but the effect is decidedly difficult to produce, and the mechanism has become obsolete owing to its unsatisfactory working.

In modern uprights the hammer is more free, for the escapement is *a stage higher*, between the hammer and the hopper; a piece of tape passing from the hammer to the hopper exerts an elastic pull on the hammer, assisting gravity in causing the return of the hammer, but only when the key is released.

In the grand piano the hammer is left as independent as possible, so as to ensure rapid repetition; and I have not yet found or read of a horizontal action in which any accessory mechanism can influence the return of the hammer. Therefore in the horizontal piano (and probably in the ideal upright) the hammer at the moment of hitting the wire is an unencumbered projectile, and the variables (1) and (2) are not separable.

It should be remembered that *staccato* and *legato* effects are functions, not of the hammer, but of the damper. But after all, the most important element in a good touch is the player's ability to strike the different notes in chord with different intensities. The artist instinctively gives their relative importance to the various notes of a chord as surely as to those of a melody; and this is one of the features which distinguish him from the mere executant or the most perfect player-piano. F. J. ALLEN.

Cambridge, June 10.

A Mechanical Vacuum-Tube Regulator.

THE mechanical vacuum-tube regulator, in which the position of a movable glass sheath relatively to the kathode determines the speed of the kathode rays, mentioned in NATURE of June 19 (p. 415) as recently brought before the Cambridge Philosophical Society by Mr. R. Whiddington, is not new, Mr. J. C. M. Stanton, Mr. H. L. T. Wolff, and myself having, in 1898, devised a similar arrangement, which is described and illustrated in the discourse which I gave at the Royal Institution in that year.

We had previously shown, in a Royal Society paper read in 1897, that the speed of the kathode rays is increased by diminishing the size of the kathode itself, and what is new and interesting is Mr. Whiddington's discovery that the mechanical regulator operates by reason of the effective size of the kathode being diminished owing to the electrostatic repulsion of the rays by the negatively charged glass sheath.

The Crossing of Water by Ants.

IT may not be new to observers of animal life, but I have been much interested in watching the common house ant here. We have an American fly-trap: the sugar was one day covered with ants, so I placed the trap on a finger-bowl standing in a plate of water. The ants, when they came to the edge of the water, ran round the bowl until convinced there was no way across, and then calmly "took to the water," and ran across it by aid of surface tension without getting their feet wet. Having presumably been home to the nest, they returned for more sugar, crossing in the same way, and this went on regularly, a steady procession crossing the water.

JOHN C. WILLIS.

Jardim Botanico, Rio de Janeiro, June 4.

ETHNOGRAPHICAL WORKS.[1]

(1) THIS magnificent monograph of the races of Borneo, by Dr. Hose and Mr. McDougall, illustrated by an unrivalled gallery of artistic views, covering the life of the natives of that island from the swinging-cot to the grave, will be welcomed with enthusiasm by all classes of readers. The ground had indeed to some extent been prepared by the publication in 1896 of Mr. H. Ling Roth's "Natives of Sarawak and British North Borneo," which actually contained (i., 37), seventeen years before the appearance of the present work, a "List of Tribes in Borneo," specially prepared by Dr. Charles Hose.

The book before us is a singularly happy example of joint authorship. Dr. Hose, with his record of twenty-four years' service and priceless experience under the Sarawak Government, supplemented (as he tells us himself) by his travels in other parts of Borneo, the neighbouring islands of the Archipelago, and the Malay Peninsula, was, indeed, more than ordinarily fortunate in securing a collaborator whose special qualifications as reader in mental philosophy at Oxford were crowned by his experience in the field as a member of Dr. Haddon's famous expedition to the Torres Straits and Borneo in 1898. The chief cornerstone of the book is, of course, the invaluable classification (ii., ch. xxi) of the tribes of Borneo, which is supplemented by an admirable appendix on the statistics and comparative literature of the same subject by Dr. Haddon, who correlates so far as possible the ethnological work of the best Dutch authorities. The classification in the text, described (ii., 224) as resting only "on a slight basis," gives us the mature views of Dr. Hose's unequalled experience, and satisfies us that the foundations of anthropological science in Borneo have here, once for all, been "well and truly laid."

Excluding the coastwise "Malays," the authors recognise six main ethnic groups, viz., Kayans, Kenyahs, Klemantans, Muruts, the nomadic Punans, and Ibans, or Sea "Wanderers," commonly called "Sea Dayaks." But since (ii., 245) both Kenyahs and Klemantans are "sections of the aboriginal population of nomadic hunters (Sc. Punans) who have absorbed Kayan culture," these six clearly represent but four original stocks, viz., Kenyah-Klemantan-Punans, Kayans, Muruts, and Ibans; and this agrees with the statement made elsewhere that "the present population of the island is derived from four principal sources," the last three being regarded by the authors as later immigrants.

The members of the first group are identified as "Indonesians," that much-misused term which, as

[1] (1) "The Pagan Tribes of Borneo." A description of their Physical, Moral, and Intellectual Condition, with some Discussion of their Ethnic Relations. By Dr. Charles Hose and William McDougall, F.R.S. With an Appendix on the Physical Characters of the Races of Borneo, by Dr. A. C. Haddon, F.R.S. Vol. i., pp. xv+283+143 plates. Vol. ii., pp. x+374+211 plates+4 maps. (London: Macmillan and Co., Ltd., 1912.) Price 42s. net. 2 vols.

(2) "In the Shadow of the Bush." By P. Amaury Talbot. Pp. xiv+500+plates+map. (London: W. Heinemann, 1912.) Price 18s. net.

(3) "Monumental Java." By J. F. Scheltema. Pp. xviii+302+xl plates. (London: Macmillan and Co., Ltd., 1912.) Price 12s. 6d. net.

defined by the authors, means a predominantly "Caucasic" (and dolichocephalic) race modified by Mongol admixture, the latter strain supplying an element which, as the authors remark (ii., 228), has been wrongfully ignored by some writers. The second main stock is the brachycephalic "Malayan" or "Southern Mongol" element, called "proto-Malays" both by our authors and Dr. Haddon. This element is described (ii., 229) as "a blending of the Mongol stock (or of a part of the Indonesian race) with darker" proto-Dravidian stock, "of which the Sakai of the Malay Peninsula (and perhaps the Toala of Central Celebes) seem to be the surviving representatives in Malaysia." Thus the chief factors in the population are due to varying blends of two main stocks, the one Indian, the other Mongolian, these elements agreeing with those that are found, though quite differently blended, on the neighbouring mainland of Asia. Yet the negrito element, which occurs both in the Malay Peninsula and the Philippines, seems now to be in total default in Borneo, and of Melanesians, according to Dr. Haddon, there are also no traces. It should be noted that Dr. Haddon (ii., 313) regards the Punans and Kenyahs as "mainly proto-Malayan in origin," whereas the authors classify them definitely as Indonesians.

FIG. 1.—Youthful Sea Dayaks in gala dress. From "The Pagan Tribes of Borneo."

It would take many pages of NATURE to do full and adequate justice to all sections of this book. A veritable museum of Bornean ethnology, its cases contain, as in the matter of the Kayan headhunting cult (the stupid European exaggerations about which receive satisfactory castigation, i., 76), weird forms of burial, *tatu* rules, strange forms of spirit-worship and possession, and so forth, many of the most suggestive specimens of modern race-lore.

We may conclude with an item of personal interest in reference to totemism. In vol. ii. (p. 112 and footnote) Messrs. Hose and McDougall, boldly heterodox, avow and give reasons for their belief in the possibility of deriving the clan totem from that of the individual. Upon this very point Mr. Lang, in 1908, remarked to the present writer: "I am unable to conceive the reason, when everybody has his own *ngarong*, which he has not hitherto bequested, for a rule that Mary's or Jane's *ngarong* must for ever belong to her descendants. . . . Given the individual with his *rapport*, no one has shown how it became hereditary, in the female line, at a time, too, when the man's children (or the woman's) had also *their* individual *rapport*."

The writer of the words just cited *silet*, alas, *aeternumque silebit*, but the controversy continues, and it should, perhaps, in justice be conceded that the case made out by Messrs. Hose and McDougall is, so far as it goes, a strong one. It would have been interesting if they could have told us of any communities where the children were regularly named after plants or animals, or other natural objects. We must not, however, be led into a discussion on the origin of totemism, which is too large a question to discuss here, and must therefore recommend the authors' views to the attention of the advance guard of totemic experts.

(2) Mr. P. Amaury Talbot's "In the Shadow of the Bush" gives us an intensely vivid and illuminating picture of the Ekoi, a semi-Bantu people of the south-east corner of Nigeria, a region that recalls the mingled mystery and horror of—

> Enter these enchanted woods,
> Ye who dare. . . .
> Thousand eyeballs under hoods
> Have you by the hair!

Here all is blasted by the terrible blight of negro witchcraft. Indeed, the attention will doubtless be immediately riveted by the account of the Human Leopard and Alligator Societies (first revealed to most Englishmen by the writings of the late Mary Kingsley), the late (1912) activity of which recently drove the local Government to action and provoked an interchange of questions in the Imperial Parliament.

Ethnography in the widest sense, linguistics (especially on the Bantu affinities of Ekoi and on its secret signary, "Nsibidi"), folklore, native art, even archæology, all these, with much valuable natural history, go to make up a fascinating volume full of direct and irresistible appeal. The achievement is worthy of one who, besides his administrative experience, can claim to have made history in companionship with the late Boyd Alexander.

(3) The record of official ineptitude and rapine pictured in Mr. Scheltema's erudite and enlightening "Monumental Java" is almost incredible. Thus (p. 240) Mr. Scheltema, with biting sarcasm: "We are told in legendary lore of statues which flew through the air . . . dissolving into space; the statues of the Boro Budoor developed that faculty in an astonishing degree!" The climax was reached in 1897, when the late King of Siam, on his visit, was invited and allowed to remove (p. 244) from that "superb temple, whose soul is the soul of Java," eight cartloads of irreplaceable statuary! Such vandalism was in defiance of the protests of Dutch scholars, whose noble efforts, like those of Raffles (pp. 55, 76, 238), are freely acknowledged. The work clearly illustrates the real significance of "Boro Budoor" as a sculptured record of the history of Buddhism, the type being that of the Mahayanistic or northern Church (pp. 222,235), not the Hinayanistic or southern type, as was claimed for his Church by the late royal visitor.

W. W. Skeat.

THE BRILLIANT FIREBALLS OF JUNE 14.

On June 14 at 8h. 4m., when the sun was shining, and at 10h. 0m., in the bright moonlight, very large meteors made their appearance. The former gave a startling flash, even in the daylight, and the latter was strikingly brighter than the moon, according to the testimony of several observers.

Neither of the fireballs passed over any part of England, though witnessed by many persons from the eastern and south-western counties respectively. The earlier fireball at 8h. 4m. appeared over the sea off the eastern coast near Harwich and Aldborough, and it had numerous spectators in Kent, Essex, Suffolk, and Norfolk. The other passed above the sea far west of Land's End, and had a long and horizontal flight of 490 miles directed from south-east to north-west from over L'Orient, about sixty miles south-east of Brest in France, to eighty miles west of Dunmore Head in the south-west of Ireland.

The following are the resulting heights, velocities, &c., of the two fireballs, which have been computed from a considerable number of descriptions forwarded to me from many parts of the country :—

1913, *June* 14.

G.M.T. ...	...	8h. 4m. ...	10h. 0m.
Magnitude	=	much brighter than ☽	brighter than ☽
Height at first	=	77 miles	54 miles
,, end	=	29 ,,	54 ,,
Luminous course	=	58 ,,	490 ,,
Velocity per second	=	22 ,,	26 ,,
Radiant point	=	$263^\circ + 64^\circ$	$282^\circ - 23^\circ$
Name of meteor	=	ζ Draconid	ψ Sagittarid

Long as the flight of 490 miles undoubtedly is for the second fireball, it is probably much less than the actual course. When the object was last seen from Ireland it was really rising in the air, and was still burning strongly when low apparent altitude carried it behind either trees or buildings, as viewed by several observers. I suppose it is possible for a meteor to escape out of the atmosphere when its flight is horizontal and its material capable of withstanding absolute disintegration. We want more observations from the west of Ireland.

The daylight fireball at 8h. 4m. left a streak for about three minutes, and several of the observers state that a noise like thunder followed its disruption in two or three minutes. One person at Watford avers that he is certain the meteor was not more than twenty yards distant from where he stood, for he witnessed the object descend in front of some trees.

W. F. DENNING.

THE STATE AND MEDICAL RESEARCH.

A COMMITTEE with executive functions, to be known as the Medical Research Committee, has been appointed for the purpose of dealing with the money made available for research under the Insurance Act. The Committee is constituted as follows :—

The Right Hon. Lord Moulton of Bank, F.R.S. (chairman).
Dr. C. Addison, M.P.
Mr. Waldorf Astor, M.P.
Sir T. Clifford Allbutt, K.C.B., F.R.S., Regius professor of physic, University of Cambridge.
Mr. C. J. Bond, senior honorary surgeon, Leicester Infirmary.
Dr. W. Bulloch, F.R.S., bacteriologist to the London Hospital, and professor of bacteriology in the University of London.
Prof. M. Hay, professor of forensic medicine and public health, Aberdeen University.
Dr. F. Gowland Hopkins, F.R.S., reader in chemical physiology in the University of Cambridge.
Sir W. B. Leishman, F.R.S., professor of pathology, Royal Army Medical College.

The appointment of the Committee is the outcome of the final report of the Departmental Committee on Tuberculosis, which was summarised in an article in NATURE on April 24 (vol. xci., p. 191). In this report the Committee recommended the appointment of an Advisory Council and an Executive Committee, and both have now been constituted. The Advisory Council is to make suggestions, and to submit the Executive Committee's budget to the Government, and to advise the Executive Committee.

The Executive Committee is to frame a budget to be considered with the Advisory Council before being submitted to the Government; to determine the scheme of research work; to make periodic reports, and generally to organise and supervise research work.

The Departmental Committee suggested that the work of research could be carried out advantageously on the following, among other, lines :—

(*a*) A central bureau should be established and should be the headquarters of the Advisory Council and Executive Committee. The central bureau should have a statistical and sociological department, in the work of which should be included the coordination and correlation of results. With regard to statistical investigations, every effort should be made to utilise, where possible, and cooperate with the statistical departments of the different Government departments. Statistics should be so collected and framed as to be comparable with the existing statistics of mortality. There should also be a library and publishing department. The central bureau should be under the immediate control of the Executive Committee.

(*b*) Clinical, pathological, bacteriological, chemical, and other scientific researches should be carried out by competent investigators employed by the Executive Committee in institutions approved by it.

(*c*) When the Government, on the recommendation of the Executive Committee, and after consulting the Advisory Council, deems such arrangements desirable, researches of the same nature as those referred to in the preceding paragraph should be carried out in an institution or institutions (including laboratories and hospital wards) which should be under the immediate control of the Executive Committee to the extent and for the purpose in question.

(*d*) Money should be available in order that special inquiries—*e.g.* of a statistical and sociological nature—should be carried out by the Executive Committee if necessary, independently of any particular institution.

(*e*) The question whether a sum of money, not exceeding 1000*l.* per annum, should be available as a prize or prizes for the best original research work done should be considered. The money should only be awarded if the discovery is of sufficient importance and utility.

As regards research workers the Departmental Committee recommended that some workers of proved and exceptional ability should be enabled to devote their whole time to research work, and should be given a definite and adequate salary, and be entitled to a pension. The Committee also considered that efforts should be made to retain for research work young and talented investigators who would otherwise tend to drift into other lines.

The Departmental Committee computed that the income for the purposes of research under the Insurance Act will amount to about 57,000*l.* a year, and the Medical Research Committee will be called upon to draw up a general plan of research to be entered upon at once, and to be carried out year by year. But before the Minister responsible for national health insurance consents to the adoption of the plans of the Research Committee they will be subjected to examination and criticism by the Advisory Council, which is a large and representative body including most of the members of the Departmental Committee. It was appointed by Mr. Lloyd George after receiving suggestions for suitable names from each of the universities of the United Kingdom, from the Royal Colleges of Physicians and of Surgeons, from the Royal Society, and from other public bodies interested in the question. It includes medical representatives of the four National Health Insurance Commissions, and the other Government departments concerned in medical work.

SIR JONATHAN HUTCHINSON, F.R.S.

WHEN the history of modern medicine comes to be written it is certain that Sir Jonathan Hutchinson, who died in his eighty-fifth year at Haslemere on June 23, will occupy a more prominent position than that usually assigned to him by his contemporaries. He had the misfortune to be at work when Pasteur and Lister opened up new, attractive, and practical fields of research, carrying with them all the eager intellects of a younger generation, and leaving the subject of this notice to explore the inexhaustible fields of clinical medicine. From the year 1844, when he was apprenticed to Dr. Caleb Williams, of York, at the age of sixteen, until the day of his death, within a month of finishing his eighty-fifth year, he never ceased to study the manifestations of health and disease, and to place his observations and inferences on record.

Sir Jonathan Hutchinson was an inductive philosopher who patiently and accurately collected facts to provide a sure basis for the principles of scientific medicine. The monument he leaves behind him is seen in the volumes of the "Archives of Surgery," "Atlas of Illustrations of Clinical Surgery," and the hundreds of clinical records which are to be found in medical literature of the last fifty years. He leaves behind him no brilliant discovery to fix his name in the public memory, and yet it may be claimed for him that he did more than any man of his time to solidify the foundations of the surgeon's art.

He was a self-made surgeon, neither the follower nor the leader of any school. It is true that after coming to London in 1850, at the age of twenty-two, he came under the influence of Lawrence and of Paget at St. Bartholomew's Hospital for a few months, but the spirit which dominated him when he ultimately settled in London was the quiet inquiring and observing mood which he acquired in the seclusion of his Quaker home in Selby. Before he was in his thirtieth year he was on the staff of the leading eye hospital (Moorfields), Blackfriars Hospital for Diseases of the Skin, the Metropolitan and the London Hospitals, where he had to deal with all the problems of general surgery.

With those great and varied clinical fields at his disposal he was able, in less than ten years from the time he settled in London, to produce convincing proof that a host of conditions which were regarded as separate diseases were really the remote manifestations of syphilis, and amenable to specific remedies.

The varied and puzzling diseases to which the skin was liable had a special attraction for Sir Jonathan Hutchinson, and it was at an early stage of his career that he began a systematic investigation of the cause and nature of leprosy. In 1859 he came to the conclusion that it was due to eating imperfectly preserved fish, and that the disease was therefore non-contagious and preventable. Fifty years later found him still searching in various parts of the earth for evidence to support his original contention.

The persistency which he applied to the study of leprosy he gave to all the various lines of research he took up. He was a student of growth; he never ceased recording facts and cases which were likely to reveal the principles which regulate the growth and development of the animal body. His lectures at the Royal College of Surgeons in 1881 on the pedigree of disease are happy illustrations of the methods by which he sought to advance this kind of knowledge. He was a surgeon who made a reputation not by the use of the operating knife, but by the application of his intellect to the understanding and cure of disease. He operated with success; he introduced new procedures, but he recognised that recourse to operation was necessitated by the imperfections of the healer's art.

He was an educationist, believing that all teaching should be objective. He did much as chairman of the Museum Committee and as president of the College of Surgeons for the great museum founded by John Hunter; he established and furnished three museums in the Polyclinic (Medical Graduates' College) in Chenies Street, in his native town of Selby, and in Haslemere, where he latterly made his home.

NOTES.

WE heartily congratulate Dr. A. F. R. Wollaston on his return from a successful visit to the Ingkipulu Mountains (Nassau range), Netherlands New Guinea. Last year Dr. Wollaston gave an account of the unlucky attempt of the British Ornithologists' Union Expedition in "Pygmies and Papuans," and quite recently Capt. C. G. Rawling has published another book on the same expedition, "The Land of the New Guinea Pygmies." On the present occasion Mr. C. B. Kloss, curator of the Kuala Lumpur Museum, accompanied Dr. Wollaston, and, in addition to an engineer and five native collectors, they took with them seventy-five "Dyaks," and a large escort was provided by the Netherlands Government. Four and a half months were occupied in reaching the mountains from the coast. The geographical results cannot be worked out for some time. Extensive zoological collections were made which comprise many new species; among them is a very beautiful bird of paradise which may be new. A hitherto unknown tribe of a rather short people of Papuan type were met with at an elevation of some 4000–6000 ft. Despite the very cold nights they wear no clothing. They are mainly collectors and hunters, but also grow sweet-potatoes, tobacco, and sugar-cane. They carry bows and arrows and shoulder-bags containing apparatus for making fire, tobacco, knives, spoons, and other small belongings in true Papuan style. Their knives are made of a hard, slaty stone that can be brought to so keen an edge that bamboos can be cut with them. The people are said to be extremely attractive, most friendly, and in some respects more intelligent than the people on the coast. We await with interest Dr. Wollaston's account of his adventurous journeyings, and sympathise with him in the loss of a considerable proportion of his notes due to the capsizing of a canoe.

A shameful outrage has just been perpetrated at the Gatty Marine Laboratory of St. Andrews, the gift of Dr. C. H. Gatty to the University. The laboratory has always been freely open to scientific workers of both sexes without distinction of religion or political feeling, and might therefore have been expected to be immune from attack; yet it has been fired, apparently by militant suffragettes, who have thus destroyed much of the work of members of their own sex. Several large original coloured drawings—all the exquisite work of a lady, the late Mrs. Albert Günther—have been irretrievably ruined by the fire. Fortunately most of the fine original drawings of marine animals made by Mrs. Günther were in the corridor and other rooms, away from the main workroom, and so securely framed that though begrimed with soot, they are practically as before. The coloured and uncoloured plates for the next Ray Society work had been lying for four or five months on a table in an adjoining room, and they also escaped. It appears that on Saturday, June 21, the incendiaries effected an entry by smashing one of the windows on the south side of the laboratory, after plastering it with soft soap and paper. Explosives and combustibles were placed in one of the cubicles and lit, and the perpetrators of the outrage escaped through a window. The print of a small shoe, and suffragette literature stuck between the wall and a rain-pipe, were the only traces left. Fortunately the fire was seen by a fisherman, who gave the alarm, but the large workroom was wrecked and the roof ruined before the firemen obtained control of the fire. We sympathise with the director, Prof. McIntosh, who has always done so much to help on the scientific education of women at the University of St. Andrews.

The Gustave Canet lecture of the Junior Institution of Engineers will be delivered by Dr. Dugald Clerk, F.R.S., on the working fluid of internal-combustion engines, on Monday evening, June 30, at the Institution of Electrical Engineers, Victoria Embankment, W.C. The chair will be taken by the president, Sir A. Trevor Dawson, R.N.

The death is announced, in his thirty-fourth year, of Prof. C. C. Poindexter, one of the most promising of the younger negro educational leaders in America. After graduating at Ohio State University in 1903, he spent two years as a graduate student at Cornell. Four years ago he went to Fisk University, Nashville, as assistant-professor of biology, from which post he was promoted, after two years' service, to a full professorship.

The annual exhibition of antiquities discovered during excavations at Meroë, Sudan, carried out in connection with the Institute of Archæology, University of Liverpool, will be held in the rooms of the Society of Antiquaries, Burlington House, Piccadilly, W., from Tuesday, July 8, to Friday, July 18, inclusive. The exhibits will include decorated pottery vases, objects of faience and of bronze, intaglio-rings, &c., plans and photographs, and copies of frescoes and sketches in colour.

It was announced in the issue of Nature for May 29 (p. 338) that of the 100,000*l.* bequeathed by the late Sir J. Wernher, Bart., for charitable and educational purposes, 5000*l.* was a grant to the Institution of Mining and Metallurgy. At a recent meeting of the institution, the president, Mr. Bedford McNeill, announced that Lady Wernher had added a second 5000*l.*, making a total of 10,000*l.* The only condition attached is that Lady Wernher desires that the principal sum shall remain intact as an aid in permanently strengthening the institution. The income is to be devoted to the ordinary purposes of the institution.

The *Japan Chronicle* reports the death, at St. Petersburg, on May 27, at fifty-one years of age, of Dr. Shogoro Tsuboi, professor of anthropology at the Tokyo Imperial University. The deceased, who had been attending the meeting of the International Association of Academies at the Russian capital on behalf of the Japanese Academy, was regarded as the greatest authority on his subject in Japan. In 1884 he established the Tokyo Anthropological Society, and started a vernacular magazine which has done much to further the development of the science in Japan. Dr. Tsuboi was an honorary member of our Royal Anthropological Society, and a corresponding member of the Berlin and Paris Anthropological Societies.

The sixth of the series of International Fishery Congresses, established at Paris in 1900, is appointed to be held at Ostend on August 18–20, under the patronage of his Majesty the King of the Belgians. The Board of Agriculture and Fisheries has arranged to be represented officially at the congress, and has also sent a fisheries exhibit to the International Exhibition now being held in Ghent, of which the section devoted to fisheries will be closely associated with the congress. It is hoped that British fishery interests will be fully represented at the congress, and all interested in fish and fishing and the various related industries, and in the studies connected therewith, are invited to take part in the proceedings, by the reading of papers and otherwise. The subscription for members, giving the right to take part in the discussions and excursions, and to receive the publications of the congress, has been fixed at 10 francs (8*s.* 4*d.*). Full particulars can be obtained from the general secretary to the congress, Kursaal, Ostend, Belgium, direct, or through the Board of Agriculture and Fisheries, 4 Whitehall Place, London, S.W.

The annual congress of the Royal Sanitary Institute is to be held this year at Exeter on July 7–12, under the presidency of Earl Fortescue, who will deliver the inaugural address. A popular lecture on imported foods from a Colonial point of view will be given by Sir John McCall, Agent-General for Tasmania. Sir William Collins will lecture to the congress on "The Chadwick School of Thought: An Appeal from the New Sanitarians to the Old." The work of the congress will be divided into four sections, which, with their presidents, will be:—Sanitary Science and Preventive Medicine, Mr. A. Wynter Blyth; Engineering and Architecture, Mr. H. P. Boulnois; Domestic Hygiene, Mrs. Michelmore, Mayoress of Exeter; Hygiene of Infancy and Child Study, Mr. E. J. Domville. During the meetings the following associations will hold conferences:—Municipal representatives, medical officers of health, engineers and surveyors to county and sanitary authorities, veterinary and sanitary inspectors.

The report of the council of the Concrete Institute, recently presented at the annual general meeting, shows a gratifying increase in membership, and an increasing interest in everything pertaining to the theory and practice of construction in concrete, plain and reinforced. The science committee has under consideration a system of standard notation for calculations in structural engineering, and also, in conjunction with the reinforced concrete practice standing committee, a proposed standard specification for reinforced concrete work. Among other work in hand the committee is investigating the effect of oils and fats on concrete, and the adhesion of and friction between concrete and steel. The practice standing committee of the institute has drafted reports on the surface treatment of concrete, and cracks in concrete, which were submitted for discussion at a general meeting, while the committee on tests has many matters under investigation, including the collection of data regarding the moduli of elasticity of concrete for stresses within working limits. The activity of the institute is a healthy sign of the attention which English engineers are giving to the vast possibilities of reinforced concrete, already more fully developed and realised in some other countries.

Mr. Stefánsson's expedition has started for the Beaufort Sea, and will be followed with intense interest by all interested in polar exploration. It means to attack the last great problem of the Arctic. It has been maintained by certain authorities of the highest standing that there is an extensive land to be discovered in the Beaufort Sea quadrant, but the question has long been disputed. Mr. Stefánsson hopes to settle it, and is giving himself nearly four years in which to do so. There will be much occasion for scientific research, and these are days of large scientific staffs on polar expeditions. The staff of the present expedition numbers no fewer than fifteen, and if land is discovered and the expedition is in proper state to take advantage of the discovery, there will be unsurpassed opportunities for scientific work. So far as it is possible to judge in advance, the leader of the expedition appears to expect moderately favourable conditions for the voyage northward from the North American Arctic coast. With easterly winds a clear sea is practically assured; westerlies will pack the ice. It is believed that a condition of balance between these two extremes is to be expected, and the resulting conditions should not offer serious obstacles to a well-tried vessel under so well experienced a commander as Captain Bartlett.

In the House of Commons on June 18 Mr. Cathcart Wason asked what percentage of men have failed with the colour-vision tests introduced on April 1, and how this percentage compares with that of former years; and how many men have passed with the wool test and failed with the lantern test, and *vice versâ*? The Parliamentary Secretary to the Board of Trade (Mr. Robertson) replied:—"The total number of men examined in colour vision from April 1 to May 31 was 1689, and of these 105, or 6·22 per cent., failed. Of the 105 failures, fifty-five failed in both the wool test and lantern test, and fifty in the lantern test only. None failed in the wool test only. I regret that it is not possible to give corresponding figures for previous years, since the statistics available for previous years relate to examinations, and not to individuals. I may mention, however, that in 1912, out of 7326 examinations in colour vision, 163, or 2·22 per cent., resulted in failure. The figures for the two periods are not comparable, both because of the difference of basis and because the Board of Trade have reason to believe that the number of candidates examined in the last two months includes an abnormal proportion of persons who have never been examined before, among whom, naturally, the percentage of rejections is disproportionately high."

The committee of the twelfth International Geological Congress has now issued the third and final general circular. Applications to join excursions have been received more rapidly than was anticipated, therefore intending participants should delay no longer. Delegates appointed by universities, &c., are reminded that their application for membership should be sent in at once. The monograph on coal resources will be issued in three volumes (not two) and folio atlas—price, to members, 20 dollars, if ordered from Morang and Co., Toronto, before August 15. Changes are announced in several excursion programmes. Excursion A9 will start from Kingston at the foot of Lake Ontario. The visit to the Dinosaurian bone beds near Munson, Ex. C1, may not be possible, but those who specially desire to visit the deposits should advise the secretary. The Sudbury ore region will be visited on Ex. C1, in order that participants in excursions C1 and C2 may meet in Victoria, B.C., on August 26. Special attention is directed to Ex. C5 on account of its many attractions, including a "show" by native Indians on Grand Manitoulin Island. Ex. C8, Juneau-Yakutat section, will afford a unique opportunity for studying active glacial phenomena. Particulars are given of reductions in railway fares in Canada and the United States, and a list of hotels with their charges is provided.

The Chemical Industry and Engineering Exhibition at the Agricultural Hall, which was opened by Lord Desborough last week, is an interesting and successful development of a similar exhibition held two years ago. Its essential aim is to give chemical manufacturers an opportunity of inspecting the most recent forms of machinery and appliances rather than to display the actual products of chemical manufacture, although a number of the latter, of a more special character, are included. The bulk of the floor-space is accordingly allotted to apparatus and machinery, of which a large proportion is concerned with the transport and treatment of the products dealt with in chemical industries. Acid-resisting materials of so-called "passive" iron ("Ironac" and "Tantiron"), and acid-proof stoneware suitable for pipes, pumps, valves, taps, the cascade concentration of acids, &c., are prominent in this connection, together with a number of new forms of air-compressors, boiler-furnaces, and vacuum drying apparatus. Safety appliances for use in works are also well represented. These include safety-helmets, face-masks, respirators, &c., and a variety of appliances for life-saving and first-aid in case of accidents. The exhibits of chemical products comprise a well-selected collection of mercurials, bismuth compounds, and other pharmaceutical preparations, an exhibit designed to show the progressive stages in the manufacture of coal-tar colours from the raw materials to the finished dyestuffs, and such varied products as china clay, hydrogen peroxide preparations, and materials for the generation of acetylene. Good exhibits of laboratory apparatus are contributed by a number of well-known firms, and an exceptionally interesting collection of old glass apparatus which had been in actual use by Brandt, Hennell, and Warington has been loaned by the Society of Apothecaries. Mr. Walter F. Reid has acted as president of the exhibition, Mr. Thos. Tyrer as chairman of the advisory council, and Mr. F. W. Bridges as organising manager.

The *Daily Malta Chronicle* of May 31 reports a lecture delivered by Mr. Francesco Calleja on the early culture of the island. He laid stress on the importance of Phœnician influence, and quoted a number of words to prove that the Greek language was largely indebted to the Semitic tongues. These are positions which many modern archæologists decline to accept. For instance, Mr. D. G. Hogarth is inclined to regard the Phœnicians as mere huckstering traders, who followed sea-ways long before opened by others; and Dr. Farnell shows that Babylonia exercised practically no influence upon Greek cults and beliefs. On the philological side, until the Minoan inscriptions collected by Sir A. Evans are interpreted, it is premature to postulate the origin of the Ægean languages; and when the new material is available it will probably be found that Phœnician influence is much less important than the lecturer is inclined to believe.

Naturen for May contains an obituary notice, with a portrait, of Vilhelm Ferdinand Johan Storm, late conservator of the zoological collections of the Klg. Norske Videnskapsselskaps, who died on May 19 of the present year. Dr. Storm, who was born on September 28, 1835, took an active part in the affairs of the museum for more than fifty-seven years.

As a supplement to the second edition of his "Herpetologia Europæa" (Jena, G. Fischer), of which a notice appeared in Nature at the close of 1912, Dr. E. Schreiber has published a German translation of the Latin diagnoses of the various genera and species of reptiles and amphibians given in the original work.

According to the June number of *The Museums Journal*, the executive committee of the Museums Association is endeavouring to enlist the services of members of that body possessing expert knowledge of particular subjects—both in science and art—for the purpose of naming specimens that may be submitted to them by members and associates. Several gentlemen have already consented to undertake these duties, and it is proposed, if the scheme is well taken up, to publish lists of the names of the experts in *The Museums Journal*.

The very remarkable success that has attended the appointment of personal guides at the British Museum and its Natural History branch in Cromwell Road induced Lord Sudeley to inquire in the House of Lords of his Majesty's Government on April 29 whether arrangements could not be made for a similar system of popular instruction in other museums and institutions in the metropolis. The motion was supported, on behalf of the Education Committee of the London County Council, by Lord Greville, and was also favourably received by other speakers. It was, however, pointed out that there were certain difficulties in the case of the National Gallery on account of students' days, and in the Wallace Collection owing to the limited amount of standing room.

In the recently published volume of the Journal of the Royal Agricultural Society for 1912, Mr. A. D. Hall discusses the value of soil analyses to the farmer. He shows the anomalous results often obtained by a chemical examination of the soil, and deals at greater length with the importance of a better knowledge of the physical conditions in the soil. Although chemical methods may indicate certain manurial requirements of any given soil, a more trustworthy pronouncement as to its suitability or otherwise for the growth of particular crops can only be made after a soil survey.

A comprehensive survey of the conditions of the date-sugar industry in Bengal and an account of its chemistry and agriculture are contributed by Messrs. H. E. Annett, G. K. Lele, and Bhailal M. Amin to the Memoirs of the Department of Agriculture in India (vol. ii., No. 6, 1913). Covering as it does such a wide range of questions, and being to a large extent technical in character, it is not possible to do justice here to the greater part of the paper. Much interest, however, attaches to the suggestions for future improvements, among which may be mentioned the introduction of the Palmyra palm, so that the production of sugar by this and the date palm would extend over the whole year. In this way the erection of large central factories might be rendered possible. Consideration of the amounts of sugar obtainable from various sugar-yielding plants shows that greater quantities are to be expected from the date palm than from sugar cane in this district, and that the average yield of the former per tree is about seven times that of the sugar maple. Greater output of sugar and greater purity of product would also accrue from the disinfection of the tapped surface and of the collecting vessels by means of formalin.

THE whole of vol. xxii., part i., of the Memoirs of the Indian Meteorological Department is devoted to tables containing monthly and annual rainfall normals at all stations maintained by the Imperial and provincial Governments where records for at least five years are available. There is no discussion attached to this very valuable mass of materials, but the number of years over which the data extend has been given for each station, in order that an estimate may be formed of the trustworthiness of the results. As might be expected from other publications of the department, some of the figures are very remarkable. Among the average annual amounts may be mentioned:—Cherrapunji (Assam), 426 in.; Málkompeth (Satara, Bombay), 274·8 in.; Launglon (Burma), 234·3 in.; Rújanpur (Punjab), 3·7 in.; Rohri (Sukkur, Bombay), 3·1 in.; Jhatput (Baluchistan), 3·0 in. At "stations outside the Indian land area" still smaller values are quoted: 2·7 in. at Aden, 2·5 in. at Bahrein (Persia) and at Perim (Asiatic Turkey).

THE October, 1912, number of the *Sitzungsberichte* of the Vienna Academy of Sciences contains a short paper by Dr. W. Altberg, of Odessa, on the use of the resistance offered by a small sphere to the passage of a current of gas past it as a measure of the velocity of the gas. He used a steel sphere 0·6 cm. diameter, suspended by a metal filament 0·0025 cm. diameter, 75 cm. long, in the centre of an air duct through which a stream of air of known velocity could be passed. The deflection of the suspension from the vertical was measured by means of a microscope reading to 0·001 cm. The author finds that the arrangement is easily set up, adjusts itself almost instantaneously to changes of velocity, and allows velocities from 70 to 270 cm. per second to be determined with accuracy by means of the relation shown by Becker to hold for lower velocities, *i.e.* the resistance offered by the sphere is the sum of two terms, the first representing Stokes's law—resistance proportional to the radius of the sphere, the velocity and viscosity of the medium—the second representing Newton's law—resistance proportional to the square of the radius, the density and the square of the velocity of the medium.

THE *Verhandlungen* of the German Physical Society for April 30 contain a preliminary account of the measurements made by Dr. R. Reiger, of the University of Erlangen, on the effect of introducing exploring electrodes of various kinds into the positive column of the discharge through a vacuum tube. The change in appearance of the discharge was studied by photography, and the effect on the total fall of potential down the tube was measured. As a result the following conclusions are drawn:—In the immediate neighbourhood of the exploring electrode free electric charges are produced, and the total fall of potential is increased by an amount which increases with the diameter of the electrode and with the gas pressure in the tube. The material of the electrode and whether it is covered with glass or not make little difference for small electrodes, but for those of large diameter metals produce greater disturbances than insulators. On both anode and kathode sides of the electrode there are large falls of potential, that on the anode side being the greater. This produces serious errors when observations with double electrodes near together are made. In all cases it is advisable to use as thin exploring electrodes as possible.

WE have received an illustrated pamphlet of seventy pages, by Herr Walther Dix ("Das selbstgefertigte Lichtbild," Quelle and Meyer, Leipzig, price 1 mark), which seems to indicate that even in Germany it is desirable to urge the advantages of photography and its applications in connection with the teaching and the study of chemistry and physics. The author divides his subject into sections, and gives examples of the various uses of photography, after referring shortly to methods of making lantern-slides and paper prints. He says that photographs can well illustrate the details of various pieces or series of apparatus and the methods of using them; the methods of experimental work; the arrangement of important technical installations, if possible, by way of preparation for a visit to the works; the latest progress in connection with recent discoveries that the student deals with in his course of study; and the graphic representation of various matters, as by curves, which, by showing clearly the points to be demonstrated, will make them more easily remembered. The examples given are taken from many different sources and well illustrated.

A REMARKABLE advance in the preparation of "conductivity water" is described by Mr. R. Bourdillon in the Transactions of the Chemical Society. In the case of one sample of water, which was stored in a vacuous vessel during five years in contact with platinum electrodes, the conductivity was reduced by Kohlrausch some years ago to 0·04 gemmho; but when the water is to be used in contact with air it has been regarded as a high standard to attain to a conductivity as low as 1 gemmho in ordinary laboratory practice. The production by Bousfield of unlimited quantities of "gemmho water" by continuous fractional distillation of tap-water satisfied this requirement admirably. A further substantial improvement was subsequently effected by fractionally distilling the product under reduced pressure. In Mr. Bourdillon's apparatus the fractionation is intermittent and not continuous, but by passing purified air through the steam as it condenses a large middle-fraction amounting to 6 or 7 litres can be collected with a conductivity of the order of 0·1 gemmho. Such highly purified water cannot be used in contact with air, but in an enclosed vessel (protected by a current of purified air whenever it is opened) the rise of conductivity is only 0·004 gemmho per hour in contact with clean electrodes, or 0·01 gemmho in contact with electrodes that have recently been used for dilute salt-solutions. The value of this new development in measuring the conductivity of very dilute solutions is too obvious to require further emphasis.

THE second number has reached us of a new periodical, *Zeitschrift für Betonbau*, dedicated to the science of construction in reinforced concrete; it contains descriptions of various works carried out in this material, besides theoretical investigations from various engineers. The most novel feature of this number is a description of a swimming bath 25 metres long and 12 metres wide, containing 510 tons of water. This is supported on three points on the top of low piers, and is housed in a large building, the construction of which is described. A large bridge near Pressburg, with one span of 30 metres and another of 18·40, is described, and the computations of bending moments and reactions leading to the determination of the necessary reinforcement are set out very fully. The character of this paper bears ample testimony to the thorough manner in which Austrian and German engineers are taking up the designs of structures in this material.

Engineering for June 20 contains an illustrated account of the Hamburg-Amerika liner *Imperator*. This vessel left the mouth of the Elbe on Wednesday, June 11, for her first regular voyage. Her dimensions are approximately 50,000 tons register, 880 ft. in length, 98 ft. in beam, and 63 ft. in depth from main deck to keel. The depth from the upper boat-deck to keel is 101 ft. 8 in. The *Vaterland* was launched recently for the same company, and a third sister vessel is on the stocks; these vessels will be only slightly greater than the *Imperator*. The horse-power of the latter is 62,000, derived from Parsons turbines, and the speed is 22·5 knots. The vessel is equipped with eighty-three boats, sufficient for 5500 people, *i.e.* 300 more than she will carry, counting both passengers and crew. The boat-lowering gear is very complete; there is one electric motor on the boat-deck for every three boats, and there are special arrangements for maintaining horizontal the boat while being lowered. In addition to the commodore, the ship carries four captains, who have commanded large steamers successfully, and one of these will be always on watch, while the fourth takes general control of the crew.

THE Cambridge University Press has arranged for the issue of a series of volumes under the general title of "The Cambridge Psychological Library," to be edited by Dr. C. S. Myers, University lecturer in experimental psychology and director of the psychological laboratory. Among the volumes already arranged are:—"Psychology," Prof. James Ward; "The Nervous System," Prof. C. S. Sherrington, F.R.S.; "The Structure of the Nervous System and the Sense Organs," Prof. G. Elliott Smith, F.R.S.; "Psychology in Relation to Theory of Knowledge," Prof. G. F. Stout; "Mental Measurement," Dr. W. Brown; and "Collective Psychology," Mr. W. McDougall, F.R.S.

MESSRS. JOHN WHELDON AND CO. have just issued an ornithological catalogue containing titles and other particulars of more than 1500 books and papers, and including selections from the libraries of several eminent ornithologists.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR JULY:—

July 1. 15h. 26m. Saturn in conjunction with the Moon (Saturn 6° 30′ S.).
3. 16h. 0m. Venus at greatest elongation west of the Sun.
5. 3h. 0m. Jupiter at opposition to the Sun.
,, 13h. 39m. Mercury in conjunction with the Moon (Mercury 3° 49′ S.).
7. 3h. 0m. Mercury at greatest elongation east.
16. 15h. 29m. Jupiter in conjunction with the Moon (Jupiter 4° 47′ N.).
18. 13h. 0m. Neptune in conjunction with the Sun.
,, 13h. 49m. Uranus in conjunction with the Moon (Uranus 3° 24′ N.).
20. 6h. 0m. Mercury stationary.
21. 12h. 52m. Venus in conjunction with Saturn (Venus 1° 18′ S.).
28. 3h. 12m. Mars in conjunction with the Moon (Mars 5° 41′ S.).
,, 20h. 0m. Uranus at opposition to the Sun.
29. 6h. 12m. Saturn in conjunction with the Moon (Saturn 6° 42′ S.).
,, 19h. 30m. Venus in conjunction with the Moon (Venus 7° 40′ S.).

MINOR PLANETS.—The April number (vol. ix., No. 9) of *The South African Journal of Science* contains an article by Mr. Robert T. A. Innes, entitled "The Minor Planet MT. 1911: and on Minor Planets in General." The Union Observatory at Johannesburg devotes a considerable portion of its time to these small bodies, and the work it does is shown in relation to the minor planet problem in general. This article will be found of particular interest to those whose astronomical work lies in other directions, for Mr. Innes writes generally on the subject of these bodies, and particularly of MT. 1911. To mention one or two points of prominent interest, he states that in 1893 no minor planet would be given a permanent number until five observations were available, but to-day such a number is not allotted until observations spread over six weeks are available, and a satisfactory orbit is computed. Reference is made to Eros, to the nearly simultaneous publication of Sir David Gill's result of the solar parallax determination from observations of the minor planets Victoria, Iris, and Sappho, the value he obtained being 8·802″±0·005″, and to Hinks's value of 8·806″±0·004″ from his fine Eros work. Dr. Metcalf's method of minor planet search, that of guiding the telescope so that the plate remains approximately at rest with regard to the usual motion of the minor planet while the stars trail, is mentioned, and numerous other important items, such as the different groups of minor planets, the arrangements for organised effort, the discovery of Palisa's MT. 1911, and its subsequent rediscovery.

CORDOBA CATALOGUE OF 5791 STARS.—Dr. C. D. Perrine, in the twentieth volume of the Results of the

National Argentine Observatory in Cordoba, presents a catalogue of 5791 stars. The work is the outcome of 28,718 observations made with the 5-in. Repsold meridian circle during the six years 1885–90. The observations are of a general nature over the southern sky, and form a continuation of the general catalogue. Auwers's list of 303 fundamental stars was observed in 1889 by Prof. Updegraff, and the results are included in this catalogue. There is also included a list of sixty-three comparison stars for the minor planet Victoria, observed in 1889 by Prof. Updegraff, and this is given separately, in addition to being included in the regular catalogue. There was no unusual change or condition of the meridian circle during the period mentioned, so far as is known, and the reductions were made in precisely the same manner and with the same system of constants as in the general catalogue. The catalogue also includes the results of a comparison with Boss's Preliminary General Catalogue of the stars common to both.

The Milky Way and the Distribution of Stars with Peculiar Spectra.—The distribution with reference to the galaxy of the many stars having peculiar spectra classed by the late Mrs. Fleming has been analysed by Mr. T. E. Espin, and the results appear in the March-April number of the Journal of the Royal Astronomical Society. The distribution evidence suggests that the order A, F, G, K, M of the Harvard classification of stellar spectra requires rearranging thus, A, G, M, K, F. The author makes some interesting speculations on the structure of the galactic system.

THE MICROSCOPE SUBSTAGE AND ITS ADJUSTMENTS.

There are one or two points, particularly in the substage arrangements, which are distinct and characteristic of English and Continental microscopes. In the English instrument of any pretensions it has always been the custom to provide a centring substage, and this carries both the optical portion of the substage condenser and the iris diaphragm. It has to be assumed, therefore, that the iris diaphragm is centred permanently and accurately to the optic axis of the substage condenser, its perfection therefore depending on the extent to which this assumption is justified.

In the case of the Continental microscope, where a centring substage condenser is provided, it is mounted so that the optical part is centred independently of the iris diaphragm, the latter, in fact, being mounted below the substage condenser and having certain adjustments which are in no way connected with the centring arrangement. It therefore follows that in the Continental type the iris diaphragm may be, and indeed often is, permanently out of centre with the optic axis of the objective. The substage condenser has therefore to be centred in relation to two axes, the centre of the iris diaphragm and the optic axis of the objective, which themselves are not in exact alignment. It is obvious that under such conditions the provision and use of a centring appliance for the adjustment of the optical part of the condenser will never result in correct alignment of the various parts. With the object of overcoming this defect, at least in part, some of the better Continental models have been provided with an independent adjustment to enable the mechanic to centre the condenser to the optic axis, after he has centred the iris diaphragm. The condenser is mounted in a ring provided with three screws, the setting of which admits of the optical part of the condenser being centred, but this is, of course, not an adjustment of which the average user would care to avail himself. In the English arrangement, where the iris diaphragm is correctly centred to the substage condenser, centration of the whole substage fitting results in correct alignment with the remainder of the optical system of the microscope.

For the most critical work, therefore, it would appear that the English method is to be preferred. On the other hand, where a microscope is being used for laboratory work, and is only occasionally being used for the testing of objectives or for critical purposes, there is no doubt that the Continental type has much to recommend it. The fact that the iris diaphragm may be contracted to any desired degree, and may then be shifted laterally so that oblique illumination in any azimuth and in any zone of the field of view can be obtained at will, is a great convenience, and for anything like rapid testing of objectives is almost essential.

In the English stand it becomes necessary to provide stops of various sizes and shapes, which can be placed at the back of the substage condenser, to enable oblique illumination to be obtained in any desired manner.

Where absolute accuracy is required it would appear that an arrangement in which both substage condenser and iris diaphragm are capable of independent centration might be a desideratum. In such a case the iris diaphragm would be centred first, and then the optical part of the substage condenser introduced, and that centred independently. By this means the iris diaphragm, the substage condenser, and the objective would be in exact alignment, and the arrangement would be such that work of the most critical character could be carried out. It must be admitted, however, that the conditions under which such a method would become necessary rarely, if ever, arise, so that a well-made instrument provided with the Continental type of substage, in which the iris diaphragm may be decentred, is a very desirable adjunct to any good microscope.

As an indication of the perhaps unnecessary elaboration that has obtained in English stands, one may mention the provision of a fine adjustment to the substage condenser. It is difficult to conceive under what conditions this becomes necessary. A well-made rack-work should provide all the accuracy of adjustment that is required. If it does not it either implies that the mechanical construction of the microscope leaves something to be desired, or that the user has not acquired the necessary manipulative skill to focus his substage condenser with sufficient accuracy, the latter alternative being the more probable.

AUSTRALIAN METEOROLOGY.

The Australian Meteorological Bureau has issued a series of interesting maps showing the normal distribution of temperature and rainfall over the Australian continent. The variety of climate which Australia offers is well illustrated by these charts. The mean summer temperature of the south coast of Victoria (between 60° and 65° F. for January) is about the same as the mean summer temperature of London, while 400 miles to the north the heat is tropical, with a mean temperature of more than 80° F., increasing to more than 85° F. in the greater part of the north-west and central regions. The trend of the isotherms near the coasts shows the usual oceanic effect; they bend southwards in the winter and northwards in the summer in passing from continent to ocean. The isotherms are closest together near the southern coast in summer and near the northern coast in winter.

A fault which might be remedied in future issues is the omission of any scale of distances or parallels of latitude and longitude from the charts.

The rainfall charts have been compiled from data extending over twenty to forty years, with a few stations with only fifteen years' record, indicating that, meteorologically at any rate, Australia is no longer in relative infancy. During the summer months, when the variation of temperature is most rapid near the south coast, the rainfall is greatest on the north and north-east coasts, and the isohyets are closest together in these regions. The distribution gradually changes, and during the winter months the rainfall and its variation are greatest in the south and south-east districts. The change in the position of the isohyets from month to month is very regular; the motion is similar to that of a pendulum, the distribution in the warm months being at one end of the swing and that in the cold months at the other.

In New South Wales, at Forbes, near the centre of gravity of Australia's population, and not far from the site of the new Federal capital, there is practically no variation in the rainfall from month to month; each month has about 2 in. of rainfall. Utilising this fact and the regularity of the change for other regions, the Commonwealth Meteorologist has constructed a rainfall "clock." Isohyets of appropriate shape are drawn on a card placed beneath another card with the outline of Australia cut out of it. The lower card is rotated about an axis through Forbes, and as it moves the rainfall distribution for different months appears, the appropriate positions for each month being shown by an index mark. The remarkable regularity which renders possible this simple device leads the Commonwealth Meteorologist to suggest that Australian meteorology may be of such importance for general investigations as to warrant the establishment of observatories there, internationally supported and controlled.

E. G.

THE RESEARCH DEFENCE SOCIETY.

THE Research Defence Society held its annual general meeting on Tuesday, June 24, at the Royal College of Physicians. The chair was taken by the president of the society, Sir David Gill, and there was a very large attendance. The speakers were:—Bishop Frodsham, founder of the Australian Institute of Tropical Medicine; Sir Thomas Barlow, president of the Royal College of Physicians; Lord Cromer, Sir Hugh Bell, and Mr. Waldorf Astor. The report, presented by Mr. Sydney Holland, chairman of committee, gave a good account of the society's work during the past year with special reference to the campaign against anti-vivisection shops. It stated also that the council of the Royal Society for the Prevention of Cruelty to Animals is sending out a referendum to all the members of that society. The point is, whether it was right or wrong to reject Lord Cheylesmore from the council of the Royal Society for the Prevention of Cruelty to Animals on the ground that he is a vice-president of the Research Defence Society. Seeing the advantages which animals have gained from experiments on animals, and the many restrictions placed on experiments on animals in this country, we think that a man may very properly hold office in both societies; and we are glad that Lord Cromer and Sir Hugh Bell spoke very strongly on this point.

Mr. Waldorf Astor, in an admirable speech, referred to the good news, this week, that the Government has allotted 57,000*l.* annually to research in relation to tuberculosis, and has appointed the Committee and the Advisory Council for this great work. Sir Thomas Barlow spoke of that unity of purpose which is between the men of science and the men in practice: how the doctor and the surgeon are indeed guided and helped by the physiologists and pathologists. Bishop Frodsham spoke of the Christianity of all work done, carefully and wisely, for the relief of suffering humanity; and, as Bishop of North Queensland, he has seen more than most of us of the misery caused by certain obscure tropical diseases, and has done more than most of us to alleviate it. Thus the subject which the Research Defence Society exists to popularise was presented from diverse points of view. Take what point of view we will, it is a subject of national importance.

THE BELFAST MEMORIAL TO LORD KELVIN.

THE statue of Lord Kelvin which has been subscribed for by the citizens of Belfast was unveiled by Sir Joseph Larmor, M.P., F.R.S., on Thursday last, June 19, in the presence of a large and distinguished gathering. The Chancellor of the Queen's University (the Earl of Shaftesbury, K.P.) presided, and the attendance included the Lady Mayoress of Belfast, the Vice-Chancellor of the Queen's University of Belfast, members of the Senate of Queen's University, and many of the leading citizens of Belfast.

In the course of his remarks, the chairman said that from the time of the death of Lord Kelvin the wish was uppermost in his (Lord Shaftesbury's) mind —as indeed he felt sure it was in the mind of everyone present—that there should be erected within the city of Belfast a fitting memorial to a man whose fame had gained for him a paramount position in the city of his birth and in the city with which he and his family were so intimately connected, as well as in the whole world. That day they were to see the consummation of their aspirations, and he offered his warmest thanks to Sir Joseph Larmor, who had so kindly come to perform the unveiling ceremony.

Sir Joseph Larmor then delivered an address, of which the main part is subjoined:—

I am deputed to represent on this occasion a company of subscribers, our fellow-citizens, who have thought it right that the genius of Lord Kelvin, and the great activities which kept him in the forefront of the advance of physical science in an age in which it has transformed the world, should receive permanent commemoration in the city of his birth and parentage, in the community among whom he passed the early years of his life, and to whom, in his later years, he put in an almost passionate claim that he belonged. We do not forget how profoundly he was moulded by the great city of Glasgow, with which his active career was so conspicuously associated. The intimate conferences from his early manhood with the pioneers of industrial development such as that city has possessed ever since the days of James Watt—discussions along the lines of unfolding problems of mechanical power, of naval construction, of the art of navigation—were just what was required to develop the student and natural philosopher into his other aspect, more familiar to the world at large, as the prophet and guide in the utilisation of the vast opportunities opened up, for the practical convenience of life, by modern scientific discovery. By no amount of mere natural ingenuity, after the manner of an inventor or a man of affairs, could anyone have attained to this position; an essential condition was sustained intellectual discipline such as Lord Kelvin enjoyed from his early years.

Fortunate in his home training, here and at Glasgow, under the careful and most competent direction of his father, he had completed the excellent general education which the University of Glasgow then afforded at an age when, in our leisurely days, he would still have been a schoolboy. He was thus able, like many a Scotch and Irish student before and since, to enjoy to the full the opportunities for advanced study, for initiation into the flowing tide of knowledge, which the University of Cambridge has always afforded to those who have known how to search for them with self-reliance and sincerity. And he had the good fortune to be able to combine serious studies, in a noteworthy degree, with active and fruitful relaxation; for he was one of the founders of the University Musical Society, and at the same time a prominent and successful oarsman. Thus he was not tempted to blunt his intellect, even temporarily, by early over-exertion; and though the examiners were not able to assign him the first place in the race for degrees over the limited prescribed course, even that was prejudged, for they were well aware, as one of them expressed it, that there was a man among the candidates they were to test whose pens they were scarcely qualified to mend. By the continued forethought of his father he passed on from Cambridge to Paris, then the chief centre of mathematical and physical science; he arrived provided with ample personal introductions, so that the diary which he sent home gives a most interesting account of the lives and activities of the investigators who were there at work in the middle of the last century. Young as he was, we can recognise that he moved among them on equal terms, and could impart as much as he gained. Inspection of his notebooks of this period, which fortunately have been preserved, and may in time be given to the world, shows that, as has been the case with so many men of genius, the main formative ideas came to him in early years. These rough records reveal that in his student time at Cambridge, or very soon after, he was already in effective possession of most of the advances which he gradually matured and made public during the next ten years: the period in which he was chiefly concerned with the theoretical side of electrical science. When, nearly twenty years ago, in the height of his fame, he took part in the centenary celebration of the Institute of France as one of its eight foreign associate members, he recalled his obligations to Paris and to her great men of fifty years before, in words of dignity and charm which sent a thrill of patriotic pleasure through the brilliant audience that he addressed. He was equally at home, and enjoyed equal affection and honour, among his compeers in Berlin, in Rome, in Washington; in fact, he had come in his later years to be venerated as embodying the universal ideal of the scientific spirit, transcending all limitations of nationality.

The fame and achievement of Lord Kelvin thus belong to all the world; yet we of Ulster have taken care to assert our special interest in his career. I am sure he would have cordially welcomed our claim that he is of ourselves. The connection of the Scottish universities, especially that of Glasgow, with the Ulster people has been intimate and prolonged. In the eighteenth century these great institutions were, owing to racial and religious affinities and geographical proximity, a main centre of our own higher education. But if we were thus under obligation to Scottish learning and intellect, there is also the other side of the account. In Francis Hutcheson, Ulster gave to Glasgow the pioneer of the Scottish school of philosophy, and one of the great names in the history of ethical speculation. Somewhat later we sent from Belfast to Glasgow and Edinburgh one who will always be held in honour, as chief among the founders of modern chemistry, Joseph Black, the clear-sighted discoverer of latent heat and of fixed air, the congenial friend of Adam Smith, David Hume, and Lavoisier. In our own time we gave the great man whom we now commemorate, supreme both in unfolding the intellectual foundations of physical science and in stimulating its fertile applications in an age of which they have been the special characteristic.

Our interest in Lord Kelvin has another aspect, namely, that in this city we have been in a very direct sense his scientific pupils. When some of us were students at the Queen's College, now the University, the chair of natural philosophy was held by Prof. Everett, who had come to us direct from service as Lord Kelvin's assistant in the University of Glasgow, and whose whole scientific activity and enthusiasm were directed towards the exposition of his master's fundamental work with which he had been thoroughly imbued in Glasgow; it was then fresh, and indeed largely in the making, and, it must be admitted, no easier for us (his students) to understand on that account. We had here, as professor of engineering, his elder brother, James Thomson, afterwards also given to Glasgow, a pioneer, greater than we then knew, in the consolidation of science with practice; the volume containing his scientific papers, recently published, bears witness to his ample share in the genius of the family, and to his intimate relations with Lord Kelvin. We had Thomas Andrews as professor of chemistry, whose profound scientific achievements, executed with modest apparatus of local construction, have shed permanent lustre on his native province. And not least, we had John Purser as professor of mathematics, a congenial scientific and personal friend of Lord Kelvin, at the same time in close contact with his own famous mathematical school of the University of Dublin, one of the choice minds of the time, who was wont to enchant those of us who could follow him by brilliant informal discourse about the problems of the day. The scientific work of Lord Kelvin was thus closely appreciated and studied among us here, as early as it could have been anywhere; he has been a permanent element in the intellectual life of the city of his early years, and on that account this local memorial, so spontaneously provided by his fellow-citizens, is a most appropriate tribute to his memory.

His name will pass down the ages as the outstanding guiding spirit of the period when the weapons of physical science were brought out of her secluded armoury, and turned to the reconstruction of our material civilisation. For we have now passed on rapidly from the age of steam into the age of electricity; we have had the good fortune to watch in our own day the progress of that subtle agency of silent power, until it has transformed most of the departments of industrial and social life. The dreams which were mixed with the wonder of the early electric discoverers have been more than accomplished. But this advance has become possible only by being the most conspicuous example of ordered and persistent scientific method that the world has seen. Every minute natural manifestation of electric agency, whether detected by the foresight of men like Faraday, or revealed in part by accident, has had to be accurately and closely analysed, as a prelude to eliciting its possibilities on an industrial scale. The method of true progress must have been impressed especially upon Lord Kelvin during those strenuous telegraphic years, when he was by force of circumstances dragged out of his study to battle with practical engineering difficulties—when, by submitting every phenomenon to that refined measurement and calculation which alone can lead to long secure trains of prediction and adaptation, he transformed the problems of submarine telegraphy from a blind, impracticable tangle into an ordered science. That achievement proved to be the crucial step in preparation for the present age of electricity. His disinterested persistence, through many subsequent years, in the same self-appointed task of rational measurement of electrical quantities and their relations, with the aid of the colleagues whom his zeal enticed into the service, formed the preparation, in all essentials, for uninterrupted progress, as soon as opportunity came in the world of affairs for the larger industrial electric developments to be pushed on. When these immense engineering advances were in full evolution, he was growing old, but his eager foresight still dominated the practical field.

Only in one respect did he fall short, in the theoretical electric advance, when he arrested his fruitful trains of inference on the interconnections of these partially concealed agencies, in order to search strenuously during long years for their complete elucidation, in some form such as could be exhibited and probed in a mechanical working model. Through this partial lapse of faith, this logical reluctance to take risks in following up the incomplete clues offered by nature, it fell to the most illustrious of his pupils and disciples, Clerk Maxwell, with greater daring and temporary disregard of difficulties, yet ever stimulated and guided by his master's own most instructive and inspiring though halting efforts, to connect light and heat in close linkage with electricity and magnetism, and so embrace all branches of physical science in one compact synthesis. This has been the great fundamental achievement in physical science of our age, probably the greatest since Newton announced and developed the law of gravitation. With the eye of faith, waves precisely the same in kind as those of light, only vastly magnified in size, had thus already been familiar to the initiated for twenty years, with fully mental vision of their constitution and behaviour, flashing across space in electric pulses, when at length, by an accident such as comes only to the worthy, the crowning honour of first detecting their actual bodily existence was grasped by Hertz. Then, as is usual in such cases, once a practical start has been gained—the more recent advance in the practice of artificial flight is another example—development was pushed rapidly on in many hands, by theory and experiment working together, until phenomena that it had taken a quarter of a century for eager expert searchers to detect at all, have now become, in the form of wireless telegraphic signals, almost a commonplace of everyday life.

We can recall some of the personal qualities of the great man whom we here commemorate, his splendid unconscious humility, his gentleness, his keen interests and enthusiasm, and readiness to learn from every true worker and to help him onward, his patience in controversy combined with the tenacity that indicates seriousness of purpose. In the words transferred to him by Huxley, a stout opponent in more than one discussion, "Gentler knight there never broke a lance."

Sir Joseph Larmor, on concluding his address, said it was his privilege to ask Sir Robert Anderson to accept, on behalf of the city of Belfast, that memorial to one of the great men whom Belfast and the province of Ulster had given to the Empire.

Sir Robert Anderson said that he esteemed it a very high honour to be asked to occupy the place on that occasion of the Lord Mayor, and to take over from his townsmen the custody of that beautiful memorial. He could assure them for the Corporation that the statue would receive every care and attention. He had no doubt that future generations would appreciate that memorial, not only as a work of art, but also for the influence it would exercise in stimulating students to try to emulate Lord Kelvin.

The Vice-Chancellor of Queen's University proposed that the best thanks of the subscribers be given to Sir Joseph Larmor for unveiling the memorial, and for his address. Proceeding, he referred in eulogistic terms to Sir Joseph Larmor's scientific work, and spoke with pleasure of the early association of Sir Joseph Larmor as a student of the Queen's College, Belfast. The proposal was seconded by Sir Otto Jaffé, and carried with acclamation.

At the close of these proceedings, the statue was unveiled by Sir Joseph Larmor amidst the applause of the assembled company. The ceremony concluded with a vote of thanks to the sculptor.

Lord Kelvin's statue, Botanic Garden Park, Belfast. Photographed by Mr. A. R. Hogg, Belfast.

Description of the Memorial.

The Botanic Gardens is one of the public parks of Belfast, and is situated about a mile and a half from the centre of the city. The position chosen for the statue adjoins the site of the new public museum which is shortly to be built.

The statue is the work of the well-known sculptor Mr. Albert Bruce-Joy. The figure itself is about 10 ft. high, and stands on a granite pedestal of about 13 ft. in height. As our illustration shows, the late

Lord Kelvin is represented standing erect. In the extended left hand there is a design of one of his discoveries—the adaptation of a gyroscope—and in the right hand is a pencil pointing to the drawing. By the side of the figure stands a representation of the Kelvin compass.

The inscriptions are as follows:—

The front of the pedestal bears the single word "Kelvin." On the right side is the following inscription:—

Sir William Thomson, Knt.,
Baron Kelvin of Largs,
P.C., O.M., G.C.V.O.,
Born in Belfast, 1824,
of Ulster Lineage.
Died at Largs, 1907.
Lies interred in Westminster Abbey.

The inscription on the left-hand side of the pedestal reads as follows:—

President of the Royal Society,
Chancellor of the University of Glasgow,
Following 53 years of service in the
Chair of Natural Philosophy.
Pre-eminent in elucidating
The Laws of Nature and in applying them
to the service of Man.

Memorial Tablets.

It may be mentioned that the committee in charge of the memorial has made provision for the placing, in the Hall of Queen's University, of a brass tablet in memory of Lord Kelvin's brother, Prof. Sir James Thomson, who filled the chair of engineering in Queen's College, Belfast, from 1857 to 1873.

A brass tablet is also to be placed in the Common Hall of the Belfast Royal Academical Institution as a memorial to Lord Kelvin's father, Prof. James Thomson, who was professor of mathematics in the Belfast College from 1814 to 1832. In addition, a memorial plate to Lord Kelvin is to be placed in the City Hall, as well as a tablet upon the house in College Square East, Belfast, where Lord Kelvin was born.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Leeds.—Dr. H. S. Raper, lecturer in pathological chemistry in the University of Toronto, has been appointed lecturer in chemical physiology.

The chair of applied chemistry (chemistry of leather manufacture), which becomes vacant on October 1 by the resignation of Prof. H. R. Procter, will be occupied after that date by Dr. E. Stiasny. Dr. Stiasny has been assistant-professor in the department for the last four years, and was previously professor in the Imperial Institute for Leather Industries at Vienna.

The University has recently received a valuable addition to its scientific collections in the presentation by Mrs. A. H. Clarke, of Earl's Court, of the collection of Continental and exotic Macrolepidoptera made by her late husband. The collection enriches the entomological resources of the University by more than 12,000 specimens, all carefully set, arranged, and labelled, and to this Mrs. Clarke has generously added her husband's working library of entomological literature, itself a present of great value and utility. The University authorities wish it to be known, in conformity with Mrs. Clarke's desires, that, after the immediate work of arranging and cataloguing has been concluded, the collections will be available for reference by entomologists generally upon application to the professor of zoology at the University.

London.—The Senate on June 18 re-elected Dr. W. P. Herringham as Vice-Chancellor for a second year. Four new appointments were made to University professorships, including Mr. E. H. Lamb to the chair of civil and mechanical engineering, tenable at East London College, and Dr. C. G. Seligmann to a part-time chair of ethnology at the London School of Economics. The title of emeritus professor was conferred upon Sir William Ramsay. Lord Haldane was appointed Creighton lecturer for next session.

The D.Sc. degree has been granted to E. R. Watson, an external student.

An anonymous donor has offered 300*l*. towards the institution of a lectureship in palæobotany at University College.

The prize distribution and conversazione of King's College, King's College for Women, and King's College Theological Department will be held at King's College, Strand, on Wednesday, July 2.

The Hon. Mrs. Ronald Greville, daughter of the late Mr. William McEwan, a munificent benefactor of the University of Edinburgh, has presented to the University Mr. McEwan's Edinburgh residence.

The title of emeritus professor of engineering has been conferred by the governing body of the East London College (University of London) upon Prof. D. A. Low, professor of civil and mechanical engineering, who has served in that institution for twenty-six years.

The prize fellowship of 120*l*. offered by the Federation of University Women has been awarded to Miss M. A. Whiteley, D.Sc. Dr. Whiteley is assistant-lecturer in chemistry at the Imperial College of Science and Technology, and is the author of several communications dealing with compounds of the barbituric acid series, and published in the Proceedings and Transactions of the Chemical Society.

The West Riding of Yorkshire Education Committee has decided to include in the vacation course to be held during August at the Bingley Training College, a laboratory course of experimental science, with lectures and discussions, under the direction of Prof. A. Smithells. This course is intended for science teachers in secondary schools, and especially for those who teach the subject to girls and desire to acquaint themselves with methods of correlating it with domestic subjects. It will relate chiefly to the subject of combustion and will discuss general questions connected with the teaching of elementary physical science, with special reference to experimental work; provide examples of the teaching of science in relationship to the phenomena and appliances of daily life and especially of domestic life; and give a connected account of the modern science of combustion and the chemistry of flame. The course is open to all teachers of science on the payment of the fees. Full particulars can be obtained on application to the Education Department, County Hall, Wakefield.

The Royal Commissioners for the Exhibition of 1851 have made the following appointments under their scheme of science research scholarships, upon the nomination of the universities and colleges mentioned. The scholarships are of the value of 150*l*. per annum, and are ordinarily tenable for two years:—University of Edinburgh, H. Levy; University of Glasgow, A. Gray; University of St. Andrews, R. F. Thomson; University of Birmingham, W. E. Garner; University of Bristol, F. G. Wilson; University of Leeds, H. Ogden; University of Liverpool, J. H. T. Roberts; University of London, W. B. Haines; University of Manchester, J. Chadwick; Armstrong College, Newcastle-on-Tyne, S. Robson; University College, Nottingham, T. A. Smith; University of Sheffield, C. C. Bissett; University College of North Wales, Bangor, R. Jones; University College, Cork, J. C. Johnson; University College, Galway, H. N. Morrison; McGill University, Montreal, O. Maass; Queen's University, Kingston, Ontario, J. R. Tuttle; University of Sydney, S. E. Pierce; University of Melbourne, N. R. Junner; University of New Zealand, P. W. Burbridge.

WE learn from *Science* that the total State grant to the University of California for the next biennium amounts to about 771,400*l*. Among the items contributing to this large sum may be mentioned:—Support and maintenance of the University, 80,000*l*.; agriculture—support and maintenance of all branches —140,000*l*.; replacement of buildings and equipment at Lick Observatory, 10,000*l*.; University extension, 10 000*l*.; Scripps Institution for Biological Research, 3000*l*.; 200 acres for experiment station in southern California, 12,000*l*.; laboratory building for experiment station in southern California, 20,000*l*.; the State University fund to be automatically appropriated during the coming two years for the support and maintenance of the University, amounting in total to 361,000*l*. From the same source we find that Yale University will received 95,000*l*. from the estate of Dr. Francis Bacon, who died last year. Mrs. Mary Emery has contributed 25,000*l*. to the Ohio-Miami Medical College of the University of Cincinnati for the endowment of a chair of pathology; and a sum of about 16,000*l*. from the estate of Dr. Francis Brunning has also been received by the University, the income of which will be used for the endowment of a second chair.

AN appeal for funds for the Home Science Department of King's College for Women has been issued. It is signed by Lord Rosebery, as Chancellor of the University of London, as well as by the Vice-Chancellor and Principal of the University. A site of $2\frac{1}{2}$ acres of Blundell House grounds on Campden Hill has been secured, and private gifts to the amount of 100,000*l*. have been subscribed during the last year and a half towards endowment, building of laboratories, and hostel. The London County Council has also made a maintenance grant to the department, thereby showing appreciation of the value of the courses, and the Exchequer grant to King's College for Women was made partly in respect of the work of the Home Science Department. The University has approved the granting of a diploma in household and social science, and in view of the new status thus assured it is necessary to complete the college by providing, in addition to laboratories and the hostel, lecture rooms and teaching rooms, common rooms for staff and students, and that accommodation essential to the life of a college or institution of a university character. A library will be needed, also a refectory. For this purpose a further sum of 50,000*l*. is required. Donations may be sent to the bursar, Home Science Department, King's College for Women, 13 Kensington Square, W.

DR. F. W. MOTT gave the third Chadwick lecture at the Royal Society of Arts on Friday, June 20. Sir James Crichton Browne was in the chair. The subject of the lecture was "The Influence of Nutrition and the Influence of Education on Mental Development." Dr. Mott commenced by pointing out the close association of body and mind; he observed that the child's brain, in order to grow and develop mental powers, must have the innate capacity to grow, and a proper supply of pure oxygenated blood wherewith it can take up the necessary materials for growth and function. A pure blood-supply, he argued, could only occur in a normal healthy body in which all the organs and tissues were cooperating for the common weal; the body could only be maintained in health by adequate and proper nourishment amidst hygienic surroundings. He next referred to collective and individual responsibility in respect to the child's nurture and mental development, and proceeded to give physiological reasons why the brain required stimulus from without for development. The importance of the tactile muscular sense, which contributes to every other sense, was emphasised, and he showed how the minds of Laura Bridgeman and Helen Keller were developed to a high degree of intelligence through the finger-tips. Sleep, rest of the brain, and the storage of mental energy were next touched upon as an important factor in the development of mind. Dr. Mott then passed on to consider the improvements in some modern systems of education; the happy passing away of the old system of payment of teachers by results, the desirability of educating according to physiological principles of development of function. The object of education should be to develop the physical, intellectual, and moral characters of the individual so as to make a final efficient product to fill a place in the social organism.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, June 11.—Dr. Aubrey Strahan, president, and afterwards Mr. W. Whitaker, in the chair.—Dr. Hans **Salfeld**: Certain Upper Jurassic strata of England. The localities dealt with are the Dorset coast from Kimmeridge to Abbotsbury, and the Wiltshire exposures at Swindon and Westbury. The formations concerned are the Portlandian, Kimmeridgian, and for a starting-point the Upper Oxfordian. The Upper Oxfordian = upper part of the English Corallian (+Kimmeridge Clay locally) is divided into three zones, found at Osmington, Westbury, and Swindon. The Kimmeridgian is divided into five zones, and is equal mainly to the Lower Kimmeridge Clay of English authors. The Portlandian is divided into nine zones; but the term as used includes the Portland Oolites, Portland Sands, and Upper Kimmeridge Clay of British authors. Three new genera of ammonites are named, and two new zonal species of ammonites defined.—A. **Jowett**: The volcanic rocks of the Forfarshire coast and their associated sediments. In Forfarshire these sediments are frequently amygdaloidal, the production of the cavities having been accompanied by the buckling and fracturing of the layers of sediment. Such effects may result from the pouring of molten rock over wet unconsolidated sediment; steam being produced within the sediment, but unable to escape owing to the presence of the overlying rock. Further evidence of the pouring of molten rock into water is furnished by the occurrence of a rude pillow-structure in some of the lavas. Several lenticular conglomerates are interbedded with the volcanic rocks, resting upon eroded surfaces of the latter. Most of the volcanic rocks are olivine-basalts, rhombic pyroxene as well as olivine sometimes being present. Some contain rhombic pyroxene to the exclusion of olivine. The fine sediments consist of a variable proportion of quartz and mica and a little felspar, together with chlorite, iron oxides, and occasional minute fragments of volcanic rock. Calcite, quartz, chalcedony, and chlorite are the commonest minerals in the amygdales, in both lavas and sediments.—J. **Parkinson**: A group of metamorphosed sediments situated between Machakos and Lake Magadi in British East Africa.

Physical Society, June 13.—Prof. C. H. Lees, vice-president, in the chair.—G. E. **Bairsto**: Some experiments on tinfoil contact with dielectrics. This paper describes some experiments showing how the accuracy of the different kinds of electrical measurements that are made on condensers is influenced by the use of an imperfect tinfoil contact. While considerable errors are liable to be made in deducing the specific direct-current conductivity of a dielectric between tinfoil armatures, the same is not true for measurements of the alternating-current conductivity. The influence of the bad contact is twofold. First, it decreases the apparent capacity by inserting in series with the condenser under test a very large but still finite air condenser. This causes a decrease in the measured conductance. Secondly, because of the decrease in area of contact, it decreases the magnitude of that component of the conductivity which is independent of the frequency—*i.e.* the purely ohmic conductivity. It is shown experimentally, even under the worst possible circumstances, the dielectric being only lightly bound up with the interleaved tinfoil, that for telephonic frequencies the maximum difference between the observed conductivity and true conductivity is 15 per cent., and of capacity 5 per cent. With the condenser tightly bound with tape and wedges of wood inserted, the maximum difference was only 4·5 per cent. in the conductivity and 2·5 per cent. in the capacity. Finally, the influence of imperfect contact upon the accumulation of residual charge is considered.—G. D. **West**: A method of measuring the pressure of radiation by means of thin metal foil. The pressure of the radiation emitted by a carbon filament lamp at a distance of a few centimetres is sufficient to cause a microscopically measurable deflection of the end of a suspended strip of gold or aluminium foil, and by this means the radiation pressure can be calculated knowing the weight of the strip. The results agree to within about 10 per cent. with the energy content per cubic centimetre as measured by the initial rate of rise of temperature of a copper plate exposed to the radiation. The best results are obtained by working in an atmosphere of hydrogen, 1 cm. to 2 cm. pressure, but good results are obtained with hydrogen at atmospheric pressure. Air at 1 cm. to 2 cm. pressure also gives good results. —Dr. W. **Wilson**: The emission of electricity from hot bodies and the quantum theory. The paper gives a theory of the emission of electricity from hot bodies which is based on the quantum theory of energy. A formula connecting the thermionic current and the temperature of the emitting body is deduced. This formula closely resembles that of Richardson, and agrees slightly better with experimental results.

Mineralogical Society, June 17.—Dr. A. E. H. Tutton, F.R.S. president, in the chair.—W. L. **Bragg**: Crystal-structure as revealed by Röntgen radiation. An analysis of the diffraction patterns obtained when X-rays traverse a section of a crystal shows that in many simple crystals the diffraction is caused by a set of points arranged on a space-lattice. That is the case when the molecule contains either a single heavy atom of at least twice the atomic weight of the other constituents, or only two atoms of nearly the same atomic weight. By comparison of the patterns given by certain alkaline halides, such as KCl and KBr, a definite structure of these cubic crystals is clearly indicated, and it would appear that the atoms are arranged on a space-lattice the elementary parallelopiped of which is a cube, alternate atoms being along the axes, so that the atoms of one kind form a face-centred cubic space-lattice. These conclusions are confirmed by a comparison of the distances between planes parallel to the various faces of these crystals carried out by means of the X-ray reflection-spectrometer, and it appears that a single atom is associated with each point of the space-lattice which diffracts, in the case, for instance, of the alkaline halides, calcite, fluor, blende, and pyrites. If the suggested structure of the crystals is correct, a simple calculation gives the absolute wave-length in centimetres of the homogeneous components in the X-ray beam from a platinum antikathode.—H. V. **Ellsworth**: The crystal habit of topaz from New Brunswick, Canada. Topaz, a rare mineral in Canada, occurs in York County, New Brunswick, associated with wolframite, molybdenite, and a little fluor. On the crystals the forms 110, 120, 011, 112, are prominent, but other pyramid and prism forms are sometimes present, sixteen forms altogether being observed. Dull faces were coated with silver by Brashear's process, in which an ammoniacal solution of silver nitrate is reduced by a sugar solution.—Dr. G. T. **Prior**: The meteoric stone which fell at Baroti, Punjab, India, in September, 1911. The stone, which belongs to the "intermediate chondrite" group of Tschermak's classification, was found on analysis to contain about 9 per cent. of nickel-iron and 7 per cent. of troilite, which were disseminated in small particles through a colourless matrix of enstatite and olivine showing only few chondrules.—Dr. A. W. **Gibb**: Kämmererite from Unst, Shetland Islands.

Royal Meteorological Society, June 18.—Mr. C. J. P. Cave, president, in the chair.—J. S. **Dines**: Pilot balloon observations in Barbados, 1911–12. These balloon ascents were carried out by Prof. J. P. d'Albuquerque and other gentlemen, on behalf of the joint upper air committee of the Royal Meteorological Society and the British Association. Great difficulties were experienced in carrying out the work, the most serious of which was due to the adverse effect of the climate of Barbados on the rubber fabric of the balloons, thus causing them to deteriorate more rapidly than in colder regions. Consequently no very high ascents could be obtained.—H. W. **Braby**: The Harmattan wind of the Guinea coast. This is a north-east wind which blows during the winter months along the coast of Upper Guinea from French Guinea to the Cameroons. It is exceedingly dry and brings with it fine sand which enters the crevices of doors and windows, covering everything with a film of dust. The sun is partially obscured and distant objects become invisible. This wind, which blows intermittently from November to March, is locally known as "the doctor."—Dr. E. C. **Snow** and J. **Peck**: The correlation of rainfall. The authors dealt with the monthly rainfall from a number of stations in the south-eastern counties of England for the four years 1908–11, and found that the rainfall in two or three of the months is more highly associated with that in certain other months than with the rainfall in the remaining months.

DUBLIN.

Royal Irish Academy, June 9.—Prof. Sydney Young, F.R.S., vice-president, in the chair.—R. **Southern**: Clare Island reports. (1) *Polychaeta errantia*. In this paper the families Syllidæ to Paraonidæ were treated systematically. The total number of species found in these families was 143. Of these, nine were described as new, belonging to the genera Sphærosyllis (1), Pionosyllis (1), Streptosyllis (2), Opisthodonta (1), Pholoë (1), Præegeria (1), Mystides (1), and Paronides (1). A new genus, Prægeria, was described, belonging to the family Pisionidæ, previously known only from the west coast of South America. In addition, twenty species were added to the British fauna. (2) Hirudinea. The leeches found in the Clare Island area comprise eleven species, of which six are freshwater species, and five are marine. Of the freshwater forms, *Hemiclepsis marginata* was found for the first time in Ireland.—E. **Heron-Allen** and A. **Earland**: Foraminifera from the area of the Clare Island Survey. The authors have worked out as independent units of their study thirty-seven stations in the area. Of these, eleven were shore-sands, five were dredgings taken by themselves from small boats, and the rest were dredgings made by them on board the fisheries cruiser *Helga*, kindly placed at their service by the Irish Fisheries Board. The authors record fifteen species new to science, thirty-five species new to Great Britain, and twelve species recorded for the second time in British waters. The most important contribution to zoology is a complete revision and rearrangement of the genus Discorbina, the affinities of which have become almost hopelessly confused in the literature of the subject. Altogether two hundred and ninety-nine species are recorded from the district.

Paris.

Academy of Sciences, June 16.—M. F. Guyon in the chair.—P. **Appell** and H. **Vergne**: A transformation of a movement of a given conservative holonomial system into the movement of another system given the same freedom.—Charles **Moureu** and Georges **Mignonac**: The ketimines. It is suggested that imines derived from aldehydes of the type R.CH : NH should be termed aldimines, whilst those derived from ketones of the type RR'.C : NH are called ketimines. A new general method of preparing the latter is described based on the condensation of a nitrile with alkylmagnesium bromide, and the treatment of the compound thus formed with hydrochloric acid in dry ether under special conditions. Eight ketimines have been prepared, the properties of which are given.—M. de **Forcrand**: The Trouton coefficient and the heat of vaporisation of pure bodies boiling at low temperatures. Data for helium. The empirical formula recently proposed by the author is applied to the cases of chlorine, radium emanation, oxygen, nitrogen, hydrogen, and helium, and the values calculated for the latent heats of vaporisation compared with the experimental figures; the agreement is fairly satisfactory. The case of helium is dealt with in detail.—Eugène **Fabry**: An attempt at a demonstration of Fermat's theorem.—H. **Jonas**: A transformation which depends on a partial differential equation of the third order.—Paul **Montel**: Total differentials and monogenous functions.—Michel **Petrovitch**: Hypertrigonometric series.—Ch. **Platrier**: The holomorphic solutions of certain linear integral equations of the third species.—Theodor **Poschl**: The canonical equations of non-holonomial systems.—Z. **Carrière**: A new method of measuring the velocity of fluids. A small jet of steam is introduced into the flowing gas the velocity of which it is required to measure. A series of small isolated clouds is formed, which are studied by a rotating mirror and a formula deduced giving the velocity.—Marcel **Moulin**: The terminal curves of a chronometer balance spring.—Pierre **Weiss**: The magnetisation of crystals and the hypothesis of the molecular field.—G. **Sagnac**: Interferential strioscopes and simplified interferometers with inverse circuits. Stationary vibrations on a transparent silver film.—F. **Bodroux** and F. **Taboury**: The bromination of some ketones and some secondary hydroaromatic alcohols. The method of bromination of *cyclo*hexanone and *cyclo*hexanol described in a previous paper has been extended to some homologues of these compounds.—J. **Durand**: The fossil shells in inclusions in the clear crystals of gypsum of the Oligocene at Narbonne. The shells observed include Potamides, Lymnœa, Planorbis, and Helix. The inclusion of such shells in gypsum crystals appears not to have been noted before; it is of interest as regards the theory of the formation of certain gypsums.—L. **Reutter**: Chemical researches on cocoa seeds.—P. A. **Dangeard**: The action of radiation in a mixture of colouring matters. A mixture of chlorophyll and pinaverdol was exposed on a collodion film to light; the pinaverdol is transformed and finally destroyed by the energy absorbed by the chlorophyll. Pinaverdol exposed under similar conditions in the absence of chlorophyll to light is unaffected.—Y. **Manouélian**: Researches on the cardiac plexus and on the innervation of the aorta.—Marcel **Belin**: The action of oxidising substances on toxins *in vivo*. The experiments were made with guinea-pigs and the oxidising substance employed was sodium chlorate in doses of 0·08 gram per kilogramme of body weight. A favourable action was observed with typhoid fever and streptococcus infections.—Charles **Nicolle** and A. **Conor**: Vaccinotherapy in whooping-cough. Inoculation with living cultures of Bordet's micro-organism resulted in cure of about one-third of the cases, improvement in a third, and the remainder were stationary. One hundred and twenty-two children were treated, and in no case was the inoculation followed by any general or local reaction.—M. Emm. **Pozzi-Escot**: Researches on the mechanism of the acclimatisation of yeasts to formaldehyde. Formaldehyde loses its antiseptic properties in yeast solution owing to its combination with the amido-compounds present. There is no evidence that formic acid is formed by oxidation.—W. **Kopaczewski**: An analytical dialyser.—Henri **Agulhon**: The action of boric acid on zymase; comparison with the action of phosphates.—Mme. and M. A. **Chauchard**: Quantitative study of the action of monochromatic ultra-violet rays on amylase. The photochemical action of the ultra-violet rays on amylase is proportional to the absorption of these rays by the solution containing the ferment.—Jean **Bielecki** and Victor **Henri**: Quantitative study of the absorption of the ultra-violet rays by monoamines, diamines, nitriles, carbylamines, amides, and oximes of the fatty series.—H. **Zilgien**: The transformation of calomel into soluble mercury salts in the digestive fluids.—Emile **Haug**: The western termination of Sainte-Baume.—Léon **Bertrand** and Antonin **Lanquine**: Tectonic observations in the neighbourhood of Grasse.—E. Hernandez **Pacheco**: The Miocene mammals of Palencia in the Spanish *Meseta*.—Carl **Störmer**: An expedition for the observation of the aurora borealis at Bossekop in the spring of 1913. Six hundred and thirty-six pairs of simultaneous photographs of the aurora were taken, of which 450 pairs were good enough to furnish material sufficient to calculate with great precision the form, situation, and altitude of the principal species of the aurora borealis.

Cape Town.

Royal Society of South Africa, May 21.—The president in the chair.—A. G. **Stigand**: Notes on Ngamiland. A general account of Ngamiland and its inhabitants. —H. A. **Wager**: Some new South African mosses.—W. A. Douglas **Rudge**: Magnetic observation taken at Bloemfontein. In this paper some account is given of the diurnal range of the declination at Bloemfontein during the period from August to December, 1912.

Tables are given showing the daily range of the variation, and also the times of the maximum and minimum declinations to the east. The mean value of the declination is about 24° W. The greatest deviation from this occurs during the afternoon, and amounts in some cases to 7·2 minutes of arc, less than 24°. The total change in the declination has been as much as 10·8 minutes in the day. Twelve curves are given. The change in the position of the maximum, and also of the range, is of the same order as that noted by General Sabine in the records taken at Cape Town more than sixty years ago.—R. B. **Thomson**: Note on the vertebral column of the Bushman race in South Africa. The object of the investigation was to determine whether racial character could be said to exist in the cervical and thoracic vertebræ, such having already been pointed out in the lumbar and sacral regions. The results would tend to show that the bodies of the cervical and thoracic vertebræ are relatively narrower in their anterior-posterior diameter, and deeper in their vertical depth by about 5 per cent as compared with Europeans. The vertebral foramen in both regions is relatively longer, but not to such a marked extent in the thoracic region. The vertical anterior and posterior depths of the bodies of the cervical and thoracic vertebræ show that these vertebræ, in common with the lumbar, are not adapted to the vertebral curves. The adaptation of the curves must therefore be purely undertaken by the cartilaginous disc.

CALCUTTA.

Asiatic Society of Bengal, June 4.—Rasik Lal **Datta**: The action of nitrosyl chloride on secondary amines, methylbenzylnitrosamine and ethylbenzylnitrosamine. The amines experimented with were methylbenzylamine and ethylbenzylamine, the corresponding nitrosamines being obtained as yellowish oils.—Sarat Chandra **Jan**: A new compound of ethylacetoacetate with mercuric oxide. The preparation of the compound $3HgO,4CH_3COCH_2COOC_2H_5$ is described.—Rasik Lal **Datta** and Haridas **Mukherji**: The double mercuri-periodides of substituted ammonium bases. Terrapropylammonium mercuri-periodide. A description of the preparation of the salt $5N(C_3H_7)_4I,HgI_6$ is given.—Hem Chandra **Das-Gupta**: Two-shouldered stone implements from Assam. A short note describing two small stone adzes approaching the Burmese type, obtained from the districts of Tezpur and Cachar in Assam and now in the collection of prehistoric antiquities of the Indian Museum. The occurrence of these implements in areas through which the wave of Khasia immigration may have passed is of some interest in view of the relationships which exist between this tribe and the Mon-Hkmer peoples of Burma.—Prof. George H. **Carpenter**: A new springtail from Galilee. In describing a new species of Cyphoderus from near Tiberias the author notes its resemblance to forms from the valley of the White Nile.—Dr. N. **Annandale**: Polyzoa from the Lake of Tiberias. A large number of specimens of Phylactolæmatous Polyzoa were obtained in the Lake of Tiberias, but only two species were represented, a hitherto undescribed Plumatella, remarkable for its yellow lophophore, and *Fredericella sultana*, Blumh. Reasons are given for regarding the Galilean race of the latter as distinct from the common European form, and particulars of its biology are noted.—Dr. N. **Annandale**: Note on a sponge larva from the Lake of Tiberias. Free-swimming larvæ of Nudospongilla were found to agree in the more important characters with those of Spongilla. In view of the resemblance between the skeleton of the former genus and that of some marine sponges the point is of interest.

BOOKS RECEIVED.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH

No. 2279, VOL. 91] THURSDAY, JULY 3, 1913 [PRICE SIXPENCE

Registered as a Newspaper at the General Post Office.]

THURSDAY, JULY 3, 1913.

AN EPITOME OF GEOMETRICAL CRYSTALLOGRAPHY.

Statische und kinetische Kristalltheorien. By Dr. J. Beckenkamp. Erster Teil. Pp. viii + 206. (Berlin: Gebrüder Borntraeger, 1913.) Price 9.60 marks.

THE style of this book recalls that of parts of the "Encyclopädie d. math. Wissenschaften." A summary is given of practically the whole of geometrical crystallography, both experimental and theoretical. There is included, for instance, an account of crystalline symmetry and structure theory, together with a description of the common types of twinning, habit, &c. Physical crystallography, including the optical, elastic, and electrical behaviour of crystalline media, lies outside the scope of the book.

It will be readily realised that so large a field cannot be adequately covered in 206 pages. The author confines himself almost entirely to the quoting of results. For example, formulæ are given to obtain the most probable values of the true angles between four crystal-faces from the observed angles, and also formulæ for calculating the angles between these four faces and the remaining faces; but no indication is given of the method of arriving at these results. Again, though the thirty-two crystal classes are described in detail, no proof is given of the fact that there are exactly thirty-two classes—and similarly throughout the treatise.

Dr. Beckenkamp is evidently interested in the history of crystallography; and he begins each section with a historical summary of work done on the subject-matter of that section from the earliest days of the science, with quotations from various authors and valuable references.

The book is illustrated by 303 excellent diagrams, well drawn, and easy to follow except for those illustrating the author's theory of molecular groups, which are on rather too small a scale to be clearly visible.

The style of the work is clear and interesting, and the book is divided into sections of a convenient length, so that the reader is not tired by over-concentration on a particular theme.

The book will be a useful addition to the literature of the subject, especially as a work of reference; but even the beginner will find it attractive, though he will require to supplement it by some work which goes into more detail. Perhaps the least satisfactory part is that dealing with the author's own structure theory. He has scarcely succeeded in making his point of view clear; and, in fact, the task of explaining a new structure theory of crystals in six pages without the assistance of a single mathematical formula would lie beyond the powers of any writer. But doubtless this will be remedied when part ii. appears.

HAROLD HILTON.

A HISTORY OF CHEMISTRY.

A History of Chemistry from the Earliest Times till the Present Day. By the late Prof. J. C. Brown. Pp. xxx + 543. (London: J. and A. Churchill, 1913.) Price 10*s.* 6*d.* net.

THE late Prof. Campbell Brown, of the Liverpool University, was in the habit of delivering annually a series of lectures on the history of chemistry to his senior students as part of their degree course, and he had the intention, on his retirement, of preparing these lectures for publication. His sudden and unexpected death while still in the occupation of his chair prevented him from personally realising his wish. Mrs. Campbell Brown, with the assistance of Mr. Henry H. Brown, and Prof. Brown's late chief assistant, Mr. W. H. Roberts, has, however, sought to give effect to his intention, and the present handsome volume is the result of their labours. Its compilation has obviously been a labour of love, and forms a fitting memorial to a singularly earnest, conscientious, and high-principled man who played a notable part in the educational history of Liverpool, and particularly in the creation and development of its University. Its preparation for press must have been a matter of no little difficulty, and the form in which it is now presented reflects great credit upon Mr. H. H. Brown and his coadjutor.

The original matter was largely in the form of notes, more or less complete, which the lecturer was accustomed to amplify and comment upon at the moment, and there is little doubt that, had Dr. Brown lived to complete the work, much additional matter would have been included. Possibly, also, some omissions and corrections would have been made in the light of more exact knowledge. The book makes no pretensions to research among original authorities, and it is obvious that the lecturer had been content to take his facts and interpretations from well-known sources, such as Thomson, Hoefer, Kopp, Meyer, Ladenburg, Berthelot, and others that might be named. In many cases the illustrations, as well as the phraseology, afford the key to the source of the statements. The book is eminently readable, and may be recommended to the student who

T

desires only a very general acquaintance with the main lines of the historical development of the science, without too much critical detail. Considering the immensity of the subject, a great amount of information has been packed into the five hundred pages of which the work consists.

The book is prefaced by a short biographical note in which the main features of Dr. Brown's character, and the chief incidents in what was practically a lifelong connection with Liverpool, are dealt with sympathetically. There is also an excellent and characteristic portrait of the professor by way of frontispiece. T.

REPRODUCTION AND DEVELOPMENT.

(1) *Vertebrate Embryology: Comprising the Early History of the Embryo and its Foetal Membranes.* By Dr. J. W. Jenkinson. Pp. 267. (Oxford: Clarendon Press, 1913.) Price 12*s*. 6*d*. net.

(2) *Problems of Life and Reproduction.* By Prof. Marcus Hartog. Pp. xx + 362. (London: John Murray, 1913.) Price 7*s*. 6*d*. net.

(1) DR. JENKINSON'S "Vertebrate Embryology" will be welcomed by all students of that subject in this country. Hitherto the only book on embryology of convenient size and suitable for elementary students has been Bryce's volume in "Quain's Anatomy," but this work is devoted almost exclusively to human embryology, and is avowedly intended for students of medicine rather than for those taking zoology for an honours degree in science. Dr. Jenkinson's book will not be without utility to the more advanced workers in the subject, including original investigators and teachers. To each chapter there is appended a short bibliography which affords a valuable guide to the literature.

In the first chapter, which is introductory in character, it is shown that the structural differentiation which occurs in embryonic development (and also in later life) takes place by movements either of single cells or of cell aggregates, and finally through the assumption by the cells of the histological characters peculiar to each kind of tissue. It is pointed out further that it is not a process of cell division which produces the differentiation, since differentiation already exists in the ovum prior to segmentation, and is, indeed, the real cause of the differentiations which subsesequently manifest themselves. The second chapter is upon growth, and is illustrated by figures of growth taken mainly from the work of Minot, and showing the daily percentage increments in the weights of man and animals.

Chapters iii. and iv. are upon the germ-cells, and contain admirable accounts of the phenomena of spermatogenesis, oogenesis, and fertilisation. The author accepts the view that the germ-cells are not all formed in or from the germinal epithelium, but that the first to develop come from the endoderm or splanchnopleure (mesoderm) of the gut or yolk-sac, and reach their final resting-place by migrating there. There is no mention, however, of Miss Lane-Claypon's statements (at present unconfirmed) regarding the origin of ova from ovarian interstitial cells after the attainment of sexual maturity. The author states that the follicle cells are also probably derived from the germinal epithelium, but the recent work of Miss McIlroy is not quoted. In referring to the corpus luteum, the author says that this organ secretes a substance which appears to be necessary for the proper attachment of the embryo by means of the placenta. The theory has often been stated in this form, but it now appears to the reviewer that in a work like the present it might be better to assert merely that the hypertrophy of the follicle cells is functionally correlated with the contemporaneous uterine hypertrophy, which is a necessary factor in the growth of the placenta and the nourishment of the embryo, and cannot occur in the absence of luteal tissue in the ovary. The truth of the hypothesis stated in this general form seems to be beyond question, whereas the exact nature of the correlation is a problem which still awaits complete solution.

Space does not admit of more than a passing mention of the succeeding chapters; they deal with segmentation, the germinal layers, the early stages in the development of the embryo, the fœtal membranes, and the placenta. The chapter on the placenta is of especial interest, for Dr. Jenkinson writes with the authority of an original investigator. The physiological side of the subject is not neglected, and there are new and interesting details concerning the œstrous cycle. A word must be added in praise of the numerous illustrations, which, with very few exceptions, were drawn specially for this book.

(2) Prof. Hartog's work consists of a collection of essays contributed at various times during the last twenty-one years to different journals, and embodying his views on certain biological questions of importance. The majority of the articles are republished with little alteration, but the fourth chapter, in which the author's views on the physics of cell-division are put forward, has been almost entirely re-written.

The first chapter is entitled "Some Problems of Reproduction," and contains an account of the author's theory as to the significance of the polar bodies, which are regarded merely as the products of brood-divisions of the ovarian egg.

The author points out that "the abortion of certain members of a brood or group to the favour of others" is a phenomenon of frequent occurrence in nature, and he instances those flowers which produce more ovules than ever ripen into seed. According to his theory, the expulsion of the polar bodies is simply an incident recalling the past history of the race, and the physiological explanations are uncalled for. On this view the remarkable constancy of the phenomenon among the higher animals seems to be insufficiently accounted for, while the reduction processes remain imperfectly explained.

In the second chapter the author deals with the problem of heredity, and comes to the conclusion that at present the facts can only be elucidated by the light of mental, not material, processes. While inclining to the memory theories of Butler and Hering, he expresses himself also as favourable to an explanation assuming the succession of a series of complex chemical changes after the manner postulated by Delage or by J. T. Cunningham in his hormone theory of heredity. In the third chapter the author returns to the subject of brood formation and its relation to ordinary cell-division, and the various types of brood formation are briefly described. Chapter iv. first appeared under the title, "The Dual Force of the Dividing Cell," but in this work it has undergone much revision, and is headed "The New Force, Mitokinetism." In addition to the existence of a well-known physical force, and others the physical interpretation of which is uncertain (such as protoplasmic streaming), the author invokes the aid of a new force which he calls "Mitokinetism," besides assuming the existence of further forces which have no clear analogies either in physics or in biology. The whole chapter, though ingenious, is highly speculative, and consequently difficult to criticise in a short review.

In chapter v. Prof. Hartog returns to the subject of nuclear reduction, which is already touched upon in chapter iii. His view may be summarised in the statement that the process is a necessary consequence of cell fusion, instead of a preparation for it. The author appears to us to lay altogether undue stress upon the difference between the two theories. He points out that a reduction must take place somewhere, otherwise the number of chromosomes would go on increasing in geometrical progression. This is, of course, obvious, and since the reduction usually (though not invariably) takes place in the last division of gametogenesis, it appears to us legitimate to regard it as a preparation for zygotic union.

In the next chapter Prof. Hartog reverts to his views on fertilisation. He suggests that owing to the ambiguity of the term "fertilisation" it had better be replaced by "syngamy" when used in its strict morphological sense as the fusion of two cells or nuclei. He makes the interesting suggestion that the formation of the fertilisation membrane is the last relic of the time when the newly-formed zygote usually went into a resting condition.

In chapter vii. the author again gives the arguments in favour of the theory that acquired characters can be inherited, and in chapter vii. the case against a purely mechanistic interpretation of life is once more stated. Great stress is laid on the vital powers of readjustment and compensation under diverse conditions, and the possession of a spontaneity which is never possessed by machines, since these work for the mechanician, whereas the living organism works and adapts itself to its own racial needs.

The chapter on the biological writings of Samuel Butler is well worthy of perusal, and we feel indebted to Prof. Hartog for giving us a further insight into the fascinating personality of the author of "Erewhon." The last two chapters deal with education problems, and though not without interest, seem rather out of place in the present book. Though containing little that is new, the volume supplies a useful summary of the author's views on many subjects, and as such it forms a welcome addition to the "Progressive Science Series."

FRANCIS H. A. MARSHALL.

FOUR ZOOLOGICAL TEXT-BOOKS.

(1) *Elementary Biology: Animal and Human.* By J. E. Peabody and A. E. Hunt. Pp. xiv+212. New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1912.) Price 4s. 6d. net.

(2) *An Introduction to Zoology.* With Directions for Practical Work. (Invertebrates.) By Rosalie Lulham. With Illustrations by V. G. Sheffield. Pp. xv+457. (London: Macmillan and Co., Ltd., 1913.) Price 7s. 6d. net.

(3) *Teachers' Manual of Biology.* By Prof. M. A. Bigelow. Pp. ix+113. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1912.) Price 1s. 8d. net.

(4) *A Manual of Zoology.* By Prof. R. Hertwig. Third American from the ninth German edition. Translated and edited by Prof. J. S. Kingsley. Pp. xii+606. (New York: Henry Holt and Co., 1912.)

(1) THE lively book by Messrs. Peabody and Hunt strikes a modern educational note, for the primary emphasis is placed on *practical values*. It is intended as a guide to school-

teachers. Animals are discussed in order to throw light on the biology of human life, in order to help towards healthy living. Everyday functions get a prominent place; bees, mosquitoes, and flies come to the front; the discussion of birds and fishes leads on to the question of their conservation; the Protozoa are used to illumine man's cellular processes; bacteria receive much attention. Precise practical work is, of course, insisted on as a discipline, and many of the conventional tasks are included. But there are as many which have a fresh practical turn.

The lessons on everyday hygiene, on foods, and on the use of alcohol and tobacco seem to us very sound, and, in short, what we like about the whole book is its persistent endeavour to bring the biological instruction into direct touch with human life. There is no risk that the study of pure science will be in this way endangered, and there is every likelihood that the education of the young citizen will be immensely improved. The book is generously provided with interesting illustrations, many of them photographs.

For future editions we would make the suggestion that the authors do not attempt to cover quite so much ground. Thus the paragraph on the relatives of the earthworm would be much better deleted unless more can be said, and there are many other cases where this book would be improved by recognising the necessity for others. We should like to express our appreciation of the wholesome view that "no study of human biology should be allowed to leave in the mind of the student the idea that he is merely a chemical engine adapted only for the generation of a certain amount of physical energy."

(2) Miss Lulham is to be congratulated on the success of her "Introduction to Zoology," which fills a distinct gap. It introduces the student to the study of living creatures (Invertebrates only) with habits and habitats and interrelations, and it has been written from experience. It abounds in valuable practical hints. There is a convincing reality about the book, and a real feeling of the open air, two qualities which are enhanced by the unusually skilful and spirited figures which have been prepared by Miss Violet Sheffield. This introduction should be of great value to teachers of nature-study, to students working alone, and to those who wish to supplement their more analytic and anatomical work by some sound oecology.

Miss Lulham deals excellently with earthworm and starfish, pond-snail and prawn, but she is at her best when she comes to spiders and insects—to which much more than half the book is devoted. It will be a good thing for the study of natural history if this exceedingly educative "Introduction to Zoology" comes into widespread use, as it certainly ought to do. For it is unusually true to its excellent motto:—

Ἐν πᾶσι γὰρ τοῖς φυσικοῖς ἔνεστί τι θαυμαστόν.

(3) Prof. Bigelow's manual is really a sort of teacher's appendix to accompany "Applied Biology" and "Introduction to Biology," by Anna N. Bigelow and himself. He gives useful hints as to the best way of using the "Applied Biology" (without which this manual is of relatively little use), and advice in regard to material for practical work, methods, equipment, and literature. The orientation of the biological studies in relation to human life is a prominent feature in Prof. Bigelow's plan of instruction, and he is emphatic in regard to the indispensableness of the biological foundation. In regard to sex-hygiene, for instance, he says: "The most practicable step now possible in the world-wide movement for sex-education is the development of the full possibilities of the biological studies that touch the problems of reproduction."

(4) Prof. R. Hertwig's "Zoology" has passed through nine German editions and continues to be a favourite manual. It gives a general introduction to morphology and physiology and a systematic treatment of the various phyla, with special attention to particular types. Its virtues are general trustworthiness, clearness, and a judicious selection of essentials. Its deliberate defects are that it is too much pemmican and not very interesting, and that it says very little about the life of animals. Prof. Kingsley has prepared a revised American edition, especially adapted for American needs. It is to a considerable extent a new book, and it is a competent piece of work sure to be of great utility. It has been very carefully edited, and it includes not a few original figures. We cannot profess, however, to have any belief in the usefulness of the summaries of important facts given at the end of each phylum; many of the propositions are too terse to be true, and altogether they smack of the cram-book. J. A. T.

OUR BOOKSHELF.

Ueber einfache Pflanzenbasen und ihre Beziehungen zum Aufbau der Eiweissstoffe und Lecithine. By Dr. G. Trier. Pp. iv+117. (Berlin: Gebrüder Borntraeger, 1912.) Price 5·60 marks.

THIS work is a valuable contribution to plant chemistry by a well-known worker who, by his own researches, has considerably enlarged our knowledge in this special domain. He has found it possible to give a summary of recent work and theoretical views of a complex character which is extremely interesting but might easily have been made a very dull affair. After briefly formulating the simple bases and amino-acids occurring in plants, the author proceeds to discuss their relationships and the probable way in which they are actually built up in the plant. He develops a simple hypothesis by which amino-ethyl alcohol (which he himself recently isolated as a product of the hydrolysis of lecithin) and amino-acetic acid are formed from glycol and glycollic acid, and regards these substances as the simple bricks from which the complex lecithins and proteins are built up.

In this synthesis the primary stage is a Cannizzaro transformation of glycollic aldehyde to the corresponding alcohol and acid, which the author regards as effected by an enzyme mutase, citing evidence in support of this view. It may, however, be suggested that this action is a direct effect of light, as in the case of many similar changes recently studied. Some of the author's views as to the manner in which complex alkaloids, for example laudanosine in the *iso*quinoline group, are built up from a single aromatic amino-acid are ingenious and very probable. Interesting chapters in the work deal with such questions as the biological significance of the betaïnes, the occurrence of methylation in the plant, the nature of the phosphatides and lecithins and the synthesis of the purine bases within the plant.

Some of the author's remarks on p. 70 with reference to the non-production of nicotinic acid in nature would appear to need modification owing to the discovery, since the work was published, by Suzuki and Matsunaga of this acid in rice-bran; this acid has great significance as derived from a β amino-acid.

The work would be greatly improved by equipping it with an index. W. A. D.

La Sécrétion Pancréatique. By Emile F. Terroine. Pp. 133. (Paris: A. Hermann et Fils, 1913.) Price 5 francs.

This little book on the pancreas forms one of a series of biological monographs which are appearing under the direction of Prof. Dastre, of the Sorbonne. The first chapters treat the subject historically, and show by what slow steps the early knowledge of this important organ was obtained, and the important character of Claude Bernard's pioneer work.

The bulk of the book is, however, taken up with a discussion of modern views, which were initiated by Pawloff and elucidated by the great discovery made by Bayliss and Starling of the part played by a chemical stimulus in stirring up the organ to activity. This material, called secretin, is formed in the intestine, and reaches the pancreas by the blood-stream; so that the mechanism may be described as a "humoral reflex" as against the nervous reflex which was formerly supposed to exist. Secretin is not the only chemical messenger in the body; physiologists now are acquainted with a considerable number of these "hormones," and their discovery has created a great revolution in our conceptions of physiological and pathological processes.

What secretin is chemically is not yet known; the culmination of the work in the unravelling of its composition is reserved for the future.

The pancreas is full of interest because it also possesses an internal secretion, but that aspect of the subject is not treated in the present volume.

Dr. Terroine's book is to be thoroughly recommended to all who desire a clear account of recent progress and present doctrines concerning pancreatic activity. W. D. H.

The Posture of School Children: with its Home Hygiene and New Efficiency Methods for School Training. By Jessie H. Bancroft. Pp. xii+327. (New York: The Macmillan Co., 1913.) Price 6*s*. 6*d*. net.

It is beginning to be understood by parents and teachers that the complete education of children includes physical as well as mental training. The schools now no longer ignore the bodies of the pupils, but by medical inspection, graded physical exercises, which are remedial when necessary, and by careful sanitation, every effort is being made to make the children healthy in body as well as well trained mentally. In this useful undertaking doctors and teachers are cooperating, and one of the evidences of this joint endeavour is the appearance of numerous books intended to provide teachers with scientific and technical knowledge in an attractive form. The present volume is by the assistant-director of physical training in the public schools of New York City, and gives teachers guidance as to how to correct poor posture in the class-room, to prevent the various forms of curvature, and generally to assist normal growth.

Weather Signs and How to Read them. For Use at Sea. By W. Allingham. Pp. v+117. (Glasgow: James Brown and Son, 1912.) Price 2*s*. net.

The author states that this booklet is a compilation written as an aid to the rising generation of mariners. Considered from this viewpoint we have no hesitation in saying that it will be found interesting and useful. Weather is closely connected with barometric pressure, air and sea temperature, state of sky, &c.; but the predominant factor is pressure. Several chapters are devoted to these subjects and to the construction and use of synoptic and synchronous weather charts; the advantage to sailors of charts of monthly average barometric values is referred to specially. The author makes it quite clear that he holds decided opinions on several subjects, some of which differ from generally accepted views, *e.g.* in the chapter dealing with cloud forms and signs he considers it difficult to accept as a working hypothesis the supposed connection between clouds and dust particles, at least many leagues from land. He also urges simplification in cloud nomenclature, "for under the present involved divisions clouds are doubtless as often described erroneously as they are correctly." The supposed influence of the moon on weather is justly ridiculed, and the work is brought up to date by useful details of the advantages derived from radio-telegraphy.

The Ionisation of Gases in the Schumann Region.

IN NATURE for June 12, Prof. Lyman discusses the evidence relating to the ionisation of air in the Schumann region, and concludes that ionisation of air can be produced by wave-lengths longer than λ1700.

The reasons why I consider that λ1350 is nearer to the limiting wave-length at which the ionisation of air sets in are as follows:—Using a discharge in hydrogen as a source of ultra-violet light and transmitting it through a quartz window (0·3 mm. thick), I was unable to get any ionisation in filtered air. I only obtained big effects with a certain piece of fluorite as the window. Another piece of fluorite which did not transmit the ionising light was transparent to about λ1350. Prof. Lyman's researches show that the hydrogen discharge emits very intense ultra-violet light distributed over a large number of wave-lengths between λ1200 and λ1600. Hence, with thin quartz, there was plenty of light available down to λ1450, but it produced no effect in my experiments. Similarly, wave-lengths down to about λ1350 produced no appreciable effects.

Lenard and Ramsauer used a very intense aluminium spark as their source of light, and found that the light from it transmitted through fluorite produced enormous ionisation in air. On the other hand, the light when passed through quartz did not produce any effect. According to Prof. Lyman's photographs, the wave-lengths available from the Al spark in air are a strong group of lines near λ1300, some weak lines near λ1500, and strong lines near λ1600 and λ1720–λ1800. Thin quartz cuts out the group λ1300, but allows the others to pass. We are not told explicitly whether the spark in Lenard and Ramsauer's researches was ever placed close to the quartz window to avoid air absorption; if so, the λ1500 and λ1600 groups would be effective. Fluorite, on the other hand, transmits the λ1300 group as well, and Prof. Lyman considers that the ionisation observed is probably due to these lines. He points out that my interpretation of his remarks, viz. that λ1300 represents the longest wave-lengths which are effective in ionising air, does not represent his views correctly. He considers that Bloch's recent work on the ionisation of air by a mercury lamp indicates that wave-lengths longer than λ1750 are effective.

I expect it will be agreed that by air we mean the usual mixture of oxygen and nitrogen free from all the more condensable gases. Lenard and Ramsauer found that ordinary dust-free air was certainly ionised by the light transmitted through quartz from their powerful source. It was only when very drastic methods of purification were adopted that the air was no longer ionised by the light transmitted through quartz. Although Bloch used dust-free air in his experiments, there is no evidence that he took the rigorous precautions which Lenard and Ramsauer assert are necessary to get rid of all the impurities which give rise to ionisation with comparatively long wave-lengths. In Bloch's arrangement, the mercury lamp was totally immersed in the stream of air, and consequently all the light emitted was available for ionisation, and hence the traces of impurities have every chance to be ionised. Bloch does not give any details, but I think the supports, insulated wires, &c., connected with the lamp inside the ionisation chamber might act as sources of impurities in Lenard and Ramsauer's sense.

If we consider the quantum theory of radiation to apply to ionisation of gases by light, then the energy available in the quantum, hn, must exceed the work V_0e required to separate an electron from a molecule. Palmer's experiments (*Phys. Rev.*, xxxii., p. 1, 1911) may perhaps be taken to indicate that the oxygen accounts for most of the ionisation in air. Taking the longest wave-length which ionises air to be λ1350, and $h=6{\cdot}55\times10^{-27}$, and $e=4{\cdot}65\times10^{-10}$, we get $V_0=9{\cdot}2$ volts. Now the ionising potential for oxygen according to Frank and Hertz is 9·0 volts. To maintain that λ1800 is nearer to the long wave-length limit implies that the quantum theory is not applicable to ionisation by light, for there is no reason to doubt the accuracy of the experiments of Frank and Hertz.

The Microtropometer.

MANY roads to progress in physical investigation are brought to an abrupt end through the lack of measuring instruments of sufficient sensitiveness. In the attempt to bridge over one of these disabling chasms the writer was led to the following device, which appears capable of some development. The principle can be illustrated with reference to a particular case. Suppose we have a Boys's radio-micrometer, which we will call the secondary instrument. If we project on to the vane of this an image of a Nernst lamp filament the beam of light from the mirror of the instrument may be deflected through one thousand scale divisions. Suppose now that the image of the filament is 1 mm. wide, and that it is projected by the mirror of another radio-micrometer, which we may call the primary one.

It is evident that a movement of this primary image through a distance of 1 mm. can produce a movement of the beam of light from the secondary instrument through 1000 mm. Hence, a movement of the image of the filament cast by the primary instrument through 0·001 mm. would give a deflection of about 1 mm., and a movement of the primary image through 1/1,000,000 mm. would move the secondary image through one-thousandth of a mm. If now the secondary instrument be made to throw a similar image on to a tertiary radio-micrometer, the motion will again be magnified one thousand times, so that an original movement of a millionth of a mm. produces a final movement of 1 mm. Evidently by increasing the number of instruments in arithmetical progression we increase the magnification in geometrical progression.

I have applied the method to two radio-micrometers with very satisfactory results. The principle, however, can be applied to any instrument in which a beam of light is used as an indicator—*e.g.* the primary instrument may be a galvanometer, an electrometer, a double-thread-suspension mirror, or a string-galvanometer (in the last case the image of the string taking the place of the image of the filament). The secondary instruments may be radio-micrometers, thermo-couples, bolometers, selenium cells, or other detectors of radiation. It will appear, therefore, that the principle is one capable of wide application to cases in which great sensitiveness of measurement is required—from wireless telegraphy to physiology. In fact, we may say that any existing instrument which uses light as an indicator can be made more sensitive.

Practical difficulties arise from the impossibility of obtaining any instrument with absolutely constant zero; moreover, fluctuations in the intensity of the energy stream from the source of radiation, represented by the Nernst filament, would cause trouble where great magnifications were desired. This last difficulty might to some extent be surmounted by using as a secondary instrument the two strips of a bolometer, so that fluctuations would make proportional changes in both strips, whereas a deflection gives a differential effect. Experiments, however, on the application of the principle are in progress.

Wireless Antennæ.

IN recent issues of NATURE several correspondents, in referring to the fact that a metal bedstead or a few wires stretched a few feet above the ground will make a wireless antenna, have overlooked a most important point, viz. that with such an antenna the ordinary methods of tuning are quite useless.

A piece of wire netting suspended a few feet above the ground makes a most effective aërial, and enables one to receive loud signals from long-distance stations, but signals from Eiffel Tower, C'eethorpes, &c., will all be mixed up, and the ordinary tuner will not separate them effectively. It seems to me that this proves that the usual theory of the waves travelling through space in the air above the earth's surface and being cut by the aërial does not *wholly* account for the facts.

Wireless signals that are feeble when the surface of the earth is dry, becoming much stronger after rain, and the well-known fact that these waves travel much better over sea than over land, all seem to indicate that the aërial waves are *at least* supplemented by waves that travel along the surface of the earth, and that the wire netting, bedsteads, &c., act as counter capacities, allowing these waves to flow from the earth through the receiver. The capacity of a small piece of wire netting near the ground is much greater than a very extensive aërial high up.

Canterbury. A. LANDER.

The Occurrence of "Anomalocera pattersoni," Temp., in Mounts Bay.

IT is stated by Mr. L. H. Gough ("Report of the Plankton of the English Channel," 1903), that the copepod *Anomalocera pattersoni*, R. Temp., may generally be regarded as an oceanic species. Gough's observations tended to show that Gran was correct in assuming this to be the case, although Cleve considered the species to be neritic. Sars, in his "Crustacea of Norway," speaks of the occurrence of this copepod "off the south and west coasts of Norway, generally congregated in great shoals," but throughout the reports published in connection with the international fishery investigations, no record occurs of its similar abundant occurrence in the English Channel.

It is interesting to record, therefore, that during an intensive survey of the planktological conditions of Mounts Bay, performed from the s.y. *Mera* on June 2, an extensive shoal of the species was met with at the surface on a position 50° 4′ 20″ N. × 5° 27′ 55″ W. The product of a five minutes' haul with the coarse tow-net amounted to 34·75 c.c. of material, of which at least three-fourths was made up of Anomalocera, both in its adult and developmental stages. The visitation of this copepod, in association with several other oceanic forms of phyto- and zooplankton, to a comparatively close inshore position may possibly serve as an indication of somewhat abnormal hydrographical conditions, but unfortunately no physical observations are yet to hand to enable a comparison to be formed.

Artificial Hiss.

LORD RAYLEIGH'S "sound more like an *f* than an *s*" (NATURE, May 29, p. 319) is due, according to Köhler's observations (*Zeits. f. Psych.*, 64, p. 93), to a slightly too high pitch. A Galton whistle, set for a tone of 8400 v.d., will give a pure *s*.

THE BICENTENARY OF THE BOTANIC GARDEN OF ST. PETERSBURG.

THE bicentenary of the foundation of the Imperial Botanic Garden at St. Petersburg was celebrated with unusual pomp on June 24. The history of the garden, its share in the botanical exploration of north, central, and east Asia, and the practical completion of its reorganisation on modern and truly liberal lines justified the festive character of the proceedings. They were initiated on the eve of the jubilee by a special service, attended by the staff of the garden, in the Peter-Paul's Cathedral, and the laying down of a wreath of roses at the tomb of Peter the Great, the founder of the garden, and on the following morning by a little shower of honours for the director and his staff.

The principal ceremony took place in the afternoon in a building attached to the old herbarium, in the presence of a brilliant gathering, including the Princes Peter and Alexander of Oldenburg, Prince Gagarin, representing Princess Eugenia of Oldenburg, under whose patronage the garden is placed, the Ministers of Agriculture, Commerce, Justice, Public Cults, and Marine, and other prominent officials, and a large number of delegates from the Russian academies, universities, botanic gardens, and kindred institutions, and from foreign countries. The solemn meeting was preceded by a Te Deum, and formally opened by the Minister of Agriculture, Mr. Kriwoshein. A rescript from the Emperor was read, in which it was announced that the garden would henceforth be known as the Imperial Botanic Garden of Peter the Great. Then followed an eloquent address by the director of the garden, Prof. A. Fischer von Waldheim, in which he traced the history of the garden and its present organisation and object; the reception of the delegates, and the presentation of medals and souvenirs commemorating the jubilee.

The next day was reserved for the inspection of the garden, museum, and laboratories, and in the afternoon a visit to Peterhof, where the guests experienced an exceptionally cordial reception. In the evening the festivities came to a conclusion with a gala performance in the opera house in the Narodni Dom.

Most of the botanical gardens and many of the other botanical institutions sent their congratulations, whilst Bulgaria, Denmark, England (Kew and Chelsea), Germany, and Sweden were represented by delegates.

The garden was founded by Peter the Great about 1713, so that it is practically as old as the capital itself. The site selected for it was on one of the islands in the Neva, low-lying, boggy land, and the object the cultivation of medicinal plants mainly for the army and navy. Hence it was called the Apothecaries' Garden, and the island itself Apothecaries' Island. Among those attached to it were Siegesbeck and Falk, well known from their connection with Linnæus. In 1823, however, the garden was put on an entirely new footing by Alexander I., who raised it to the rank of a scientific institution under the title Imperial Botanic Garden. His first director was F. E. L. Fischer (1823–1850), who had already risen into notice through his successful management of the famous garden at Gorenki, near Moscow. Thanks to his wide connections with botanists and botanical gardens outside of Russia—he was *inter alia* a personal friend and life-long correspondent of William Hooker—and his active encouragement of botanical research in the Russian Empire, he was able in a short time to build up a very large collection of living and dried plants.

After Fischer's retirement in 1850 the history of the garden was of a somewhat varied character. From 1830 to 1863 it was under the ministry of the Imperial Court, and there was at times a danger of its becoming reduced to a nursery for table decorations for the Court; but when, in 1863, it was transferred to the Ministry of Agriculture it was definitely saved from that fate, and it soon regained, and, in fact, eventually exceeded, its old reputation under the double directorship of Trautvetter and Eduard Regel, and afterwards under Regel's undivided control. If Regel, by training and taste, inclined more towards horticulture and a lighter conception of the aims of phytography, his collaborator and colleague, the scholarly *botanicus primarius* and academician C. Maximowicz, excelled through the rare thoroughness and comprehensiveness of his taxonomic work. Both were fertile writers, and the exploration of Turkestan, Siberia, and Central Asia, which in those days proceeded with such marvellous energy, found in them most able interpreters. Maximowicz died in 1890, and Regel followed him soon.

After the short directorship of Batalin, the present director, A. Fischer von Waldheim, until then professor of botany in the University of Warsaw, was appointed in 1897. With him a new era began. It has so far resulted in the comprehensive reorganisation of the establishment and its transformation into a great national institution for the study of pure and applied botany, comparable to the institutes of Kew and Dahlem, although less universal in its range in so far as it is expected to serve in the first place the special interests of the Russian Empire. To quote from the official French guide, published on the occasion of the jubilee, the Imperial Botanic Garden of Peter the Great is intended for the study of the plants which form the flora of Russia and the adjoining parts of Asia, of economic botany, plant anatomy and physiology, of plant parasites and the means to fight them, for seed control, and the cultivation and testing of plants of practical importance for agriculture, horticulture, industries, and medicine, and finally for the popularisation of the botanical sciences.

The garden covers an area of fifty acres, of which thirty go to form what is called the "Park," or garden proper, whilst 7·5 acres are under glass and more than twelve are occupied by buildings. The scientific staff consists of the director, three chief botanists, one chief conservator, five conservators, two assistant conservators, and one librarian. For purely administrative purposes the director has at his disposal a secretary, a cashier, an "intendant," a clerk, and two assistant clerks, these officials forming the "chancery," or director's office. The garden work is superintended by two head gardeners, with two assistants and thirty-five gardeners. There are about fifty "fixed" labourers of both sexes, and about as many artisans, guards, porters, and inferior hands. The Botanic Garden comprises, beside the "Park" and the glasshouses, the following distinct departments:—the herbarium, the museum, the library, the zoological laboratory, the seed control station, the phytopathological station, the "seminarium," or depôt for seeds, gathered in the garden or sent in by travellers and explorers, or received in exchange or by purchase, the "chancery," and the school for gardening.

A splendid new building for the herbarium and library has just been completed, whilst another for the museum collections, and on a similarly large scale, is to be commenced next year. The garden has also its own electric station and electric engineer. It is not possible here to enter into any details concerning those departments, but it may be mentioned that the herbarium and the library, both of which are among the richest in the world, will no doubt remain for long the most valuable portion of the establishment and the centre of its activity. The herbarium is the recipient of the collections of the numerous expeditions organised by the Colonisation Commission (since 1908), and devoted to a grandly planned botanical survey of the Asiatic possessions of the empire. As a similar survey is in course for Russia proper, a collection is building up probably quite unique in its completeness and representative character. A considerable addition to the staff is contemplated, and concurrently an increase of the budget of the garden to 160,000-170,000 roubles (16,000*l*.–17,000*l*.).

This brief account would be incomplete without a word of admiration for the liberal and far-seeing spirit in which the jubilee was conceived, and the whole-hearted sympathies with which everyone, from the representatives of the Imperial Family and the Government down to the last delegate, joined in the recognition of the national importance of the work done by the establishment, and still more of the work which is to go forth from it in the future. There was not much boasting, but a joyful expectation of new and greater achievements.

O. S.

THE DAWN OF WESTERN CIVILISATION.[1]

THE volume before us is the final contribution to our knowledge of the Baoussé-Roussé Caves. It may be recalled that volumes dealing with the history, the geology, the palæontology, and the anthropology of the deposits in these caves have been reviewed already in NATURE.[2] To complete the picture it was necessary that we should know the archæology, and this the volume now under notice supplies. From the nature of the subject with which it deals it can be well understood that the volume is in no way inferior in interest or importance to those which have preceded it.

The deposits in the caves are, from the viewpoint of the archæologist, assignable to the Mid-Moustier, the Superior Moustier, and the Mid-Aurignac periods; neither the first nor the last phase of the Aurignac culture is represented. The caves therefore afford evidence of having been occupied at two distinct periods, with a considerable interval of unknown length during which they were not occupied by man.

As to the first or Moustier period, it is significant that the worked stones are of an undoubted Moustier pattern, but yet they are not all associated with the remains of a Moustier fauna. In the Grotte du Prince, for example, five foyers have been distinguished, the stones from which only differ in the character of the material which was used. Of these five foyers, however, the two lowest are associated with the remains of animals which lived during the Chelles period, species which denoted a warm climate—the hippopotamus, the *Rhinoceros Merckii*, the *Elephas antiquus*; the third foyer was associated with a mixed Chelles and Moustier fauna, whereas the two upper foyers only yielded remains of the latter fauna. It thus results that in this cave we have a Moustier culture contemporaneous in part with a Chelles fauna, a contradiction which provokes the question whether in such a case it is more justifiable to attach importance to the industrial stage reached by man in his development or to the associated fauna, suggestive as it is of climatic and geographical conditions. Although much might be said in favour of either view, we agree with M. Cartailhac that, in this instance at least, it is safer to base our conclusions on the character of the implements, particularly as we should expect the Chelles fauna—a fauna of a warm climate—to linger longest in the south of Europe, where it might well be contemporary with the Moustier fauna in a more northern latitude.

As to the second or Aurignac period, we are glad to find M. Cartailhac availing himself of the opportunity afforded him to give in a separate chapter an excellent résumé of the history and of our knowledge of the Aurignac phase from the days of Lartet and Gabriel de Mortillet to the present day when, thanks to the brilliant work of Abbé Breuil, we may consider the Aurignac period as firmly and permanently established. The particular interest in the period lies in the fact that, owing to the greater variety of the tools, the presence of ornament, and the first definite appear-

FIG. 1.—Necklac.s of the Aurignac period.

[1] "Les Grottes de Grimaldi (Baoussé-Roussé)." Tome ii., Fascicule ii. Archéologie. By Emile Cartailhac. Pp. v+215–324+plates xii–xxiii. (Imprimerie de Monaco, 1912.)

[2] October 10, 1907; July 27, 1911.

ance of grave furniture, we are permitted a more intimate insight into the life and habits of Palæolithic man.

It is an interesting yet readily intelligible reflection that, although the mass of the deposits postulates a long period during which the layers gradually accumulated, although the fauna changed considerably during that time, yet the same weapons are found in the upper as in the lower beds. The explanation, of course, is that at all periods the dwellers in the caves were hunters, and the same weapons were required, although the animals which they hunted might and actually did differ. Another conclusion to which we can, we think, with reason arrive is that there was no very great lapse of time between the end of the Moustier period and the middle of the Aurignac period; in other words, the first of the divisions into which this last period has been divided does not, at Grimaldi at any rate, appear to have been of sufficient length to have made its presence felt.

It is to the middle of the Aurignac period that the graves, of which there were no fewer than thirteen, should be ascribed. Further, the graves were clearly of the same date, judged by the character of the associated relics, although it is curious to find the methods of burial were not identical; for example, the dead were in some cases disposed at length, at other times they were found in contracted positions.

Like its predecessors, the volume is perfectly produced and illustrated. An admirable bibliography concludes the volume, and the fact that the literature dealing with these caves covers a period stretching from 1786 to 1912 is perhaps sufficient evidence of their infinite power to stimulate interest and investigation.

The text of the volume at present under review, while as strictly scientific and accurate as possible, is warmed by many sympathetic references, M. Cartailhac having, from his lifelong labours in this field of archæology, acquired no little affection for these long-forgotten followers of the chase, no little insight into their habits and life.

WILLIAM WRIGHT.

THE DIVINING ROD.

WITHIN the last few years many experiments have been performed in various countries to test the claims of water diviners, and among those who have published papers on the subject are Graf Karl von Klinckowstroem, of Munich, and Dr. Armand Viré, director of the Laboratory for Underground Biology in Paris. A series of experiments at Guildford has also been organised by the editor of *The Sanitary Record and Municipal Engineering*, under the auspices of a number of scientific men, including Prof. Henry Adams, Dr. Herbert Lapworth, and Dr. Samuel Rideal.

Graf von Klinckowstroem, in a paper published in parts 1, 2, and 3 of the *Zeitschrift des Vereines der Gas- und Wasserfachmänner in Oesterreich-Ungarn* for 1913, gives, in the first instance, an account of certain supposed successes in water-finding, which Dr. Achille Poskin, of Spa, has gathered together from various sources. These are not very interesting, as the observations do not appear to have been controlled by impartial witnesses possessing some knowledge of scientific methods.

But Dr. Poskin also includes an account of five experiments undertaken by him, in which the diviners indicated places where water was found. Dr. Poskin believes that he himself possesses the power of detecting water by means of the divining rod. In any case, it is quite certain that "dowsers" are frequently successful in indicating points where water is subsequently found; the real question is, whether these indications are produced by anything outside themselves, or whether they are purely subjective.

In the same paper Graf von Klinckowstroem has translated into German a paper describing my own experiments, accounts of which were published in *The Times* and in *The Journal of the Royal Society of Arts* in 1911. He admits that the experiments were performed with all reasonable care, and without any prejudice, but he describes them, using stronger language than I did, as a fiasco for the diviners who were tested, and then gives a number of possible reasons why the experiments may have failed. He does not give enough weight to the fact that in every case the experiments were conducted under conditions which the dowser in question thought reasonable, and were directed to test powers which he alleged he possessed. This seems to be the only reasonable way of attacking the question from a scientific point of view; it is not for the investigator to say what the dowser can do, or under what conditions he can do it, but when the dowser has stated what his powers are, to arrange an experiment which shall test the alleged powers.

M. Armand Viré (*La Nature*, April 19, pp. 332–338) has conducted a series of experiments in order to ascertain whether the diviners could determine the existence of underground cavities which did not contain water; the results given by M. Viré include a considerable number of "successes," but he passes over too lightly the cases in which the indications given by the diviners are inaccurate. It will be interesting to await the result of an experiment which he proposes to undertake later, in order to discover the shape and extent of caves or grottoes the existence of which has not yet been proved, and the plans for which will only be prepared after the diviner's plans have been reduced to paper.

The series of experiments recently performed in the neighbourhood of Guildford have now been completed, and the committee of investigation has published its report. The members point out that, while there appeared to be some evidence that certain persons may be sensitive to underground water, their sensitiveness "is not sufficiently definite and trustworthy to be of much practical value." They also allude to the lack of agreement with each other which the results show, and they take this as evidence that the movements of the rod are due to subjective and not to objective causes. These are precisely the opinions formed as a result of my own series of experiments; and it may still be assumed that no adequate evidence has been produced in favour of the existence of something acting outside the dowser which causes his twig or other indicator to move when it is over water.

In *La Nature* for May 10 (p. 379), M. Gustave Le Bon has published an article recording the success of certain diviners in discovering the metals contained in five envelopes (viz., aluminium, copper, silver, lead, and zinc); but, as he admits, the method of experiment was not satisfactory, since he thinks he may unintentionally have given signs of approval while the diviners consulted together as to what metals were contained in the envelopes, and since the method of procedure involved the displacement of the envelopes by the diviners, thus giving them an opportunity of forming an opinion based on the different weights, &c., of the metals. He also mentions that M. Coupaux, who performed similar experiments, only had one success out of five, but that the diviners objected to these experiments because the metals were enclosed in glass tubes, and, as they allege, the glass prevents their feeling the influence of the metals.

On the whole, M. Le Bon is of opinion that there is enough evidence to warrant further examination into the claims of diviners; he thinks, however, that the commission appointed by the Académie des Sciences to examine into the question so far as it relates to the discovering of springs ought to do more, and he asks that this commission may also undertake experiments similar to those which he has performed. My own experiments in this direction went to show that the experienced diviners with whom they were tried were not able to discover gold or silver by means of their rods; for though one diviner scored a remarkable success in a single instance, he was absolutely wrong in the other experiments of the same kind which he performed. Nevertheless, this single success (fortuitous as I believe) confirmed an intelligent friend who witnessed it in his belief that the powers of the diviners are real!

J. Wertheimer.

DR. P. L. SCLATER, F.R.S.

Zoologists throughout the world will join with their English brethren in lamenting the death on June 27—albeit at the advanced age of eighty-four—of Dr. Phillip Lutley Sclater, F.R.S. The second son of the late Mr. W. L. Sclater, of Hoddington House, Hants, the deceased naturalist was born in 1829, and received his education first at Winchester and subsequently at Corpus Christi College, Oxford, where he graduated first class in mathematics, and subsequently became honorary fellow of his college. In 1855 he was called to the Bar as a member of Lincoln's Inn, and in 1875 he acted as private secretary to his brother, the Hon. G. Sclater-Booth (afterwards Lord Basing), when President of the Local Government Board. So early as 1850 he had commenced to write on zoology. Soon after his call to the Bar he devoted himself mainly to natural history, and he was elected secretary to the Zoological Society of London in 1859, which important post he retained till 1902, when advancing years led to his voluntary resignation.

During the greater part of that prolonged period Dr. Sclater was the ruling spirit of the society, and it was to his organising capacity and untiring energy that the menagerie in Regent's Park attained the pre-eminent position it occupied, both as a zoological centre and a place of popular resort, at the time of his retirement. He was also editor of the society's numerous publications, to which he communicated an extraordinary number of valuable papers and memoirs; and it was during his term of office that the Proceedings became entitled to rank as one of the very foremost zoological journals in the world.

But the executive and scientific work connected with the Zoological Society by no means sufficed to absorb all the energies of its secretary, for in 1859 he became editor of the *Ibis*, a then newly started ornithological journal, and held that post until 1865, to resume it, in conjunction with the late Mr. Howard Saunders, in 1883, and to hold it, either alone or associated with others, throughout the rest of his working career. Dr. Sclater was also one of the founders of the British Ornithologists' Union, of which body he long occupied the presidential chair. Of even more importance, perhaps, was Dr. Sclater's share in the foundation and maintenance of the "Zoological Record," as without that wonderful work of reference zoology at the present day would be an absolute impossibility.

Dr. Sclater was also one of the pioneers—if not the actual founder—of the modern science of geographical distribution; and it is to him that we owe such now familiar terms as "Palæarctic" and "Nearctic," which are excellent examples of the classic form of scientific nomenclature in which he delighted.

The prodigious amount of scientific work, more especially in ornithology, produced by Dr. Sclater may be inferred from the fact that a record of his career published some years ago contains entries of something like 1200 different papers and memoirs. From a popular point of view one of the most attractive works with which he was connected was Wolf's "Zoological Sketches," while his monographs of various groups of South American birds are models of their kind.

For the greater part of his long life Sclater was a man of intense activity and energy, and only during the last few years did he show signs of failing health. Injuries received in a carriage accident a few weeks ago hastened the termination of a long life devoted to the advancement of zoological science.

R. L.

NOTES.

THE window in Westminster Abbey in memory of Lord Kelvin will be unveiled at the 3 p.m. service of the Abbey on July 15.

WE are informed that the following have been elected life honorary members of the Geological Society of South Africa:—Dr. J. S. Flett, F.R.S., assistant director, Geological Survey of Great Britain; Dr. A. Lacroix, professor of mineralogy, Natural History Museum, Paris; and Prof. E. Weinschenk, Alte Akademie, Munich, Bavaria.

THE death is reported, in his seventy-seventh year, of Mr. W. A. Conklin, director of the zoological department of the Central Park, New York, from 1865 to 1898. After the latter date he was engaged in importing wild animals into the United States. From 1878 to 1893 he edited *The Journal of Comparative Medicine and Veterinary Archives.*

IN the article on the Birmingham meeting of the British Association that appeared in NATURE on June 12 it was stated that an organised programme of the field work in connection with the Geological Section had been prepared by Dr. T. Groom, with the supervision of Prof. Lapworth. We now understand that this is not the case. The excursions in connection with the Geological Section have been organised by Prof. Lapworth, and not by Dr. Groom.

AN earthquake occurred in southern Italy shortly before 10 a.m. on June 28, strong enough to damage buildings in several villages of the province of Cosenza. No lives were lost, though more than twenty persons were injured by falling masonry at Rogiano Gravina. The shock was felt at Messina and Naples, which are respectively about ninety and 150 miles from the epicentre. The province of Cosenza includes one of the more pronounced seismic regions of Calabria, in which originated the severe earthquake of February 12, 1854, and, in part, the still more destructive shock of September 8, 1905.

It is proposed to commemorate in 1914 the seventh centenary of Roger Bacon's birth (1214) by erecting a statue (by Mr. Hope Pinker) in his honour in the Natural History Museum at Oxford, and by raising a fund for the publication of his works. An influential committee, with Sir Archibald Geikie, K.C.B., P.R.S., as chairman of the executive, has been formed to carry these purposes into effect. Roger Bacon was the champion of experimental science and the advocate of positive knowledge at a time when logic reigned supreme; and we are glad that his important place in the history of science is to be made more widely known. The committee proposes:—(1) To hold a Roger Bacon commemoration at Oxford in July, 1914, when the statue will be unveiled, and addresses will be given by distinguished scholars; (2) to issue a memorial volume of essays dealing with various aspects of Roger Bacon's work, written by specialists in the various subjects; (3) to arrange for the editing and printing of Roger Bacon's writings, so far as funds will allow. The first volume (now in the press) will contain his unpublished treatise and commentary on the pseudo-Aristotelian "Secretum Secretorum," edited by Mr. Robert Steele. The second volume will probably contain the medical treatises, an edition of which is being prepared by Dr. E. T. Withington and Mr. A. G. Little. The committee points out that other volumes should contain a complete edition of the "Opus Tertium" (fragments of which were printed in 1859, 1909, and 1912); the "Quaestiones" on Aristotle's physics and metaphysics, and on the "De Plantis"; the "Communia Mathematicae," and perhaps the "Computus Naturalium; while new and critical editions of the "Opus Majus," of the fragmentary "Opus Minus," and of the less important "De Naturis Metallorum" and "Tractatus Trium Verborum" are desirable. A general committee (of which the Chancellor of the University of Oxford has consented to be hon. president) is being formed, consisting both of collaborators in the editorial work and of subscribers. Subscriptions in aid of the foregoing objects should be sent to the secretary of the executive committee, Colonel Hime, 20 West Park Road, Kew.

THE Historical Medical Museum now open in Wigmore Street, Mr. H. S. Wellcome's magnificent collection, is one of the most interesting sights of London. All ages and all countries have been ransacked to make it complete; we go from Babylon to here, and from the dawn of the art of healing to now. Medicine, like man himself, is of lowly origin; we have to keep reminding ourselves that evolution is creative wisdom, not blind force, alike in the one case and in the other. On the threshold of the museum we are met by hideous idols, and all the ugliness of witch-doctors and devil-dancers; and there, in the midst of all these savageries, is an exquisite model of the Wellcome Floating Tropical Research Laboratory, and a long array of the latest and rarest germs under microscopes. We stand in the hall of statuary, and look past a most unspeakable "ancient Mexican deity of healing" to Apollo and Æsculapius; or we study the weaved-up follies of charms, amulets, and talismans, until we find—it is an error of judgment—a crucifix among them. The museum is a fine place to wonder and think in—so many hundreds of instruments now discarded and labelled and put under glass; so many appliances become curiosities; so many ways of healing deserted. Then comes the dismal thought that a hundred years hence all our present apparatus will likewise be useless:—

> "It makes me mad, to see what men shall do—
> And we in our graves—"

Truly, one must take a pinch of philosophy, and a pinch of faith, to keep one's head in this museum. With these, it is possible to receive such a history lesson as will not be forgotten for many years.

A STANDING Committee of the House of Commons on June 26 discussed a Bill to prohibit experiments upon dogs. The chief operative clause in the Bill proposes to enact that "from and after the passing of this Act it shall be unlawful to perform any experiment of a nature causing or likely to cause pain or disease to any dog for any purpose whatsoever, either with or without anæsthetics, and no person or place shall be licensed for the purpose of performing any such experiments." Strenuous opposition was offered to the Bill on behalf of medical science. An amendment was carried postponing the coming into operation of the Act until January 1, 1914. Sir F. Banbury, who has charge of the Bill, agreed to consider the incorporation of an amendment to leave out from "anæsthetics" to the end of the clause and insert "except on such certificate being given as is mentioned in the Cruelty to Animals Act, 1876, that the object of the experiment will be necessarily frustrated unless it be performed on a dog, and that no other animal is available for such experiment." The effect of that would be to bring the dog within section 5 of the Cruelty to Animals Act, and it is in harmony with the majority report of the Royal Commission. The Committee is to resume the consideration of the Bill as we go to press.

Yale University proposes to hold a centenary celebration next November in commemoration of the geological work of James D. Dana. A series of lectures will be given which will be published later in a Dana memorial volume on problems of American geology. The lectures will be given on the Silliman Foundation, and the dates will be announced after the opening of the next academic year. We learn from *Science* that the lecturers and their respective subjects are as follows:—Introduction: The geology of James Dwight Dana, Prof. W. N. Rice, Wesleyan University. (1) Problems of the Canadian Shield: The Archeozoic and its problems, Prof. F. D. Adams, McGill University; the Proterozoic and its problems, Prof. A. P. Coleman, University of Toronto. (2) Problems of the Cordilleras: The Cambrian and its problems, Dr. C. D. Walcott, Smithsonian Institution; the igneous geology and its problems, Prof. W. Lindgren, Massachusetts Institute of Technology; the Tertiary structural evolution and its problems, Dr. F. L. Ransome, United States Geological Survey; the Tertiary sedimentary record and its problems, Dr. W. D. Matthew, American Museum of Natural History.

The National Geographic Magazine for April takes the form of an admirably illustrated monograph, describing the results of the Yale University Expedition to Peru in 1912, under the charge of Prof. H. Bingham. The most important result was the discovery of the great deserted city, Machu Pichu, on the Urubamba River, north-west of Cuzco. The national legends indicate that the original home of the Incas was at a place called Tampu Tocco, "the temporary abode with windows," which has now been identified with Machu Pichu, the principal temple of which contains three remarkable windows, through which the three Inca groups are said to have emigrated. The inaccessible position of the city rendered it possible for the Incas to conceal its existence from the Spaniards. The wonderful megalithic masonry constructed in the premetallic age, the strange temples in which the cult of the sun and auguries from sacred serpents seem to have been practised, the remarkable burial caves in which the corpses were interred in a crouched posture, the bronzes and pottery, are all described in Prof. Bingham's report. It constitutes a record of important archæological discoveries conducted in a most inaccessible region under extreme difficulties. The investigation of this district opens out a new chapter in the ancient history of Peru.

In Bankfield Museum Notes, second series, No. 2, the keeper, Mr. H. Ling Roth, issues another of his useful monographs on primitive industries—"Ancient Greek and Egyptian Looms." After an investigation of the facts, supplemented by illustrations and comments derived from a wide survey of the evidence, he comes to the following conclusion. The ancient Egyptians had two forms of loom: the earlier or horizontal form, still surviving in a modified form in Egypt and Seistan; second, the vertical, a later but not universally later form. In the Greek loom the type was upright, the warp threads being kept taut by weights, and similar to the form in central and northern Europe. It probably was provided with a heddle, but this is not certain: a spool was used; the weavers were women, and the weft was beaten upwards or away from the weaver. There seems to be no connection between the Greek and Egyptian types. But in form of looms used by the two peoples the Egyptians were considerably in advance of the Greeks. An interesting part of the monograph is the experiments made by modern skilled weavers to work these primitive machines.

The introduction of the string galvanometer and its improvement by Prof. Einthoven, of Leyden, have furnished physicians with a new weapon in the exploration of the heart's activity. It is now possible by the use of this sensitive instrument to record photographically the electrical changes which accompany cardiac activity, and the variations these undergo in heart disease furnish the observer with absolutely sure signs of the character of the ailment. The older methods of observation (the stethoscope, &c.) will still remain in use, for, unfortunately, the outfit for obtaining the electro-cardiogram cannot be placed either in the waistcoat pocket or even in a top-hat. It demands a special laboratory and an expensive installation. Electro-cardiography will therefore still remain a method limited to large institutions or to a few specialists. We have received from the Cambridge Scientific Instrument Co., of Cambridge, an interesting catalogue of the apparatus they supply for the purpose, which contains instructions as to the way to use it. Specifications for complete outfits are given, but the cheapest is more than 200*l*.

The current number of *The Quarterly Journal of Microscopical Science* (vol. lix, part 1) bears striking testimony to the excellent work done by the Glasgow school of embryologists, under the leadership of Prof. Graham Kerr. Miss Monica Taylor contributes a very valuable account of the development of the remarkable South American eel-like fish *Symbranchus marmoratus*, with some beautiful illustrations. Nothing has hitherto been known of the development of these remarkable fishes, but abundant material was collected by Dr. Agar in the Gran Chaco in 1907, upon which Miss Taylor's work is based. There are no fins in the adult fish, but the larva has well-developed pectorals, which are used mainly as respiratory organs and drop off bodily when the perfect branchial respiration is established. Miss Jane I. Robertson, from the same school, contributes a useful memoir on the development of the heart and vascular system of *Lepidosiren paradoxa*, which will be welcomed by comparative anatomists. The University of London is also to the fore in embryological research, as witnessed by a memoir on the reproductive cycle in the marsupial *Dasyurus viverrinus*, by Prof. J. P. Hill and Dr. C. H. O'Donoghue.

The variations in the common fresh-water nerite (*Neritina fluviatilis*), which are illustrated by a coloured plate, form the subject of a paper by Dr. R. Hilbert in the 34 *Bericht Westpreuss. Bot.-Zool. Vereins*. These variations, which are very marked, are associated not only with locality, but also with environment, which is likewise extremely variable; some of these molluscs living in water with strong springs, some in small, slow brooks, others in rapid streams or large rivers, and yet others in calcareous, brackish, and even thermal waters. These different stations and physical conditions constitute, in the author's opinion, the starting points of the numerous variations in form and colour so characteristic of the species.

After a considerable, but unavoidable, delay, the concluding portion of the late Mr. J. E. Robson's "Catalogue of the Lepidoptera of Northumberland and Durham" has been published in the Natural History Transactions of Northumberland, Durham, and Newcastle-upon-Tyne, vol. xv., part 2, this issue forming the completion of the old series. In an introduction to the minute moths of the group Tineina, which forms the subject of this part of the work, the author remarks that two or three species of that group which occur in the area under consideration are unknown elsewhere in the British Isles. "One insect, *Acrolepia vetuletella*, has not been recorded elsewhere than in the county of Durham, though I believe a solitary example was taken . . . at Richmond, in Yorkshire. Another, *Lithocolletis insignitella*, . . . has not been taken in England except between Hartlepool and Castle Eden, where it occurs in enormous numbers."

The *Bulletin International* of the Academy of Sciences of Bohemia (Česka Akademie Císaře Františka Josefa) for 1912 brings the progress of scientific work in Bohemia before a wide circle that must remain ignorant of the national language. The papers in this volume are in one case in French, and in all other cases in German, and the majority deal with mathematical or geological inquiries. B. Němec continues his studies on fungi, and L. Pračka provides two papers on variable stars. V. Rosický has made a complete examination of seventeen crystals of miargyrite ($Ag_2S.Sb_2S_3$), resulting in the measurement of twenty-three new forms from the Bohemian specimens alone. F. Slavík directs attention to the formation of aragonite at ordinary temperatures in mine-waters at Příbram. B. Ježek describes a new rhombic thallium mineral, orbaite, from Macedonia, based on the acid HAs_3S_5, with the composition $TlAs_2SbS_5$. A. Hofmann and F. Slavík report on gold and on telluride ores in quartz-veins near the Bavarian border, where mining was carried on so far back as the thirteenth century. R. Sokol has studied the terraces of the Elbe valley, and J. Woldřich goes beyond Bohemia to the Carpathians above Dobschau, where, in examining mountain structure, he has found interesting traces of a flora that is probably of Devonian age.

Vol. xlvii. of the *Nouveaux Mémoires de la Société Helvétique des Sciences Naturelles* is occupied by two important papers. E. Ganz writes on the stratigraphy of the Middle Cretaceous of the northern Alps of Switzerland, beginning with the "Schrattenkalk" (Barrémian), and ending with the Cenomanian "Seewerkalk." Many geologists will remember the fine cliff-sections of these series in the Säntis area, and the contrast between the scenery presented by them and that on the margin of our Surrey Downs. On p. 140 the author reminds us of the sandy character of the lower Albian and of the clays of the upper Albian in both the Alpine foothills and the south of England. He adopts "Gault" as a stratigraphical and not a lithological term, embracing the Albian and the Gargasian series when these cannot be divided on a map. Since the latter includes the zones of the English Lower Greensand down to the base of the Sandgate Beds, and also, at the top, the *Schloenbachia rostrata* beds of the Upper Greensand, this "Gault" is closely synonymous with the serviceable "Selbornian" of Jukes-Browne, and with "Albian" as used by certain authors. The second memoir is a morphological study by C. Bärtschi of "Das westschweizerische Mittelland," the lowland stretching from the Lake of Geneva to that of Constance. Here the great extension of the Rhone glacier has left abundant traces. The remarks on drumlins and kames will especially interest British readers.

The meteorological chart of the Indian Ocean for July, issued by the Meteorological Office, contains useful notes on the cyclonic storms of that region. It is pointed out that in this month the south-west monsoon dominates the meteorological conditions over the Bay of Bengal and the Arabian Sea; intelligence received from the Indian Meteorological Department showed that towards the end of May the prevailing weather conditions in those districts were quieter than usual for the time of year. The tracks laid down on the chart show that the storm centres move to the westward or north-westward across the north of the Bay of Bengal. In the Arabian Sea the monsoon at times attains a force of eight or nine of Beaufort's scale, or from thirty to forty-four miles an hour, but such cyclonic disturbances are generally of little importance. Cyclonic storms are said to be practically non-existent in July in the South Indian Ocean; details of their behaviour in that part during the cyclonic season, November to May (Nature, October 31, 1912), are also referred to in the chart now under report.

In the issue of *The Manila Times* for May 20 last, which has been sent to us, is published the report of

Father Jose Algue, head of the Weather Bureau of the Philippine Government, of the typhoon which lasted from May 4 to May 10, and caused great destruction over a large area. The first warning of this typhoon was given by the observatory of the Weather Bureau on May 4, and it was sent to the observatories of Hong Kong, Shanghai, Tokyo, and to the secondary station of the eastern Visayas. Frequently during each of the succeeding days throughout which the typhoon raged Father Algue was able to keep in touch with important observing stations, and to give instructions as to the exhibition of appropriate signals and information as to the progress of events. The telegrams sent to Hong Kong and to the other observatories of the Far East gave an account of the course of the typhoon within the archipelago; thus, for example, the telegram sent at 9.40 a.m. of May 6 read as follows: "The typhoon is at present close to meridian 122° E. and parallel 12° N., moving W.N.W.," while the message sent at 8.40 a.m. of May 7 said: "The typhoon is close to meridian 120° E. and parallel 13° N., moving W.N.W." While the vortex of the typhoon was crossing the islands of Samar and Leyte the area of hurricane winds was approximately fifty miles in diameter. Within this area both the winds and the sea were extraordinarily violent. The rapidity of the fall of the barometer was so great in the China Sea that there was a fall of 20 millimetres in one hour.

DR. L. W. AUSTIN, of the United States Naval Radiotelegraphic Laboratory, contributes, in the June number of the Journal of the Washington Academy of Science, a short article to the discussion of the cause of the difference in strengths of day and night signals. The data accumulated in his department during the last three years render it improbable that the difference is due to a decrease of absorption of the waves in the upper atmosphere after the withdrawal of the sun's rays. With arc oscillations it is repeatedly found that when the night signals are weak at the receiving station with the usual wave-length of 4100 metres, a change of the wave-length to 3950 metres strengthens them and *vice versâ*. This, in the author's opinion, points to an explanation depending on the interference of waves travelling along near the ground, with waves which have been reflected from a surface forty or sixty miles up, at which the conductivity of the atmosphere changes with more or less suddenness. In the daytime this stratification is broken up by convection and by the ionisation produced by the sun's rays.

IN the *Verhandlungen* of the German Physical Society for May 30, Dr. E. Goldstein, of the physical laboratory of the Berlin Astronomical Observatory, gives a preliminary account of a new line spectrum belonging apparently to helium. It appears that Dr. Goldstein first observed the spectrum in 1907, and in the intervening years has obtained many specimens of purified helium from Prof. Dorn, Sir W. Ramsay, Drs. Heuse and Scheel, and others, and has convinced himself that the lines are due to the helium itself or to some other elementary gas, and not to any compound. The new spectrum is characterised by the great number of close lines on each side of the yellow helium line. Prolonged cooling in liquid air has no effect on it, and up to a certain point increase of pressure of the gas increases its intensity with respect to the ordinary series spectrum. Dr. Goldstein regards the new spectrum as bearing the same relation to the series spectrum as the second spectrum of hydrogen bears to the series spectrum of that gas. A photograph of the spectrum with the scale of wavelengths is given, but the author proposes to publish his more accurate measurements in a subsequent paper.

WE have received from the Norton Company, of Worcester, Massachusetts, pamphlets describing articles for laboratory use made with the material "alundum." This substance is stated to be practically pure fused alumina, prepared from bauxite by means of the electric furnace. Its high melting point (2050° C.) renders it of value as a refractory agent in high-temperature work, and the manufacturers claim that this property, together with good thermal conductivity, makes alundum very efficient—for example, as a material for cores and muffles in electric furnaces. Crucibles, tubes, combustion boats, and similar apparatus are also described. For fashioning into articles the alundum is ground to various degrees of fineness and mixed with what are rather vaguely referred to as "materials of a ceramic nature," the mixture being subsequently fired. The finished products are therefore more or less porous. Within limits, the porosity can be varied to allow of the substance being used in making such articles as filtering tubes, filter plates, and thimbles for fat extraction. Sometimes the absorbent nature of the material would be a drawback, but for many purposes alundum products may prove useful in the laboratory.

IN *The Biochemical Bulletin* (vol. ii., No. 6, p. 237) Mr. Vernon Krieble, in a paper on the synthetic action of emulsin, states that emulsin, freshly extracted from sweet almonds, when allowed to act for three and a half hours on amygdalin, gives rise to lævo-mandelonitrile, whereas the emulsin from bitter almonds gives a dextro-mandelonitrile. No experimental details are given in the brief note quoted; these will be published later.

WE have received a copy of a lecture recently delivered before the Institute of Chemistry by Mr. C. A. Hill, on the function and scope of the chemist in a pharmaceutical works. Mr. Hill gives a useful account of the nature of the manufacturing operations involved in the preparation of pharmaceutical chemicals and drugs, and illustrates his descriptions by means of photographs of actual plant; the character of the analytical work in such an establishment is described in general terms, and the possibilities of investigation, either in connection with the improvement of working processes or of a more purely scientific character, are briefly indicated.

PROF. WALDEN has contributed to the June issue of the Bulletin of the St. Petersburg Academy some further data in reference to the relationship between conductivity and fluidity. He had already shown that, in the case of tetraethylammonium iodide, the product $\lambda_{\infty} \times \eta_{\infty}$ = const., the values of λ_{∞} and η_{∞} varying sixteen-fold, whilst the product varied only by 2 per cent. Similar experiments are now described with six additional salts, namely $N(CH_3)_4I$, $N(CH_3)_4NO_3$, $N(CH_3)_4CNS$, $N(C_5H_{11})_4I$, piperidine picrate, and triamylamine picrate, fourteen organic solvents being used altogether in the different experiments. The same remarkable constancy of the product $\lambda_{\infty} \eta_{\infty}$ was noticed in every case, whilst the two picrates gave the same constant when the measurements were extended to aqueous solutions.

A SET of a new series of Contoured County Hand Maps, issued by Messrs. G. W. Bacon and Co., Ltd., at 1*d*. net each, has been received. The maps will be of real service in those schools, fortunately an increasing number, where the teaching of geography is based upon practical exercises worked by the pupils themselves. The maps will make it possible for children to appreciate the importance of the relief of an area in determining its geographical character.

A COMPLETE catalogue of the books in the Central Lending Library at Coventry is being issued in five parts. The first part, which has been received, is concerned with scientific subjects and various arts. The catalogue is divided into an author and title index, a class list, and a subject-index. The librarians may be congratulated upon a careful piece of work which should prove very useful to readers using the library.

PARTICULARS of some of the most efficient forms of optical lanterns and accessory apparatus are stated in an illustrated catalogue just published by Messrs. Reynolds and Branson, Ltd., of Leeds. Prominence is rightly given to the Stroud and Rendell science lanterns, which can be adapted to many purposes, and are equally useful for the projection of lantern-slides, apparatus, or practical experiments in science teaching. The "Rystos" petrological micro-polariscope is an instrument designed by Dr. Dwerryhouse to project upon the screen sections of minerals and rocks as nearly as possible under the conditions in which they are seen under the microscope. The notes given in the catalogue on the arrangement of lantern and accessories for various demonstrations illustrate the flexibility of lantern apparatus for purposes of instruction.

THE Year Book for 1912 of the Carnegie Endowment for International Peace has now been issued. In a letter dated December 14, 1910, addressed to the trustees of the endowment, Mr. Carnegie said:—"I have transferred to you as trustees of the Carnegie Peace Fund, 2,000,000*l*. of five per cent. first mortgage bonds, the revenue of which is to be administered by you to hasten the abolition of international war, the foulest blot upon our civilisation. Although we no longer eat our fellow-men nor torture prisoners, nor sack cities, killing their inhabitants, we still kill each other in war like barbarians. Only wild beasts are excusable for doing that in this the twentieth century in the Christian era, for the crime of war is inherent, since it decides not in favour of the right, but always of the strong." The year-book details the steps which up to the present the trustees have taken to secure the objects aimed at by the fund. The numerous reports—of the executive committee, the secretary, and of the directors of the various divisions into which the work of the trustees is divided—all show that strenuous and successful efforts are being made in many parts of the world to educate peoples in the desirability of abolishing war as a means of settling disputes.

OUR ASTRONOMICAL COLUMN.

A SOLAR OBSERVATORY FOR NEW ZEALAND.—For many years it has been felt that the European and American Solar Physics Observatories should be supplemented by similar observatories in that great stretch of longitude which at present is not represented. The establishment of Kodaikanal was a tremendous advance in the right direction, and a further successful step was taken by the founding of the new observatory in Australia; the latter, we hope, will soon be in active operation. By the generosity of Mr. Thomas Cawthron, of Nelson, New Zealand, this chain of stations will be carried still further east by about 25° of longitude, for he has offered to build, equip, and endow a solar observatory in the vicinity of Nelson. The climate of Nelson seems admirably suited for such a station. The choice of the actual site is, according to a communication from Miss Proctor, in the hands of Sir Robert Ball, who has been requested to send a representative to select that which is most advantageous, and also to give estimates regarding the equipment. Let us hope that this, the "Cawthron Solar Observatory," will soon be in active operation also, thus completing the girdling of the earth from the solar physics point of view.

A CURIOUS ASPECT OF JUPITER'S THIRD SATELLITE.—J. Guillaume communicates to the *Comptes rendus* for June 9 an interesting observation relative to the appearance of Ganymede, Jupiter's third satellite, near the end of its transit across the planet. Instead of the regular circular disc which it usually displayed, he noticed on May 24 last that it had a gibbous form, reminding him, as he says, of Mars at the epoch of quadratures, and, furthermore, that it showed a very white north polar spot with a grey zone smaller in the eastern part than in the western part. These details were more apparent when the satellite was projected on the disc than when off it. M. Guillaume remarks that he has seen this appearance several times in 1890 and 1893 with a reflector of 0·216 metre aperture, but never in such a conspicuous manner as on May 24, when he was using the equatorial coudé (aperture 0·320 metre) at the Lyons Observatory.

THE STAR CLUSTERS IN PERSEUS, N.G.C. 869 AND 884.—In vol. ii., No. 2, of the *Astronomische Abhandlungen* of the Hamburg Observatory in Bergedorf, Dr. B. Messow publishes the discussion with the results of the mean positions and brightness of 649 stars in the two clusters in Perseus N.G.C. 869 and 884, after his measures of two photographic plates. The plates were secured on October 3, 1899, by Herren Eberhard and Ludendorff, with the small photographic refractor (34 cm. aperture, 3·4 m. focal length) of the Astrophysical Observatory at Potsdam, and the exposures lasted five minutes each under good observing conditions.

Towards the end of the memoir he makes a comparison with ninety-six stars of the same cluster, taken by Rutherford during the years 1870–74 and measured by Miss Young, and he finds that they agree within very small limits, with the exception of one star. Omitting this, and two others which were measured only on one of his two plates, the differences Young minus Messow were as follows:—

$$D_{\alpha} = 0{\cdot}000s. \qquad D = +0{\cdot}01'$$

A further investigation of the differences between Young and Messow as regards proper motion leads the latter to state that the two star clusters have not altered their position in space. The memoir concludes with a catalogue of the positions of the 649 stars for 1899–1900, together with their estimated and measured magnitudes.

Oxford University Observatory.—From the thirty-eighth annual report of the Savilian professor of astronomy we learn that the Cambridge ledgers containing the corrections to the Cambridge meridian observations from all the separate plates taken at Oxford have now been completely revised and discussed for magnitude equation. It has been found that the observations of faint stars are affected by considerable and rapidly changing errors, such as Prof. Arthur Searle found at Harvard. To enable this work to be accomplished, the work on differential star places had to be temporarily put aside. We are further informed that two zones (+64° and +63°) of the Vatican plates have been completely reduced with the exception of one doubtful plate in zone +63°. This plate has since been repeated at Rome.

THE THIRD INTERNATIONAL ROAD CONGRESS.

The Permanent International Association of Road Congresses, which held its first meeting in Paris five years ago, completed its third congress in London on Saturday last. The attendance of home and foreign members and visitors was far greater than at either of the two previous meetings, and there is no doubt that both in the quantity and quality of the matters discussed, and the general interest taken in the road inspections and in the road-making apparatus shown at the exhibition, this congress showed a marked advance on the two previous ones.

Too much was attempted. Papers on nine important questions had been invited, and the response was such that more than 120 papers replying to the questions alone had been received, to be translated into the three official languages—English, French, and German—and summarised for discussion by carefully selected reporters. The discussions were on these summarised reports, and as the resolutions voted on after their discussion reach 4500 words in English, 5500 in French, and about the same in the German readings, it will be seen that much has been attempted.

The questions on which papers were invited were the following:—(1) The planning of new streets and roads; (2) the best types of surfacing to be adopted on bridges; (3) the great question of bituminous construction of macadamised roads; (4) wood paving; (5) the best methods of lighting streets and highways; (6) the causes of deterioration of road surfaces noted since 1908; (7) the regulation of fast and slow traffic; (8) the functions of road authorities; (9) finance and the incidence of taxation necessary for the upkeep of the roads.

In addition, communications on many important subjects were invited, but on these, although many of them contained much valuable data, there was no time for discussion.

The resolutions discussed and voted on are really condensed summaries of the average opinions contained in the papers, and therefore have a certain value as indicating the general trend of well-informed opinion on road matters in the year 1912, for on account of the time necessarily occupied in the preparation, printing, translation, and summarising most of the conclusions arrived at last week were based on papers written nearly a year ago.

It was, of course, inevitable that a great mass of the contributions came from countries where road construction and road problems are not in a very advanced state, so that the real interest to the more scientific members present lay in the opportunities that these meetings give for personal discussion of the problems which are now presenting themselves in this most interesting branch of engineering.

All who are studying the modern road development which is called for by the steady demand for door to door transport of passengers, as well as goods, know that the question of the time is how to produce road surfaces which are efficient from the point of view of reducing so far as possible the running cost of the vehicles which use them, at the lowest cost for road construction and annual maintenance.

It is almost unnecessary to repeat what has been so often urged, that road engineering demands as intimate a study of the action of the wheel rolling on the road surface as has been devoted to the same question on railways, with such marked economy in the cost of railway transportation. On account of the widely varying type of the vehicles running on the roads and of the great variety of their means of propulsion, and of the fact that for many years to come horse-drawn as well as mechanically-propelled vehicles will use the same road surface, the problems of construction and maintenance are certainly more complicated than those of the railway.

At the informal meetings of the more scientific of the engineers who visited London last week many interesting views were interchanged which cannot fail to further the science of road engineering, as has been found to be the case at the international meetings of the Iron and Steel Institute, where such informal discussions have always been the real feature of the meetings.

On account of the abundant supply of bituminous binding material provided by the tars and pitches from our gasworks, England has made an exceedingly good start in the science of binding road surfaces with tarry matter. On the other hand, America made her first road developments by using the bitumens which are either obtained from natural deposits or as the residuals from the distillation of some of the earth oils. Quite recently the demand for the various forms of petroleum for power and heating purposes has increased the production of the bituminous residuals, and it is likely that the low cost of freight will enable America to supply these residuals to English road engineers as a formidable rival to the tars and pitches which have been in use up to the present.

One of the most interesting features to the scientific members of the congress has been the inspection of the trial lengths of roadways laid down by our Road Board to enable various road materials, such as the roadstones, the tars, and bituminous binders, to be tested under fixed and regular conditions of heavy traffic at Sidcup, Wandsworth, Fulham, and on other roads and streets in and near London. In addition, the latest scientific development of road apparatus was shown to the members of the congress at the National Physical Laboratory at Bushy, where the "road machine" was shown in action; this machine having been designed to reduce the time necessary to test road materials from many months down to a corresponding number of hours. The machine was only completed a few weeks ago, but the few tests already made on improved road surfaces have already directed attention to several interesting phenomena which had long been suspected by road engineers, but were incapable or difficult of proof on the ordinary roadway on account of the great variations in weather, traffic, and other matters which render accurate comparative tests difficult, if not impossible.

OPENING OF THE NEW WING AT ROTHAMSTED.

ON Friday, June 27, the new wing of the Rothamsted laboratories was opened by the Right Hon. Walter Runciman, President of the Board of Agriculture, in presence of a large and distinguished company, which included Earl Grey, Earl Denbigh, Earl Rosse, Lord Lucas, Prof. H. E. Armstrong, Mr. G. W. Lamplugh, Dr. W. N. Shaw, Sir William Tilden, Sir David Prain, Dr. G. J. Fowler, Dr. J. A. Voelcker, and others.

The new wing (on the right) adjoining the old one-storey building of the Rothamsted Experiment Station.

In his opening remarks the chairman (Sir John Thorold) stated that the wing now ready for opening was the third great advance during the last few years at Rothamsted. The first was made in 1906, when Mr. J. F. Mason gave the James Mason Bacteriological Laboratory, and provided funds for its maintenance; the second was made in 1907, when the Goldsmiths' Company gave a grant of 10,000*l.* towards soil investigations; and the third became possible when the Government instituted the Development Fund, out of which part of the cost of new buildings could be met.

In declaring the buildings open, Mr. Runciman sketched out the history of the Rothamsted Experiment Station from its beginning in 1843 to the present time. The experiments grew out of some pot trials made by Lawes as a young man in the late 'thirties. The first result was the discovery of superphosphate, which alone had proved of almost incalculable benefit to the world, markedly increasing the yields of some of the British and Continental crops, and rendering possible the economic growth of wheat in Australia. Feeding experiments on animals came later, and proved of fundamental importance both to farmers and physiologists. During the fifty-seven years of their partnership, Lawes and Gilbert had investigated most of the important problems connected with British agriculture, and laid the whole community under a great debt of obligation to them. The work thus begun had expanded considerably under Mr. Hall's directorship (1902–12), and the growth was such that the new wing was already full, and the director, Dr. Russell, was preparing plans for new buildings to be erected in commemoration of the centenary of the birth of Sir John Lawes (1814) and Sir Henry Gilbert (1817). Mr. Runciman expressed the hope that the centenary fund would be well and widely supported.

Mr. J. F. Mason, M.P., who followed, recognised that farmers had evolved an admirable system of agriculture, but pointed out that every industry benefited by scientific aid. He instanced the steel industry as one in which science had done great things. Already science had done much for agriculture, and there is every reason to suppose that it will do more.

Earl Denbigh and Sir Hildred Carlile both paid high tributes to the work that is being done at Rothamsted in relation to British agriculture, while Earl Grey emphasised the enormous part that has been played by science in the development of Canadian agriculture.

The buildings were then inspected. They include a large soil laboratory and directors' room on the ground floor, a botanical laboratory, library, and chemical laboratory on the first floor, and a glass-house for water cultures on the roof. Special rooms are provided in the basement for polarimeter work and for soil incubations. The laboratory is served throughout with electric current, which is generated in an adjoining dynamo and battery house. The total cost of the building and fittings is about 3400*l.*, and the expenditure on the new farm (which has been taken over to supplement and extend the old experimental fields) is about 3200*l.* Towards this the Board of Agriculture has made a grant of 3100*l*. out of the Development Fund, and has also promised an annual maintenance grant of 2500*l*. from the same source. These grants are made on the "pound for pound" principle, *i.e.* they are given subject to an equal amount being raised from other sources. The Society for the Extension of the Rothamsted Experiments was founded for the purpose of collecting subscriptions, and is now making a further appeal. Subscriptions and donations should be sent to the secretary, the Rothamsted Experiment Station, Harpenden.

It is hoped to raise 6000*l*. as the centenary fund, and thus to qualify for a further grant of 6000*l*., making a total of 12,000*l*., a sum which it is estimated will give buildings and appliances adequate for some years to come.

THE GLASGOW MEETING OF THE INSTITUTION OF NAVAL ARCHITECTS.

THE Institution of Naval Architects held a successful and largely attended summer meeting in Glasgow on June 23–27. An interesting series of visits to works and excursions had been arranged, that to Messrs. Beardmore's shipyard, and the excursion to Arran with which it was combined, proving particularly enjoyable. While most of the papers dealt with purely technical matters, one or two were of more general interest.

In a paper on safety of life at sea, Mr. Hillhouse summed up the present state of affairs from the point of view of the naval architect. Apart from careful navigation the three factors on which we have to rely are wireless telegraphy, subdivision of hulls, and a sufficiency of boats. Of these, the adequate subdivision of hulls presents very serious constructional difficulties, and offers few advantages in the case of fire, while it is almost impossible to provide sufficient small boats and to guarantee that they shall all be usable in the moment of emergency. The one thing on which we can insist is careful navigation, although this may involve some reduction in speed.

Dr. S. J. P. Thearle directed attention to a number of cases in which cracks have developed in the shell plating of a steel vessel at points removed from rivet-holes and from the edges of the plate. These have been found to occur only in the vicinity of a frame unsupported by any beam, and are evidently due to "fatigue" following alternate stressing of the plate by "panting."

In a paper on the effect of form and size on the resistance of ships, Mr. J. S. Baker dealt with the effect of an increase in the length of the parallel portion of a vessel and of fullness of form. The problem was first attacked from a theoretical point of view on the assumption of stream-line flow; the distribution of pressure around the hull was computed; and a law deduced for the speed at which transverse wave-making occurs. These results were compared with those obtained from model experiments, and from these the author deduces an expression for the most economic length of parallel body to be associated with a given entrance and run.

Prof. A. H. Gibson and Mr. Hannay Thompson read a paper dealing with the theory of "suction," or interaction between passing vessels, and with an extensive series of experiments carried out to investigate this important question. The vessels used were respectively 90 ft. and 30 ft. in length, displacing respectively 96 and 2·6 tons. The experiments were divided into two sets, one dealing with the behaviour of the vessels when moving at different distances apart and at different speeds with helms lashed amidships, and the other dealing with the helm angles necessary to maintain a straight course and with the forces and moments operative to produce deflection of the course under similar conditions. The experiments were carried out in deep and open water, and the authors conclude that even in these circumstances interaction is a very real danger to navigation under certain conditions. The danger would appear to be greatest when the larger vessel is passing the smaller in fairly close proximity at a speed not greatly in excess of that of the smaller. In such circumstances, particularly if the larger be at the time accelerating with a view of drawing out of range of the smaller, the latter may be drawn into collision, except in so far as prevented by the helm, from distances as great as three or four lengths of this vessel. With the vessels within one length of each other the helm required to keep the smaller on its original course varied with its longitudinal position relative to the larger, and with their relative speeds. When all circumstances favoured interaction a helm angle of as much as 20° was necessary to prevent collision. Generally speaking, since the helm effect increases somewhat more rapidly than that of suction, a vessel is more easily controlled against these forces at high than at low speeds.

An interesting paper by Mr. A. Cannon records the results of experiments with an apparatus designed by Sir H. Biles on principles laid down by Colonel Russo, R.I.N., to investigate the effect of internal loose water upon the rolling of a ship amongst a regular series of waves, while a paper by Mr. Lloyd Woodward, dealing with the theory of the same subject, forms a useful supplement to this. The experiments point to the conclusion that, generally speaking, the addition of free water decreases the angle of roll, and always does so if its quantity is limited. If, however, the quantity is fairly large, and particularly in short and high waves, the effect is to increase the angle, and under a certain combination of wave-lengths and height the angle may become dangerous. Further, these large angles are attained in a very few rolls, and it is quite possible for them to be attained in an actual ship, although the resistance to roll may be very great.

In a paper which was taken as read, Prof. L. Gümbel dealt with the cavitation of screw propellers, concluding that the tendency to cavitation not only increases with a diminution in the depth of immersion and with the amount of dissolved air in the water, but also depends very largely on the pitch of the propeller, on the angle formed by the feather edge in the cross section of the blade, and on the amount of slip. As regards the latter point, the limit of slip which may take place without cavitation is reduced as the speed of the vessel increases. On the other hand, the occurrence of cavitation is not dependent on the surface pressure over the blade area. A small angle at the emersion edge is more easily obtained with a broad-bladed propeller than in one with narrower blades. In this fact lay, in the author's opinion, the secret of the success that had been obtained with turbine screws with broad blades. Since, however, broad blades involve increased friction, an attempt should be made to so form the cross section as to get a narrow blade with the minimum possible angle of emersion.

Other papers descriptive of the results of trials on modern vessels propelled respectively by geared turbines and by Diesel engines enable an interesting comparison to be gained between the performance of these types of motor. In the turbine installation of 2400 b.h.p. the steam consumption was only 12·55 lb. per shaft h.p., the ratio of effective h.p. to shaft h.p. attaining a maximum value of about 58 per cent. at about 480 revolutions per minute. With the Diesel engines, of 1000 h.p., the remarkably low consumption of 0·37 lb. of oil per shaft h.p. was obtained.

In the concluding paper of the meeting Messrs. Reid and Mavor made out an excellent case for electrical propulsion in conjunction with Diesel engines in the type of large canal barge or freighter used to such an extent on the great inland waterways of North America. The efficiency of such a vessel depends very largely on the ease and rapidity with which it can be manœuvred, reversed, accelerated, and backed, during its frequent passages through the locks on these waterways, and this puts the direct-coupled Diesel engine, under present conditions, out of court.

THE NATIONAL PHYSICAL LABORATORY

Opening of New Building.

THE new building at the National Physical Laboratory, Teddington, was opened by the Right Hon. A. J. Balfour on the day of the annual visitation, Thursday, June 26. The opening ceremony was held in the structure designed for the new wind-channel for aëronautical work. A large and distinguished company foregathered, including Sir Archibald Geikie, who presided, Colonel Seely (Secretary of State for War), Lord Rayleigh, Lord Allerton, Lord Welby, Viscount Esher, Lord Montagu of Beaulieu, Sir Oliver Lodge, Sir Wm. Crookes, Sir Wm. Ramsay, Sir John Brunner, Sir Albert Spicer, and Dr. R. T. Glazebrook (director of the laboratory).

The chairman, in his opening remarks, referred to the amazing growth of the laboratory and the place it had taken as one of the most important national institutions in this country.

Dr. Glazebrook dwelt on the noble liberality of the friends who had so splendidly supported the laboratory in the past, and Lord Rayleigh emphasised the fact that funds were still needed for equipment purposes. Lord Rayleigh went on to express the hope that in the future larger funds would be available to enable greater attention to be paid to research in pure science, as well as to work calculated to further the immediate ends of industry.

Mr. Balfour gave an interesting and thoughtful address dealing largely with the national advantages of the study of pure science. In the course of his address he remarked :—

Measuring is the very life-blood of physical science. It lies at the root of almost all great discoveries and their application to practice. It is impossible not to acknowledge the benefit which mankind has received by the command which science has given us; and measurements and testing are absolutely essential to science. The great features of a national laboratory are its impartiality, its ability to bring an adequate staff and adequate machinery to bear on problems, and the standard of perfection which it sets for instruments and which serves as an ideal for manufacturers to work to. The advantages to industry are beyond all doubt and beyond all question.

But the successes of the future of industry depend on the abstract of purely scientific investigations of the present, and it is to the labours of the man of science working for purely scientific ends, and without any thought of the application of his doctrines to the practical needs of mankind, that mankind will be most indebted as time goes on. The general public does not realise that it is to the results of pure science that we have owed in the past, and shall owe more and more in the future, all great advances in industrial knowledge and practice. Still less does it realise that the man of science who is working continuously towards that end is only half a man of science, and is not likely to do his scientific work nearly so well as if he were simply and solely occupied in advancing that branch of knowledge with which he is connected.

When these important truths have sunk into the public mind, we may see, as a reflection of that new conviction, a different attitude adopted by those who have to settle what expenditure should be presented to Parliament for its sanction, and the attitude which Parliament itself may take in the face of such suggestions. The growth of this great institution during its very few years' existence justifies us in looking forward to a great and glorious future for it. The thanks of the public are due to the brilliant and hard-working staff of the laboratory who, under no small difficulties, are the real authors of the triumph which we are met to celebrate.

After the opening ceremony, an inspection was made of the new building, and visitors wandered at will through the various departments of the laboratory, in which a series of interesting demonstrations had been arranged.

The new building marks the completion of a scheme for the erection of laboratories for metallurgy and optics, and of a building for administration purposes. The late Sir Julius Wernher made himself responsible for the funds for the metallurgical laboratories, and for the rest, the Treasury, the 1851 Commissioners, and some of the City Companies have made generous contributions.

One of the main objects for which the new laboratories have been erected was to enable the testing work, until recently carried out at Kew Observatory, to be transferred to Teddington. Kew Observatory is in future to devote itself purely to meteorological objects—it is now, in fact, the central observatory of the Meteorological Office—while the testing of instruments of all kinds will be undertaken exclusively at Teddington.

The new building provides accommodation for the administration and optics departments, together with workshop and packing rooms. The optics wing is designed to accommodate the optical testing work hitherto carried out at Kew and in a suite of rooms at Bushy House. The latter rooms are now occupied by the thermometer-testing observers from Kew, while the remainder of the Kew test-work has been housed in the metrology department.

The new building, of which we show an illustration, is a three-storey structure built of purple Surrey bricks with red brick facings. The architecture is of the Queen Anne period, and the structure bears a general resemblance in style to Bushy House, alongside which it stands, and which, it will be recalled, formerly housed the whole of the work of the laboratory. The new building impresses one as being generously lighted and very substantially built, and reflects great credit on the architect, Mr. W. D. Caröe, and on the clerk of the works, Mr. R. Allen Jane.

Great care has been bestowed on the fireproof qualities of the building; the floors and stairs are of ferro-concrete throughout, and generous provision has been made for fire hydrants. This feature is, of course, doubly important in a building one of the functions of which is to house important records.

The ventilation is controlled by a large fan on the roof, communicating by ducts to extractors in the ceilings of the different rooms. Fresh air is admitted through louvres behind steam-heated radiators provided with suitable baffle plates.

The corridors throughout are covered with Doloment patent flooring; the woodwork is chiefly oak, the effect of which is altogether admirable.

To take the central block of the new building first. Opening on to a large central hall on the ground floor are the accountant's offices and strong-room, reception-rooms for visitors, and a telephone exchange room; on the first floor are the director's room and the secretarial offices; on the second floor, *inter alia*, the "White Library," a publications room, and a lecture theatre. The library is being furnished by the Drapers' Company in memory of the late Sir William White, to whose good-will and energy the laboratory owes a great deal. A brass memorial tablet records that "The Worshipful Company of Drapers of the City of London, mindful of the last wishes of Sir William Henry White, K.C.B., F.R.S., gave to the Laboratory the bookshelves in this library." The fittings are being carried out in old oak, and the library, with its panelled walls, recesses, and gallery, brings to mind some of the college libraries at the older universities.

It is anticipated that the new lecture-room will afford facilities for meetings of scientific societies, for many of which an annual visit to the laboratory has become a recognised function. It is hoped also that opportunity will be afforded to the members of the staff of hearing distinguished visitors at a fortnightly or monthly colloquium.

New building of the National Physical Laboratory.

The central block is isolated from the north and south wings by fireproof doors.

On the ground floor of the optics division are two large semicircular arch-shaped tables made of cast-iron. One of these is vertical and the other horizontal. They are used to test the accuracy of graduation of theodolite circles and sextant arcs. One face of each table is machined, and to it are bolted at definite angles collimators pointing to the centre of the semicircle. The tables rest on isolated masses of concrete weighing some 20 tons; and to avoid troubles due to seasonal and extraneous temperature changes, the tables and supports are hollow throughout, and are kept at uniform temperature by circulating water through them. In the same room is a tilting table with standard wedges for testing clinometers. The photometer and spectacle-lens benches are mounted in an adjoining room, along one end of which is a movable partition which can be removed when extra long-focus process lenses are being tested. A rapid and convenient system of light-tight blinds is a noteworthy feature of the fittings. The testing of microscopes is conducted in an adjoining room.

On the first floor, a group of rooms is allotted for testing terrestrial telescopes. One of these can be completely darkened for the purpose of examining the parallelism of the axes of binoculars, or the illumination of cross wires. Test objects and scales of various forms, and at distances up to 400 yards, have been erected.

A long ferro-concrete balcony (which, by the way, was cast in one mould complete) extends along the outside of the first floor. This will enable open-air tests to be made on instruments.

On the second floor, the equipment for examining photographic lenses is grouped in adjoining rooms. Here are, for example, the Hunter apparatus for obtaining a numerical estimate of definition; the Beck bench for measuring focal length, astigmatism, curvature of field, &c. The testing of photographic shutters is carried out here, by the use of vibration galvanometers tuned to resonance with electrically-driven tuning-forks or vibrating bars.

Next is the room devoted to spectroscopy, and in particular to the examination of refractometers and spectrophotometers. A feature of the room is a large roller shutter by means of which the room can be readily divided into two. The shutter is provided with suitable apertures, to fit the various instruments under test, and will be brought into use when it is important that the eyes of the observer should not be exposed to bright lights during the test.

The remainder of the rooms are given up to the general photographic work of the laboratory. There is an unusually well-designed and ventilated suite of dark-rooms with light-trapped doors and the like. Other rooms are specially designed and illuminated for photographing apparatus and diagrams.

The roof of the building is flat and asphalte-covered, and on it at one end is arranged an observatory. This is to be fitted with a telescope with an equatorial mounting, and a dome. The telescope is designed so that object-glasses sent for test can be mounted as in actual use.

The north wing contains the packing-rooms and the associated clerical offices, together with store-rooms and wood and metal workshops. Arrangements have been made here for the engraving of instruments with the familiar NPL mark—outward and visible sign that an instrument has passed its tests. Copious provision was necessary for dealing with the packing and unpacking of cases containing instruments, the handling of which under the old arrangements was fast becoming a problem owing to the volume of stuff which had to be dealt with. There is a large Waygood lift, to which leads a sunk track for wide rubber-wheeled trolleys. Thus these latter can be run on the lift, and so to the various corridors and rooms. There is a second lift to the workshops. In this block, a common-room for the laboratory boys has been provided.

The foregoing description will perhaps give an idea of the admirable manner in which the new building has been designed for its work.

DEATH BY ELECTRIC CURRENTS AND BY LIGHTNING.[1]

Death by Electric Currents.

I BELIEVE that no loss of human life from industrial currents of electricity occurred before 1879, though currents strong enough to have caused death were employed in lighting the operatic stage in Paris (at the first performance of Meyerbeer's "Le Prophète") so long ago as 1849, and in lighthouses on and off the coast of England in 1857. In 1879 a stage carpenter was killed at Lyons by the alternating current of a Siemens dynamo that was giving a voltage of about 250 volts at the time. The man became insensible at once, and died in twenty minutes; artificial respiration was not applied. The first death in this country took place at a theatre in Aston, outside Birmingham, in 1880, where a bandsman short-circuited a powerful electric battery, became insensible, and died in forty minutes. Since that date the annual number of deaths from electric shock has steadily increased, particularly during this century, in which the industrial employment of electricity has extended so widely, and is now quite large. In the ten years 1901–10 the Registrar-General's returns show a total of 183 such deaths in England and Wales, the population having risen from 32½ to 36 million during that period. In the three years 1901 to 1903 there were twenty-five deaths; in 1908, twenty-five; in 1909, twenty-nine; in 1910, twenty-six. Only two of these 183 victims were females, because women are so much less exposed to contact with dangerous electric currents than are men. Many deaths by electricity occur annually on the Continent, though I can only bring forward a few scattered figures to prove it. In Germany, thirty-three were killed in 1908; fifty-two in 1909; forty-six in 1911. In Austria eleven were killed by electricity in 1907; ten in 1910; ten in 1911. In Switzerland, twenty-one were killed in 1905; nineteen in 1906. I think it probable that about 200 persons are killed by electricity annually over the whole of Europe. As regards the United States of America, where electricity is so very extensively employed, I have not been able to find any statistical records. So long ago as 1888 Brown estimated that during the past five years some 200 people had been killed by handling live electric wires. One must remember that in America life is held very cheap, and that safeguards and protective legislation tend to be regarded as undue restrictions upon industry and commerce. I imagine that not fewer than 200 persons are accidentally killed by electric currents every year in America. As a rule, only a single person is killed by electricity in any single accident; but in an accident occurring in 1909 at Olginate, a village in Lombardy, ten people were killed outright by a three-phase current at 3000 volts, one was saved by artificial respiration, and about a dozen more were severely injured (Hoest).

The interest of men of science, of physicians and pathologists, in such deaths was first shown in France. In 1882 the celebrated French medico-legal expert and pathologist, Brouardel, made a careful *post-mortem* examination of a man killed in Paris at the Tuileries by a 250-volt alternating current, and he decided that death was fulminating, due to the electric discharge, and directly caused by arrest of the heart. Bourrot at the same time examined a second and similar case *post mortem* and came to the conclusion that death was due to violent excitation of the vagus nerve and consequent arrest of the heart, with the result that the heart could not resume its functions, and death by asphyxia followed. In 1885 a man killed instantaneously by electric shock at the Health Exhibition in London was examined forty hours after death by Sheild and Delépine. *Rigor mortis* was marked; extreme fluidity of the blood was observed, even the right heart being free from clots. The authors came to the conclusion that "No doubt the vital spots at the base of the brain are in such cases markedly implicated."

During the last twenty years a great many *post-mortem* examinations have been made in cases of sudden death by electric shock. Burns of greater or less superficial extent are generally seen at the points where the electric current has entered and left the body. In the second place, abnormal fluidity of the blood has often been found *post mortem*; in this, those cases of sudden death by electric shock resemble cases of sudden death by asphyxia. In the third place, no pathological changes are regularly found in the heart muscle, although there are good reasons for believing that in most instances death is directly due to paralysis of the heart. In the fourth place, the central nervous system often shows neither macroscopical nor microscopical changes of importance, except in the cases where relatively large quantities of electricity have passed through the body for long periods of time. In a word, the *post-mortem* evidence as to the cause of death by electric currents in industrial accidents is generally negative, but may suggest asphyxia in some cases, in others organic vascular and nervous lesions in the brain and cord.

It is upon the evidence obtained by the experimental electrocution of animals that most of our knowledge as to the modes of death by electric shock rests. No electrical apparatus capable of producing currents strong enough to kill animals was invented before about the middle of the eighteenth century. At that time electricity suddenly developed into a popular and spectacular science in France and Germany, just as in the middle of the nineteenth century table-turning, spiritualism, and clairvoyance were popularly taken up all over England and America with the greatest energy. In neither case was much real scientific progress made by this arousal of popular interest; birds, beetles, and other living creatures were electrocuted by frictional electricity by Gordon (1745), Gralath (1746), Nollet (1749), and many others (Benjamin). It was noted that the birds exhibited ecchymoses where the electric sparks struck them, much like the ecchymoses seen on persons killed by lightning (Nollet). Priestley in 1767 killed kittens and dogs with the discharges of condensers, and tried without success to resuscitate a kitten by artificial respiration, distending the lungs by blowing with a quill into the trachea. Abildgaard (1775), using condensers and Leyden jars, tried without success to electrocute a three-months-old foal; he succeeded in killing cocks and hens by electric discharges sent through the head, and made the important observation that fowls treated in this way and to all appearances dead could be brought back to life by electric shocks sent through the body from breast to back, but remained dead if not treated in this manner. To mention only a few out of many of those who have since made similar investigations:—

In 1885 Mann made some very interesting experiments on the effects of electricity on the action of the human heart. He applied the electrodes to the præcordia and back, and found that a slowly alternating current of from 15 to 30 milliamperes did not prejudice the heart's action.

In 1885, and further in 1887, d'Arsonval made some interesting remarks on deaths caused by industrial electric currents, advancing the views as to their mode of production that he has continued to hold faithfully

[1] From the Goulstonian lectures for 1913, delivered before the Royal College of Physicians of London by Dr. A. J. Jex-Blake.

ever since. These deaths, he said, were brought about in one of two ways:—

(1) By direct action, the mechanical effect or disruptive action of the electric current on the tissues; or

(2) By indirect or reflex action on the nervous centres.

In the first case death is final; in the second it is often apparent only, so that the victim may recover if treated by artificial respiration immediately after receiving the shock. Most of the victims of industrial electric accidents had died of asphyxia, he believed. The alternative view that these deaths were due to cardiac failure was first emphasised in 1890 by Tatum, and his is the view very generally held at the present time. It was put on a more scientific basis in 1898 by Prevost, who showed that the cardiac failure was the result of fibrillation or fibrillary tremulation of the muscle of the heart, the German *Herzdelirium*, investigated in 1850 by Hoffa and Ludwig. The extremely well-designed and well-executed experiments of Prevost and Battelli (1899) proved the great importance of cardiac fibrillation in causing the death of animals of various kinds when exposed to the passage of electric currents through different parts of their bodies. They also illustrated the various effects of electric currents of different varieties—alternating, continuous, sudden discharges from condensers and induction coils—on these animals, and proved that when apparently killed by a current at a low voltage, animals might be brought to life again by the shock of the much stronger currents forced through their bodies by the application of high voltages. These authors also demonstrated that while an alternating current with a frequency of 150 alternations a second might be fatal to dogs at an E.M.F. of only 15 to 25 volts, when the alternations were increased to 1720 a second, no fewer than 400 volts were required to produce death. Using high-frequency currents with from 400,000 to 1,000,000 alternations a second, d'Arsonval (1893) found he could stand the passage of as much as 3 amperes through his body, a current twenty or thirty times as great as that required to kill a human being at the ordinary rates of alternation employed industrially. The experiments of Cunningham (1899), d'Arsonval (1910), Weiss and Zacon (1911), are also worth recording, and have added considerably to our knowledge of death by electric currents. Weiss and Zacon found that chloral anæsthesia gave dogs no protection against electric shocks. With alternating currents given for a few seconds, death would occur when about 70 to 100 milliamperes traversed the thorax with the heart *en route*; with continuous currents, death was not caused unless the current was as large as 300 milliamperes, roughly speaking. If, however, smaller electric currents were administered for long periods, it was found possible to produce death by tetanus and asphyxia; thus currents of 35 to 45 milliamperes were too small to produce cardiac fibrillation, but after about ten minutes' application caused death by continued inability to breathe, and slow asphyxiation. It may be noted that Prevost and Battelli found that dogs were not killed by alternating currents as great as 4 amperes at 1200 volts, passed through the body from one hind leg to the other; the reason being that with this arrangement of the electrodes the rate of flow of electricity through the muscle of the heart was not large enough to cause it to fibrillate.

One may conclude that living animals of different species are killed by electricity with very different degrees of facility. For example, many experimenters have endeavour to electrocute frogs, but all, I believe, without success, whatever the current used and however it may have been applied. The frog survives electric shocks and the prolonged passage of electric currents at all sorts of voltages—10, 100, 1000 volts and more—and shocks from induction coils and charged Leyden jars. The only inconveniences it suffers appear to be transient pareses or paralyses, and, in the case of strong currents passed for many seconds or minutes, the formation of burns. The frog is thus immune because its heart always begins to beat again regularly and normally after the passage of the electric current, and because its respiration does the same; and also, as Priestley pointed out in 1767, because "its constitution enables it to subsist a long time without breathing." At the other extreme of the scale comes the dog, which can be killed with certainty by an alternating current of perhaps 15 volts or 60 milliamperes, if it is applied so as to pass largely through the heart muscle for a couple of seconds only.

As regards the death of human beings, it may be brought about by electric currents in several different ways.

(*a*) There is no doubt that it might be due to prolonged tetanus of the muscles, which could prevent the performance of respiratory movements, and so lead to death by asphyxia after some minutes. But I am not able to find that it ever has come about in this way as a matter of fact, the victim always being able either to break the contact and interrupt the passage of the current for himself, or to call for help and get the contact broken by somebody else before asphyxia has occurred in this way.

(*b*) In man primary heart failure is undoubtedly the commonest mode of death by electric currents. The experiments on animals already detailed show that such deaths are due to fibrillation of the ventricles of the heart. The fibrillation has been seen occurring in the hearts of two criminals electrocuted in America and examined immediately after death (Schumacher); a few minutes later the left ventricle was firmly contracted and empty, while the right ventricle and the auricles were relaxed in diastole and full of blood. It is probable that in the adult man, as in the dog, horse, and ape, fibrillation of the heart, once it is established, is irremediable, practically speaking.

(*c*) and (*d*) Death by failure of the respiration while the heart continues to beat, brought about by nervous inhibition, or by failure of both heart and respiration together, is probably not so common in man. There is a great want of evidence on this point; naturally enough, as the people who are present at deaths by electric shock are generally workmen who do not busy themselves with observations of the pulse and the respiration of the victim. A good many cases have been recorded in which death did not occur until ten, twenty, or forty minutes after the shock had been received, and was then apparently due to failure of the respiration to re-establish itself. The experiments upon animals would lead one to believe that such deaths are really due to failure of the respiratory centre in the central nervous system. The *post-mortem* evidence in such cases should suggest death by asphyxia, and such evidence has sometimes been found after death by electric shock.

(*e*) Brief reference may be made to the fact that a good many cases have been recorded in which the victim of an electric accident has died after a few days or weeks from complications (shock, gangrene, suppuration, exhaustion following extensive amputations) arising out of the injuries caused by the electric current.

With alternating currents, death has occurred from shocks at voltages as low as 65 volts, and a good many instances of death at such pressures as 100 to 120 volts have been recorded. It is only in very exceptional circumstances that these low voltages can cause death; unless the patient's skin is wet and he makes a good contact, not only with the electric conductor, but also through wet boots or clothes (according as he is standing or sitting), with the ground or some other conductor, there is not the smallest chance of death by currents at such low voltages.

As regards continuous currents of electricity, I have not found records of many fatal accidents at voltages below 220 volts, but in one case a direct current at only 95 volts caused death, in another a current at 110 volts. The minimum number of milliamperes required to kill a human being under conditions favourable for killing is not known. Weiss calculates that from 70 to 90 milliamperes of an ordinary alternating current would be enough if the current went through the chest and heart; d'Arsonval states that much less than 100 milliamperes suffice to kill. Trotter found that continuous currents up to 35 milliamperes, though almost insupportably painful, were not fatal when passing from the hands to the feet. But when very large industrial currents are forced through the body by high voltages, we meet with the paradox that, while small currents may kill instantaneously, large currents are much less fatal. For example, the American electrocutions have shown that alternating currents of 5 or 8 amperes may pass for many seconds through the body without causing permanent arrest of the heart or respiration. In several recorded non-fatal cases of shock by alternating or three-phase currents at 10,000 volts, it is true that no measurements of the amperes passing through the victims were made, but it is reasonable to suppose that they may have amounted to several amperes. It is plain, then, that currents of a fraction of an ampere may cause sudden death by throwing the ventricles of the heart into fibrillary contraction, though much larger currents of several amperes do not act thus, and so are not fatal. But I do not know of any examples or experiments to show at what point or amperage the transition from small dangerous to large non-dangerous currents takes place.

So far as one can guess, in the absence of any experimental proof, it seems that a continuous current must be two or three times as strong as an alternating current, to kill a human being. So far as sudden death is concerned, electric currents are dangerous to man in proportion to the degree to which they tend to pass through the heart.

The prognosis in cases of severe electric shock has been very variously estimated. Cunningham (1899), for example, speaks of artificial respiration as "the only, and almost invariably futile, method in vogue in electrical accidents at the present day," for the resuscitation of persons apparently killed by electric shock. The opposite view is held by Lauffer (1912), who says "there are few cases of electrical accident where the victim cannot be restored from the electrical shock, if appropriate immediate efforts at resuscitation are instituted."

The treatment—artificial respiration by Schäfer's or Sylvester's methods—is still that advised by Priestley in 1767. The importance of getting to work with the artificial respiration without a moment's delay has often been emphasised by those who have had much experience of electrical accidents. No less important is the necessity for continuing artificial respiration until *it is certain* that death has occurred; nothing less than cooling of the body or the onset of *rigor mortis* should be considered to be evidence of death here.

DEATH BY LIGHTNING.

Up to the present time, meteorologists have furnished us with singularly little definite knowledge about the electrical properties of lightning strokes and the electrical quantities concerned in their production. They may be summed up as very strong electric currents of very brief duration and very high potential, containing thousands or possibily millions of foot-tons of energy. When human beings are struck, a part at any rate of this energy is converted into heat, producing various bodily lesions in most instances. Death by lightning-stroke is much commoner in most countries than it is in ours. In England and Wales the Registrar-General reported 124 fatal instances of lightning-stroke, 108 in men and sixteen in women, during the ten years 1901–10, a yearly average of only 12·4 deaths, or 0·36 per million living. In Hungary the annual death-rate from lightning is said to be sixteen per million living (Milham); in Styria and Carinthia about ten per million, in Prussia 4·4, in France and in Sweden three, in Belgium two, so far as the imperfect statistics available go (McAdie and Henry). In the United States of America the annual death-rate per million is high, about ten, in consequence of the frequency of thunderstorms on one hand, and of the large percentage of the inhabitants engaged in outdoor labour on the other; about 700 or 800 deaths from lightning were estimated to occur in the United States every year by Henry in 1900, in a population of seventy-six millions. Many more people are struck by lightning than are killed. For example, Jack records an instance in which a church was struck; 300 people were in it, 100 were injured and mostly made unconscious, thirty had to take to their beds, but only six were killed. Weber gives an account of ninety-two people struck in Schleswig-Holstein; ten were killed, twenty paralysed, fifty-five stupefied, and seven only slightly affected. In 1905 a tent with 250 people in it was struck, and sixty were left on the ground in various states of insensibility; one was killed outright, another breathed for some minutes before dying, the rest recovered. As many as eleven and eighteen persons have been killed by a single stroke of lightning. Vincent mentions a stroke that threw down 1200 and killed 556 out of a flock of 1800 sheep.

As to the exact way in which lightning causes death, some experiments of Prevost and Battelli, in which the discharges of induction coils and condensers were employed, seem to show that it is by central inhibition and cessation of the respiration in many cases, in others by cardiac fibrillation and stoppage of the heart. The bodies of persons killed by lightning exhibit no characteristic pathological changes except the production of burns and the curious subcuticular or subcutaneous stainings known as "lightning figures," that often imitate the fronds of ferns or leaves or branches of trees, and have given rise to a deal of baseless speculation as to their mode of production. Among the most interesting of the other and far rarer *post-mortem* lesions observed are lacerations of the soft tissues and fractures of the bones. The exact mechanism by means of which lightning lacerates tissues and fractures bones is obscure. In cases where the heel is lacerated and the os calcis comminuted, one may perhaps imagine that an extra development of heat and steam has taken place here, with the result that the electric discharge has, so to speak, blown its way out of the body. The example described by Clark and Brigham proves that enough heat may be developed in so deeply situated a bone as the orbital plate of the frontal bone to char it, so that it is not unreasonable to suppose that small steam explosions may result if the lightning develops a less degree of heat in a moist tissue. But it is not quite easy to imagine how the tibia and fibula could be broken, without showing any external injury, as in Penfold's case, if the fractures were caused by small steam explosions taking place inside these bones. Yet there is no alternative explanation to offer. For I do not think it is imaginable that any known forces of electric attraction or repulsion could exert enough violence to break bones. At any rate, the physicists appear to know nothing of electric forces of the magnitude that would be required here. In a few well-recorded instances which are extraordinary almost to the point of being incredible, strokes of lightning have effected amputations.

Unless sudden death follows, the probability that a person struck by lightning will recover is large; Dechambre collected 365 instances in which the immediate effects of the stroke were survived, and found that only fifteen of these victims died subsequently from late effects of the lightning. It seems to be very generally assumed that immediate treatment would improve the prognosis considerably, and that many of the people killed by lightning are only apparently dead, and still capable of recovery if properly treated during the next few minutes. I do not know of any statistical evidence to prove this point.

At the present day only general advice can be given, as the accumulated records have shown that no place above ground is completely protected against lightning. It is certainly safer to be indoors than out, and a large house is much safer than a shanty. The windows and doors of the room in which one is should be shut, and one should keep away from the walls, and particularly from the fireplace, because, when a chimney-stack is struck, the contents of the chimney and the fireplace are often blown out into the room and cause bodily injuries. A great many people have been struck in sheds and barns, especially when they have been near doors or windows, or in currents of air. Turley recommended the centre of a railway carriage at a distance from the engine as the securest place of all; Schefčik, a feather bed. To take refuge in the cellars merely to avoid a thunderstorm is not necessary as a routine, though in exceptional cases it may be advisable.

The advice given by various authors to persons caught out of doors in a thunderstorm is contradictory. It is probably unwise to take shelter in a shed unless one can get out of the way of doors, windows, and draughts while one is in it. A shed containing domestic animals is certainly more dangerous than the open. If one has to remain in the open, there are certain things that should be avoided at any cost. The first of these is the proximity of wire fences, because when such a fence is struck the electric discharge may be carried along the wires and cause death at a distance from the place actually struck. The second is proximity to such things as hedges, ponds, and streams, isolated trees, crowds of people, and herds of domestic animals. Crowds of people or animals seem to have a mild attraction for lightning, very possibly by virtue of the warmth and dampness they impart to the atmosphere immediately round them. It has often been said that to have had the clothes thoroughly wetted by rain and rendered conducting gives some protection to people who are struck by diverting the path and violence of the lightning from the body to the clothes. I have found seven well-recorded instances in which the effect of the stroke was to blow all, or practically all, the wetted clothes off the body, by the generation of steam as I believe. There can be no doubt that a part of the energy of the lightning was expended on the clothes in these cases, but three of the seven victims were killed notwithstanding. So the protection of wet clothes cannot be considered at all complete.

So far as treatment is concerned, persons struck and apparently killed by lightning should at once be given plenty of fresh air, their clothes should be loosened, and artificial respiration by Schäfer's or Sylvester's method should be applied and should be continued until either recovery occurs or cooling of the body and *rigor mortis* show conclusively that death has taken place. In the medical writings of from fifty to two hundred years ago one often sees bleeding recommended, and this might well be of service in those cases of lightning-stroke in which the heart goes on beating while the respiration stops. If it were immediately—within a few minutes—available, to give strong electric shocks to the præcordia would be well worth trying in desperate cases. As regards other remedies—such as stimulants in all forms, hot or cold applications, the inhalation of pungent vapours—very many have been recommended, but none seem to have met with any success.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

SHEFFIELD.—Mr. W. G. Fearnsides, fellow and lecturer in natural sciences at Sidney Sussex College, and demonstrator in petrology in the University of Cambridge, has been appointed to the Sorby chair of geology.

ACCORDING to an announcement in the "Political Notes" of *The Times*, there is reason to believe that the Government has abandoned the intention of introducing this session the Education Bill which was to have embodied the scheme under consideration by Lord Haldane's Cabinet Committee. Every effort is being made to lighten the Government programme so that Parliament may be prorogued at a reasonable date in August.

IT is announced that their Majesties intend to invite to a garden-party at Buckingham Palace on Saturday, July 19, representatives of the teaching profession in London. We understand that invitations will shortly be issued to responsible head-teachers and principals of schools, institutes, and colleges of every type constituting the public system of education in the county of London. A special choir of children selected from public elementary schools will sing before their Majesties.

IN support of the foundation of a Western University in Central China, a meeting of members of Parliament was held in the House of Commons on June 26. Canon Lord William Gascoyne-Cecil said that nothing is being asked for out of the pocket of the British taxpayer. The suggestion is that the British Government should forgo part of the Boxer indemnity. We learn from *The Times* that it was pointed out that the Boxer indemnity claimed by Great Britain amounted to more than 7,000,000*l*., and of that amount only 199,000*l*. has been paid. A sum of 250,000*l*. spread over a long period would meet the cost of the new University. A motion that a deputation be appointed to urge upon the Prime Minister the desirability of a Government grant, either out of the Boxer indemnity fund or otherwise, towards the establishment of the proposed University was agreed to.

THE Board of Education has issued (Cd. 6866) the regulations, which will come into force on August 1, for university tutorial classes in England and Wales. The Board will be prepared to make special grants in aid of part-time courses in subjects of general as distinct from vocational education, given under the educational supervision either of a university or university college, or of an educational body containing representatives of such places of higher education. The university or supervising body must be responsible for the framing of the syllabus, and the selection of a suitable tutor; and the instruction must aim at reaching, within the limits of the subject covered, the standard of university work in honours. The course must extend for each class over a period of not less than three years, and must occupy at least two hours a week for twenty-four weeks in each year, at least one-half of the time being devoted to class work.

IN the issue of *Science* for June 13 further large gifts to higher education in the United States are announced. Mr. Andrew Carnegie has undertaken to provide 200,000*l*. for the medical department of Vanderbilt University. Of this sum 40,000*l*. is to be given to the University immediately for the erection and equipment of laboratories. The income from the remaining 160,000*l*. is to be paid annually for the support of the department through the Carnegie Corporation. A condition of the donation provides that the direction of the educational and scientific work of the department shall be committed by the board of trustees to a small board of seven members, three of whom shall be eminent in medical and scientific work. Messrs. J. B. and B. N. Duke have given 160,000*l*. more to Trinity College in North Carolina. The college has thus secured the 30,000*l*. promised by the Rockefeller Foundation, and has added 200,000*l*. to its endowment. Governor Sulzer has signed a Bill granting 50,000*l*. for a building for the State College of Agriculture at Syracuse University.

THE report for 1913 of the council of the City and Guilds of London Institute has now been published. In it is passed in review the work of the City and Guilds (Engineering) College, the City and Guilds Technical College, Finsbury, the South London Technical Art School, the Department of Technology, and the Leather Trades School. The audited accounts and balance-sheet of the institute are given, and the reports of the heads of the various colleges and schools are included. During the past session the Department of Technology registered 4552 classes in the United Kingdom in 331 towns. These classes were attended by 53,999 students; this number represents, however, only a proportion of the total number of students in attendance at courses of technical instruction largely influenced by the work of the department. The examinations of the department were held in seventy-five technological subjects, for which 22,111 candidates were presented in the United Kingdom alone. While the total number of candidates shows a decrease on the number for 1911, the proportion of passes in the examinations has, on the contrary, risen by 4 per cent., which suggests that the fall in the number of candidates is largely due to the exclusion of a number of insufficiently prepared students from the examinations.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 19.—Sir Archibald Geikie, K.C.B., president, in the chair.—Sir James **Dewar**: Atomic specific heats between boiling points of liquid nitrogen and hydrogen.—I. The mean atomic specific heats at 50° absolute of the elements a periodic function of the atomic weights.—Hon. R. J. **Strutt**: An active modification of nitrogen produced by the electric discharge. V. (1) An improved practical method of preparing and storing nitrogen for the experiments is described. (2) It is shown, notwithstanding criticisms of certain other experimenters, that the presence of traces of oxygen in the nitrogen used is not essential, or even favourable, to the phenomena. The nitrogen used, purified by cold phosphorus, does not contain oxygen to the extent of one part in 100,000. Passing it over red-hot copper in addition makes no difference. The intentional addition of oxygen does harm; 2 per cent. obliterates the effects altogether. Hydrogen and carbon dioxide as impurities are much less harmful, but traces even of water vapour have a very bad effect. (3) Nitrides are formed by the admixture of active nitrogen with vapour of mercury, cadmium, zinc, arsenic, sodium, and sulphur. These are decomposable by water or potash solution, yielding ammonia. (4) Carbon disulphide yields a blue polymeric nitrogen sulphide, and polymeric carbon monosulphide. Chloride of sulphur gives ordinary yellow nitrogen sulphide. Stannic chloride and titanium tetrachloride also yield solid products. In the latter case nitrogen was proved to be present. (5) All organic compounds tried, except carbon tetrachloride, yield hydrocyanic acid freely, but not cyanogen, as was proved by chemical tests. When chlorine is present, cyanogen chloride is formed. Benzene yields (almost certainly) cyanobenzene. (6) The intensity of the cyanogen spectrum with organic compounds is no index of the quantity of hydrocyanic acid being formed. Preponderance of the red cyanogen bands is associated with cyanogen chloride or bromide. On a general view of the evidence, there does not appear to be any definite connection between the development of spectra by active nitrogen and the chemical actions in progress.—Dr. J. A. **Harker** and Dr. G. W. C. **Kaye**: The electrical emissivity and disintegration of hot metals. Preliminary experiments have been carried out on the volatilisation and electrical emissivity of a number of metals, mostly in nitrogen at reduced pressures. The metals were heated by alternating current and no applied potential was employed. (1) The emission of positive electricity occurs at temperatures from about 1000° to 1400° C. For metals which melt within this range, a sudden and marked increase in the positive current often occurred at the liquefying point—due, probably, to the sudden release of occluded gas. (2) Oxygen appears to augment the positive current. (3) At higher temperatures, negative electricity predominates and increases rapidly with the temperature. The negative current attained with iridium at the melting point was 80 milliamperes, with tantalum at 1670° C. 220 microamperes, with iron at the melting point 90 microamperes. In the case of carbon in air at atmospheric pressure, an ionisation current of $3\frac{1}{2}$ amperes was obtained. (4) The negative current at moderate pressures appears to be largely increased if the conditions are such that considerable sputtering of the metal occurs. (5) The negative currents are probably a consequence of chemical reaction between the metal and the surrounding gas. (6) Carbon becomes plastic in the neighbourhood of 2500° C. At such temperatures it also readily sublimes.—Dr. A. O. **Rankine**: A method of measuring the viscosity of the vapours of volatile liquids, with an application to bromine. In this method of determining viscosities the rate of transpiration of the vapour through a capillary tube is controlled by the vapour pressures of the liquid itself, a difference of pressure being established in the process of virtually distilling the liquid through the capillary. The pressures can be estimated without the use of mercury gauges—a state of affairs especially desirable in the case of the halogens. The viscosities of unsaturated bromine vapour over the approximate range 10° C. to 250° C. have been measured, and, except at the lowest temperatures, are found to agree well with Sutherland's formula, notwithstanding the fact that all the temperatures are below the critical.—E. E. Fournier **d'Albe**: The efficiency of, selenium as a detector of light. The efficiency of a selenium preparation used as a detector of light is defined as the amount of additional conductivity imparted to it by the unit of incident light. Since many factors affect the efficiency of a given selenium bridge, standard conditions are chosen, chief among them being an illumination of one lux. The law of light action is studied, and the total effect is shown to be proportional to the square root of the incident energy, while the instantaneous effect is proportional to the energy. This is verified down to an illumination of 0·00001 metre-candle. It is shown that selenium is the most efficient light detector known, that it is capable of discriminating minute differences of luminous intensity far beyond the capacity of the eye, and that, with suitable means of detecting minute currents, it should offer a means of testing the quanta theory of light by direct experiment.—A. E. **Oxley**: The Hall effect in liquid electrolytes. Experiments have been made on aqueous solutions of copper sulphate, silver nitrate, cadmium sulphate, and on copper sulphate gel. Each substance was placed in a small cell of glass or mica, and was subjected to a uniform magnetic field. A Paschen galvanometer was used to measure the transverse potential difference. In a uniform magnetic field this transverse potential difference is due partly to a true Hall effect (depending on the difference of the ionic mobilities), and partly to a concentration Hall effect (depending on the sum of the ionic mobilities). The latter effect is primarily the one which has been measured in this research, and the former, which is smaller, is included. Eight experiments have been made, and the transverse potential differences, which changed sign on reversal of the magnetic field, have been found to agree with the calculated values. The relation between the transverse potential difference and the intensity of the magnetic field, for an aqueous solution of copper sulphate, is linear.—Prof. W. B. **Morton**: The displacements of the particles and their paths in some cases of two-dimensional motion of a frictionless liquid.—S. **Chapman**: The diurnal variations of the earth's magnetism produced by the moon and sun.—Prof. H. A. **Wilson** and Marjorie **Wilson**: The electric effect of rotating a magnetic insulator in a magnetic field.—A. **Hopwood**: The magnetic materials in claywares. The author has found that white, cream, grey, yellow, buff, red, or brown claywares are feebly or moderately magnetic owing to the presence of unfused grains of unchanged ferruginous minerals and fused globules of complex ferruginous silicates; while flashed, brindled, or blue claywares are always strongly magnetic owing to the presence of complex ferruginous silicates and finely disseminated magnetic oxide of iron. The origin of the complex ferruginous silicates in claywares is quite different from that of the magnetic oxide of iron. While the latter is produced either by the orientation of the magnetite, originally present in the clays, or by the reducing action of the kiln gases on the precipitated or colloid oxides, hydroxides, or carbonates of iron disseminated throughout the clays, the former are produced by the fusion of the granular or concretionary ferruginous minerals, *i.e.* iron pyrites, siderite, hæmatite, magnetite, biotite, &c., occurring in the clays with the surrounding matrix.—A. **Hopwood** and C. **Weizmann**: Synthesis of the anhydrides of α-aminoacyl glucosamines.—H. S. **Jones**: The flexure of telescope mirror-discs arising from their weight, and its influence upon resolving power.—Prof. W. H. **Young**: Fourier series and functions of bounded variation. In the present communication it is shown that in a number of fundamental theorems the derived series of the Fourier series of a function of bounded variation may take the place of the Fourier series of a summable function, and this even when the function of bounded variation is not continuous, or still less an integral. In particular, the coefficients of such a series may be used as convergence factors, with results which approximate to, or are even identical with, those obtained when the convergence factors are the coefficients of a Fourier series. The use of these convergence factors transforms, in fact, when the function of bounded variation is odd, a Fourier series into a Fourier series, and an allied series into a Fourier series when the function of bounded variation is even.—Prof. W. H. **Young**: A condition that a trigonometrical series should have a certain form. In the present communication a necessary and sufficient condition that a trigonometrical series should have a form in which its coefficients are expressible in terms of Stieltjes integrals with respect to a function of bounded variation is obtained.—Prof. W. H. **Young**: Trigonometrical series the Cesaro partial summations of which oscillate finitely.

PARIS.

Academy of Sciences, June 25.—M. F. Guyon in the chair.—M. **d'Arsonval**: Some remarks on the papers read at the meeting at Toulouse of the Congrès national du Froid.—J. **Guillaume**: The present sunspot minimum. During the seventy-three days from April 12 to June 23 no spot has been noted on the sun's disc.—A. **Tian**: An experimental determination of the light energy absorbed in a photochemical reaction. A description of a null method based on the use of a thermopile. In the photochemical decomposition of hydrogen peroxide there is no proportionality between chemical action and the energy absorbed, even when the light used contains no infra-red rays.—Jacques **Carvallo**: A photo-electric phenomenon presented by liquid sulphur dioxide. In a preceding communication it has been shown that liquid sulphur dioxide submitted to a constant potential difference between two platinum electrodes is traversed by a current which tends to a constant limit. This phenomenon is sensitive to the action of light: each exposure causes a sudden decrease in the current. The effects have been proved to be due to ultra-violet rays.—Thaddée **Peczalski**: A relation between the law of compressibility of gases and the coefficients of expansion.—André **Léauté**: The high-frequency oscillations in very short electric arcs. From the experiments described a new position is proposed for safety fuses in connection with high-tension circuits.—P. Th. **Muller** and R. **Romann**: The electrolytic dissociation of a salt, governed by the mass law. A study of the conductivity of solutions of piperidine cyanacetate. For this salt the ionisation, measured by the conductivity of the solution, is governed by the law of mass action.—Marcel **Boll**: The photochemical decomposition of solutions of oxalic acid in presence of uranyl nitrate. The electrical conductivity measurements showed that the reaction was unimolecular, the solution being illuminated with monochromatic light. The energy absorbed during the reaction is much lower than the quantum of Einstein.—Marc **Landau**: The phenomenon of photocatalysis. All compounds of uranium possess marked photocatalytic properties; there is no relation between the values for the photocatalytic power and the radioactive power of these compounds. Catalysis takes place even when the uranium compounds used as catalysers are insoluble.—E. **Rengade**: The melting points, specific heats, and heats of fusion of the alkali metals. Measurements of these three constants are given for sodium, potassium, rubidium, and cæsium. The value of L/T was about 1·68 for all four metals.—Léon **Guillet** and Victor **Bernard**: Variations of the resilience of copper and of some of its alloys as a function of the temperature. Curves are given for copper, six brasses, cupro-nickel, German silver, and two aluminium bronzes.—René **Dubrisay**: The neutralisation of chromic acid.—Paul **Pascal**: Remarks on the additivity of the physical properties in the organometallic series.—A. **Colani**: Study of the chloro-oxalate of thorium.—J. B. **Senderens**: Oxidation of the alcohols under the influence of heat alone. Ethyl, *iso*butyl, and *iso*amyl alcohols are rapidly oxidised by air at temperatures between 380° C. and 450° C. Ignorance of this fact has led to catalytic properties being erroneously assigned to certain substances.—G. **Favrel**: A new series of *iso*pyrazolones.—G. **André**: The relation of the mineral acids and bases in plant tissues.—C. **Gerber**: The latex of *Ficus coronata*, an incomplete plant pancreatic juice, without amylase, and with proteolytic diastase predominating. NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2280, VOL. 91] THURSDAY, JULY 10, 1913 [PRICE SIXPENCE

Registered as a Newspaper at the General Post Office.]

THE DAVY-FARADAY RESEARCH LABORATORY

OF THE

ROYAL INSTITUTION,

No. 20 ALBEMARLE STREET, LONDON, W.

DIRECTOR

Professor Sir JAMES DEWAR, M.A., LL.D., D.Sc., F.R.S.

This Laboratory was founded by the late Dr. Ludwig Mond, D.Sc., F.R.S., as a Memorial of Davy and Faraday, for the purpose of enabling properly qualified persons to conduct Chemical and Physical Research.

Workers admitted are entitled to the use of the extensive chemical and physical apparatus belonging to the Laboratory.

The Director may, subject to the approval of the Laboratory Committee, supply special chemicals, or authorise the Mechanician to construct special apparatus for individual investigators.

MICHAELMAS TERM.—Monday, October 6, to Saturday, December 20.

LENT TERM.—Monday, January 12, to Saturday, April 4.

EASTER TERM.—Monday, April 27, to Saturday, July 25.

Applications for admission to the Davy Faraday Research Laboratory to be addressed to the Assistant Secretary, Royal Institution, No. 21 Albemarle Street, London, W.

EAST LONDON COLLEGE

(UNIVERSITY OF LONDON).

Faculties of Arts, Science, and Engineering.

FEES: TEN GUINEAS PER ANNUM.

NO ENTRY FEE & NO REGISTRATION CHARGES.

Special fees and facilities for Post Graduate and Research Students in all Faculties.

M.A. CLASSES FOR MATHEMATICS.

Calendar, with lists of Graduates, University and College Scholarships, Academic and other distinctions, post free on application to the Registrar, or the Principal,

J. L. S. HATTON, M.A.

Telephone No: East 3384.

THE MANCHESTER MUNICIPAL

SCHOOL OF TECHNOLOGY

(University of Manchester.)

The Governing Body of the Municipal School of Technology, Manchester, offers five RESEARCH SCHOLARSHIPS in TECHNOLOGY, each of the value of £40 per annum, with fees remitted, tenable for one year. Application for these Scholarships must be made not later than July 14, 1913, to the Registrar, from whom forms of application and full particulars may be obtained.

The Prospectus, forwarded free on application, gives particulars of the course leading to the Manchester University degrees in the Faculty of Technology, in the following Departments:—

MECHANICAL ENGINEERING,
ELECTRICAL ENGINEERING,
SANITARY ENGINEERING (including Municipal Engineering),
THE CHEMICAL INDUSTRIES (including General Chemistry, Bleaching, Dyeing, Printing, Papermaking, Brewing, and Metallurgy),
THE TEXTILE INDUSTRIES,
PHOTOGRAPHY AND THE PRINTING CRAFTS,
ARCHITECTURE.

UNIVERSITY OF MANCHESTER.

CHEMISTRY COURSES.

A Prospectus containing full particulars of the Lecture and Laboratory Courses preparing for both the ordinary and Honours Degrees in Chemistry will be forwarded on application to the Registrar.

Applications for admission to the Research Laboratories should be made to the Director of the Chemical Laboratories.

COUNTY OF NORTHUMBERLAND.

WALLSEND SECONDARY SCHOOL AND TECHNICAL INSTITUTE.

The Governors invite applications for the position of HEADMASTER of the WALLSEND SECONDARY SCHOOL and TECHNICAL INSTITUTE, now in course of erection. The gentleman appointed will be required to act as Headmaster of the Boys' Department of the Secondary Day School (accommodation 140), and to supervise evening class instruction in Applied Science. The appointment will commence at a time to be mutually arranged not later than March, 1914.

In considering applications, preference will be given to graduates in Pure or Applied Science who have had some industrial training, and who have had teaching experience in a Technical School and in the organisation of technical instruction.

Salary £300, rising by increments of £10 to £375, together with a sum not exceeding £25 to meet a like sum paid by the Headmaster in respect of premiums for a deferred annuity. Canvassing directly or indirectly will disqualify.

Form of application, which must be returned by August 30, 1913, may be obtained by sending stamped addressed envelope to the undersigned.

C. WILLIAMS,
Secretary to the Education Committee.

The Moothall,
Newcastle-on-Tyne.

PRELIMINARY NOTICE.

SOUTH WALES & MONMOUTHSHIRE SCHOOL OF MINES,

TREFOREST, GLAMORGAN.

The FIRST SESSION of the new School of Mines—founded by the Coal Owners of the South Wales and Monmouthshire Coalfield—for the training of all grades of Colliery Officials, will commence on MONDAY, OCTOBER 6, 1913.

A Three Years' Day Mining Course of 30 hours per week, and Part Time (one day per week) Courses are being arranged for the training of Colliery Managers, Mine Surveyors, Mine Chemists, Mine Mechanics and Mine Electricians.

Fully equipped Chemical, Electrical and Engineering Laboratories will be available.

For further particulars regarding admission, fees and curriculum, apply to the Principal, School of Mines, Treforest.

COUNTY TECHNICAL & SECONDARY SCHOOL, WORKINGTON.

Applications are invited for the following posts:—

(1) ASSISTANT in the ENGINEERING DEPARTMENT, to deal chiefly with Electrical and Elementary Mechanical Engineering Subjects. Preference will be given to candidate having either school experience, or qualifications in practical metal work. (Whitworth Exhibitioner.) Commencing Salary at the rate of £120 per annum.

(2) TEACHER of CHEMISTRY and METALLURGY. Preference given to candidate with a practical knowledge of the iron and steel industry, and with some teaching experience. Commencing Salary at the rate of £150 per annum.

It is desired to appoint essentially practical men to each of the above posts.

Salaries rise in accordance with the County Scale, and duties commence in September next in each case.

Applications giving full particulars of training and experience, together with copies of three testimonials and names of three referees, are to reach me not later than July 19.

G. H. WOOLLATT, Principal.

UNIVERSITY OF BIRMINGHAM.

(FACULTY OF SCIENCE.)

LECTURESHIP IN GEOLOGY AND GEOGRAPHY.

The Council invites applications for the post of LECTURER in GEOLOGY and GEOGRAPHY. Stipend £200 per annum.

Applications, accompanied by six copies of testimonials, or such other credentials as the candidates may prefer to offer, should be sent to the undersigned on or before July 21.

The successful candidate will be required to enter on his duties at the commencement of the session, October 7.

Further particulars may be obtained from

GEO. H. MORLEY, Secretary.

UNIVERSITY COLLEGE OF WALES, ABERYSTWYTH.

(*A Constituent College of the University of Wales.*)

DEMONSTRATORSHIP IN CHEMISTRY.

The Council invite applications for the post of DEMONSTRATOR and ASSISTANT LECTURER in the DEPARTMENT of CHEMISTRY at the above-named College. Salary £120 per annum.

Applications, together with testimonials, must reach the Registrar not later than Friday, September 12, 1913.

Full particulars may be obtained from the undersigned.

J. H. DAVIES, M.A., Registrar.

THURSDAY, JULY 10, 1913.

ATOMS AND MOLECULES.

Les Atomes. By Prof. Jean Perrin. Pp. xvi + 296. (Paris: Félix Alcan, 1913.) Price 3.50 francs.

IN these days, when such notable and extensive advances are being made in nearly all fields of physical research, it is extremely desirable that the results which mutually bear upon one another should from time to time be collected together and recorded in more or less popular language. If, in addition, a leading expert can be persuaded to undertake the record, the event of its publication is still more to be welcomed. Prof. Perrin is the ideal author for a book on atoms and molecules. He has virtually made them visible and established their reality, and it is scarcely too much to say that his work on Brownian movement is the most notable of recent physical researches.

It is not always that the brilliant experimentalist is an equally brilliant exponent, but in the present case it is true, and the book makes fascinating reading. It must not be supposed that Prof. Perrin has confined his attention to the particular sphere of work with which his name is so intimately associated. Naturally enough, the details of theory and experiment are treated more completely in those chapters which are mainly records of the author's work. But the book as a whole has a broad outlook, and the atomic theory is considered from many different points of view and in the light of all the recent developments of the subject.

The first two chapters are devoted to a historical survey of the chemical and physical sides of the atomic theory and the early methods of estimating the size and number of the atoms. Then follow the chapters on Brownian movement previously referred to, in which the author shows how it is possible by four distinct methods to measure the atoms, with remarkably consistent results. The later chapters on opalescence, the quantum theory, and radio-activity have the same end in view, and in conclusion the author compiles the values obtained by thirteen different methods for Avogadro's number. A quotation from the author is the best comment on these noteworthy results.

"On est saisi d'admiration devant le miracle de concordances aussi précises à partir de phénomènes si différentes. D'abord qu'on retrouve la même grandeur, pour chacune des méthodes, en variant autant que possible les conditions de son application, puisque les nombres ainsi définis sans ambiguïté par tant de méthodes coïncident, cela donne à la realité moléculaire une vraisemblance bien voisine de la certitude."

Chapter vii. is one of special interest. In it the author deals with the determination of e, the atom of electricity, by the method of falling drops. He takes the view that the accuracy claimed by Millikan for his measurements is not justified on account of the magnitude of the correction to Stokes's law which has to be applied, and produces evidence which he regards as removing the well-known discrepancy between his own and Millikan's estimates. It remains to be seen whether Prof. Millikan assents to this view.

THE CULT OF THE THUNDERSTONE.

The Thunderweapon in Religion and Folklore. A Study in Comparative Archæology. By Dr. Chr. Blinkenberg. Pp. xii + 122. (Cambridge University Press, 1911.) Price 5*s.* net.

THIS little book forms an interesting addition to the archæological and ethnological series for which anthropologists are indebted to the Cambridge University Press. The author shows much erudition and industry in his search for specimens illustrating the cult of thunderstones which are preserved in the museums of England and the Continent. He has explored the voluminous literature of the subject, and he has added a series of illustrations which add much to the scientific value of the monograph.

His theory assumes that the cult of the thunderstone was an element of human culture which, at an early date, that is to say, in the Stone age, was gradually spread from people to people over a great part of the world; that it appears in the early Ægean culture; that the ideas of tabu or sanctity attaching to these stones indicate the rise of the belief from primitive conceptions of nature and religion. In other words, he supposes that as early as the Stone age men compared the effects of the lightning-stroke to that of the axe wielded by primitive man, and that this explanation accounts for the superstition in most parts of the world.

Various difficulties, of which the author is aware, prevent the acceptance of this theory of origins. The most important is that the superstition has not been traced among those races which possessed a Stone age culture down to modern times—the peoples of Australia, Oceania, and North America while in South America, to say the least, the evidence is weak. On the other hand, it is common in Africa, among races which have no such theory of the origin of objects which they supposed to be divinely produced. These facts being admitted, a different explanation suggests itself as being more probable. Such things usually come to light after torrential rains, and are thus naturally attributed to the thunder which accompanies the storm; and thus, besides flint axes, things like belemnites, fossil echini, and other quaintly shaped stones come to be revered like lithic artefacts.

It is also very doubtful if Mjölnir, the hammer of Thor, or the double-axe of Crete come within this category. The former was not a stone, but a forged metal axe, and the sanctity of the latter was possibly due to its use as a sacrificial implement. Poseidon's trident, again, was more probably the fish-spear which is the natural weapon of a sea-god.

In short, thunderstones, sacred fossils, sacred axes, and tridents may have their origin in general animistic conceptions, and their cult need not necessarily have arisen in any single centre or from any one train of thought. However this may be, the facts which the author has collected form a useful contribution to the study of primitive beliefs.

PURE AND APPLIED CHEMISTRY.

(1) *Problems in Physical Chemistry with Practical Applications.* By Dr. E. B. R. Prideaux. Pp. xii + 311. (London: Constable and Co., Ltd., 1912.) Price 7*s.* 6*d.* net.

(2) *An Introduction to the Physics and Chemistry of Colloids.* By Emil Hatschek. Pp. ix + 94. (London: J. and A. Churchill, 1913.) Price 2*s.* 6*d.* net.

(3) *Exercises in Gas Analysis.* By Dr. Hartwig Franzen. Translated from the first German edition (with corrections and additions by the Author) by Dr. Thomas Callan. Pp. vii + 120. (London: Blackie and Son, Ltd., 1913.) Price 2*s.* 6*d.* net.

(4) *Theorie und Praxis der Grossgasindustrie.* By Rudolf Mewes. Band 1. Hälfte 1. Pp. xx + 403. (Leipzig: H. A. Ludwig Degener; London: Williams and Norgate, n.d.) Price 18*s.* net.

(5) *Lehrbuch der Thermochemie und Thermodynamik.* By Prof. Otto Sackur. Pp. viii + 340. (Berlin: Julius Springer, 1912.) Price 12 marks.

(6) *A Foundation Course in Chemistry.* For Students of Agriculture and Technology. By J. W. Dodgson and J. Alan Murray. Pp. x + 244. (London: Longmans, Green and Co., 1913.) Price 3*s.* 6*d.* net.

(7) *Qualitative Determination of Organic Compounds.* By J. W. Shepherd. Pp. xvi + 348. (London: W. B. Clive, 1913.) Price 6*s.* 6*d.*

(1) DR. PRIDEAUX has compiled a book of problems to serve as exercises for students in physical chemistry. The students who have worked through these will not be able to complain that they have not been exercised sufficiently, as the examples selected are very numerous and by no means all easy. They are, however, selected directly from the original literature, and so require the student to give real solutions to real problems, instead of the sham answers to fictitious questions which so frequently disfigure books of chemical calculations. The form in which this excellent material has been published is much less satisfactory. The table of contents suggests that the volume is composed of eight chapters, but these do not appear in the text. The reader is informed on each of the 300 pages that the book he is studying is called "Problems in Physical Chemistry," but no hint is given as to the topic that is dealt with on the pages at which the book is opened. The eight chapters run on continuously, and almost the only way to discover where one chapter ends and another begins is to turn back to the table of contents, for the chapters are not even allowed the luxury of beginning at the head of a fresh page. As no index has been supplied, the contents of the book are far less accessible than they need be to a reader who does not wish to work right through the book from beginning to end.

(2) A somewhat similar complaint may be made in reference to the reprint of Mr. Hatschek's articles on colloids. These are divided into ten chapters, but the chapter-divisions do not correspond in every case with the natural divisions of the subject, and subject-headings are not given, so that the classification of the material is not immediately obvious. This defect is, however, very largely remedied by the provision of a very detailed table of contents and two indexes. The book has the great merit of presenting in a simple and readable form all the leading points of a difficult and little-known subject. It may be commended without hesitation to the many readers who at the present day are being compelled by the pressure of technical or scientific problems to acquire some knowledge of "colloid chemistry."

(3) The English translation of Dr. Franzen's "Gas Analysis" forms a very useful introduction to the subject. Directions are given for carrying out forty-two exercises. Thirty-three of these have to do with the analysis of gases. The remainder, which are collected under the heading

of "Volumetric Gas Analysis," are not exercises in the volumetric as contrasted with the gravimetric analysis of gases, but have to do with the analysis of solids and liquids by measuring the volumes of gas set free from them. In this section, for instance, are described the methods of estimating nitrates by the Lunge nitrometer and analogous processes. The book is presented in an attractive form, and carries out admirably the purpose of the author and translator to provide an introduction to the larger standard works on gas analysis.

(4) The German treatise on the theory and practice of the gas industry is a large work of which the present volume constitutes "I. Band, I. Hälfte." It includes the historical development of the principles of mechanics and physics, and the fundamental laws of thermodynamics. The subjects treated include isothermal and adiabatic compression, change of state, evaporation and boiling, viscosity of gases and vapours, specific heats, entropy of water-vapour and vapours used in refrigeration, radiation and conduction, flow of liquids, vapours, and gases. The chemist or engineer who is called upon to handle gases on a large scale will find in this treatise all that he is likely to require in the way of scientific preparation for his work.

(5) Prof. Sackur's "Text-book of Thermochemistry and Thermodynamics" deals with the fundamental laws of heat and of thermodynamics, which are then applied to many of the chief problems of physical chemistry. Thus we find chapters devoted to the theory of solutions, including van't Hoff's equations for osmotic pressure, and to chemical equilibrium based upon the equations of Helmholtz and of van't Hoff, and applied, for instance, to calculate the heat of ionisation from the change of the ionisation-coefficient with temperature. There are also chapters on the applications of thermodynamics to electrochemistry, thermoelectricity, and capillarity. The last chapters deal with radiation and with Nernst's "heat-theorem."

(6) The "Foundation Course in Chemistry" of Messrs. Dodgson and Murray is a well-written book of rather exceptional character. Special attention is paid to topics which have an interest for agricultural students, but this is by no means a drawback from the point of view of the general reader, as it gives an air of reality to the whole treatment of the subject. Structural formulæ are freely used for inorganic as well as for organic compounds, and a long chapter is given up to the chemistry of aliphatic compounds under the title "Paraffins and their Derivatives." The chapter on general principles gives a clear exposition of the doctrine of equivalents, but is scarcely an adequate exposition of the atomic theory, as Avogadro's hypothesis, which is the real basis of the modern system of atomic weights, is postponed to a later chapter, and is there treated only in the most incidental manner.

(7) The modern system of examinations is responsible for the development of a form of qualitative organic chemistry in which attempts are made to determine the nature of organic compounds without carrying out a combustion or quantitative analysis of any sort. This type of organic chemistry is only distantly related to the requirements of scientific or technical research, and has only a very limited range of usefulness. But if the student is aware of the supreme necessity of quantitative work there is little harm in allowing him to get some practice in recognising the qualitative properties of the chief radicles. Mr. Shepherd's book gives a scheme whereby the most important groups of organic compounds may be identified by qualitative tests; the scheme has been in use for some years, and has thus been adequately tested by actual work in the laboratory.

OUR BOOKSHELF.

A Text-book of Experimental Metallurgy and Assaying. By A. R. Gower. Pp. xiv+163. (London: Chapman and Hall, Ltd., 1913.) Price 3*s*. 6*d*. net.

The new edition of this book conforms to the syllabus of the Lower Examination in practical metallurgy of the Board of Education. The first portion of the book consists of a series of experiments and explanations to illustrate the reactions occurring in various metallurgical operations, while the second part deals, in quite a satisfactory manner, with elementary assaying. It would have been an advantage if the book gave a little more guidance to the beginner, for very often he does not realise the economic character of metallurgy. For instance, a student sometimes thinks that as sodium carbonate is used in the laboratory as a flux for silica, therefore it would be charged into a blast-furnace smelting copper ores when silica has to be removed. The first chapter of this book may give some students an impression of this kind, for the substances classed as used in metallurgical operations are not all commonly so employed, although frequently used in experimental metallurgy and assaying. Then, again, in the chapter "Formation of Alloys," the theoretical quantities of the metals have been given, and no allowance made for loss in the case of volatile metals.

During the past twenty-five years the book has proved of use, and the present edition should be of assistance to those preparing for the Board of Education examination, and if the exercises are performed under the supervision of a teacher, none of its minor defects will cause the beginner to gain wrong impressions.

Ministère de l'Agriculture. Direction Générale des Eaux et Forêts. 2e partie. Eaux et Améliorations Agricoles. Service des Grandes Forces hydrauliques dans la Région des Alpes. Résultats des Etudes et Travaux à la Fin de 1911. Tome v., 1912. Pp. 530.

THE present volume is the fifth of the series published by the French Ministry of Agriculture since the inauguration of the Service of the Great Hydraulic Forces in Alpine regions, and it brings the account of operations down to the end of the year 1911. Of the 530 pages of which the volume consists, 487 are devoted to a tabulation of the results obtained from observations in the basins of the Arve, the Fier, the Isère, and the Drôme. A series of nine charts also accompanies the report, covering the regions of the Arc, the Breda, the Durance, and the Guil.

It is interesting to note the expedients and devices by which an investigation, demanding for its most effective development the employment of expert scientific observers, has been enabled to be carried on to a large extent by voluntary workers and local auxiliaries, for the most part untrained and indifferently coordinated. Such agencies in many cases have had to be relied upon for the collection of data, and as there is a constant change of personality in the assistants, the difficulties in the way of securing trustworthy records are sufficiently obvious.

"However," concludes the prefatory note, "in spite of defects, of which we more than anyone are conscious, we are convinced that the study of hydraulic forces, so far as circumstances permit, constitutes none the less a real utility"—and a cursory glance through the pages of statistical matter, carefully annotated and compiled, bears incontestable witness to the patient labour and exactitude of those engaged in the French hydrographical service and of M. de la Brosse, its chief engineer.

Weather Bound. By R. T. Smith. Pp. 319. (Birmingham: Cornish Bros., Ltd., n.d.) Price 15*s*. net.

THE author gives, in great detail, summaries of results of twenty-seven years' observations at five stations situated to the west of Birmingham, in a series of tables and diagrams occupying 170 pages. He adds a diary, "Weatherwise and Otherwise," for the same period, which occupies sixty pages, and explanatory text (seventy-two pages). He also gives a diagram of the normal course of the meteorological elements throughout the year, which is unintelligible owing to want of explanation. The amount of industry displayed is worthy of praise, and most of the tables appear to contain climatic data of real value, but the author's exposition cannot be recommended to the attention of serious students of meteorology.

R. C.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Radio-activity and the Age of the Earth.

IN his letter in NATURE of June 26, Dr. Schiller quotes with disapproval Mr. Holmes's deduction that the "heavy metallic core" of the earth "must be completely destitute of radium"; for this deduction, in Dr. Schiller's opinion, "involves the improbability that the heaviest metal of all, uranium, has not gravitated to the 'metallic core,' and does not explain why this core should be destitute of radio-active substances."

In the next paragraph, however, Dr. Schiller suggests a possible escape from the difficulty with the words, "it is possible that under the physical conditions obtaining in the interior uranium does not dissociate, or does so much more slowly."

Last autumn, as a sequel to certain speculations into the effects of pressure on the mineralogical constitution of the earth's crust at great depths, I was led to a consideration of this very question of the dissociation of elements when subjected to the high temperatures and pressures that prevail at such depths.

So far as I was able to discover, no determination of the specific gravity of radium had then been made, presumably for lack of sufficient material; but, judging from its chemical relationship with barium, the atomic volume of radium must be much greater than that of uranium. Heat is known to be evolved during the disintegration of radium, so that the breakup of this element is an exothermic change. I am writing this letter whilst travelling, and am, consequently, unable to verify my impression that heat is also evolved during the conversion of uranium into radium. But in any case, the passage of uranium into radium may be expressed in a general way by some such equation as the following:—

$$U = Ra + m + e,$$

where m indicates the loss of mass due to liberation of helium in the successive stages of disintegration, and e the loss of energy represented by the various manifestations of energy. Since radium has a higher atomic volume than uranium we see that the progress of this reaction from left to right means an increase in volume and an evolution of energy, part of which is doubtless speedily transformed into heat. In fact, it is exactly the kind of reaction that would be inhibited by high pressure and temperature conditions.

That high pressure should be able to prevent the disintegration of uranium seems reasonable, if one accepts the electronic constitution of the atom. Judging from the extreme length of the half period of disintegration of uranium under surface conditions, the constituent electrons of an atom of uranium perform on the average a vast number of revolutions before the system arrives at the position of instability that permits the escape of a helium atom. In fact, the uranium atom is evidently stable during an enormous number of revolutions or vibrations. And if, when the electronic system arrives at last at an unstable configuration, a sufficiently powerful counterbalancing force can be applied from without, then the system will be helped past the danger point and be able to commence another long cycle of movements before the dangerous configuration is again assumed.

In view of the experiments of Humphreys and Mohler upon the displacement of the spectral lines, and the work of Richards on the compressibility of elements, amongst other facts, it is evidently possible to influence intra-atomic activity by means of forces applied from without. It seems probable, therefore, that pressure, if sufficiently great, could be transmitted to the interior of a uranium atom and supply the countervailing force required to help the atom past a position of instability. Once we realise this probability, we see a cogent reason why the interior of the earth should be free from radium and all other radio-active substances the formation of which from heavier elements demands an increase in volume, these heavy elements being at great depths only potentially radio-active.

From this point of view radio-activity is, as Dr. Schiller suggests, "an acquired habit of the substances that exhibit it," the habit being acquired when such an element passes by any means whatever from great depths below the earth's surface to regions of less pressure.

In a paper just issued in the Records of the Geological Survey of India (vol. xliii., part 1) I have given a preliminary account of these speculations concerning the mineralogical constitution of the earth's crust, and in a final paragraph have appended a brief reference to this question of the inhibition of the disintegration of uranium at great depths below the earth's surface.

L. L. Fermor.

Pianoforte Touch.

In connection with the discussion on this subject originated by Prof. Bryan's paper, I may mention that I have been making some measurements during the past winter with the view of obtaining some idea of the velocities and forces involved in the motion of the transmitting mechanism. By fitting an electric chronographic arrangement to an upright piano I have been able to measure the actual times taken in different stages of the movement with different degrees of loudness.

Among other results, I have found that the time during which the hammer is flying freely towards the string after losing contact with the propelling mechanism varies from about 0·04 sec. for *pp* to 0·001 sec. for *ff*. The distance of flight was about 1 cm., so the velocity ranged from 25 to 1000 cm. per sec. At the latter extreme, however, the force used in striking the key was greater than would be used in ordinary playing. On the other hand, when a weight was allowed to fall on the key from the smallest height to produce a note the time could be brought up to 0·07 sec., corresponding to a velocity of only 14 cm. per sec.

With regard to the much disputed point as to whether it is possible to vary the quality of the note independently of the loudness, this must, I think, still be regarded as an open question. Very positive affirmations are made by musicians on both sides. From a physical point of view the suggestion made by Mr. Tobias Matthay in his work on touch seems to be the only possible way to explain the effect, if it exists, viz. that the quality can be spoiled by vibrations of the hammer-shaft at the instant of striking the string. In accordance with this, Mr. Matthay holds that the tone is good when the final velocity is given to the key gradually, and is bad when the same velocity is imparted by a sudden blow. That vibrations of the shaft occur is, of course, undoubted, but whether they are sufficient to cause an appreciable effect is another matter. On the other side, recent German theorists, such as Breithaupt, Steinhausen, and Ritschl, deny the effect altogether. The last-named author holds that good touch consists in the power to produce fine gradations of intensity and in complete mastery of *legato* and the use of the pedal.

The essential question seems to be whether good and bad touch can be distinguished in a *single note* struck and allowed to die away, or in a succession of notes following each other at so long intervals as to be musically detached. As I understand Prof. Bryan, the improvement effected by his invention is chiefly apparent in a sequence of notes forming a melodic phrase. Further, I think that the exact dynamical effect of the contrivance on the motion of the key has not been made quite clear in the published account.

The Reflection of X-Rays by Crystals.

It is interesting to find that an X-ray bulb having a rhodium antikathode gives off a strong, sharply defined (and therefore very homogeneous) beam which is reflected from the (100) face of rock-salt at a glancing angle of 6·2°. Its mass absorption coefficient in aluminium is 3·2. A second weaker beam is reflected at an angle of 5·8°, and this appears to complete the rhodium X-spectrum. Assuming the correctness of my son's determination of the spacing of the atoms of rock-salt (in a paper read before the Royal Society on June 26), the wavelength of the stronger beam is $0·61 \times 10^{-8}$, and of the weaker $0·57 \times 10^{-8}$. It can be calculated that radiation of about this wave-length should be emitted by a rhodium antikathode; the argument is given in a paper recently read before the Royal Society (see abstract on p. 496 of this issue).

Platinum and rhodium give much stronger homogeneous reflected rays than iridium, tungsten, or nickel. The current produced in an ionisation chamber 15 cm. long, filled with SO_2, the slits being 3 mm. long and 0·8 mm. wide (Proc. Roy. Soc., lxxxviii., p. 428), is so great that the leaf of a Wilson electroscope races across the field of view at the rate of thirty or forty measurable divisions (three or four scale divisions) in a second. The setting must be exact, and the bulb should be very soft.

Rosehurst, Grosvenor Road, Leeds.

Wireless Antennæ.

Prof. Fleming, in a recent letter to a contemporary journal, has made a suggestion similar to that of Mr. A. Lander, in Nature of July 3 (p. 451), to the effect that the space wave in wireless telegraphy is supplemented by some effect which travels through the earth. Indeed, it would appear natural to expect that, in addition to the electric disturbance which must travel outwards in all directions over the conducting surface of the earth when the electrical potential at any point on this surface is disturbed, the passage of the electromagnetic waves through the air above the earth's surface should be accompanied by some form of electrical disturbance along the conducting earth's surface beneath them. This is, however, a subject that, so far as I am aware, has not yet been tackled by mathematical physicists, and I would point out that it is well worth their attention.

In connection with the matter, it may be of interest to mention that I find that my own body, without any wires or anything else, will serve as antenna for the reception of signals from the Admiralty. My receiving apparatus is on the ground floor of my house in Chester Square, and with my ordinary aërial disconnected I find I can get the Admiralty signals, faintly but quite audibly, simply by touching with my finger the terminal to which the aërial is usually connected. No doubt in this case my body does not act as an aërial in the ordinary way, but merely as a capacity into which the electrical disturbance arriving through the earth passes in and out through the receiving apparatus. The Admiralty station is, of course, comparatively near, and the signals are very powerful. This explains why it is only Admiralty signals that I am able to receive by this method.

I am unable to agree with Mr. Lander in his remarks as regards tuning, as I find that with my bedstead aërial it is just as easy to tune in and out such signals as I am able to receive as it is with my proper aërial, which is suspended on poles above the roof of the house. The Eiffel Tower signals are always difficult to tune out, for the reason, as I suppose, that they are of irregular wave-length, while I find it impossible to tune out the Admiralty by reason of its power and proximity. Norddeich and other unidentified signals that I obtain are, however, tuned in and out both with the bedstead aërial and with the other with equal facility.

For time signals very accurately tuned waves, such as are sent out by Norddeich, are perhaps not altogether an advantage, as badly tuned waves, such as are sent out by the Eiffel Tower, are much more easily picked up by all and sundry.

A. A. Campbell Swinton.

66 Victoria Street, Westminster, S.W., July 7.

A Mechanical Vacuum-Tube Regulator.

May I supplement Mr. Campbell Swinton's letter in Nature of June 26? The device of sliding a glass sleeve over the kathode for the purpose of varying the hardness of a discharge tube was also used and fully described by Wehnelt in 1903 (*Deutsch. Phys. Gesell. Verh.*, 5, 14, p. 259), some five years after Mr. Swinton.

The important part that the electrification on the walls plays in a discharge tube is not, I think, generally realised; and Mr. Swinton is not quite right in assuming that Mr. Whiddington's explanation is novel.

The electrification on the glass walls adjoining the kathode, and its concentrative effect on the beam of kathode rays, were remarked by Goldstein in 1901 (*ibid.* 3, 15, p. 192).

I remember some half-dozen years ago, Sir J. J. Thomson, in one of his lectures at Cambridge, gave a similar explanation of the formation of the fine pencil of kathode rays which can be seen crossing the bulb from the centre of the kathode in a soft X-ray tube. He attributed the effect entirely to the negative electrification of the glass round the kathode. The pencil of rays is as definite with a plane kathode as with a concave one.

But X-ray tube-makers have long been aware that, by withdrawing the kathode from the bulb into a side tube, the discharge can be hardened. In the earliest X-ray bulbs, the kathode was always mounted in the body of the bulb; but the advantages of a side tube had been realised by 1896, and the design has since been universally adopted.

Mr. Swinton was also responsible about 1897 for another adjustable form of X-ray bulb, in which, instead of a sliding sleeve, a movable kathode could be advanced in or out of a side tube. The bulb is at present in the Röntgen's Society's historical collection in the South Kensington Museum.

G. W. C. Kaye.

June 28.

In order to remove the possibility of any misunderstanding that may arise from Mr. A. Campbell Swinton's letter in Nature of June 26 (p. 425), may I state that the mechanical vacuum-tube regulator is *not* claimed by me as new in the paper referred to. If Mr. Campbell Swinton will read the actual paper he will find it clearly stated that the regulator was discovered by him.

Richard Whiddington.

St. John's College, Cambridge, July 7.

The Humphrey Owen Jones Memorial Fund.

The committee formed to carry out the generally expressed desire that some suitable memorial of the late Humphrey Owen Jones, F.R.S., should be established, has received subscriptions amounting to about 360*l*. It is proposed to devote the sum collected to the endowment of a teaching post in physical chemistry in the University of Cambridge.

The committee desires to close the subscription list at the end of this month, and requests further intending subscribers to send their contributions to the account of the H. O. Jones Memorial Fund, Messrs. Barclay and Co.'s Bank, Cambridge, before that date.

W. J. Pope
(Chairman of the Committee).

The Chemical Laboratory, Cambridge, July 7.

Smithsonian Physical Tables.

Attention was directed by Mr. C. T. Whitmell on p. 320 of Nature of May 29, to a "very awkward error" in the Smithsonian Physical Tables (1896). The institution is always glad to have attention directed to errors for correction in subsequent editions, but as this particular error does not appear in the first revised, second, third, fourth, and fifth editions, it seems rather unfortunate to have discredit thrown on the tables through an error long since corrected.

C. D. Walcott,
Secretary.

Smithsonian Institution, Washington, U.S.A.,
June 21.

MODERN VIEWS OF ELECTRO-THERAPEUTICS.

During the last few years our views upon the true meaning of the action of electricity upon living subjects have been growing much clearer. We begin to see the principles upon which our practice should be based, and already, as a consequence of this, our methods are changing and our results are growing more valuable.

There are two factors which have brought this about. One is the recognition of the importance of the theory of ions in all matters which concern the movement of electric currents in living tissues, and is due to the genius of Leduc, and the other is the recognition of the thermal action of high-frequency currents, an action which remained unappreciated, even if not unknown, until it was insisted on and emphasised by Nagelschmidt. It is upon these two basic facts, the chemical or ionic effects and the thermal effects of electric currents, that the electro-therapeutics of the future will be established.

First, as to the chemical aspect of the medical applications of electric currents. To begin with, all movements of current in the body, whether the currents are direct, interrupted or alternating, are ionic movements pure and simple, and their effects are due to the chemical displacements produced. We may not speak of effects which are additional to or independent of the ionic movement, for such effects do not exist. The current in the body is the double ionic movement only. The treatment by electric currents is a chemical treatment, and its chemical actions must explain the results obtained.

The stimulation of nerve and muscle is a chemical stimulation by displacement of ions. Nernst, in fact, has expressed the formula for nerve excitation in terms of ions. The sensation felt in the skin during the passage of a current is a chemical effect, and by altering the composition of the saline solution with which the electrodes are moistened, its character can be altered so that the sensory effects become more noticeable either at the negative or at the positive electrode. With sodium carbonate it is the negative electrode (ions of CO_3) which gives the greatest sensation. With sodium chloride it is the positive electrode (sodium ions), and so on in great variety.

Thus a practical lesson may at once be drawn from a knowledge of ionic effects, namely, that a solution of sodium carbonate should not be used for moistening the electrodes in electro-diagnosis, because in that procedure a small negative electrode is used with high concentration of current, and in these circumstances the presence of a carbonate in the liquid causes unnecessary pain to the patient. Again, in using chlorine ions for the softening of scar-tissue it saves the patient some discomfort and facilitates the toleration of massive currents to use the chloride of ammonium at the anode in preference to that of sodium, because the ammonium ion affects the sensory nerves of the skin in a less degree than the ion of sodium.

There is another direction in which the application of the principles of ionic movement has increased the therapeutic powers of electrical applications, and that is in the direction of treatment by larger currents. If we look in the text-books of electro-therapeutics we see continually that currents of 5 or 10 milliamperes are prescribed. Formerly that was as much as could be given without causing discomfort or producing superficial burns. The metal-plate electrodes and the small buttons or discs covered with a thin layer of chamois leather and set in handles and applied to the affected region did not permit the use of large currents; Leduc has told us why this is the case. With such electrodes the ions of hydrogen and hydroxyl which are formed at the metallic surfaces can quickly reach the skin surface. They are strongly caustic and tend to produce pain and burns, and this can be obviated by the use of electrodes composed of thick, folded cloths over which is laid a metal electrode faced with two or three layers of thick felt. The whole is moistened with appropriate saline solutions and bandaged to the patient, who thus can tolerate applications of 50 milliamperes or more, and that for times of fifteen or twenty minutes or longer without any burning or blistering of the skin.

It is not surprising that this change of method brings results which are superior to those of the past. Indeed, if the theory of ions in medical electricity had done nothing else of value, it would deserve all praise for having taught us how to use larger currents. Take, for instance, the treatment of paralysed muscles. A distinguished French writer has recently told us that he has gradually increased the duration of his electrical applications in such conditions to periods of one hour twice daily, and uses rhythmic currents which are not less than 25 milliamperes, and that in the infantile paralysis of children the little patient is so slightly inconvenienced by these applications as to play and even to sleep while they are proceeding; also that the results of such intensive treatment are entirely good, and produce not the least sign of fatigue or exhaustion.

The ionic theory of electrical treatment which has shown us how to use large currents has also shown the necessity for them. If the results to be gained are produced by the chemical interchange set up in a tissue, it is manifest that to obtain them one must use a strength of current which is capable of producing a distinct effect; and for the same reason the time of an application must be lengthened. The chemical changes caused by a current of 50 milliamperes for twenty minutes are ten times greater than those given by 10 milliamperes for ten minutes, and are therefore ten times more likely to produce an appreciable effect. The results of adopting this view and of increasing the quantity of current employed may make all the difference between success and failure. It is thus that the treatment of neuralgias can be made effective, and the same occurs in the treatment of many affections of the joint structures.

In the ionic theory of electrical treatment we have to consider two factors—the chemical interchanges set up within the tissues and the introduction of ions from without. The second of these considerations has added notably to the scope of electrical treatment. In the treatment of superficial morbid states there can be no doubt of the actual penetration of the external ions into the part treated; and the use of the zinc ion introduced at the positive pole from material moistened with a solution of a zinc salt has led to the successful treatment by electrical means of a whole series of superficial ulcerative conditions of the skin and the various orifices of the body.

In the treatment of affections of the deeper tissues the method of the introduction of ions from pads moistened with appropriate solutions has also achieved many successes, notably in conditions of so-called neuralgia, states which are almost always due to neuritis or perineuritis—for example, in many severe neuralgias of the trigeminal nerve. Quinine and salicylic acid, the latter especially, are useful in these conditions when introduced by the electric current.

In chronic gouty conditions the introduction of the salicylic ion is also of great value. Iodine ions and lithium ions to a lesser extent also seem to be useful in gouty conditions. The chlorine ion, recommended by Leduc for its softening action upon scar-tissue, has proved itself valuable.

Leaving the chemical effects of electrical currents, let us turn to the consideration of the thermal effects. The use of electricity for thermal effects requires currents of large magnitude, and therefore requires that the ionic effects shall be reduced to a minimum. The currents of high frequency answer these requirements. With them the duration of each wave of current is so brief that the ionic movement set up is imperceptible; the displacement which the ions undergo in the very small fraction of a second for which each wave continues is minute and does not strain the elasticity of the protoplasm, if one may make use of such a phrase. On this account the currents employed may reach an ampere or more, and the usual ionic effects of currents, such as pain and muscular contraction, are absent. The thermal effects become manifest in proportion to the magnitude of the currents employed. The practical recognition of the thermal action of high-frequency currents remained long unnoticed, in spite of the great popularity enjoyed by high-frequency treatment some time ago. Somerville may be said to have awakened medical practitioners to its possible importance by his paper in 1906 on the effect of high-frequency currents in raising the surface-temperature of the body.

When we look back upon the cases which have been reported as cured by currents of high frequency we may now recognise that a large part of them can be justly attributed to thermal actions and the vasomotor effects secondary to these. The circulatory effects, the relief of various states of spasm and congestion, and of painful affections of the joints, of neuritis and neuralgia come into this category. An improvement in the lymph circulation due to the warmth would account for the results obtained with high-frequency currents in certain local infections and inflammations.

In another section of high-frequency treatment, namely that of the use of the effluve or of showers of sparks in cutaneous affections, we also have to deal with thermal effects, intense but minutely localised, though it is possible that in these cases there may be another factor concerned, namely the influence of the ozone, and of the nitric acid vapours which are associated with luminous electrical discharges.

We now perceive that in high-frequency applications we have an agent for the direct warming of the tissues traversed by the current, and that the future development of high-frequency treatment will be based upon these thermal effects. The progress which has been made by Nagelschmidt and others with the large currents obtained from the modern type of high-frequency apparatus, which uses sustained oscillations, and is known under the name of diathermy, serves to emphasise this aspect of high-frequency currents. Duddell's singing arc in a modified form is used for the production of the oscillations in the diathermy apparatus.

Again, in electro-diagnosis we are on the threshold of another change. The long and patient work of many investigators upon the use of condenser discharges has begun to bear fruit, and it is clear that from the condenser we gain greater information than the induction coil and the galvanic current can give us as to the degree of abnormality in muscle in cases of paralysis, while the process of testing with condenser discharges is simpler in application and far less painful to the patient. Whereas hitherto neurologists have been content to divide muscles into two categories, those with "normal" reactions and those with a reaction of degeneration, the condenser method now permits the recognition of a considerable number of intermediate degrees. The method is based upon the observation of the minimum capacity needed to provoke the muscular contraction. As a muscle deviates from the normal standard it comes to need waves of longer and longer duration in proportion to its degree of damage, and these waves are best obtained by using a series of condensers of progressively increased capacity, charged from a constant source and discharged through the patient. Many of the muscles formerly described as normal because they had not lost the power of responding to induction-coil currents can now be seen to present different degrees of deviation from the normal, and those classed together as showing a reaction of degeneration can also be divided into distinct groups. Working with 100 volts to charge the condensers, one can use a series of ten or twelve capacities, ranging from 0·01 to 2·0 microfarads, and can find muscles showing their initial contraction at almost every step in the scale.

The work of Boudet de Pâris, Hoorweg, Zanietowski, Weiss, Doumer, Cluzet, and of many other patient students of condenser discharges must be gratefully acknowledged in this connection. They have gradually brought their methods through the laboratory stages and rendered them suitable for everyday clinical work so that electro-diagnosis in the immediate future is sure to develop in the direction of condenser discharges, and the old method with induction coil and battery current may be regarded as obsolete.

With these evidences of progress the electro-therapeutist of to-day can feel more hopeful. He is no longer tied to the old routine methods, and sees before him the commencement of a therapeutic method based upon the laws of chemistry and physics.

H. L. J.

INTERNATIONAL FISHERY INVESTIGATIONS.[1]

THE series of reports now under review on the work of the International Council for the Study of the Sea furnishes evidence of continued activity in many branches of the work. One of the most interesting new features is described in the hydrographical bulletin, which contains an account of a series of observations on tempera-

[1] Conseil Permanent International pour l'Exploration de la Mer. Bulletin Hydrographique pour l'Année Juillet 1910–Juin 1911.—Bulletin Planktonique pour les Années 1908–11.—Publications de Circonstance, No. 62.—Rapports et Procès-Verbaux des Réunions, vol. xiv., 1910–11.—Bulletin Statistique des Pêches maritimes des Pays du nord de l'Europe, vol. vi., pour l'année 1909.—Investigations on the Plaice. General Report by Dr. F. Heincke. 1. Plaice Fishery and Protective Measures (Preliminary brief summary of the most important points of the Report).—Procès-Verbaux des Réunions du Conseil et des Sections, Copenhague, Septembre 1912.

tures, salinities, and direct-current measurements made from ten vessels which were anchored for fourteen days (June 1 to 14, 1911) in a series of positions in the North Sea, selected with the view of studying the principal currents. A repetition of observations of this character from time to time as opportunity offers cannot fail to give information of the utmost value.

The plankton bulletin is composed entirely of tables, recording the species found in samples taken during the years 1908 to 1911; and from the number of records given it is evident that this side of the investigations has recently received far less attention than was formerly given to it. This is probably due to two causes. In the first place, the amount of time which is necessarily consumed in examining and recording a large series of plankton samples is very great indeed, and in the second place a doubt exists in many minds as to whether any very useful results will accrue from an indefinite continuation of work on the plan which up to the present has been followed. What seems to be required at the moment in plankton work is more freedom and liberty to the individual worker to devise and test new methods of quantitative investigation, which may eventually enable a trustworthy estimate of the annual and seasonal fluctuations to be arrived at by some means less open to criticism on the ground of trustworthiness and at the same time not so prohibitively laborious as the enumeration method of the Kiel school of workers.

For investigations on the minutest plankton forms—the nannoplankton of Lohmann—the enumeration method will doubtless have to be retained, and the plan for the preservation of samples for this purpose, described by Gran in *Publications de Circonstance*, No. 62, marks a useful step in advance. The method consists in adding to samples of sea-water, taken with a water-bottle from known depths, a small quantity of Flemming's strong solution. The samples may be kept in this way for many months, and, without any attempt at washing out the Flemming's solution, portions of the sample can be centrifuged, the minute plankton forms which are thus separated out being identified and counted under the microscope.

Vol. xiv. of the *Rapports et Procès-Verbaux* contains a number of papers of great interest dealing with investigations of food fishes. Dr. P. P. C. Hoek reports on the Clupeoids (other than the herring), Prof. D'Arcy Thompson on the later stages of the Gadoids, Dr. Masterman on the later stages of the Pleuronectidæ, and Dr. Johansen on the eggs, larvæ, and later stages of Pleuronectidæ from the Baltic. Dr. Ehrenbaum contributes a summary of a more extensive report which he is preparing on the mackerel, which not only brings together previous work, but also gives much new information on the habits and life-history of this important fish, at the same time making it clear that much further investigation is necessary. He points out amongst other things that little or nothing is known of the small adult stages of this common fish, which, in spite of extensive fishing with nets that certainly ought to capture them, have rarely been taken, and then only in very small numbers.

Finally, the volume contains a useful report by Dr. Redeke on the present condition of our knowledge of the races of marketable fishes, in which the importance of further researches into this subject is made clear.

The International Council publishes as a separate volume what is described as a "preliminary brief summary" of the first part of Prof. Heincke's general report upon investigations on the plaice. This first part is entitled "Plaice Fishery and Protective Measures," and from the *procès-verbaux* of the meeting held in Copenhagen in September, 1912, we learn that the summary was then laid before the council and referred by it to a special committee. The latter committee was not, however, prepared to adopt immediately the recommendations made by Prof. Heincke, and the matter was further deferred.

These recommendations, put forward in a somewhat tentative way, comprise the imposition upon an international basis of a size-limit for plaice, below which the fish may be neither landed nor sold. It would appear that the great destruction of immature plaice which now takes place could only be effectively stopped if this size-limit were fixed at 25 to 26 cm. Such a high limit would, however, mean the immediate ruin of many inshore fisheries carried on by sailing trawlers. As most of these vessels on the continental side land their plaice *alive*, Prof. Heincke suggests that a lower size-limit of 22 or 23 cm. might be allowed for fish which are so landed. It must be pointed out, however, that this would not meet the difficulty in English ports such as Lowestoft and Ramsgate, where a size-limit of 25 or 26 cm. would probably mean the ruin of the trawling industry. Prof. Heincke emphasises the fact that the introduction of a size-limit would, in the first instance, be in the nature of an experiment, and that it is not possible to say beforehand with any certainty exactly what effect it would have on the fishery. The problem is, in fact, a much more complex one than it at first sight appears to be. A consideration of the present preliminary report rather suggests that the International Council has not yet had that problem adequately laid before it in all its numerous aspects and in a sufficiently comprehensive way. The council would scarcely at present be justified in proposing restrictions which would certainly, in the first instance, injure very seriously the livelihood of many owners and fishermen who are dependent upon the smaller boats.

AMERICAN UNIVERSITIES AND COLLEGES.

THE seventh annual report of the president and treasurer of the Carnegie Foundation for the Advancement of Teaching bears ample witness to the stimulating powers which come from the wise administration of an income of nearly 130,000*l.* a year in furtherance of a definite end. Here it is the provision or supplementing of pensions for the teachers of institutions of university rank. The trustees' report is as interesting and informing as ever. The glimpses one gets into the heart of higher education in the States offer some comfort to the Englishman who is inclined to lament what he may call the mediævalism of our ancient universities. After all, there is in the States the Brown University, the governing body of which must contain a majority of Baptists; the same denomination also controls the destinies of the great University of Chicago, the president and two thirds of the trustees of which must conform. Neither of these institutions can share in the benefits of the Carnegie fund because of their religious restrictions, but, as a result of the existence of that fund, Brown is saving 1,000,000 dollars and Chicago 2,000,000 dollars, each for its own pension purposes.

The report contains a survey of State and municipal schemes for teachers' pensions, which is particularly interesting to us at the present moment. In many, if not in most, States, the "flat-rate" system has been adopted. A pension of 400 dollars after thirty to forty years' service is the normal arrangement. New York is more liberal. It provides pensions equal to one-half the retiring salary after thirty years' service. No pension is to be less than 600 dollars, and none more than 1500 dollars. The upper and lower limits in Boston are 600 and 312 dollars respectively, the basis of calculation within those limits being one-third the annual salary. Philadelphia gives from 400 to 800 dollars on the half-salary basis. Many cities and States have, however, not yet made provision of this kind for the staffs of their public schools, but the movement is progressing, thanks to the example of the Carnegie foundation.

The influence of the foundation has been particularly beneficent in the vexed question of college or university entrance requirements. "The border-line between secondary school and college resembles nothing so much as a species of border warfare," but colleges are steadily changing their standards of admission by requiring the completion of a satisfactory four-year course instead of a certificate of having completed so many "units" of study—a system not unlike that which encouraged elementary-school teachers to pile up as many South Kensington science certificates as possible, in order to increase their chances of promotion.

Nothing illustrates more effectively the good which this annual survey of higher education in the States is exerting than the chapters on "Advertising as a Factor in Education," "Education and Politics," and "Sham Universities." Readers of American journals know something of the first, but probably they have not realised the full extent of the evil. The examples pilloried in this chapter come as a violent shock to our sense of academic decorum. The trustees think the use of pictorial and coloured circulars by universities and colleges is distinctly limited, and they see objections to the practice of printing academic biographies of professors in the college prospectus, but Reed College at Portland, Oregon, exceeds all bounds by including in these biographies "editorships of college annuals, class votes on popularity, degrees that are expected, academic biographies of professors' wives, the number of their children, and finally portraits" of the staff. Even this gross breach of academic decency is beaten by McMinnville College, which advertises a "hand-picked" faculty producing "a product second to none in America." But Muskingham College, Ohio, bears the palm in this type of vulgarity. Its alumni include "the most beloved Bible teacher in America." It represents itself as at the geographical centre of the Church (Presbyterian), and prints "a rude cartoon of an old shoe filled and overflowing with riotous students, while a figure in academic costume chases others away with a bundle of sticks." Below the cartoon are verses of which this is a specimen :—

There is a college president, like the woman in the shoe,
Who has so many children that he doesn't know what to do.
He tries to treat them fairly, and give them each some room,
But the college grows so grandly, like a town site on the boom,
That unless her friends soon rally and provide another shoe,
He must say to all new-comers: "Get out of here! Skiddoo!"

Abuses of this kind obviously do much to discredit all that is really good in the higher education of the States.

The Educational Bureau at Washington is also waking up to some well-known evils. The Commissioner has been looking into the question of universities and colleges which confer degrees. He finds only fifty-nine the degrees of which are wholly satisfactory, and 161 where they are approximately so, but the report under review tells us that these are less than a fourth of the institutions in the country which call themselves universities and colleges, all of which grant degrees.

The trustees of this foundation deserve the thanks of the American community for the courageous way in which they are discharging their great trust. J. A. GREEN.

NOTES.

As announced already, the dedication of a window in memory of Lord Kelvin will take place in Westminster Abbey on Tuesday, July 15, at 3 p.m. The window, which is the result of action taken by engineers in the British Dominions and the United States, has been placed in the north aisle of the nave, in close proximity to the one erected in 1909 by civil engineers to the memory of Sir Benjamin Baker; and it has been designed and made by the same artist, Mr. J. N. Comper. A special service, with music, is being arranged by the Abbey authorities, and Mr. R. Elliott-Cooper, president of the Institution of Civil Engineers, will make the formal presentation of the window on behalf of the donors. Members of the American engineering societies and of the Canadian Society of Civil Engineers who may be in London at the time are invited to attend the dedication ceremony, whether they subscribed to the cost of the window or not, and they may obtain cards of admission by writing before Monday, July 14, to the secretary of the Institution of Civil Engineers, 12 Dartmouth Street, Westminster, S.W.

The allocation by the Mansion House Committee of the Scott Fund shows every evidence of a most careful consideration of all the interests involved. The allocation falls under the three main headings of provision for the relatives of those lost (or, in one instance, incapacitated), for the publication of the scientific results, and for memorials. The provision for the relatives includes 8500*l.* each for Lady Scott and Mrs. Wilson, 6000*l.* for Mrs. Scott and her daughters, 4500*l.* for Mrs. Bowers and her daughters, and 3500*l.* in trust for the child Peter Scott, with smaller sums for Evans's family and to meet need in other two cases. The arrangements for publication of the scientific results have failed to commend themselves to one member of the committee, but they can scarcely, on general grounds, be regarded as ungenerous. One of the honorary secretaries of the Royal Geographical Society, Capt. H. G. Lyons, F.R.S., appropriately undertakes their editorship, and representatives of that body and of the Royal Society, with Surgeon Atkinson, will control the work. A total sum of 17,500*l.* provides, besides the cost of publication, for the services of three biologists, three geologists, two physicists, other specialists, and a draughtsman, and the figure of 800*l.*—an ample but not excessive provision—is earmarked for the production of charts and maps. As regards the arrangements for memorials, a tablet in St. Paul's Cathedral is fitting; a group of statuary was doubtless inevitable; it is proposed that it should stand in Hyde Park facing the Royal Geographical Society's house. A contribution to a memorial to Oates, which is being raised by his regiment, is admirable as a special expression of regard for the memory of one whose relatives need no assistance from the fund. The published results of the expedition will not form its only scientific memorial; the establishment of a trust fund of some 10,000*l.* for the endowment of future polar research will perhaps in the long run preserve most honourably the memory of a great scientific expedition, and would, in the belief of the committee, have commended itself greatly to its leader.

The council of the Royal Society of Edinburgh has awarded the Gunning Victoria Jubilee Prize for the quadrennial period 1908–12 to Prof. J. Norman Collie, F.R.S., for his distinguished contributions to chemistry—organic and inorganic—during twenty-seven years, including his work upon neon and other rare gases. Prof. Collie's early papers were contributed to the Transactions of the society. The council has also awarded the Makdougall-Brisbane prize for the biennial period 1910–12 to Dr. John Brownlee, for his contributions to the theory of Mendelian distributions and cognate subjects, published in the Proceedings of the society within and prior to the prescribed period.

At a meeting of the electing trustees of the British Museum, held on July 2, Sir Archibald Geikie, K.C.B., P.R.S., was elected a trustee of the British Museum in succession to the late Lord Avebury. Sir A. Geikie was already an *ex-officio* trustee, in virtue of his position as president of the Royal Society; but his tenure of that office comes to an end in November next, and his services would have been lost to the British Museum but for his present election as a trustee for life.

An association of amateurs interested in wireless telegraphy and telephony has been formed, under the title of "The London Wireless Club." A meeting will be held in September next, for the purpose of electing a committee. The honorary secretary *pro tem.* is Mr. R. H. Klein, 18 Crediton Road, West Hampstead, N.W.

Sir Robert Lucas-Tooth has given a donation of 1000*l.* to the fund that Capt. J. K. Davis is raising in this country for Dr. Mawson's Australasian Antarctic Expedition. We learn from *The Times* that Capt. Davis leaves England on July 18 for Australia. On his arrival there the *Aurora* will be refitted and will proceed to Commonwealth Bay to bring back Dr. Mawson and his six companions at present in the Antarctic.

The discussion by a Standing Committee of the House of Commons of the Bill to prohibit experiments on dogs was continued on July 2. As was pointed out in our issue of last week, the Bill proposes to enact that it shall be unlawful to perform any experiments of a nature causing or likely to cause pain or disease to any dog for any purpose whatsoever, either with or without anæsthetics. At the Committee meeting on July 2 an amendment was carried that the Bill should apply only to inoculation experiments. The Bill is again under consideration by the Committee as we go to press.

The annual conference of the Museums Association, which is to be held at Hull this year, will open on Monday next, July 14, under the presidency of Mr. E. Howarth, curator of the Sheffield Public Museums and Art Gallery. Many interesting subjects are to be discussed, among them being the possibility of showing our museums and art galleries to the blind, arising out of experiments made by Mr. J. A. Charlton Deas, at Sunderland Museum and Art Gallery. The peripatetic guides at the British Museum (both Bloomsbury and South Kensington) will attend to give their experiences in the personal conduction of visitors around these institutions, and Prof. Rathgen, of Berlin, is to discourse on the decay and preservation of antiquities. The local secretary for the meeting is Mr. Thos. Sheppard, of the Hull Museum. The secretary of the association is Mr. E. E. Lowe, curator of the Leicester Museum and Art Gallery.

The Institut de Paléontologie Humaine, founded by Albert I., Prince of Monaco, has issued a report of the investigations conducted in 1912 by MM. Breuil and Obermaier. The most interesting discoveries are two fine examples of the decorated staves called by French archæologists *batons de commandement,* from Spanish caves; a rough delineation of an animal, perhaps a horse, and a male human figure from the grotto of San Garcia in Burgos; and a remarkable series of figures from the Sierra Morena and Velez Blanco caves, illustrating the evolution of design in a female idol of the early Neolithic age. The explorers record their obligations to an English antiquarian, Col. Willoughby Verner, for his researches in the Peleta cave at Benaojan, Malaga, and describe the visit of M. Breuil, under the guidance of Prof. Sollas, to the well-known Bacon Hole, near Swansea, which corroborated the identification of the Palæolithic drawings on its walls.

American archæologists, having settled the main problems which the continent presents, are now devoting themselves to regional, intensive exploration. Mr. Clark Wissler has recently issued in Bulletin 9 of the Geological Survey of New Jersey a preliminary report on archæology. The surface sites so far reported are rare except in restricted areas, which correspond with the distribution of the Lenápé Indians during the early settlement period, and it thus appears that all such remains belong to the historic Indians and their immediate ancestors. No positive traces of a pre-Indian culture have been discovered. Long lists and descriptions of the remains are given, classified as camp and village sites, shell-heaps, cemeteries, rock shelters, quarries, caches, and trails, the camp and village sites being most abundant. Stone implements are abundant, but as regards palæoliths, though the existence of such seems to have been demonstrated by Volk in the Delaware Valley, some archæologists are not satisfied that they are human in origin.

We have received the Livingstone College Year Book for 1913, which gives particulars of the work done there, extracts from the letters of old students, &c. The college is established for the training of missionaries in the elements of medicine and hygiene. An appeal is made for 10,000*l.* for paying off a mortgage on the property and establishing a small endowment fund.

Parts 1 and 2 of *Mikrokosmos* (7 Jahrg., 1913–14) contain several well-illustrated articles of interest to microscopists, *e.g.* a simple illuminating apparatus, a new form of mechanical stage, preparation of material, development of protozoa, &c. Herr Günther and Dr. Stehli contribute lists of common plants in suitable condition during April and May for the demonstration of special structures, &c., which are indicated, with their habitat.

A ninth research report, by Dr. Houston, director of water examination, has been issued by the Metropolitan Water Board. It deals with a search for the typhoid bacillus in *raw* river water and crude sewage, and is a continuation of the author's former investigations on the same question (see second, fifth, and seventh research reports). Twenty-eight samples of crude sewage were examined, mostly from Barking or Hendon, also from Dublin, Belfast, Edinburgh, and Aberdeen, but in no case was the typhoid bacillus detected. Dr. Houston concludes that the home of the typhoid bacillus is not so much in impure water, or even in the crude sewage from a large community, as in the "factories" of disease, as exemplified by the "carrier" case.

Among the cases referred to in a recent batch of Opinions (52 to 56) issued by the International Commission on Zoological Nomenclature at Washington is that of the rodent genus Ondatra, frequently considered as applicable to the South American coypu, commonly known as Myocastor or Myopotamus. In the opinion of the majority of the committee this usage is, however, considered erroneous, the name really belonging to the musk-rat, originally described as *Mus zibethicus.*

To the May number of *The National Geographic Magazine* Mr. E. C. le Munyon communicates a richly illustrated account of his experiences in conveying a motor-car for the use of the Tasha-Lama from Tientsin across the Gobi to Urga, in northern Mongolia. One of the plates shows a vast flock of sheep, probably of the Hunia breed, on the march to Pekin, whence a large quantity of the wool—which is chiefly employed in carpet-making—is exported to America. The author also encountered enormous herds of wild horses and "antelopes," the latter being doubtless the Mongolian gazelle or one of the allied species. It may be added that the motor reached its destination in excellent working order.

A paper by Prof. A. Keith on the teeth of prehistoric man is published in the Odontological Series of the Proceedings of the Royal Society of Medicine, vol vi. After noticing certain variations from the modern type characteristic of many prehistoric molars, the author proposes the term "taurodontism" for the modification in which the crown tends to become excessively wide in proportion to the root, while "cynodontism" is suggested for the opposite condition. Taurodontism is stated to be excessively developed in Neanderthal man, whose teeth, although primitive or simian in some features, are regarded as highly specialised in others; the dentition of the Galley Hill man is, however, regarded as still more simian in character.

In an article in the June number of *The Zoologist* on his experiences of hunting the hump-backed whale from one of the two whaling stations at Durban, Mr. T. B. Goodall directs attention to what he regards as a misinterpretation of the relationship of the plates of whalebone to the plate in the whalebone-whales. It is generally stated in text-books that these plates are outgrowths of ridges on the palate, comparable to the rugæ on that of cattle. Mr. Goodall states, however, that the plates arise on the outer sides of two median raised ridges of mucous membrane, which can apparently be raised or depressed. These ridges, or folds, he thinks, probably represent the gums, although it is also suggested that they may correspond to the upper lips. In consequence of this, the plates of whalebone, according to the author, appear to be quite distinct from the palate, and to be outside the gums and inside the cheeks, or, on the hypothesis that the longitudinal folds are the upper lips, the plates "are really modified hairs of a veritable moustache on an inverted upper lip." It is added that the weight of one of these whales is computed at a ton to the foot, so that a 60-ft. humpback would weigh 60 tons. A newly-born humpback is stated to have measured 16 ft. in length, and to have weighed a couple of tons.

DR. GERTRUD TOBLER has given an elaborate account of the genus Synchytrium in her recently published work, "Die Synchytrien: Studien zu einer Monographie der Gattung" (Jena: G. Fischer, 5 marks). The group (Chytridiales) to which this genus belongs includes the most interesting of the lower fungi, and Frau Tobler's detailed studies include its morphology, cytology, development, influence on the host plants, and geographical distribution, together with systematic descriptions of the fifty-one recognised species and a list of their host plants. The work also includes a historical summary and a full list of literature, and there are four plates.

THE greater portion of tome 25, No. 4, of the *Bulletin de la Société Impériale des Naturalistes de Moscou* is occupied by two papers on the mechanical tissues of plants. In the first paper W. Rasdorsky gives a useful historical summary of previous work on this subject between 1873 and 1910, and of the present state of knowledge concerning the mechanics of vegetable tissues in both flowering and flowerless plants. In the second paper this author and I. A. Kalinnikow give a long account of their own researches with apparatus devised by themselves for testing the strength of fibres and other tissues. The results are set forth in numerous tables and diagrams, relating chiefly to experiments with the stalks and blades of palm leaves and with various kinds of iron and steel. Plant fibres were found to have about the same tensile strength as wrought-iron, and in some cases approached that of steel, while they greatly exceed iron and steel in elasticity, though falling far short of these metals in ductility.

A COPY has reached us of the first report of the Forest Branch of the Department of Lands, British Columbia. This branch was created in February, 1912, and the result of the first year's work reflects great credit upon the Chief Forester, Mr. H. R. Macmillan, and his assistants. British Columbia contains one of the few great bodies of commercial timber left in the world which are not yet materially reduced by destructive lumbering, and, with the possible exceptions of Siberia, Brazil, and the north-western United States, the timber wealth of British Columbia is unparalleled in any other country, since it contains not less than one hundred million acres of forest land. At the present rate of cutting, making no allowance for annual growth, it would take nearly 250 years to use up merely the mature timber now standing; the annual growth of the forests is even now, though they are not yet adequately protected against fire and waste, not less than five times the present annual cutting. Great stress is laid on the need for a prudent policy of forest utilisation and protection, including the formation of forest reserves in such areas as are unsuited for agricultural use. The report is illustrated by thirty-three very fine photographs, which, besides their immediate purpose, serve to convey an admirable impression of the forest vegetation of the province in its ecological aspects.

THE useful ice reports contained in the meteorological chart issued by the *Deutsche Seewarte* for the North Atlantic Ocean for July show that early in June a great quantity of drift ice was still met with, especially north of latitude 45° N., where the Newfoundland Bank and the district to the east of it, as far as longitude 41° W., were thickly beset with bergs. South of latitude 45° N. the difficulties were not so great; drift ice had much increased since the previous month, but a further advance of the ice southwards was not observed. Two bergs were sighted on June 7, so far south as 43·1° N., 42·8° W., and the possibility of a further advance would naturally have to be taken into account.

THE valuable publication entitled *Deutsche überseeische meteorologische Beobachtungen*, vol. xxi., containing data for 1911, is issued by the Seewarte, as in previous years, with the assistance of the Imperial Colonial Office, the results being prepared with much care by Dr. P. Heidke. The volume is considerably enlarged compared with that of the previous year (NATURE, August 22, 1912) by the addition of observations at definite hours at some stations in the Cameroon district and in German South-West Africa. The discussion and publication of observations for the Protectorate of German New Guinea, and for several islands in the Pacific Ocean, are also contemplated. The volume forms a most important contribution to our knowledge of the climatology of many remote regions.

WE have received from Dr. Louis Bell, whose book on illumination is so well known, a copy of a note he communicated to *The Electrical World* for May 24 on silvered mirrors and their preservation. It appears that the method of covering a silver mirror with a thin layer of collodion, first suggested by M. Perot in the *Comptes rendus* for November, 1909, may be carried out by applying the ordinary lacquer supplied commercially for protecting silverware. Dr. Bell uses clear "Lastina" lacquer diluted with two parts of the thinner provided with it, and floods the mirror with the solution. On drying, the mirror has lost about 4 per cent. of its reflecting power. A still more dilute solution was used for the 2-ft. parabolic speculum reflector of Harvard Observatory. The definition was unimpaired, and after three months of regular service the mirror had only diminished slightly in brilliancy.

THE part of the Proceedings of the Physical Society of London dated June 15 has reached us. We note that the Proceedings are now issued at intervals of two months. The present part consists of more than ninety pages, and contains twelve papers communicated to the society between March 7 and May 8. Each paper is accompanied by an abstract and by a short account of the discussion which followed the reading of it. Mr. T.

Smith's contribution to the discussion of Mr. W. R. Bower's paper on a graphical method of optical imagery covers five pages, and contains all the essentials of Gauss's analytical method and an example of its use. A paper by Dr. W. H. Eccles deals with the important question of the cause of the behaviour of the light electrical contacts used as detectors in wireless telegraphy. Dr. Eccles shows that nothing further is required to explain the behaviour of the different types of contacts than the laws of generation of heat in conductors by electric currents and the laws of thermo-electricity.

In a short note in the *Gazzetta Chimica Italiana* (vol. xliii., i., 197) Mr. A. Pieroni describes a new method of preparing colloidal solutions, which consists in dissolving, for instance, silver nitrate or copper sulphate in pyridine containing pyrogallol or tannic acid, and subsequently diluting with water. Under these conditions, colloidal solutions of copper or silver are obtained which are much more concentrated than colloidal solutions of the same metals in water only; in the case of silver, for instance, relatively stable solutions, containing 0·05 to 0·064 per cent. of the metal, can be obtained.

We have received from the United Tanners' Federation of Great Britain and Ireland a copy of "The Tanners' Yearbook" (3*s*., post free), which, besides containing a report of the work of the central committee of the Tanners' Federation during 1912, contains statistics of leather and of materials employed in the leather industry, and a number of articles on matters of technical interest. Some of these are of scientific importance; for instance, the article on the mimosa-bark industry of South Africa, by Dr. J. Gordon Parker, and that on the new synthetic tannin, "Neradol D," manufactured by the Badische Co., Ltd.

The Journal of the Marine Biological Association (vol ix., No. 4) contains an important paper by the late Mr. G. H. Drew on the precipitation of calcium carbonate by marine bacteria. Evidence is brought forward to show that the chalky mud flats forming the Great Bahama Bank and those which are found in the neighbourhood of the Florida Keys are now being precipitated by the action of a new bacterium, to which, owing to its power of precipitating calcium carbonate from dilute solutions of calcium salts, the name *Bacterium calcis* is given. The isolation and characteristics of the bacterium are described and the hypothesis put forward that in the formation of the various chalk and oolite strata the *Bacterium calcis* or similar bacteria have played an important part, as well as the Foraminifera and larger organisms; if such a view be correct these strata must have been deposited in comparatively shallow water, the temperature of which approximated to that of the modern tropical seas.

The second Gustave Canet lecture, delivered by Dr. Dugald Clerk, before the Junior Institution of Engineers, on June 30, dealt with the present state of our knowledge of the working fluid of internal-combustion engines. The combined work of English and Continental physicists and engineers has thrown much light upon the physical and chemical behaviour of flame, and it is now possible to give an approximately accurate account of the leading phenomena of combustion, explosion, and expansion, so far as concerns the engineer. Dr. Clerk gave a useful summary, together with the principal results, of modern experiments on temperatures in the gas-engine cylinder, on the internal energy of gas-engine mixtures, on explosions in closed vessels, on turbulence, and on radiation. With the view of testing the accuracy of the data thus accumulated, there are several trials on gas-engines included, together with the reduction of the results. The information thus given presents a very full statement of our knowledge, as might be expected from Dr. Clerk's personal connection with the British Association committee formed in order to study this subject. In Dr. Clerk's opinion, practical men very greatly underrate their indebtedness to theory. Some practical men have gone so far as to say that gas-engine designers have brought internal-combustion engines to their present state of efficiency without any aid from scientific theory. The increasing efficiency of the internal-combustion engine has put great pressure upon steam-engine builders, and recent steam turbine efficiencies have attained such figures that it becomes necessary for the gas-engine designer to attempt further economies in order to keep ahead of his steam rival. This he can do only by exact knowledge of his heat losses and properties of his working fluid.

We have received from Messrs. Gallenkamp and Co., 19 and 21 Sun Street, E.C., a catalogue of laboratory outfit for the bacteriological and pathological laboratory. All the general and special apparatus, as well as the necessary fittings, are included in the list, which is fully illustrated.

Catalogue No. 319, just issued by Mr. E. Baker, 14 and 16 John Bright Street, Birmingham, includes a number of rare and interesting works on many branches of science, offered at low prices. Librarians and others requiring volumes to complete sets or series, or papers on particular subjects, should see the catalogue.

Three new volumes in Prof. Ostwald's series of scientific classics—"Klassiker der exakten Wissenschaften"—published by Mr. W. Engelmann, of Leipzig, have recently been received. No. 188 (price 1.80 marks) is entitled, "Die Druckkräfte des Lichtes," and contains two papers by P. Lebedew on the pressure of light, with notes by P. Lasareff. A translation into German of A. C. Clairaut's work, published in 1743, on the theory of the shape of the earth, based upon hydrostatic principles, appears as No. 189 (price 4.60 marks), under the title, "Theorie der Erdgestalt nach Gesetzen der Hydrostatik," with notes by P. E. B. Jourdain and A. v. Oettingen. Similar valuable notes are contributed by R. Anschütz to No. 190 (price 5 marks), which contains J. Loschmidt's "Konstitutions-Formeln der organischen Chemie in graphischer Darstellung." Each of the volumes has a portrait of the original author as a frontispiece.

OUR ASTRONOMICAL COLUMN.

THE HOTTEST STARS.—Under this heading, Dr. Ant. Pannekoek communicates a short note to the *Astronomische Nachrichten*, No. 4657. It relates to the list of spectral-photometric measures made by Herr H. Rosenberg (see this column, May 29) of the temperatures of the hotter stars. Dr. Pannekoek states that from this list a regular increase of the figures takes places with the class-number of the spectra according to Miss Maury's classification. Whether this increase commences at the beginning or in which class the helium or the whitest or hottest stars are to be found cannot be clearly stated in consequence of the few stars discussed. Dr. Pannekoek utilises the large quantity of material available in the catalogue of colour-estimations by Osthoff, and while they give no results of absolute temperature, they are of value from a relative point of view. The comparison of these values with Miss Maury's types brings out the result that lowest colour number corresponds with her class IV. or IV.-V., or the typical helium stars. On either side of these classes the colour numbers increase, and the temperature decreases not only on the side of the Sirian stars of the first type, but also towards the Wolf-Rayet stars. The following is the complete table which he gives in the paper, but here Miss Maury's classes are preceded by the equivalents in Sir Norman Lockyer's classification for comparison:—

Class (Lockyer)	Class (Miss Maury)	Colour	No. of stars
Argonian	I	2·47	6
Alnitamian	II	2·36	10
Crucian	III	2·30	9
Crucian, Achernian	IV	1·94	14
—	IV–V	1·62	10
Taurian, Algolian	V	2·11	9
Rigelian, Algolian	VI	2·16	10
Algolian, Markabian	VII	2·27	23
Cygnian, Markabian	VIII	2·37	34
Sirian	IX	2·64	20
Sirian	X	3·11	14
Procyonian	XI	3·40	9
—	XI–XII	3·41	4
Polarian, Procyonian	XII	3·68	17
Polarian, Procyonian	XIII	4·12	13
Arcturian	XIV	4·45	12
—	XIV–XV	5·09	9
Arcturian	XV A	5·18	18
Arcturian	XV B	5·35	26
Arcturian	XV C	5·55	31
—	XV–XVI	6·34	5
Aldebarian	XVI	6·47	17
Antarian	XVII	6·80	15
Antarian	XVIII	6·74	15
Antarian	XIX	6·67	6

A PHOTO-VISUAL COMPARATOR FOR THE IDENTIFICATION OF MINOR PLANETS.—As the only means whereby a minor planet is distinguishable from a star of the same magnitude is its proper motion, its identification is often a matter of considerable labour proportional to the planet's magnitude and the uncertainty of the ephemeris. To this end M. J. Lagrula employs an ingenious arrangement which he describes in a note presented to the Paris Academy of Sciences (*Comptes rendus*, No. 15). It consists of a binocular combination of telescope and microscope, forming what is essentially a stereo-comparator, in which a coloured image of a photographic positive of the region to be examined is superposed on the image seen in the telescope. All objects visible in the field of the telescope, except small planets which have no counterpart on the photograph, are distinguished by the presence of a coloured disc. For use with the Gautier equatorial of the Nice Observatory copies of the photographic charts of MM. Palisa and Wolf have been found eminently suitable. As an example of the rapidity and efficiency of operating with the device the author instances detecting within five minutes an error in the published ephemerides of (233) Asterope.

METEOR DUST AS A MEASURE OF GEOLOGIC TIME.—In *Science*, No. 957, Prof. Alfred C. Lane directs attention to the possibility of using the proportion of contained meteor dust as a measure of the rate of formation of strata, and hence as a criterion of geologic time. He calculates that the earth gains 20,000 grams of cosmically derived nickel per square kilometre per annum. From this figure and the nickel content of the abysmal red clay he estimates that a layer one metre thick of the latter requires 8700 years to accumulate. The professor urges members of proposed polar expeditions to complete Nordenskjold's observations by determining the rate of deposition of cosmic dust, and optimistically anticipates that within this century there will be drilled a hole in the bottom of the sea which will give us the other datum to be determined.

THE ROYAL AGRICULTURAL SHOW.

THE extremely successful Royal Show held at Bristol, July 2–5, illustrated in a striking way the general progress being made in agriculture, horticulture, and forestry, but presented very little calling for comment from the scientific point of view. Among livestock, a remarkable novelty was the pen of primitive breeds of sheep—and crosses from the same—exhibited by Prof. Cossar Ewart and Mr. H. J. Elwes. This throws some light on the origin of domesticated sheep, and also suggests the possibility of establishing one or more new breeds capable of thriving on poor upland pastures in this country, and of yielding more valuable wool than that of the ordinary hill-breeds.

In the Agricultural Education Exhibition, Rothamsted showed an interesting series of tomato-plants in pots to demonstrate the advantage of partial sterilisation of soil in various ways. Wye College—as usual —exhibited a striking series of pests, fungoid (including a new disease of apple-buds) and insect (some in the living state). The University of Bristol was represented by the associated Royal Agricultural College (received in deputation by H.M. the King on July 4) and Long Ashton Fruit and Cider Institute. The chief feature of the former was a collection of wool-staples, including a series from the sheep in the above-mentioned exhibit of Ewart and Elwes. Long Ashton, as the chief British horticultural research centre, is evidently working with increased energy since its reconstitution and extension, and one of its most interesting exhibits consisted of specimens of a new disease of pear-blossoms, due to bacteria as yet unnamed, and causing the young fruits to fall early. The Nature-study Section, including exhibits from several western and south-western counties, was a decided improvement on past years, proving that school work is now more systematic than formerly. Gloucestershire is to be congratulated on classifying its material by subjects and not by schools.

The exhibit of British tobaccos attracted much notice, but most of those who sampled the specimens were not impressed by their quality, though no doubt home-grown material may prove useful for fumigation purposes. The Forestry Section was particularly good, and demonstrated increasing interest in a neglected industry of national importance.

Among the implements, the increasing necessity for labour-saving contrivances is evidently continuing to produce continual improvements and new types. The set of milking machines attracted a great deal of attention, especially the Swedish Omega form, of vacuum type, which gained first place in trials held earlier in the year. The difficulty of cleansing milking machines has been one of their great drawbacks, but this is largely overcome in the Omega by employing short transparent celluloid tubes instead of long rubber tubes. Probably the most ingenious new appliance to be seen in the show was the "Erto" potato-planting machine. This, in one operation, digs trenches of the desired depth, plants the tubers at any distance apart, sows manure if required, and covers up the furrows. Novelties were not wanting among the exhibits of various well-known firms specialising in farm and garden plants. Suttons showed a new variety of sunflower with red centre, Marsters new varieties of wheat, and Gartons a new oat—the "Leader"—the first to yield five grains to a spikelet.

The most striking innovation on a large scale at the Bristol Show was the establishment of an Overseas Section, and it is to be hoped that this feature may be permanently retained. So many persons are emigrating overseas that it is important to give them every chance of seeing Colonial produce and studying Colonial methods. Readers of NATURE are mostly familiar with the kind of exhibits represented in this section, but large numbers of the populace last week were obviously keenly interested in the rubber series shown by the Federated Malay States, and the sugar samples from the West Indies and British Guiana, including food products for human and animal consumption, and even a sugar-cane plant in a living and healthy state. The time appears to have come when intending colonists should all have the opportunity of elementary instruction in Colonial or tropical agriculture before leaving the home country.

J. R. A.-D.

BEDFORD COLLEGE FOR WOMEN.

THE opening of the new buildings of the Bedford College for Women on July 4 by her Majesty Queen Mary was an important event in the history of university education.

A committee was formed in 1847 by Mrs. Reid and other ladies interested in women's education, lectures being given in Mrs. Reid's private house, and in 1849 the college was definitely started in a house of its own in Bedford Square, from which fact the college takes its name. In 1874 the college moved to Baker Street, and from that year its growth has been rapid. As time went on the accommodation at Baker Street was increased until every available square foot was covered; when it became evident that a move into larger and less noisy buildings was inevitable. For this purpose the council acquired the lease of South Villa, standing on land adjoining but outside Regent's Park. Three acres of the site were added to the park, about eight acres being left for the purpose of the college and its grounds. An appeal was issued for the necessary building fund, and a loyal response was given by old students and other friends of the college. Among other gifts may be mentioned a library and its furniture by Lady Tate, a dining-hall and common-rooms by Mrs. Oliver, a grant of 30,000*l*. from the London County Council, and an anonymous gift of 30,000*l*.

The new college accommodates some 500 students, and (except for the library) was designed by Mr. Basil Champneys. It consists of four parallel rows of buildings: the library, a science block for chemistry, physiology, and physics, another science block for zoology, botany, and geology, and the hall and rooms for about eighty residents. These rows are connected at one end by corridors, by the Sir Julius Wernher reading-room, and by a block of buildings for administrative offices and for the rooms allotted to arts subjects and mathematics. This "arts" block also contains a large hall for public lectures.

In erecting these buildings the council has assumed a heavy responsibility, and in order to provide scholarships, to maintain the departments at a high level, and to keep up the fabric, an adequate endowment is urgently needed. An appeal has been issued for an endowment fund of 150,000*l*. A far humbler but very necessary appeal was also issued about a year ago for 2000*l*. to put the athletic clubs on a sound financial basis. The value of outdoor recreation to women coming from London homes, and engaged in severe mental work, can scarcely be over-estimated.

The Queen, who was accompanied by Princess Louise Duchess of Argyll and the Duke of Argyll, was received at the entrance of the college, and conducted by the Earl of Rosebery to the lecture-hall, where the council and staff were presented. She then proceeded to the two science blocks, where she inspected the students at work, and took the keenest interest in their experiments and exhibits. Afterwards she walked to the Tate Library, and then to the residents' block, where she visited some of the rooms. Meanwhile some 600 guests were awaiting her arrival in the dining-hall, the time being filled up by several speeches. The President of the Board of Education expressed strong appreciation of the work done by the college, and hopes of a great development of both school and university education in the future. In the absence of Sir John Simon, Miss Edgell (head of the department of philosophy) spoke next, and in an interesting speech outlined the progress of women's education during the last sixty years, and emphasised the great part played therein by the University of London. The Archdeacon of London pointed out the value of university education in the formation of national character. Then Lord Rosebery spoke until the Queen, having completed her tour of inspection, arrived in the hall, where she listened to a college song and received a bouquet from the students. She then said: "I have great pleasure in declaring the new buildings of this college open"; and left the college, after receiving thanks from Lord Haldane.

RUSSIAN GEOGRAPHICAL PAPERS.

Lake Balkhash.—Mr. B. F. Meffert, who visited this lake during a journey in Russian Asia in 1910, has given an account of its basin in the *Izvestiya* of the Imp. Russ. Geogr. Soc., Nos. i.–v., 1912. The basin is intimately connected with those of the lakes Sasyk-kul, Ala-kul, and Ebi-nor. The rocks are chiefly Palæozoic and eruptive rocks of various ages. Deposits dating no further back than the Tertiary are rare, and occur only in the eastern part of the basin. At some time or other before the Tertiary period the Palæozoic rocks were folded in various directions, chiefly north-west and west. When the faulting and upheavals which formed the horsts and troughs of the Tarbagatai, Dzungarian Alatau, the Chu-Ili watershed, &c., took place is not known, but in some parts they may be referred to the Tertiary period, and also the subsidence, at least of the western part of the basin, is probably of the same age. Mr. A. M. Nikolski has connected Balkhash with the Han-hai, not with the Turkestan basin, believing that the Han-hai with Balkhash was isolated before the separation of the Aralo-Caspian sea from the Siberian, and certainly no Aralo-Caspian deposits occur for some distance west of Balkhash. Marks of high water are found on the north-west of the lake 100 ft. above the present level, and therefore the lake must at one time have covered a large area to the south and east. According to Golubief, the lakes Sasyk-kul, Uyali, and Ala-kul formed one lake within the memory of man, and the difference of level between Ala-kul and Ebi-nor is only 25 ft. During last century there was a long period of desiccation, but for the last twenty years the lake has been rising. The water of the western part of the lake, into which the Ili pours considerable volumes, is quite sweet, but it is brackish in the small bays and channels.

Floral Regions of Siberia.—In the Bulletin of the Imp. Academy of Sciences in St. Petersburg, No. 14, 1912, Mr. N. I. Kuznetsof proposes a division of Siberia into floral regions, after discussing those of Ledebour, Korzhinski, and Tanfilyef. A line following the watershed between the Yenesei and Lena, approximately coinciding with geological and climatic boundaries, prolonged northwards to the watershed between the Khatanga and Anabara, and southwards to the mountains at the southern end of Lake Baikal, divides the principal regions into eastern and western parts. In the western section of the forest area arboreal species of the Altaic or western Mongolian centre prevail, in the eastern those of the Manchurian centre. Beyond the limit of arboreal vegetation determined by Siberian travellers, notably Middendorff, is the Arctic zone, its eastern part characterised by species and even families common to the Arctic regions and America, and also by representatives of the Alpine flora of the Stanovoi and Verkhoiansk ranges. Kamchatka and the Okhotsk coast down to the north of Sakhalin constitute a separate division, in which Altaic forms are absent, and peculiar species of trees, *Picea ajanensis*, *Abies nephrolepis*, and *Betula Ermanni*, occur. Foliage trees are seldom found in Siberia except in the Amur district, where Tertiary forms exist which perished in other parts of Siberia during the cold period contemporaneous with the Ice Age of Europe. The Alpine region is confined to islands and bare summits amidst the sea of coniferous forests, in the Verkhoiansk and other ranges. East of Lake Baikal *Pinus pumila* occurs, species which thrive on rocky peaks are few, and the flora passes at the north-eastern extremity of the Yablonovoi range into the Arctic flora. Lastly, there are two areas of steppe-lands, one in the west between the southern limit of the *taiga*, and the watershed between the Arctic ocean and the Aralo-Caspian depression, the other embracing the basins of the Shilka, Argun, and the Upper Amur, as far as Albazin.

Natives of Siberia.—According to Mr. S. Patkanof (*Zapiski* of the Imp. Russ. Geogr. Soc., Statistical Section, vol. xi., No. 1), the natives of Siberia number 870,536, of whom 442,459 are males. This sex generally preponderates, except in a few small tribes. The most numerous are the Buriats, who number 288,599. As regards governments, Yakutsk contains the largest number of natives, namely 235,623, and they constitute 87·5 per cent. of the total population. In Transbaikalia and Irkutsk they are also numerous, while they are few in the Amur province. There are, however, districts of Siberia where the natives are almost all the population. The other inhabitants of Siberia, chiefly Russians, number 4,889,633, so that the natives constitute only about 15 per cent. of the total population.

METEOROLOGICAL REPORTS AND SUMMARIES.

A USEFUL discussion of the cloudiness and sunshine of North America, by Mr. A. Gläser, is contained in *Aus dem Archiv der Deutschen Seewarte*, vol. xxxv., No. 1, based on published data from available sources. The subject is treated in considerable detail as regards time and place, and is illustrated by copious tables and diagrams. The few following points may be mentioned among the general features referred to. In the westward districts westerly winds bring most cloud, clear sky in summer being due to the higher saturation point of the air. Eastward of the Rocky Mountains the sky is clearer, but with northerly and southerly winds the spring is the most cloudy season. The winter barometrical minimum in the North Atlantic causes easterly winds in the eastern States, and these, mixing with the relatively warm air of the coast, produce a large amount of cloud. The high pressure in the south-east in autumn causes clear weather; in the south the greatest clearness occurs towards the end of winter. In the south-west of the United States and western Mexico the warm winds of the Gulf of California cause much cloud in summer; the clearest season is spring, and the dry northerly winds of the northern portions bring clear weather in autumn. The most bright sunshine is found in the south-west of the continent, and the least in the north-west and north-east, where the sun's power is naturally much weaker. In the region east of the Rocky Mountains there is comparatively little change in proceeding from south to north.

The Rev. L. Froc, S.J. (director of the Zi-ka-wei Observatory, near Shanghai), has issued the first part of a useful discussion of the rainfall in China during eleven years, 1900–10; the paper also includes data for a number of stations for shorter periods. Full particulars are given respecting the geographical position and surroundings of each station. In addition to the sums for individual months and years, and means for seasons and for the whole period, interesting details are given with reference to the variability of rainfall and unusual falls in the yearly, monthly, and daily periods, but the general discussion of the data and preparation of a rainfall map are reserved for the second part of the paper, to be published later on. It is remarked that the rainfall is not so excessive as in some neighbouring countries, *e.g.* the Philippine Archipelago. The following are among the heaviest of the yearly falls:—Hongkong, 2473 mm., in 1902; Fouchow, 2572 mm., in 1906; Sanchoei, 2760 mm., in 1907; Pakhoi, 2691 mm., in 1908; all in the south-east of China. The greatest daily fall was 320 mm. (12·6 in.) at Pakhoi. The diagrams show that in all districts the greatest rainfall occurs during the summer half-year.

The Commonwealth Central Weather Bureau has issued an average rainfall map of Tasmania, the fifth of the series showing the annual rainfall distribution of Australia. The most striking feature of the map is the great variation between the greatest and least average falls, viz. 17·9 in. at Beaufront, in the midland district, and 115·8 in. at Mt. Lyell, on the west coast. This coast is exposed to the moist westerly winds, and condensation is favoured by physiographic conditions, the result being a mean annual fall of 88·7 in. for the whole district generally. On the east coast the annual mean is 32·7 in. For a large area (about 3000 square miles) no records are available.

The annual report of the meteorological observatory of the Government-General of Korea for the year 1911 (Dr. Y. Wada, director) contains valuable observations taken three times daily at ten stations, with carefully prepared summaries. Weather conditions and special occurrences are denoted by international symbols, and the instruments and methods of observation are similar to those at meteorological stations in Japan, and, consequently, are all that can be desired. The absolute maxima of air temperature ranged between 88·3° F. at Fusan and 92·8° at Chemulpo, both in August, and the absolute minima between −16·1° at Ping-yang and 15·3° at Mokpo, both in January. The yearly rainfall varied from 33·3 in. at Song-chin to 76·8 in. at Fusan. The largest amount of sunshine was 2642 hours, at Ping-yang, being 60 per cent. of the possible quantity.

A report on the Mariout district, by Mr. A. L. P. Weedon, in Nos. 72 and 73 of *The Cairo Scientific Journal*, is of much interest, both from an agricultural and from a meteorological point of view. The district, which consists of a long strip of land west of Alexandria, was in ancient times famous for its fertility, but at present it is for the most part barren and waste, barley being practically the only crop grown, in some parts only, and this is dependent on the somewhat precarious winter rains. The rainfall seems to differ but slightly from that of Alexandria, which averages 220 mm. (8·7 in.) per annum. The climate depends on the temperature of the Mediterranean and the general atmospheric circulation, and from numerous quotations from ancient and modern writers it is concluded that there is no reason to believe that either of those factors, or the rainfall, has changed since Roman times. The author states that the land is capable of producing more profitable crops in the hands of more efficient cultivators, who by the employment of scientific methods could either give it a better or more regular water supply, or make a better use of the existing moisture of the soil, *e.g.* by a system of dry-farming (economising the rain-water by digging trenches before the rainy season), assisted by wells and cisterns, many of which already exist.

The Austrian Meteorological Institute has published part v. of its valuable "Klimatographie" of that country, referring to the mountainous province of Salzburg. Climatologically, Salzburg belongs to the Central European district, but owing to the Alps it is subject to many marked modifications. The portion on the northern side of the limestone Alps, being exposed to the north and north-west winds, has a decidedly damp and rainy character, with the peculiarities of the West European climate. But between the limestone and central alpine chain lies a zone of a continental, dry character, with stagnant masses of air (*Luftseen*) in the valleys, in winter excessively cold, and relatively warm in summer. In the Lungau district, Salzburg participates in the rough, inhospitable climate of the upper Mur valley. The author, Dr. A. Fessler, adopts in the main this general subdivision of the climatic conditions in his elaborate discussion, dealing with each district in great detail, and with full consideration of the effects of aspect and altitude on temperature, rainfall, and climate generally. The discussion is based on observations made at stations connected with the Central Institute, but the author is handicapped by the paucity of data in many points of climatological importance; from this point of view Salzburg compares unfavourably with other alpine districts; complete observations for, say, twenty years and upwards only exist for comparatively few stations.

GREAT ADVANCE IN CRYSTALLOGRAPHY.[1]

CRYSTALLOGRAPHY has made such remarkable progress during the last few months, and the position at the present moment is so interesting, that it was considered opportune to review it in a discourse from this historic lecture-table.

Overwhelming evidence has now been brought forward that a crystal is endowed with a definitely organised structure.[2] In the crystal of a pure substance we are dealing with a chemical element or compound, and if with the latter it may be of any grade of complexity, from a very simple binary compound to a most highly complicated one composed of a large number of atoms. If the crystal be that of an element the structure is obviously composed of the similar atoms of that element, while if it be a compound we have a structure composed of atoms of as many kinds as there are chemical elements present combined in the substance, and in the same relative proportion as is expressed by the chemical formula of the substance. In the case of a compound, moreover, the structure may also be considered to be that of the molecules of the substance, for they or a simple arrangement of a small number (group) of them form the grosser units of the structure, whilst the atoms are the ultimate units.

Suppose we now represent this molecular or polymolecular grosser structural unit by a point, and that such point be analogously situated within each unit. The essence of crystal structure then is that these points are so arranged in space that if they are joined along the three directions of space by imaginary lines the latter form a "space-lattice" (German, "Raumgitter"), each unit cell of which may be conceived to be the "brick" already alluded to in the earlier part of the lecture, and the domicile of the chemical molecule or group of molecules (indeed, it is immaterial whether the points are considered as placed at the corners or in the centres of the cells) or, in the case of an elementary substance, of a group of similar atoms. We may, therefore, define a crystal as follows:—

"A crystal of any definite chemical substance consists of a homogeneous arrangement of grosser units of matter, each consisting of one chemical molecule or a small group of molecules of the substance, and the kind of arrangement is such that these grosser units are all identically (sameways, parallel-wise) orientated, and that their analogously chosen representative points, one from each such grosser unit, form a space-lattice (Raumgitter)."[3]

There are fourteen kinds of space-lattices, slides of several of which are exhibited on the screen. Three possess full cubic symmetry, two are tetragonal, four are endowed with rhombic symmetry, and two are monoclinic; while triclinic, trigonal, and hexagonal crystals have each one space-lattice corresponding to their type of symmetry. In every case it is the full (holohedral) symmetry of the system which is present, no space-lattice possessing merely the lower degree of symmetry corresponding to one of the so-called hemihedral or tetartohedral classes of the system in question.

Now in the solid crystal, not only are the grosser

[1] From a discourse delivered at the Royal Institution on Friday, March 14 by Dr. A. E. H. Tutton, F.R.S.

[2] This was very fully illustrated by numerous experiments during the first portion of the discourse.

[3] Since this lecture was delivered (March 14) and printed by the Royal Institution, a paper by Prof. Theodore W. Richards, of Harvard University, has appeared in the Journal of the American Chemical Society for April (vol. xxxv., p. 381), in which he shows that his theory of compressible atoms leads to "crystal units" of precisely the molecular or polymolecular character described in this lecture. He supposes such crystal units to be the entities necessary to relieve metastable supersaturation, and their centres to form the points of the crystal space-grating, assumptions with which the lecturer obviously fully concurs.

units arranged so that their representative points are repeated in space with extraordinary accuracy of position, with production of unit cells or "bricks" of absolutely identical dimensions throughout the crystal, but the shapes of the grosser units themselves are identically similar and identically similarly orientated in space. Suppose, however, that the force of crystallisation, the directive molecular force concerned in bringing the molecules together in this regular order of marshalling, is only adequate just to attain this marshalling of the grosser units into a space-lattice formation, without being able to fix the units about their own centres of gravity, a certain amount of wobbling about the latter being still permitted. We might, in such circumstances, expect that some of the properties of a crystal, dependent on the space-lattice formation on lines of definite symmetry, such as the optical properties of double refraction and polarisation of light, would be developed and exhibited, while the production of exterior plane faces would be either only partial, with rounded edges and the exhibition of plasticity and viscosity, or would not be achieved at all, the objects produced being still fluid. One cause of such a condition of partial success at crystallisation might well be that the substance was composed of a large number of atoms arranged in a long chain, such as the well-known "long chain compounds" of organic chemistry, which would offer considerable resistance to marshalling. The author believes that herein lies the explanation of the remarkable "liquid crystals" which Prof. Lehmann has made the subject of his particular study, many of which are of just such long-chain character.

FIG. 1.—Liquid crystals of ammonium oleate.

By the kindness of Prof. Lehmann, who has sent over specimens of some of the most characteristic of his substances for the special purpose of this lecture, and of Mr. Poser, of Messrs. Zeiss, who construct an admirably convenient form of heating microscope and projection arrangement for demonstrating the formation of liquid crystals and their behaviour in polarised light, it is possible to exhibit some of the typical phenomena of these interesting objects on the screen. The substances in question are chiefly such as form two or more polymorphous forms, each stable within a limited range of temperature, and the liquid crystals are usually the second phase observed on allowing the truly liquid heated substance to cool; the liquid crystal phase is produced at a definite temperature during the cooling, and persists throughout a definite interval of temperature during the continued cooling.[4] The view here put forth is apparently in agreement with that of Lehmann himself, as most recently expressed both in letters to the lecturer and in a memoir of July 27, 1912, to the Heidelberg Akademie der Wissenschaften, in which he says that in all probability: "Die Rundung der Formen hänge zusammen mit der Plastizität der Stoffe und habe ihren Grund in unzureichender molekularer Richtkraft, welche wohl genügt, ein Raumgitter herzustellen, nicht aber regelmässige Treppenstufen, wie es nach Hauys Theorie zur Bildung ebener Krystallflächen nötig wäre." The formation of regular stepped faces (of invisibly minute steps, "Treppenstufen") the lecturer considers to occur only when the grosser units become fixed about their centres of gravity or representative points, with production of a truly solid crystal.

But now let us pass to the consideration of the internal structure of the grosser or space-lattice units themselves. Their symmetry may be, in simple cases, similar to that of the space-lattice, but in general this will not be so. Whatever the stereometric arrangement of the chemical atoms in the molecule may be, and, if more than one molecule goes to form the space-lattice unit, whatever their mutual arrangement, and therefore whatever be the outer configuration of the whole unit, when the crystal is a truly solid one, the force of crystallisation (now no longer denied) is adequate to fix each space-lattice unit, not only considered as a point with reference to its neighbours, but as regards its shape and its whole character, parallelwise and sameways orientated with respect to its adjacent fellows, and as close as possible to them. Also, if more than one molecule goes to each space-lattice unit, their mutual arrangement is achieved on a definite plan, and is the same for every space-lattice unit; these constituent molecules of the latter are also as closely packed as possible. The final result is thus to produce an assemblage of chemical atoms in which not only the demarcation frontier between the space-lattice units disappears, but also that between the constituent molecules in the cases of polymolecular grosser units. We come, ultimately, in consequence, to a structure of atoms each of which we may represent by a point.

Now, just as the genius of Frankenheim and Bravais revealed to us the fourteen kinds of space-lattices, so Sohncke made us acquainted with sixty-five regular systems of points, including many of the thirty-two classes of symmetry, but not all, which von Lang had shown crystals to be capable of possessing. Later the number was brought up to 230 by simultaneous and wonderfully concordant geometrical researches by Schönflies in Germany, von Fedorow in St. Petersburg, and Barlow in England, and among these 230 all the thirty-two crystal classes are represented, and no others.

Hence, we come to the conclusion that the skeletal framework of crystal structure is the molecular or polymolecular space-lattice, and the detailed ultimate

[4] Ammonium oleate (Fig. 1), para-azoxyanisol, para-azoxyphenetol, and cholesteryl acetate were illustrated on the screen.

structure the atomic point-system. The latter determines the class of symmetry (which of the thirty-two classes is exhibited), and therefore governs any hemihedrism or tetartohedrism, as the development of less than full systematic symmetry used to be called. But it is the space-lattice which governs the crystal system, that is, which determines whether the symmetry is cubic, tetragonal, rhombic, monoclinic, triclinic, trigonal, or hexagonal, and also determines the crystal angles and the disposition of faces in accordance with the law of rational indices, the law which limits the number of possible faces to those which cut off small whole-number relative lengths from the crystal axes. Indeed, it is because only those planes which contain the points of the space-lattice are possible as crystal faces that the law of rational indices obtains. For any three points of the space-lattice determine a plane in which similar points are analogously regularly repeated, and which is a possible crystal face obeying the law of rational indices. Moreover, those facial planes which are most densely strewn with points are of the greatest crystallographic importance, being what are known as the primary faces, either parallel to the crystal axes or cutting off unit lengths therefrom, as well as being usually the planes of cleavage.

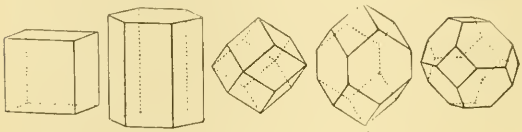

FIG. 2.—Fedorow's types of parallelohedra.

As the space-lattice units are all sameways orientated, any one atom of the molecular or polymolecular grosser unit might be equally well chosen as the representative point of the lattice, so long as a similar choice were made in every space-lattice unit, and the resulting space-lattice would be the same whichever atom were so selected. Consequently, the space-lattice is afforded by the similarly (identically) situated atoms of the same chemical element throughout the crystal structure. The combined point-system (one of the 230 possible point-systems) may thus be considered to be built up of as many identical but interpenetrating space-lattices as there are atoms in the space-lattice grosser unit. These facts are concisely expressed in the definition of crystal structure which was stated as follows by Prof. von Groth at the Cambridge meeting of the British Association in 1904:—

"A crystal—considered as indefinitely extended—consists of n interpenetrating regular point-systems, each of which is formed from similar atoms; each of these point-systems is built up from n interpenetrating space-lattices, each of the latter being formed from atoms occupying parallel positions. All the space-lattices of the combined system are geometrically identical or are characterised by the same elementary parallelepipedon."

Having thus arrived at a comprehensive idea of crystal structure on the assumption of each atom and each grosser space-lattice unit being only a point, as far as which we are on safe and assured ground, we may proceed to the consideration of the various ideas advanced concerning the character of the units of structure thus represented by points; that is, concerning the mode in which the space around the point is more or less filled up.

The valency theory of Barlow and Pope considers the atomic point to be expanded into the sphere of the atom's influence, the relative size of which in any one substance is supposed to be proportional to the fundamental valency of the chemical element of which the atom is composed. The spheres are further assumed to be pressed together on crystallisation until they fill space, becoming thereby deformed into polyhedra. The theory of von Fedorow, on the other hand, considers the grosser or space-lattice units to be parallelohedra; besides those corresponding to the fourteen space-lattices there are nine other parallelohedra (making twenty-three in all) composed of simple Sohnckian point-systems compounded of interpenetrating space-lattices. All the twenty-three parallelohedra are arranged parallelwise, and fill space without interstices. There are, however, only four types, namely the cube, the rhombic dodecahedron (which has a second vertically elongated variety), the cubo-octahedron, and the hexagonal prism, the first three being all of cubic symmetry, and the fourth of obviously hexagonal symmetry. They are shown, including the second variety of the dodecahedron, in the next screen picture (Fig. 2). He further considers that all four may be homogeneously deformed into analogous parallelohedra of lower orders of symmetry, without ceasing to fill space when closely packed. Hence, von Fedorow concludes that all crystal structures are of either cubic or hexagonal type, including not only truly cubic and hexagonal crystals, but their deformed derivatives.

Unlike the atomic polyhedra of Pope and Barlow, these parallelohedra of von Fedorow are either molecular or polymolecular, in the latter event being made up of a small number of identically or symmetrically similar subpolyhedra, termed by him "stereohedra," which represent the chemical molecules, just as already explained, when the grosser space-lattice unit is polymolecular, the stereohedra being arranged to build up

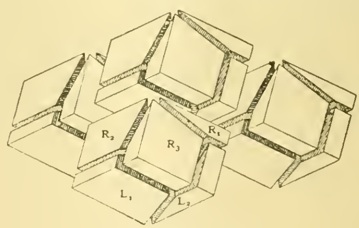

FIG. 3.—Fedorow's stereohedra.

the main parallelohedron (the space-lattice unit) on a definite plan, which may involve mirror-image juxtaposition. For example, a rhombohedral system of stereohedra is shown on the screen (Fig. 3), consisting of two kinds, R and L, one sort being the mirror-image of the other. Each rhombohedron representing the combined system is composed of six stereohedra, three of each kind, and a series of points, similarly situated one within each stereohedron R, would constitute a Sohncke point-system, while a "double-system" is obtained by adding a series similarly situated one within each stereohedron L. If a single point were taken to represent analogously each rhombohedral set of six stereohedra, we should have a rhombohedral space-lattice produced.

The valency theory of Barlow and Pope may or may not in the sequel prove to be correct, and some facts have recently been brought forward by Barker which tend to show that it will not hold in many cases of inorganic substances. Barker, who has had the good fortune to have worked in St. Petersburg with von Fedorow for more than a year, shows that, as the lecturer has always held, the true unit of volume is the molecular or atomic volume, as determined for the particular substance itself. The molecular volume is determinable by dividing the molecular weight of the substance by the specific gravity of its crystals at a definite comparable temperature, such as 20° C., but the determination of the atomic volume offers peculiar difficulty, and so far only comparative and indirect methods have been employed, chiefly by Sollas. By taking the volumes of the spherical units to be proportional to the atomic volumes (not those of the element in the free state, as enormous compression occurs on combination), and also determining the amount of free interstitial space by comparative methods of calculation, Sollas has achieved some remarkable explanations of the crystallographic characters of the two polymorphous forms of silver iodide and of the three forms of titanium dioxide, rutile, anatase, and brookite. It would not be surprising if the valency volumes of Barlow and Pope, in the cases of those elements for which their theory appears to work in a satisfactory manner, turn out to be identical with the atomic volumes as determined by the method of Sollas. As regards the compounds of carbon and hydrogen, Barlow and Pope have been most successful in accounting for crystallographic and chemical relationships, and it is at least significant that both Le Bas, from experimental work on the molecular volumes of liquid hydrocarbons, and Traube from an entirely different point of view, concur in assigning the relative volumes 4 and 1 to carbon and hydrogen atoms in combination respectively. If Traube's results for carbon and hydrogen be acccepted, so must also those for the relative volumes of the atoms of the halogens, sulphur, oxygen, and nitrogen, his values being: $F=1$; Cl, Br, and $I=7$ each; $S=6$; $O=2$; and $N=3$. As regards oxygen and nitrogen, he agrees with Barlow and Pope, but the latter take all the halogens as of unit valency volume, and sulphur as of valency volume 2. Barker shows that while in the binary sulphides, such as zinc sulphide ZnS, the sulphur is probably of volume 2, in the sulphates, such as K_2SO_4 and $BaSO_4$, it is probably 6, as Traube insists; this conclusion is also in agreement with other work of Barker on some extraordinary cases of isomorphism, including that of barium sulphate with potassium perchlorate $KClO_4$, potassium permanganate $KMnO_4$, and the extraordinary compound potassium borofluoride KBF_4.

While it would thus appear that the atomic volume (in the substance itself, and including any interspace) is the true effective volume concerned in crystal structure, and that it may be only a coincidence that, in the cases of a few prominent elements, it happens to be approximately proportional to the valencies of those elements (as certainly appears to be true in the cases of hydrogen and carbon, and possibly oxygen and nitrogen), there is a very considerable amount of the joint work of Barlow and Pope which is of permanent value. Their explanations of the preponderating cubic and hexagonal crystalline forms of the elements themselves, and of binary compounds such as ZnS, are doubtless correct, and it will be of great interest, in view of the next development to which attention must be directed, to illustrate the case of zinc sulphide.

Barlow and Pope's idea of the structure of zinc blende, which merely assumes that the volumes of the atoms of zinc and sulphur are approximately equal, is that sixteen molecules ZnS go to form the grosser unit of the crystal structure, the combined system or space-lattice unit—that is, sixteen atoms of zinc and sixteen of sulphur. Only one zinc or one sulphur atom in every sixteen is sameways orientated, and if we adopt von Groth's definition, we may give the structure of zinc blende as follows:—The crystals of zinc blende consist of two interpenetrating regular point-systems, one formed from zinc atoms, and the other from sulphur atoms; each of these two point-systems is built up from sixteen interpenetrating space-lattices, each of the latter being formed from zinc atoms or from sulphur atoms occupying parallel positions. All the thirty-two space-lattices of the combined system are geometrically identical.

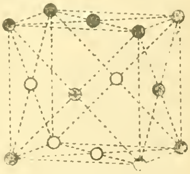

FIG. 4.—Space-lattice of centred-face cube.

Barlow and Pope have shown that the space-lattice in zinc blende is the third cubic one, in which a point is situated at each cube corner and also in the centre of each cube face. For this is the space-lattice corresponding to an assemblage of spheres of equal volume in closest packing. The space-lattice in question is shown on the screen (Fig. 4), and a pair of models of the arrangement are illustrated in the next two pictures, in the first of which the points are expanded into spheres of considerable size, and in the second they appear still further expanded into actual contact. The third stage, in which the expansion proceeds until all interstices are filled up and the spheres are converted into polyhedra, is left to the imagination. In the second picture (reproduced in black and white in Fig. 5) the mutual arrangement

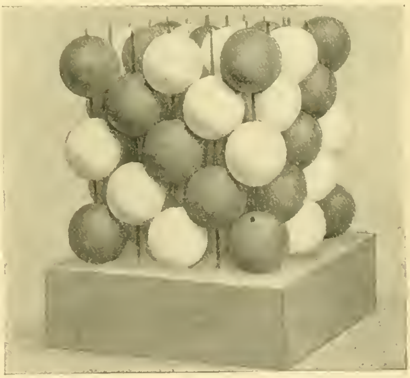

FIG. 5.—Model of arrangement of zinc atoms (shaded) and sulphur atoms (light) in zinc blende.

of the spheres of the two elements in zinc blende, zinc and sulphur, is indicated by the yellow colouring of the sulphur spheres and the grey tinting of those of zinc. The tetrahedral mode of derivation of the structure, accounting for the observed hemihedrism, is also shown in another slide (Fig. 6). The eight larger cubes which together form the grosser unit are each supposed to be occupied by four smaller cubes of the same element, arranged tetrahedrally, and of zinc and of sulphur alternately in different larger cubes; on replacing the little cubes by spheres in contact the model represented in the second picture (Fig. 5) is produced.

Now this crystalline mineral, zinc blende, has been chosen advisedly as an example of crystal structure. For a remarkable series of experiments have recently been carried out by Laue, Friedrich, and Knipping at Munich, where the lecturer had the advantage of seeing some of the first photographic results last summer. In these experiments X-rays were passed through crystals of various substances, notably zinc blende, and, in more recent experiments by Laue at Zurich,

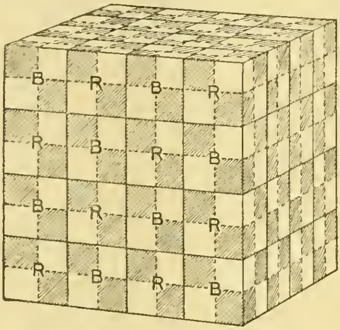

Fig. 6.—Scheme of tetrahedral arrangement of zinc (B) and sulphur (R) atoms in zinc blende. Unshaded cubes unoccupied.

quartz. The issuing rays were received on a photographic plate, on which they recorded a pattern of spots having the symmetry (full holohedral) of the space-lattice present as the foundation of the crystal structure. These interesting photographs thus afford the first experimental and visible proof of the truth of the structure assigned to crystals by geometricians and crystallographers.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—At the annual Degree Congregation the degree of Doctor of Science was conferred on the following:—E. E. Fournier d'Albe, Hamilton McCombie, George William Todd, and Donald Levy. The occasion was also marked by the unveiling of a fine portrait of the Chancellor (the Right Hon. Joseph Chamberlain), the generous gift of Mrs. Chamberlain, "as a token of my own interest in all that concerns the University, and my earnest hope that future generations will see it develop into all that its founders dreamed of when it was established."

Edinburgh.—The honorary degree of LL.D. was conferred on July 4 by the University on Mr. H. A. L. Fisher, Vice-Chancellor of the University of Sheffield; Emeritus Professor Greenfield; Sir James Guthrie; Lord Justice Hamilton; Mr. John Stewart, Nova Scotia; Prof. F. Strassmann, Berlin; Prof. J. Arthur Thomson; the Hon. James Wilson, Washington, U.S.A.; and (*in absentia*) Prof. Thomas Gilray, University of Otago, N.Z.

Prof. C. G. Barkla, F.R.S., professor of physics in the University of London (King's College), has been appointed to the vacant chair of Natural Philosophy, in succession to the late Prof. J. G. MacGregor.

Prof. J. W. Judd, C.B., F.R.S., has been appointed emeritus professor of geology in the Imperial College of Science and Technology by the council of the college.

Mr. Andrew Carnegie has intimated to M. Liard, Vice-Rector of the University of Paris, that he will give 4000*l.* towards the construction of the new chemical institute which is being erected in the Rue Pierre-Curie, Paris.

Dr. L. H. Bailey, widely known as the chairman of President Roosevelt's commission on country life, has resigned the post of head of the New York State College of Agriculture, Cornell University, after a tenure of ten years. He has held the professorship of agriculture at Cornell since 1883. Dr. Bailey is resigning in order to secure more time for research.

Among recent Irish appointments we notice that Prof. Gregg Wilson, professor of zoology in Queen's University, Belfast, has been appointed a member of the first Senate of the University in succession to the late Prof. John Park. Mr. Edgar H. Harper has been appointed professor of mathematical physics in University College, Cork, and Mr. E. W. Hoare lecturer in veterinary hygiene in the same college.

Recent changes at Johns Hopkins University include the promotion of Dr. J. E. Gilpin, now associate professor of chemistry, to be collegiate professor, and of Mr. E. W. Berry, now associate in palæobotany, to be associate professor of palæontology. Prof. D. S. Johnson is appointed to the directorship of the botanical laboratory and the botanical garden, and Prof. Burton E. Livingston to the directorship of the laboratory of plant physiology.

Columbia University and Rutgers College receive bequests which may amount to 200,000*l.* each as principal beneficiaries under the will of Mrs. Mary B. Pell, the widow of John H. Pell. *Science* states that each beneficiary received a direct bequest of 40,000*l.* and an interest in large trust funds amounting to more than 400,000*l.* The fund for Columbia is to erect Pell Hall, in memory of the late Mr. Pell, who was a student of Columbia. From the same source we learn that Princeton University has received 20,000*l.* from Mrs. Russell Sage toward the construction of a dining-hall; and that the College of Agriculture of Cornell University has received a State grant of 90,000*l.*, and a grant of 14,000*l.* for the veterinary college. A part of the additional grant this year is to be used for increasing salaries.

Recent correspondence between the Maharaja of Darbhanga, who is at the head of the movement to create a Hindu University in India, and Sir Harcourt Butler, the education member of the Governor-General's Council, has, we learn from *The Times*, been published. The Maharaja points out that the subscriptions promised amount to more than 533,333*l.*, of which about 140,000*l.* has been received. Taking into account the capital value of certain grants of property and annual payments in perpetuity granted by three ruling chiefs, he estimates the amount in hand, or which may be safely taken as already in hand, to be not far short of 400,000*l.*, exclusive of the value of the Central Hindu College at Benares. He claims that a good case had been made out financially for the Government to take into consideration the legislation necessary for bringing the University into being. Sir Harcourt Butler has replied that the matter is still under consideration; but he thinks it will be of assistance to the promoters to know the conditions which the Government of India regards as precedent to the introduction of any scheme. These are the provision of a suitable site; the transfer of the Central Hindu College to the University; and the collection of not less than 333,333*l*. In this amount may be included the capitalised value of the property mentioned by the Maharaja, and the perpetual grants by three ruling chiefs, provided that the documentary title is satisfactory in the case of the latter, and the possession of the property has been made over in the case of the former. The further conditions are that the constitution of the University should proceed on lines to be indicated by the Government, and that a committee be appointed to report whether the Central Hindu College is fit to be developed into a residential and teaching university.

THE unusual increase in the number of women attending German universities, as shown by statistical returns recently issued in Germany, is of particular interest in view of the fact that women were only admitted as students in the summer of 1905. A note in the issue for July 4 of the Journal of the Royal Society of Arts states that during 1912 the number of women students in German universities has grown from 2795 to 3213, and the percentage of women now in the universities, as compared with the whole student body, is 5·4 per cent., as against 2·7 per cent. three years ago. Of the present body of women students the great majority—2900—come from Germany. Of the foreign women, Russia furnishes more than a third, America about a fourth, and other European countries most of the others. Few women students come from Asia, Africa, or Australia. The University of Berlin alone has more than one-fourth of the total women students of the Empire, the exact number of women in the large universities at present being:—Berlin, 904; Bonn, 289; Munich, 262; Göttingen, 237; Heidelberg, 219; Freiburg, 189; Münster, 172; Breslau, 150; Leipzig, 129; Marburg, 126; Königsberg, 107; Greifswald, 83; Halle, 81; Jena, 65; Strassburg, 52; Kiel, 40; Tübingen, 38; Giessen, 24; Erlangen, 21; Würzburg, 16; Rostock, 6; all others, 3. The departments of study to which the women students give preference are about the same as in former years, the enrolment in certain courses being:—Medicine, 702; mathematics and natural sciences, 579; economics and agriculture, 91; dentistry, 17; and pharmacy, 8.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 26.—Sir Ronald Ross, K.C.B., vice-president, in the chair.—F. S. **Phillips**: Phosphorescence of mercury vapour after removal of the exciting light.—Dr. G. J. **Burch**: Light sensations and the theory of forced vibrations.—P. W. **Burbidge**: The fluctuation in the ionisation due to γ rays.—J. G. **Leathem**: The force exerted on a magnetic particle by a varying electric field.—Dr. W. **Watson**: The luminosity curve of a colour-blind observer.—Prof. W. M. **Hicks**: A critical study of spectral series. Part iii.: The atomic weight term, and its import in the constitution of spectra.—L. C. **Martin**: A band spectrum attributed to carbon monosulphide. A complex band system occurring in the spectrum of the electric discharge through carbon disulphide vapour in addition to the bands due to sulphur, is also found in the spectrum given by sulphur in the carbon arc. These bands only occur in the presence of both sulphur and carbon, and are probably due to carbon monosulphide.—Igerna B. J. **Sollas** and Prof. W. J. **Sollas**: The structure of the skull of Dicynodon as revealed by serial sections. The structure of the skull has been demonstrated in a remarkably complete manner by reconstructions built up from serial sections. A single example has afforded nearly all the information which has been slowly accumulated from numerous specimens during the past half-century and has added the following facts, which are either new or were in need of confirmation:—(1) The vomer is grooved on its dorsal surface; (2) the basis cranii is continued forwards between the orbits as a median vertical plate, which lies in the groove of the vomer, and is itself grooved on the dorsal surface to receive the ventral edge of the mesethmoid; (3) the form of the mesethmoid is such as to suggest that it is an early stage in the formation of a cribriform plate; (4) septo-maxillary bones are present, lying within the internal nares without appearing on the face. They are not connected by suture with neighbouring bones and might easily be lost in fossilisation; (5) the preparietal bone is present, situated entirely in front of the pineal foramen and forming its anterior border; (6) a transverse bone exists, clearly marked off from the neighbouring bones by sutures; (7) the root of the tusk, invested by a thin layer of the maxillary bone, lies in a large cavity, to the walls of which the maxillary, lachrymal, jugal, and palatine bones contribute; (8) the sutures separating the pro-otic from neighbouring bones are clearly exhibited; (9) the labyrinth of the ear shows all the three canals with their ampullæ and a long vestibule; (10) the articular surface of the lower jaw is complex, there is a small inner portion which is concave—as in reptiles, and a large outer portion which is convex—as in mammals.—W. **Cramer** and R. A. **Krause**: Carbohydrate-metabolism in its relation to the thyroid gland. The effect of thyroid feeding on the glycogen content of the liver and on the nitrogen distribution in the urine.—Dr. G. W. C. **Kaye** and D. **Ewen**: The sublimation of metals at low pressures.—Dr. R. T. **Beatty**: The energy of Röntgen rays.—Dr. C. **Chree**: Some phenomena of sun-spots and of terrestrial magnetism. Part ii. The paper is a continuation of one termed for brevity S.M., which appeared in the Phil Trans., A. 212, p. 75. It is mainly devoted to the question of the existence of a period of approximately twenty-seven days in terrestrial magnetic phenomena. Independent studies of magnetic storms during a very long period of years at Greenwich and Toronto led Mr. Harvey and Mr. Maunder a good many years ago to the conclusion that an interval of about twenty-seven and a quarter days could be recognised between the commencements of successive magnetic storms in a greater number of cases than could reasonably be ascribed to pure chance. S.M. showed that whether one took the daily range of horizontal force at Kew, or the magnetic character of the day, there undoubtedly existed for the epoch 1890 to 1900 a period of twenty-seven days or slightly more, in the sense that if an individual day were highly or moderately disturbed, days twenty-seven or twenty-eight days later were on the average more disturbed than usual. The result was not peculiar to the large disturbances usually termed "magnetic storms," and appeared in all the years examined, whether quiet or disturbed. The present paper finds the same result to hold true of the years 1906 to 1911 when use is made of the magnetic "character" figures which have been published since 1906 at de Bilt, under international auspices. It is also found that the result is as true of quiet as of disturbed characteristics. The paper also investigates whether the phenomena presented by the twenty-seven-day period vary with the period of the year, and what the relationships are, if any, between magnetic "character" and Greenwich measures of sun-spot area and faculæ and Wolfer's sun-spot frequencies. The apparent sun-spot relationships are found to vary a good deal from year to year.—A. **Fowler**: New series of lines in the spark spectrum of magnesium. From experiments on the spectrum of the magnesium arc *in vacuo*, it has been found that there are seven lines which are associated with the well-known spark line 4481·35, their wave-lengths being 3104·91, 2661·00, 2449·68, 2329·68, 2253·94, 2202·75, and 2166·35. The eight lines, taken alternately, fall into two series having their common limit at 49776 on the frequency scale. The series are analogous to the two principal series of hydrogen lines, which have recently been investigated by the author. A. **Fowler** and W. H. **Reynolds**: Additional triplets and other series lines in the spectrum of magnesium. The paper gives particulars of eight new triplets which have been photographed in the ultra-violet spectrum of magnesium, and improved wave-lengths for some of the lines previously recorded. The Rydberg series of single lines has also been extended, and four strong solar lines of previously unknown origin have been identified with lines of this series. Attention is also directed to a probable second subordinate series of single lines. Formulæ representing the various series are given.—W. E. **Curtis**: A new band spectrum associated with helium. The paper describes a new band spectrum observed under certain conditions in vacuum tubes containing helium and hydrogen. The experiments suggest that the bands are due to helium, but until hydrogen can be more completely eliminated their origin cannot be regarded as definitely settled.—Sir W. de W. **Abney** and Dr. W. **Watson**: A case of abnormal trichromatic colour vision due to a shift in the spectrum of the green sensation curve.—Dr. E. F. **Armstrong** and Prof. H. E. **Armstrong**: Studies on the processes operative in solutions (XXX) and on enzyme action (XX). The nature of enzymes and of their action as hydrolytic agents.—Prof. H. E. **Armstrong** and H. W. **Gosney**: Studies of enzyme action. XXI. Lipase. III.—Prof J. S. **Macdonald**: Studies in the heat production associated with muscular work. Preliminary communication.—Prof. F. **Keeble**, Dr. E. F. **Armstrong**, and W. N. **Jones**: The formation of the Anthocyan pigments of plants. Part vi.—T. Graham **Brown**: The question of fractional activity ("All or None" phenomenon) in mammalian reflex phenomena.—J. H. **Andrew** and Dr. A. **Holt**: The thermal effects produced by heating and cooling palladium in hydrogen.—Hon. R. J. **Strutt**: A peculiar form of low potential discharge in the highest vacua.—A. **Mallock**: Note on copying machinery.—W. **Wahl**: The relation between the crystal-symmetry of the simpler organic compounds and their molecular constitution. Part ii.—G. A. **Shakespear**: Experiments on the temperature coefficient of a Kew collimator magnet.—W. **Jevons**: Spectroscopic investigations in connection with the active modification of nitrogen. III.: Spectra developed by the tetrachlorides of silicon and titanium.—Lord **Rayleigh**: The passage of waves through fine slits in thin opaque screens.—Prof. W. H. **Bragg**: The reflection of X-rays by crystals. II. In a previous communication (April, 1913) it was shown that the wave-lengths of homogeneous pencils of X-rays could be expressed accurately in terms of the space relations of a crystal. The formula $\lambda = 2d \sin \theta$ connected the wave-length λ with θ, the glancing angle at which the pencil was reflected in the crystal face, and d the distance between parallel reflecting planes. The angle θ could be determined with accuracy, but want of exact knowledge of crystal structure threw difficulties in the way of a complete evaluation of wave-length. W. L. Bragg, using two independent methods of research (those of the Laue diagram, and of reflection in the crystal face), has shown that in all probability the value of d is $2{\cdot}81 \times 10^{-8}$ cm. From this it follows that the wave-length of the "B peak" is $1{\cdot}10 \times 10^{-8}$. Characteristic radiations having wave-lengths $1{\cdot}25 \times 10^{-8}$ and $1{\cdot}66 \times 10^{-8}$ are emitted by bulbs having antikathodes of tungsten and nickel respectively. So far as it has been found possible to measure the absorption coefficients, they belong to rays which are characteristic of the antikathode metals, and the quantum energy—Planck's constant multiplied by frequency—agrees well with the energy of the kathode ray which, according to Whiddington, is required to excite the X-ray, or which the X-ray can excite.—W. L. **Bragg**: The structure of some crystals as indicated by their diffraction of X-rays. An analysis of the Laue diagram of sylvine (KCl) shows that the diffracting centres are arranged on a space-lattice of the simplest cubical form. The diagrams of potassium iodide and bromide show that the diffracting centres are arranged on a lattice the element of which is the face-centred cube. Sodium chloride is an intermediate case. From this and other features of the diagrams, it is concluded that in all these crystals the atoms of metal and halide are arranged in a simple cubic lattice, rows parallel to the axes containing alternate atoms of either kind. In sylvine the equal weights of the atoms render them equally efficient as centres; in KBr and KI the heavy halogen atoms alone act, and so the pattern is characteristic of the face-centred cube lattice. The diagrams of other crystals are discussed in reference to these conclusions. By means of the X-ray spectrometer, described in a previous paper, the dimensions of these lattices can be accurately compared; and the relative magnitudes of the different orders of spectra reflected from any face, and from different crystals, yield information which confirms the above conclusions. It also appears that the weight associated with each point of the lattice is proportional to the molecular weight of the substance. These conclusions yield the necessary information for the accurate calculation of the wave-length of the X-ray.—Leonard **Hill**, J. M. **McQueen**, and W. W. **Ingram**: The resonance of the tissues as a factor in the transmission of the pulse and in blood pressure.—G. F. **Davidson**: Experiments on the flow of viscous fluids through orifices.

Linnean Society, June 19.—Prof. E. B. Poulton, president, in the chair.—E. G. **Baker**: African species of the genus Crotalaria. Short descriptions are given of the 309 species known to the writer as occurring in Africa. These are arranged in the following groups:—Simplicifoliæ, 39; Sphærocarpæ, 65; Chrysocalycinæ, 7; Farctæ, 5; Spinosæ, 3; Eucrotalaria, subdivision Grandifloræ, 29; subdivision Mediocrifloræ, 61; subdivision Parifloræ, 49; subdivision Oliganthæ, 33; subdivision Stipulosæ, 18. The genus Crotalaria is allied to Lotononis, and it is generally easily distinguishable by the rostrate carina.—Dr. W. T. **Calman**: Aphareocaris, nom. nov. (Aphareus, Paulson), a genus of the Crustacean family Sergestidæ.—Dr. Agnes **Arber**: An anatomical study of the cone-genus Lepidostrobus.—G. H. **Wailes**: Freshwater Rhizopoda from North and South America. During the year 1912 gatherings from the States of New York, New Jersey, and Virginia provided records of twenty-four species and varieties of Rhizopoda, in addition to those enumerated in the paper read before the society in April, 1911. A number of gatherings received from Mr. James Murray and collected by him from various places on the east and west coasts of South America were examined, and provided records of seventy-five species and varieties of Rhizopoda, including three now described for the first time.—C. **Bucknall**: A revision of the genus Symphytum.—S. **Kemp**: Pelagic Crustacea Decapoda of the Percy Sladen Expedition in H.M.S. *Sealark*.

PARIS.

Academy of Sciences, June 30.—M. P. Appell in the chair.—Paul **Sabatier** and M. **Murat**: The preparation of several diphenylpentanes and some corresponding di*cyclo*hexylpentanes. Three of the eighteen possible isomeric diphenylpentanes have been prepared, and these have been transformed by direct addition of hydrogen in presence of nickel into the corresponding di*cyclo*hexylpentanes, the physical constants of the latter being given.—M. de **Forcrand**: The hydrates of uranic anhydride and the heat of formation of uranyl nitrate.—R. **Lépine** and M. **Boulud**: The diminution in chlorides in urine secreted under pressure. Additional experiments confirming results published in previous papers.—M. **Arnaud**: Astronomical refraction under any angle whatever. In a previous communication a formula for refraction was given and the integration solved for the particular case of horizontal refraction. In the present paper this is extended, and practical formulæ deduced giving an accuracy of $0 \cdot 1''$.—A. **Korn**: Integral equations with asymmetrical nucleus.—Ed. **Sarasin** and Th. **Tommasina**: A new study of the Volta effect made with the aid of the induced radio-activity.—Pierre **Weiss**: The magnetic fields obtained with an electromagnet furnished with ferro-cobalt pole-pieces. By the use of ferro-cobalt pole-pieces in place of soft iron an increase of about 5 per cent. in the strength of the magnetic field is obtained, the ampere turns remaining constant.—C. **Chéneveau**: The optical properties of water and its physical constitution. The variations in the optical constants of water with temperature are in agreement with the hypothesis that liquid water is a mixture of two isomers, in proportion varying with the temperature, and possessing properties depending only slightly or not at all on the temperature.—M. **Guéritot**: A thermo-electric manoscope of great sensibility. A portion of the air in a tube connecting two reservoirs is continuously heated near a bend constituting the highest point of the system. The slightest motion of this heated air is shown by a thermocouple; a displacement of gas amounting to only a tenth of a cubic millimetre is shown. Various applications of the apparatus are indicated.—Keivin **Burns**: A displacement of the lines of the spectra of certain metals produced by the presence of another metallic vapour. The cases of barium in an iron arc, manganese in an iron arc, and cadmium in a mercury arc have been studied, and it has been found that the lines of the metal present in small proportion are displaced by the vapour of the predominating metal (iron, mercury). This effect may account for some differences proved to exist between wave-lengths found in the arc and in the sun.—L. **Gay**: Adiabatic expansion in liquids. Data are given for the coefficient of adiabatic compressibility of eight liquids at 0° C. and at room temperatures.—Victor **Henri**: Chemical lability and absorption of the ultra-violet rays. Experimental results are cited in support of the proposition that bodies of which the molecules are labile, or which enter easily into reactions, absorb the ultra-violet rays strongly.—Witold **Broniewski**: The thermo-electricity of steel. It is shown that the thermo-electromotive force may give indications of the critical points of steels with equal or higher precision than the other methods in current use.—N. D. **Costeanu**: The action of carbon dioxide upon mineral sulphides. The sulphides of silver, copper, cadmium, bismuth, and antimony undergo no change when heated in a current of carbon dioxide; silicon sulphide gives carbon monoxide, sulphur, and silica under the same conditions.—P. **Lebeau** and A. **Damiens**: The composition of the gaseous mixtures resulting from the action of water upon the carbides of uranium and thorium. The method previously described by the authors for the analysis of complicated hydrocarbon mixtures, based on the use of low temperatures, has been applied to the analysis of the gases arising from the decomposition of uranium and thorium carbides by water. Five complete analyses are given.—Daniel **Berthelot** and Henry **Gaudechon**: The preparation of carbon oxycyanide. This substance is produced by the action of the silent discharge on a mixture of carbon monoxide and cyanogen.—André **Meyer**: The azoic colouring matters derived from phenylisoxazolone.—Léo **Vignon**: The composition of water-gas. A small proportion of methane appears to be normally present in water-gas; the amount of this gas is shown to increase with the amount of lime present in the coke.—J. **Clarens**: The existence of bromites. Evidence is adduced in support of the existence of a bromite in a solution of a hypobromite which has been heated for a short time to 80° C.—L. **Daniel** and J. **Delpon**: A grafted hybrid between the peach and the almond.—P. **Choux**: The genus Baseonema at Madagascar.—H. **Devaux**: The pressure of the air in the lacunæ of aquatic plants. The pressure of the internal atmosphere of an aquatic plant when submerged is equal to that of the dissolved gases.—M. **Wilmet**: The okapi. Study of an okapi kept in captivity for one month.—J. **Bounhiol**: New observations on the reproduction of the Algerian sardine.—H. **Bierry** and Mlle. Lucie **Fandard**: Variations of glycemia during inanition.—E. **Gley** and Alf. **Quinquaud**: The action of thyroid extract on the super-renal secretion.—R. **Robinson**: The genital glands and the dental system.—Albert **Robin**: Researches on the variations of phosphoric acid in the urine and liver of cancer subjects.—J. **Ville** and E. **Derrien**: Biochemical catalysis of a luminescent oxidation.—F. **Jadin** and A. **Astruc**: Arsenic and manganese in young and old leaves.—Pierre **Thomas**: The proteid substances of yeast. The albumenoid material derived from yeast is shown to be intermediate in properties between casein and egg albumen. It is provisionally named cerevisine.—Gabriel **Bertrand** and H. **Agulhon**: The presence of boron in milk and in eggs. The milk from four animals and eggs from five species of birds were proved to contain boron.—H. **Pottevin** and H. **Violle**: The comma bacillus and its toxins.—Alphonse **Berget**: A simplified barometric formula for the determination of heights. The formula proposed is $Z = D(t+269)/h$, in which Z is the difference of height, D the difference of pressures read on the barometer at the two stations, h the mean barometric pressure, and t the mean temperature. For heights below 3000 metres the agreement between this arithmetical formula and the usual logarithmic expression is shown by examples to be very close.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2281, VOL. 91] THURSDAY, JULY 17, 1913 [PRICE SIXPENCE.

Registered as a Newspaper at the General Post Office.]

CITY & GUILDS TECHNICAL COLLEGE, FINSBURY.

(LEONARD STREET, CITY ROAD.)

For students who are preparing to become engineers or chemists, and for engineering pupils who desire to supplement their practical training by a two years' course in the principles of engineering science. The instruction is mainly given in the various laboratories.

The subjects of the Entrance Examination are Mathematics and English ; but the Matriculation of any British University is accepted instead.

The Courses in Mechanical and Electrical Engineering cover a period of two years, and those in Chemistry three years. There are arrangements also for three-year courses in Engineering for those who desire. Fees £20 per annum.

PROFESSORS :

Electrical Engineering and Physics ... ... SILVANUS P. THOMPSON, D.Sc., F.R.S. (Principal of the College).

Civil, Mechanical Engineering & Mathematics E. G. COKER, M.A., D.Sc., M.Inst.M.E.

Chemistry ... ... RAPHAEL MELDOLA, D.Sc., F.R.S., F.I.C.

City and Guilds of London Institute.

EAST LONDON COLLEGE

(UNIVERSITY OF LONDON).

Faculties of Arts, Science, and Engineering.

FEES: TEN GUINEAS PER ANNUM.

NO ENTRY FEE & NO REGISTRATION CHARGES.

Special fees and facilities for Post Graduate and Research Students in all Faculties.

M.A. CLASSES FOR MATHEMATICS.

Calendar, with lists of Graduates, University and College Scholarships, Academic and other distinctions, post free on application to the Registrar, or the Principal,

J. L. S. HATTON, M.A.

Telephone No: East 3384.

UNIVERSITY COLLEGE, NOTTINGHAM.

Principal—W. H. HEATON, M.A.

The SESSION 1913–1914 begins on SEPTEMBER 29. The College provides complete Courses for the Examinations of London University for Degrees in :—

ARTS, SCIENCE,
ECONOMICS, ENGINEERING,
MINING.

And also complete Courses for Diplomas in :—

EDUCATION, CHEMISTRY,
COMMERCE, ENGINEERING,
MINING.

Particulars and prospectus may be obtained from the Registrar,

T. P. BLACK, M.A., Ph.D.

UNIVERSITY OF MANCHESTER.

FACULTY OF MEDICINE.

(Medical, Dental, Public Health and Pharmaceutical Departments.)

The WINTER SESSION will commence on WEDNESDAY, OCTOBER 1st. The courses given at the University, The Royal Infirmary and other allied Hospitals, which contain over 1,000 beds, provide full instruction for the Degree and Diploma Examinations in Medicine and Dentistry, and for the Diplomas in Public Health, Psychological Medicine, Veterinary State Medicine and Pharmacy. There are Halls of Residence both for Men and Women Students. In addition to Two Entrance Medical Scholarships, each of the value of £100, there are other Entrance Scholarships tenable in the Medical School.

Prospectuses, giving full information as to courses of study, fees, &c., will be forwarded on application to the REGISTRAR.

BIRKBECK COLLEGE,

BREAMS BUILDINGS, CHANCERY LANE, E.C.

Principal : G. Armitage-Smith, M.A., D.Lit.

COURSES OF STUDY (Day and Evening) for the Degrees of the UNIVERSITY OF LONDON in the

FACULTIES OF SCIENCE & ARTS

(PASS AND HONOURS)

under RECOGNISED TEACHERS of the University.

SCIENCE.—Chemistry, Physics, Mathematics (Pure and Applied), Botany, Zoology, Geology and Mineralogy.

ARTS.—Latin, Greek, English, French, German, Italian, History, Geography, Logic, Economics, Mathematics (Pure and Applied).

Evening Courses for the Degrees in Economics and Law.

SESSIONAL FEES { *Day:* Science, **£17 10s.**; Arts, **£10 10s.** / *Evening:* Science, Arts, or Economics, **£5 5s.** }

POST-GRADUATE AND RESEARCH WORK.

Particulars on application to the Secretary.

SOUTH-WESTERN POLYTECHNIC INSTITUTE,

MANRESA ROAD, CHELSEA, S.W.

Day Courses under recognised Teachers in Preparation for London University Degrees in Mechanical and Electrical Engineering, in Chemistry, Physics and Natural Science; and Technical Courses arranged to extend over Three Years and Prepare for Engineering, Electrical, Chemical and Metallurgical Professions. Session Fee, £15.

Evening Courses in all Departments :—

Mathematics—*J. LISTER, A.R.C.S., *T. G. STRAIN, M.A.; Physics—*S. SKINNER, M.A., *L. LOWNDS, B.Sc., Ph.D., *F. W. JORDAN, B.Sc.; Chemistry—*J. B. COLEMAN, A.R.C.S., *J. C. CROCKER, M.A., D.Sc., and *F. H. LOWE, M.Sc.; Botany—*H. B LACEY, S. E. CHANDLER, D Sc., and *W. RUSHTON, A R.C.S., D.I.C.; Geology—*A. J. MASLEN, F.G.S., F.L.S.; Human Physiology—E. L. KENNAWAY, M.A., M.D.; Zoology—*J. T. CUNNINGHAM, M.A.; Engineering—*W. CAMPBELL HOUSTON, B.Sc., A.M.I C.E., *V. C. DAVIES, B.Sc., and H. AUGHTIE; Electrical Engineering—*A. J. MAKOWER, M.A., *B. H. MORPHY, and U. A. OSCHWALD, B.A.

*Recognised Teacher of the University of London.

Prospectus from the SECRETARY, post free, 4*d.*; at the Office, 1*d.*

Telephone : 899 Western. SIDNEY SKINNER, M.A., Principal.

UNIVERSITY OF MANCHESTER.

PHYSICS DEPARTMENT.

A Prospectus giving full particulars of the Lecture and Laboratory Courses in Physics, preparing for both the Ordinary and Honours Degrees, will be forwarded on application to the REGISTRAR. Professor RUTHERFORD will meet intending Students on Thursday, October 2, at 10.30 a.m.

BATTERSEA POLYTECHNIC, S.W.

The Governing Body require the services of a LECTURE ASSISTANT and LABORATORY STEWARD in the CHEMICAL DEPARTMENT. Wages 30*s.* to 35*s.* per week. For particulars send stamped addressed envelope to the SECRETARY.

UNIVERSITY COLLEGE, READING.

PROFESSOR OF MATHEMATICS.

The Council are about to appoint a PROFESSOR OF MATHEMATICS. Applications must be received by July 21. Particulars can be obtained from the REGISTRAR of the College.

THE UNIVERSITY OF LIVERPOOL.

The Council invite applications for the post of ASSISTANT LECTURER in PHYSIOLOGY and LECTURER in EXPERIMENTAL PSYCHOLOGY. Duties to commence with the Autumn Term. Salary £150. Applications should be forwarded to the undersigned (from whom further particulars may be obtained) on or before July 31.

P. HEBBLETHWAITE, M.A., Registrar.

UNIVERSITY COLLEGE OF NORTH WALES, BANGOR.

(*A Constituent College of the University of Wales.*)

Applications are invited for the post of ASSISTANT LECTURER in MATHEMATICS. Salary £140.

Applications and testimonials should be received not later than Saturday, September 13, by the undersigned, from whom further particulars may be obtained.

JOHN EDWARD LLOYD, M.A.,
Secretary and Registrar.

July 11, 1913.

THURSDAY, JULY 17, 1913.

ARISTARCHUS OF SAMOS.

Aristarchus of Samos: The Ancient Copernicus. A History of Greek Astronomy to Aristarchus together with Aristarchus's Treatise on the Sizes and Distances of the Sun and Moon. A New Greek Text with Translation and Notes. By Sir Thomas Heath, K.C.B., F.R.S. Pp. viii+425. (Oxford: Clarendon Press, 1913.) Price 18*s*. net.

ARISTARCHUS, who flourished in the first half of the third century B.C., is chiefly known as the only philosopher or astronomer of antiquity who taught that the earth moves round the sun. This doctrine is, however, not mentioned in the only writing of his which has been preserved, and the little we know about it is derived from allusions to it made by subsequent writers. All the same, his little book, "On the Sizes and Distances of the Sun and Moon," is of great importance, and Sir Thomas Heath's new and critical edition, accompanied by a translation, commentary, and notes, is therefore a most welcome addition to the literature of astronomical history.

Considering that the idea of the earth being in the centre of the universe reigned undisturbed until less than four hundred years ago, it is one of the most surprising facts in the history of astronomy that its motion round the sun should have been proposed more than 1700 years before the time of Copernicus, and that it should only have been accepted by one single philosopher, Seleukus, as to whom it is not even certain that he went the whole way and did not merely accept the daily rotation of the earth. The editor of this new edition of Aristarchus, therefore, thought it desirable to prepare a lengthy introduction to the work, giving an account of the progress of astronomy in Greece from the time of Thales to and including that of Aristarchus. Though this is not the first time that an English writer has dealt with this subject, Sir Thomas Heath has done good work by preparing this introductory memoir, which fills more than three hundred pages, as he possesses special qualifications for writing the history of Greek science, and there are various controversial matters which cannot be too much discussed—provided it is done by writers who are as competent to do so as he is. The author gives full references to the very copious literature on the subject; indeed, he even notices some statements which he might well have ignored, such as the comically exaggerated picture drawn by Gomperz, of how Demokritus seems to have anticipated out of his inner consciousness many modern discoveries. The passages in the works of ancient writers from which our knowledge of early Greek astronomy is derived are always given at full length in translation, which many readers who may not have access to the originals will find very convenient.

The chapters on the pre-Socratic philosophers, the Pythagoreans, Plato, Eudoxus, and Aristotle, do not call for special notice. They deal very fully and fairly with all the questions about which a good deal of controversy raged fifty or sixty years ago, but which may now be considered finally settled. Nobody now believes that Plato taught the daily rotation of the earth, or that he, in his old age, was inclined to think that the sun was at the centre of the universe. The debatable question is now, how astronomy can have advanced so much during the sixty or seventy years after the promulgation of the system of concentric spheres of Eudoxus as to lead Aristarchus to announce that the earth moved round the sun in a year.

The dominating figure of this period (as regards the progress of astronomy) is not Aristotle, but Herakleides of Pontus. Of him we know with certainty that he taught the rotation of the earth and the motion of Mercury and Venus round the sun. But much greater honours were claimed for him by Schiaparelli, who, in a memoir published in 1898, tried to show that Herakleides not only must have extended his theory from the inferior to the superior planets, thus enunciating the Tychonic system, but that he must also have taken the next step in favour of the heliocentric system. He should thus have anticipated Aristarchus. The only alleged proof of this is a passage in a lost book by Geminus (who lived 250 years after Herakleides) quoted by Simplicius. That this very peculiarly worded passage is corrupt is beyond a doubt; Sir Thomas Heath shows clearly that the name of Herakleides occurring in it is a later interpolation, and he suggests that Geminus may simply have been alluding to the doctrine of Aristarchus. But in any case it is impossible to get over the express statement of Simplicius that Herakleides assumed the earth to be in the middle, while Aëtius (the compiler of the "Placita Philosophorum") distinctly says that Herakleides let the earth move, "not progressively, but in a turning manner." That is to say, it stood still, but it rotated on its axis.

There is therefore no reason to believe that Aristarchus had any predecessor in developing first the so-called system of movable excentrics, and then, by a bold step, the heliocentric system. That this met with no acceptance was doubtless due to the improved knowledge of the motions of the planets in the third century, when it was found that there were other irregularities which could not be accounted for by assuming the earth to be in motion.

The book of Aristarchus, now for the first time translated into English, is of great interest to the mathematician because the ratios of the sizes and distances which he calculates are really trigonometrical ratios, sines, cosines, &c., although at the time when the book was written trigonometry had not been invented, and no close approximation to the value of π was known. Aristarchus therefore endeavours to find upper and lower limits for those ratios by assuming propositions comparing the ratio between a greater and a smaller angle in a figure with the ratio between two straight lines in the figure. These propositions were afterwards proved by Ptolemy. To the astronomer the book is particularly interesting by the attempt made by Aristarchus to determine the ratio of the distances of sun and moon by observing their angular distance at the time when the moon was half illuminated. The very erroneous result found (19 : 1), corresponding to a solar parallax of 3′, continued to be accepted from the time of Ptolemy to that of Kepler.

J. L. E. D.

THE APOTHEOSIS OF THE POTATO.

(1) *The Potato: A Compilation of Information from Every Available Source.* By E. H. Grubb and W. S. Guilford. Pp. vii + 545. (London: Constable and Co., Ltd., 1913.) Price 8*s.* 6*d.* net.

(2) *Commercial Gardening: A Practical and Scientific Treatise for Market Gardeners, Market Growers, Fruit, Flower and Vegetable Growers, Nurserymen, &c.* By many practical Specialists, under the Editorship of John Weathers. In four volumes. Vol. i., pp. xiii + 239 + plates; vol. ii., pp. xii + 235 + plates; vol. iii., pp. xii + 240 + plates; vol. iv., pp. xii + 244 + plates. (London: The Gresham Publishing Co., 1913.) Price 36*s.* net, the four volumes.

(1) THERE are men who, having attained to wealth and fame by the agency of some humble instrument, basely repudiate and kick over the ladder by which they have risen. Not so the authors of the first book on our list. The potato has "made" them, and in return they proceed to "make" the potato. A large number of men have at times written about this vegetable, and extracts from their books and papers occupy a very large proportion of the volume. The food value, methods of propagating, cultivating, harvesting, and selling, all receive attention, but the authors are so evidently enthusiastic, and discourse so eloquently on the merits of their subject, that we are carried along with them, and forget that, after all, they are only talking about potatoes, and not about alpine plants or roses.

The book makes one realise, as nothing else we know has quite done, how manifold are the aspects from which a simple natural object can be regarded. Successive chapters give long quotations from the writings of chemists, botanists, zoologists, entomologists, mycologists, agriculturists, engineers, economists, legislators, business men, doctors, historians, geographers, all dealing with problems directly and closely connected with the potato. And the senior author shows us enough of his personality to let us see how entirely enthusiastic the plant-fancier may become over this plant. There is nothing critical about the book, and the student of science may not find much of direct value to him. Perhaps its main interest to the general reader is that it deals with one of the humblest products of the garden in the same enthusiastic and affectionate spirit as Dean Hole wrote about roses, or Farrar about "alpines."

(2) The four volumes on commercial gardening represent a somewhat ambitious attempt to put into one work the rather wide knowledge that the successful grower ought to have of crops, manures, markets, &c.; they are frankly intended for the commercial man only. Had they been confined to practical matters we should have found little fault with them, but the scope has been widened, and chapters on "science" have been inserted. It might be argued that sound science could not fail to be useful to the grower; on the other hand, it might also be argued that the busy grower has no time to concern himself with the reasons for things, but simply wants specific, trustworthy information on his problems. Either plan might have been adopted and justified. But we do not see any justification for the third plan that has been followed of putting in poor science. While a first-hand knowledge seems to have been expected of the writers on practical subjects, no such qualification seems to have been deemed necessary in the case of science. We are not referring, of course, to Mr. Massie's and Mr. Theobald's contributions, or to some of the botanical work, which is also good, but the large sections on science are in the main distinctly poor. Some of the errors are ludicrous, and could have been corrected by any good student at an agricultural college. The distinction between

aërobic and anaërobic decompositions proved entirely too much for the author:—

"Curiously enough, he says, "some scientists say that if air is admitted to the soil nitrogen is set free from the organic matter; and, on the other hand, if air is excluded, nitrogen is set free from the nitrates; and in both cases it is lost. These views would appear to be mutually destructive."

The chemist is still worse: when appealed to by growers to help in checking plant-diseases,

"the chemist, like a sensible man of business, immediately proceeded to compound his nostrums and to talk learnedly about the fungoid and other diseases, at the same time not forgetting to take the fees to recompense him for his learning and skill."

But perhaps the most severe treatment is reserved for Rothamsted.

"The cultivation seems to be of the poorest description; in fact, it can hardly be described as cultivation at all. . . . One can imagine the condition of the soil . . . it must be almost as hard as rock, and impervious to rain, air, or roots. . . . Farming on the Rothamsted principle would appear to be a very precarious business."

As all this occurs in a science section, first-hand information was apparently deemed superfluous; nevertheless, a visit to Rothamsted first of all might not have been a bad idea. After this we are quite prepared for the author's scheme for making the wheat crop yield a profit of more than 70*l*. per acre, instead of 4*l*. or less as at present. The experimental basis consists of a trial made at Ealing in 1910 with 400 seeds; the results are multiplied up till they can be expressed in terms of one acre; and this in turn is multiplied up till the author foresees that "thousands of men would be kept on the land at better wages, and our wheat crops would be increased enormously. Agriculturists would do well to consider the above figures before smiling too broadly at them." Unfortunately, agriculturists have had these paper schemes presented to them fairly often for at least 250 years past, and now they require facts. Enough has been said, however, to show the sort of "science" that is considered good enough for growers.

E. J. RUSSELL.

TEXT-BOOKS OF PHYSICS.

(1) *Experimental Mechanics and Physics.* By A. H. E. Norris. Pp. viii+176. (London: Mills and Boon, Ltd., n.d.) Price 1*s*. 6*d*.

(2) *Elementary Physical Optics.* By W. E. Cross. Pp. 312. (Oxford: Clarendon Press, 1913.) Price 3*s*. 6*d*.

(3) *Heat: A Manual for Technical and Industrial Students.* By J. A. Randall. Pp. xiv+331. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1913.) Price 6*s*. 6*d*. net.

(4) *A Synopsis of the Elementary Theory of Heat and Heat Engines.* By J. Case. Pp. iii+65. (Cambridge: W. Heffer and Sons, Ltd., 1913.) Price 2*s*. 6*d*. net.

(5) *Elementary Principles of Electricity and Magnetism for Students in Engineering.* By Dr. R. H. Hough and Dr. W. M. Boehm. Pp. vii+233. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 6*s*.

(6) *Transport de Force.* Calculs Techniques et Economiques des Lignes de Transport et de Distribution d'Energie Electrique. By C. Le Roy. Deuxième Partie. Pp. 143. (Paris: A Hermann et Fils, 1913.) Price 6 francs.

(7) *First Year Course in General Science: A Combined Text-book and Note-book.* By E. A. Gardiner. Pp. vi+113. (London: W. Heinemann, n.d.) Price 2*s*. 6*d*. net.

(1) THE title of this little book is rather misleading. The use of the word "physics" suggests that the contents of the book comprise the various branches of physics, and not merely—as is actually the case—heat and a meagre treatment of a few of the properties of matter. These subjects occupy only one quarter of the volume, the remainder being devoted to mechanics. The treatment is very simple and is suitable as an introductory course. In this respect the book will no doubt serve its purpose as efficiently as many others of its class, although it exhibits no noteworthy advances in the mode of presentation of the subject. The frequent change of type is rather an unfortunate feature, and some of the diagrams are very badly drawn, notably a cube used to represent the measurement of volume, the perspective of which is in exactly the wrong sense.

(2) This book has several very good points. The subject is treated in a straightforward and lucid manner. The author has endeavoured to develop the theory of optics upon both "ray" and "wave" bases simultaneously, and we think he has succeeded. There is much to be said for both methods of treatment, and neither should be ignored. As is natural in an elementary treatise, no very difficult problems are considered, but it is rather surprising to find practically no reference to diffraction and interference, especially as some stress is laid on the wave theory. There are many simple experiments in this connection which, far from confusing a junior student, would undoubtedly interest him. One of the most notable

features of the book is the series of diagrams, which are well drawn, and often a whole page is devoted to a single figure, with the result that a very clear representation is secured.

(3) One is inclined to think that too much is being done nowadays in the matter of adapting branches of study to the special needs of various classes of students. Text-books of physics, and presumably of other subjects also, are written from the point of view of subsequent work, and the result is often detrimental to the students themselves. It is scarcely possible to avoid a certain looseness of language and an inexactness of expression when the subject is submitted to the special mode of treatment in question. The present book is quite a good one in many ways, and no doubt contains a great deal of useful information with regard to heat and heat engines. It is good to find the subject introduced from the point of view of energy, although the discussion of the meaning of energy is evidently handicapped by the knowledge on the part of the author of the very limited training in mechanics possessed by the students for whom the book is written. To each chapter the author appends a summary in heavy type of the important conclusions therein, together with a number of problems based on the work. Apart from the limitations imposed by the mode of treatment referred to, this book is a straightforward and lucid presentation of the subject.

(4) This pamphlet is frankly published for "cramming" purposes. It is intended as a synopsis for students reading for the Mechanical Sciences Tripos, and especially for the "A" paper in Heat. In order to make this perfectly plain the author leads off with some forty lines of doggerel, which, if committed to memory, apparently ensures success in the examination. To those students who regard their study of physics from this point of view, the book will prove useful in proportion to what they remember of its contents; to the serious student it can scarcely be recommended. For so small a volume the table of "errata" is too long; indeed, it rather looks as though this handbook has been hurriedly prepared.

(5) There is room for doubt as to whether it is desirable in a book on electricity and magnetism to avoid almost entirely references to the physical, as distinct from the mathematical, side of the subject. This is the only fault we have to find with this treatise, which is otherwise quite excellent. And even this objection disappears if it can be guaranteed that the book will be read concurrently with attendance at experimental lectures and laboratory work. Most teachers find that students of physics experience much more difficulty with the mathematics it involves than with the experimental principles upon which it is based. To those students this book should prove a boon. Here they will find presented in logical order and in a simple manner an extensive series of deductions from, and applications of, the fundamental laws of electrostatics, magnetism, and electromagnetics. Numerous numerical examples are appended to the various chapters, and at the end of the book the more important formulæ developed in it are compiled in a list. The use of this list, of course, involves the adoption of a particular notation in the memory of the student, and this, perhaps, is a little inexpedient at a time like the present, when notation varies so much; but it is not easy to see how to overcome the difficulty.

(6) To those interested, both theoretically and practically, in the transmission of electrical power this volume should prove of great interest and use. The author has carried out a large number of calculations of the various electrical data required in this connection, with numerical examples. Graphical methods are frequently resorted to, and the treatment of the whole subject appears to be very complete.

(7) The chief objection to this type of book is that it is very liable to become very dirty in the hands of a slovenly boy, and very unsightly, owing to numerous corrections, when written up by a boy who, though clean, is not brilliant. The instructions for the experiments are given clearly and neatly, and it seems rather a pity to spoil their appearance. The course comprises three parts, arranged more or less in order of difficulty, and a considerable number of simple experiments in mechanics, heat, and the physical and chemical properties of water and air are dealt with. At the end of each lesson a number of questions, intended for homework, are set. Presumably the answers to these are to be recorded in a separate notebook. Why not the experimental results also?

OUR BOOKSHELF.

Vegetation of the Peak District. By Dr. C. E. Moss. Pp. x + 235 + plates. (Cambridge University Press, 1913.) Price 12*s*. net.

QUICKLY following on Elgee's "Eastern Moorlands of Yorkshire," we have Moss's book on the vegetation of the Peak district, especially in its relations to geology and the chemical nature of the soil. Faunistic relations, so ably discussed by Elgee, are not considered by Moss. As the author remarks, the Peak district has no definite geographical boundaries, but his maps of the plant formations include the area lying between Mossley and Penistone to the north, and, approximately, Congleton and Matlock to the south, embracing portions of five counties, and sources of several head-streams of the Mersey, Dee, Trent, and Yorkshire Ouse.

There are several elevations of a little more than 2000 feet, and a large proportion of the district consists of unenclosed moorland and grassland. The maps are coloured to show the plant formations of acidic peat, siliceous soil, calcareous soil, sandy soil, and of cultivated land. The plant formations are subdivided into associations. For example, the formation of acidic peat exhibits associations in which *Vaccinium Myrtillus*, *Eriophorum vaginatum*, *Calluna vulgaris* respectively dominate, and others in which two of these units are more or less equally dominant.

Following an introduction, dealing, among other things, with rainfall, temperature, and winds, are chapters on woodland, scrub, grassland, moorland, rocks and screes, marsh, and aquatic and cultivated land associations. Summaries of the plant communities (these include formations and associations) of the Peak district and of Britain conclude a most interesting book, the illustrations and maps of which are excellent. W. B. H.

Outlines of Stationery Testing. A Practical Manual. By H. A. Bromley. Pp. 74. (London: C. Griffin and Co., Ltd., 1913.) Price 2*s*. 6*d*. net.

THIS little manual deals chiefly with the technical examination of paper, though other articles of stationery are included in its scope. It avoids theoretical considerations, and gives in simple language concise instructions for the practical testing of paper, physically, microscopically, and chemically. Under the first heading come questions of colour, nature of the paper, surface or "finish," texture, opacity, ink-bearing properties, and strength. Short notes are supplied explaining these terms as applied to paper, and the methods of testing the properties indicated by them.

Few words are wasted in the chapter devoted to explaining the microscopic examination of paper. The author has managed to condense the description of the examination into five small pages, whilst another five are allotted to plates showing the microscopic characters of the principal fibres.

Under the head of chemical examination, directions are given for determining the nature and amount of the mineral matter used as "loading," and of the organic substances, such as gelatine, rosin, casein, and starch, employed in the "sizing" of paper. Methods are also propounded for discriminating the colouring ingredients and detecting chemically certain fibres and impurities. In all cases, the author claims, the chemical processes described are those which require the simplest possible apparatus. The characteristics of special kinds of paper are indicated briefly, and the book concludes with short sections on the testing of ink, gum, sealing-wax, and other miscellaneous articles included in the term "stationery." Within its limits—those of a collection of notes for use in practically examining stationery—the book will be found useful.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Pianoforte Touch.

I CAN fully endorse Dr. Heaviside's opinions as to the possibilities of the piano-player, and could only wish that there were some reasonable prospect of this instrument being used to save a great portion of the uninteresting drudgery of the usual school music-lesson. At the present time a considerable amount of school time is wasted in attempting to learn an instrument which is so difficult to play that few succeed in obtaining any satisfactory results. This system does not succeed in producing musicians any better than the ordinary school algebra lesson succeeds in producing mathematicians.

On the other hand, my recent experiments in connection with this "patent" control have led me carefully to test the existing commercial piano-players, and I can fully endorse Mr. Wheatley's complaints as to their lack of responsiveness and their persistent assertion of their mechanical individuality in opposition to the most strenuous efforts of the performer controlling them. The methods of varying expression by means of punch-holes, or by damping down all the notes on one side or other of a hard and fast dividing line, produce a very pleasing impression at first, but one soon tires of their very limited capabilities.

In these circumstances I would strongly recommend Mr. Wheatley and any other readers of NATURE who are interested in the subject to experiment with the methods of control claimed in my patent specifications. Even a rough and ready device rigged up with sticks, strings, and kitchen weights produces such a great improvement in the range of effects and flexibility of the instrument that after experimenting with such an arrangement I found it impossible to obtain any satisfaction without it. I think it may be safely said that the mechanical self-assertiveness of the instrument can be reduced to a small quantity of the second order, and can be further reduced by a method of successive approximation. So soon as dynamical considerations are introduced the possibility of accenting notes in *chords* (*i.e. proper chords*, not the miserable arpeggios which are so often substituted for them in recently cut music rolls) becomes evident, and the production of variations of tone quality by differences of touch is probably much easier when effected this way than when the keys are played by hand. All this appears less difficult to learn than the control of the speed regulator, which must always remain a difficulty.

The absence of these capabilities constitutes the great defect of the commercial player. But the ordinary "practical man" cannot understand anything based on the principles of dynamics and physics, consequently he treats the pressure as if it were constant instead of a very variable function of the time, and the result is an instrument which is mechanical and little else, and can only be played with an unnecessary expenditure of energy.

I have heard a professional pianist perform a very delicate *pianissimo* passage in which the accented notes rang out clearly and brilliantly above the background without being played any louder. It was simply a difference of tone quality produced by a corresponding difference of touch. My dynamically-controlled piano-player is quite capable of giving a very approximate reproduction of this effect, whereas I have heard an expert break down hopelessly over a similar passage at an exhibition recital of a commercial machine.

With regard to the connection between tone quality and touch, I do not think Dr. F. J. Allen's explanation meets the case. Unless there is distinct experimental evidence to the contrary, I do not think we ought to exclude the *possibility* of a double or multiple impact between the hammer and string; indeed, some of my experiences favour this hypothesis. But I am inclining more and more to the belief that the differences may be largely due to the elasticity and inertia of the stem of the hammer. The introduction of these elements converts the hammer into a dynamical system capable of independent vibration. The method of normal coordinates then enables us to represent this system by a simpler system having the same vibration periods; for example, a system of two or more particles connected by elastic springs and moving in a straight line. It is clear that the duration of contact of a pair of such particles with the wire will depend largely on the state of compression between them and their relative velocity at the instant of impact. The interval between the release of the hammer and its striking the wire is probably short compared with the time of a free oscillation of the hammer itself, and certainly short compared with the time in which such an oscillation would die out. On setting the hammers of the horizontal piano low down, the variations of tone quality entirely disappear, as one would expect.

I find another favourable condition by developing Kaufmann's method in connection with the problem of a single inelastic particle striking a wire near one end. The duration of contact is determined by the vanishing of a function which has one or more minimum values before it actually vanishes, some of these being small. A very small difference in the assumed conditions might therefore convert one of these minimum values into a negative value. Remembering that such assumed conditions are probably not even approximately satisfied in practice, we still have a result indicating that the pianoforte hammer and string may be highly susceptible to any cause which tends to vary their duration of contact.

I am specially pleased to receive Dr. Heaviside's views on this subject, and to find that he has been long interested in these difficult problems.

Since writing this I have read Prof. Morton's letter, and am very glad to receive his references to previous work on the subject. With regard to his own experiments, I think something more is necessary for my purpose than what he mentions in NATURE, namely a comparison of the striking velocities of pianoforte hammers in *different* parts of the scale. I notice Prof. Morton does not mention what particular notes were struck in his observations. It would also be important to compare the striking velocities for two notes, one in the treble and one in the bass, when simultaneously excited by a common pneumatic impulse of long or short duration, such as can be produced in these piano-player experiments with properly cut chords. With regard to the other question, I think it is unfortunate that authors like Matthay have used the terms "good" and "bad" touch in this connection. I freely admit that the heavy, inelastic impacts produced by the inexperienced performer produce such a harsh effect as to be very objectionable (and possibly this may be due to Dr. Allen's so-called "xylophone" effect); on the other hand, any playing sounds to me mechanical which does not involve considerable variation of tone quality. This appears to me to be particularly necessary in studying piano arrangements of orchestral music, where the sharp, metallic tones of the brass instruments have to be brought out in contrast to the softer tones of the strings. Possibly when fingers are used the pianist usually has too many other matters requiring his attention. But whether a metallic effect is "good" or "bad" must depend on how and when it is used, and personally I should think a constant tone quality the worst effect of all. Prof. Morton's letter, however, raises a number of other questions which would take a long time to answer, and may have to be explained in subsequent correspondence.

Mackerel and Calanus.

WE all believe that most of our common food-fishes at some stage of life feed upon plankton, but those who have looked into sea-fisheries questions know that there is a great want of actual observations connecting the occurrence of some planktonic organism in quantity with the presence of a particular fish. Consequently the following record may be of interest to both marine biologists and fisheries experts.

We are out on a scientific fisheries cruise, and in addition to members of my own family, two well-known naturalists, Prof. Newstead and Mr. Alfred O. Walker are with us on the yacht, and we have just had what we regard as a satisfactory demonstration of the connection between a large shoal of mackerel and the occurrence of *Calanus finmarchicus* in unusual quantity.

On arriving in this bay last night we found that the local boats had been catching abundance of mackerel close to. We bought some for supper (good fish for a halfpenny each), and on dissection found that the stomachs of all of them were crammed full of fresh-looking Calanus (the individual Copepods being for the most part distinct and perfect), along with a few immature Nyctiphanes and larval Decapods. Prof. Newstead and my daughter then noticed, while fishing over the side of the yacht, about 8 p.m., that the gulls in the bay were feeding in groups around patches of agitated water evidently caused by shoals of fish. On rowing out to these we saw distinctly the mackerel, large and small, darting about in great numbers in the clear water, and we also noticed every here and there on the smooth surface of the water—it was a beautifully calm evening—innumerable small whirls or circular marks which, on looking closely, I found to be caused by large Copepoda close to the surface.

About twenty years ago I sent a note to NATURE, from the yacht *Argo*, in regard to large Copepoda (I think it was Anomalocera on that occasion, and the locality was further north, off Skye) splashing on the surface so as to give the appearance of fine rain; and this present occurrence at once reminded me of the former occasion, but here the Copepod was *Calanus finmarchicus* of large size and in extraordinary abundance. They could be clearly seen with the eye on leaning over the side of the boat, a small glass collecting jar dipped at random into the water brought out twenty to thirty specimens at each dip, and a coarse grit-gauge tow-net of about 34 cm. in diameter caught about 20 cubic centimetres of the Copepoda in five minutes. The mackerel were obviously darting about, occasionally leaping to the surface (which gave the gulls their opportunity) where the whirls caused by the Copepoda were thickest, and an examination of the stomach-contents of the fish on the yacht afterwards showed us that the amount in one mackerel was about the same quantity as that caught by the tow-net in five minutes. Prof. Newstead and I have made a count of 8 c.c. of the tow-net gathering, and estimate that it contains about 2400 specimens of

Calanus. This would give about 6000 Copepods in the stomach of an average mackerel, or in a five minutes' haul of the tow-net, on this occasion.

It may be added that these mackerel were evidently not being nourished in accordance with the views of Pütter, and were clearly able to fill their stomachs from the plankton around them.

Helium and Neon.

The experiments communicated to the Chemical Society recently by Prof. Collie and Mr. Patterson, the lectures delivered by Sir J. J. Thomson, and the discussions which have taken place in Nature, on the possible synthesis of the chemical elements have aroused great interest outside England. So far as I can ascertain, opinion is much divided. For my own part I may perhaps be permitted to say that I have always entertained the idea of a possible formation of elements of the helium group from other gases by *integration*, just as these are formed from other elements by disintegration (see *Chemical News*, 1896, and *Berichte*, 1899). When I put forward this view objection was taken that 4H is greater than He, 4·032 instead of 3·99, and the same kind of objection may be raised to-day that He+O, or 3·9+16, is less than Ne, 20·2 (unless Ne is a mixture of gases).

In order that the above question might be solved definitely, I would beg to suggest that experiments should be conducted in Röntgen-tubes from the electrodes of which every trace of the gases "occluded" or firmly held by them would be first removed by continued bombardment with kathode rays.

As regards the question put forward by Sir J. J. Thomson, whether the new gas X_3, discovered by him, may be a new element that fills the vacant space in VII. group, 1 series (VII–1), in Mendeléeff's periodic system, I may be allowed to remark that Mendeléeff's prediction of the properties of the elements Sc, Ga, Ge, could be successful, because it was an *interpolation*; whereas the prediction of the properties of the element X=3 includes an *extrapolation*, which is always rather uncertain; besides, the gases of the helium group were unknown at the time of the prediction. Its properties may be derived from the following equations:—(1) Ne : F=He : X; (2) Li : F=H : X; (3) Li : H=F : X; but also (4) Fe : He=Mn : X, and (5) Cu : H=Br : X, showing how uncertain the prediction of its properties becomes, so that it is indeed probable that it will be more negative than fluorine, but not necessary that the gas should combine with the silicon of the glass.

The delicacy of Sir J. J. Thomson's new method has superseded our old methods of investigation in a way similar to that based upon radio-activity, and the results of the study of the new gases discovered by this new method are awaited by chemists with the greatest interest.

Red Water and Brine Shrimps.

By the kindness of Mr. A. W. Sheppard and Prof. A. Dendy, F.R.S., I have been enabled to examine specimens of the brine shrimps from Geelong mentioned by Mr. Whitteron in his letter (Nature, June 12, p. 372). They belong to the species *Parartemia zietziana*, described by the late Mr. O. A. Sayce in 1903 (Proc. Roy. Soc. Victoria, xv., part ii., p. 232). In Parartemia the unpaired uterine sac is produced into two large dorso-lateral lobes lying on either side of the "tail," and appearing, as Mr. Whitteron says, "like the egg sacs of Cyclops." Mr. Sayce's specimens were obtained from a "brackish-water swamp near Lake Alexandrina, South Australia." It is interesting to learn that the species is able also to live in the brine of salt-pans.

The flagellate described by Mr. Whitteron is probably allied to, and perhaps identical with, *Dunaliella salina*, which has long been known to cause a red coloration in the brine of salt-pans in Europe and Algeria. A detailed account of this form and references to the somewhat extensive earlier literature of the subject are given by Clara Hamburger ("Zur Kenntnis der *Dunaliella salina*," *Arch. Protistenk.*, vi., 1905, p. 111).

The Maximum Density of Water.

Physiographers lead us to believe that the earth is defended from a profound glaciation, cumulative from year to year, by the law that water is heaviest at a temperature of four degrees above centigrade zero. If the main cause lies here, it is desirable that this measure should have its peculiar power set forth with more precision than has been customary.

The matter usually presents itself to students rather differently. The predominant fact is the floating power of ice. Hereby the water is screened from further attacks of the cold air, and dispersal is provided in the puzzling conditions of ground or anchor ice. Next perhaps in importance is the slow conduction of cold by water. Then comes the large value of the latent heat of water. It is not obvious why there should be disastrous results if the maximum density of water were at 0° C. The four units may be viewed as a helpful margin of safety rather than as an essential; but they would appear to be negligible in comparison with the 79 units of latent heat. Water at 0° C. is by no means unstable; each gram weight as it passes into ice throws out amongst its neighbours an amount of heat which is an effective safeguard against sudden and extensive solidifying.

Radio-activity and the Age of the Earth.

I am gratified to learn from Dr. Fermor's letter in Nature for July 10 that there is a scientific possibility of conceiving how the interior of the earth may be devoid of radio-activity. But if "high pressure and temperature" can inhibit the dissociation of "potentially radio-active" substances, will they not do so also in the interior of the stars? If so, radio-activity will no longer be available to prolong their radiation of energy, and we shall be back in the old difficulty about the age of the sun. Indeed, it will be aggravated, because we now have positive evidence for a high antiquity of the earth, while still unable to explain that of the sun.

F. C. S. Schiller.

Corpus Christi College, Oxford, July 11.

THE GENERAL MAGNETIC FIELD OF THE SUN.[1]

Those who are familiar with Prof. Hale's brilliant discovery of magnetic fields in sunspots, and are aware of the difficulties connected with that investigation, will greatly admire his courage in seeking to establish the much weaker general magnetic field of the sun itself. The following condensed account of the method adopted and results obtained is given, to some

[1] Based upon an advance proof of a paper by Prof. G. E. Hale which is to appear in *The Astrophysical Journal*.

extent, in Prof. Hale's own words. As a general problem of physics, Schuster's suggestion that every rapidly rotating body may produce a magnetic field is of fundamental importance. A direct test by laboratory experiments cannot be made because of the limitations of size and rotational velocity, but advantage may be taken of the heavenly bodies where these limitations do not obtain. The most promising object for such an investigation is the sun. It is here that the direct method of determining the magnetic field by observation of the Zeeman effect is most readily employed, since the sun is bright enough to permit the use of the very high dispersion required. Further, it is possible to observe at a great number of points on the surface, and since observations may be made in both hemispheres the most perfect test of the Zeeman effect can be applied by looking for a reversal of the sign of the displacement with the polarity. The present minimum of solar activity has furnished a particularly favourable opportunity for the investigation, in consequence of the general absence of local strong fields due to spots and other disturbances.

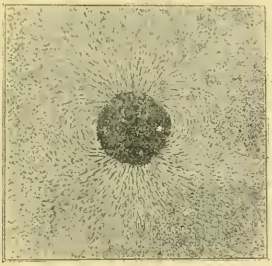

FIG. 1.—Lines of force of a magnetised sphere.

Assuming the sun's magnetic field to be similar to that of a magnetised sphere, with magnetic poles coincident with the poles of rotation, the lines of force would appear as in Fig. 1, the angle δ between them and the solar surface being given by $\tan \delta = 2 \tan \phi$, where ϕ is the heliocentric latitude. If the field were strong enough, and if the observer could look along the sun's axis and form an image of one of the poles on the slit of a spectroscope, certain solar lines would appear as doublets with components circularly polarised in opposite directions. If a Nicol prism were placed in front of the slit, with its long axis parallel to the slit, in combination with a quarter-wave plate set with its principal section at an angle of 45°, one of the components would be extinguished, while the other would be transmitted by the Nicol. Assuming the red component to be transmitted, a rotation of the quarter-wave plate through 90° would cause this to be extinguished and the violet component to be transmitted. If from the same place of observation the slit were directed to a point in 45° lat., the effect would still be clearly observable, though the transformation of the circularly polarised light of the components into elliptically polarised light would result in less complete extinction by the Nicol.

In the actual case the terrestrial observer is close to the plane of the sun's equator and must look in a direction nearly at right angles to the lines of force at the sun's poles.[2] He therefore cannot take full advantage of the fact that the total intensity of the sun's magnetisation is twice as great at the poles as at the equator. The angle between the lines of force and the line of sight, however, is reduced to zero at 35° north and south latitude; but the most favourable position for observation is 45° lat., where the effect of the ellipticity of the light is overcome by increased strength of the field.

On account of the weakness of the sun's magnetic field, complete separation into doublets is not to be expected, and the investigation must, therefore, depend upon the possibility of detecting very slight displacements of lines to red or violet, according to the position of the quarter-wave plate, with reversal of the sign of the displacements in passing from the northern to the southern hemisphere.

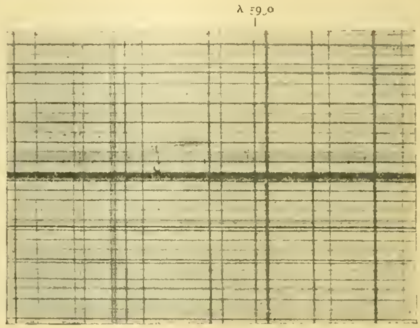

FIG. 2.—Region of λ5930 photographed in the third order with the 75-ft. spectrograph showing the division of the spectrum into 2 mm. strips by the compound quarter-wave plate. The heavy horizontal line marks the junction of two sections of the Nicol. The fifth stripe below is the "marked strip" used for reference purposes.

The first attempts to detect the solar magnetic field were made in 1908 with the 60-ft. tower telescope at Mt. Wilson, but it was not until the new 164-ft. tower telescope and 75-ft. spectrograph became available, in 1912, that definite results were obtained. With the latter instrument the sun's image is about 16 in. in diameter, and about λ5900 in the third order spectrum, where much of the work was done, the linear dispersion is 1 Ångström = 4·9 mm.; on this scale the distance between the D lines is 29 mm. For determination of focus and investigation of resolving power the extremely fine lines in the absorption spectrum of iodine were employed with advantage, and lines as close as 0·025 A.U. were found to be just resolved.

The polarising apparatus consists of a Nicol prism 18 mm. wide, built up of four sections, each 32·5 mm. long, so as to give a total length of 130 mm. The impossibility of rotating it is easily

[2] The triplets produced by light from the poles would, of course, be too narrow for observation as such, and the use of a Nicol in different positions would not affect the symmetry of the lines.

overcome by the use of a half-wave plate, as a rotation of this through a given angle is equivalent to a rotation of the Nicol through twice the angle.

The quarter-wave plate was built up of strips of mica, 2 mm. wide, mounted so that the principal sections of successive strips make an angle of 45° with the slit and 90° with each other; the Nicol would thus transmit, say, the red components of the doublets for the odd strips and the violet components for the even strips. In a photograph of the spectrum the lines would thus have a dentated appearance (Fig. 2), the magnitude of the separation of the components shown in successive strips varying directly with the strength of the field.

Every conceivable precaution appears to have been taken in setting the desired portion of the sun's image on the slit of the spectrograph, and in securing full illumination of the grating in any exposure. A valuable check on the observations was obtained by making duplicate exposures with the quarter-wave plate in the normal and inverted positions, which should give displacements of opposite sign if they are caused by a magnetic field. As a further check, at least one atmospheric line was measured on most of the plates of the first series, but afterwards they were only occasionally measured, as they were invariably found to give no shifts exceeding the errors of measurement. Possible effects of polarisation produced in the spectrograph have also been carefully considered.

The region of the spectrum selected, λ5800 to λ6000, was determined by the consideration that the magnetic separation varies directly as the square of the wave-length; too great a wave-length, however, being undesirable since the average sharpness of the solar lines decreases as the wave-length increases. Numerous difficulties arising from distortion of the cœlostat mirrors of the tower telescope and other causes were successfully overcome, and 280 photographs were obtained. For purposes of discussion the photographs and measures have been divided into four series.

For the preliminary observations it was decided to obtain a large number of measures of a few lines rather than a smaller number of measures of many lines. Three lines, showing the largest displacements, were accordingly selected for systematic investigation, namely, λ5812·139 (Fe,0), λ5828·097 (–,0), λ5929·898 (Fe,2).

The measurement of the minute displacements, amounting only to a few thousandths of a millimetre, presented great difficulties, largely arising from the natural diffuseness of the solar lines. Full details of the individual measures are given in the paper, and discordances appear to have been as faithfully recorded as the measures on which the final conclusions are based.

The tables and curves show a marked grouping of positive displacements in the northern and of negative displacements in the southern hemisphere, with values decreasing, on the average, from middle latitudes towards the equator or poles. It is also shown that the displacements were reversed in direction by turning the half-wave plate through 45° (equivalent to a rotation of the Nicol through 90°), or by inversion of the compound quarter-wave plate. Hence it is concluded that the light from the red and violet sides of the solar lines in question is circularly or elliptically polarised in opposite directions. In the northern hemisphere the light of the violet component is circularly polarised in the right-handed direction.

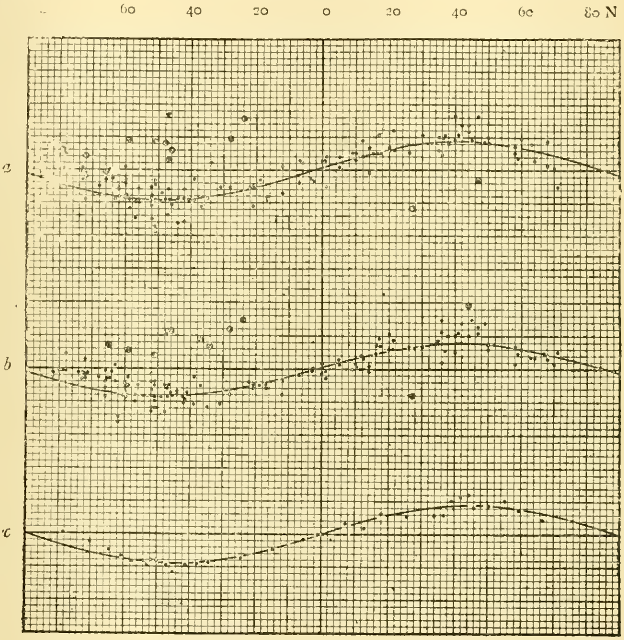

FIG. 3.—Displacements observed in different latitudes, fourth series. a, λ5812; b, λ5828; c, Mean curve of displacements including λ5930 from first and third series and λλ5812 and 5828 from fourth series. Vertical Scale: 1 division=0·001 mm.

Some of the evidence for the systematic shifts is reproduced in the appended table, giving the mean displacements for λ5930 in the first and third series, and λλ5812 and 5828 in the fourth series, as measured by Mr. Van Maanen:—

Lat.	Δ (unit= 0·001 mm.)	No. of observations	Lat.	Δ (unit= 0·001 mm.)	No. of observations
N. 68·8°	+2·2	15	S. 5·1°	-0·8	15
59·4	+3·6	15	14·3	-2·4	15
55·4	+5·1	16	24·2	-3·6	15
50·3	+4·4	15	34·1	-4·3	15
46·1	+4·1	15	37·7	-4·6	15
44·5	+6·0	15	41·0	-4·7	15
41·9	+5·7	15	45·1	-5·8	16
39·3	+5·1	15	47·1	-4·7	15
36·7	+3·0	15	49·9	-4·1	15
33·9	+2·9	15	51·7	-4·1	15
25·7	+2·7	15	52·8	-4·7	15
18·0	+3·1	16	57·3	-4·1	15
12·7	+0·8	15	60·5	-3·5	15
7·3	+1·6	15	64·5	-2·5	15
0·5	0·0	15	70·0	-1·1	15
			78·1	+0·1	15

A graphical representation of the results of this series of measures is given in Fig. 3, in which the horizontal scale is that of solar latitude, and the vertical scale that of displacements. The agreement of the data of the foregoing table with the theoretical curve derived from the average of the ordinates at 45° is shown in Fig. 3*c*.

It is considered that within the limits of precision the observations agree satisfactorily with the displacements calculated for lines originating in a source on the surface of a magnetised sphere, and observed from a point in or near the plane of the equator. On the assumption that the field is due to the rotation of a charged body, or of a body composed of neutral molecules which act as though they carried a charge, it is concluded that the sign of the dominant solar charge is negative, and that the north magnetic pole of the sun lies at or near the north pole of rotation.

The determination of the strength of the sun's field has presented some difficulty because the lines measured are so weak in the arc or spark that their separations in a magnetic field can only be determined experimentally with the greatest difficulty, or not at all. In the case of 5929·898, the procedure has been to observe the separation of the line in a sun-spot the strength of field of which was determined from other lines; as indicated by this line, the field strength of the sun at its pole is 28 gausses. The line 5812 and a nickel line 5831·821 (not yet fully discussed), by comparison with laboratory observations, lead to the values 48 and 29 gausses, but for comparison with the foregoing determination these should be increased by about 60 per cent. on account of systematic differences between the measurers. The general result is to indicate that the field strength at the sun's pole is of the order of 50 gausses. Various higher level lines, which show large Zeeman effects in the laboratory, have hitherto failed to show the effect of the sun's field, and it is therefore concluded that the intensity of the general field falls off very rapidly in passing upward through the reversing layer, more rapidly than in the case of spots.

Prof. Hale gives a careful discussion of the question as to whether the magnetic fields indicated by the observations are due to local phenomena or to the magnetic effect of a rotating sphere. In the case of spots, the Zeeman effect frequently extends beyond the penumbra, and the structure of the Hα flocculi sometimes suggests that local magnetic fields may also be caused by invisible spots, or by whirls in which no umbræ or penumbræ have appeared. There is also some evidence that the pores which occur in all parts of the sun may be small vortices which develop into spots under favourable conditions. Reasons are given for believing that the line displacements in question are not due to any of these causes. Right and left-handed whirls about spots are equally common in the northern and southern hemispheres, and there is no reason to suppose that they could produce the systematic displacements, of opposite sign in the two hemispheres, which have been observed. In fact, in the majority of the observations no spots whatever and very few calcium flocculi were visible on the sun. If the pores are electric vortices, like the spots, there is no reason to suppose that pores of one polarity preponderate in the northern hemisphere and those of opposite polarity in the southern, unless local differences in rotational velocity are sufficient to account for such small vortices as the pores may represent; this possibility, says Prof. Hale, deserves more careful consideration than he has yet been able to give it, but even if there were a clear preponderance of pores of opposite sign north and south, it would be difficult to account for the curve of observed displacements.

Serious objections having been urged against all theories of terrestrial magnetism, it can scarcely be hoped that any one of them can be applied without modification to the sun, especially in view of its high temperature, low density, and gaseous condition. In the case of spots, neutral molecules cannot produce the observed fields unless an improbable degree of separation of the positive and negative electrons is assumed. Harker's experiments,[3] however, have led Prof. Hale to suppose that in a spot there must be a flow of negative electrons from surrounding regions into the cooler umbra, and that the whirling of these in the vortex may account for the strong magnetic fields observed.

An extension of Dr. Harker's work made at Pasadena by Mr. King has further shown that although the ionisation current decreases as the pressure increases, it is still appreciable at pressures up to twenty atmospheres. On account of the greater mobility of the negative electrons, their tendency to flow towards regions of lower temperature, and the evidence afforded by Mr. King's experiments that solar ionisation is not limited to the region above the photosphere, it is evident that the electrical and magnetic phenomena of the interior of the sun must differ radically from those of the earth. But since the negative electrons will tend, on the average, to lie farther from the

[3] NATURE, July 18, 1912, p. 517.

sun's centre than the positive, the polarity of any general field that may thus result from the solar rotation should correspond with that of the earth's field.

There is reason to believe that in the solar atmosphere the negative electrons lie farther from the photosphere, on the average, than the positive electrons. The rotation of the atmosphere with the sun would thus tend to set up a magnetic field of the same polarity as that of the earth. At the base of the atmosphere this field would oppose the field due to the rotation of the body of the sun. Hence, assuming a suitable distribution of the positive and negative electrons, it may be possible to account in this way for the observed decrease in the strength of the general field at increasing distances from the photosphere. Prof. Hale thinks that it may even turn out that the Zeeman effect observed is due to the rotation of the solar atmosphere, and not to the rotation of the body of the sun.

Further work will be necessary before such questions as these can be fully discussed, and an extended series of observations, including lines representing a wide range of level, is contemplated.

The space at our disposal is too restricted to permit full justice to be done to this fine piece of work. It will be sufficiently evident, however, that Prof Hale has conducted the investigation with his accustomed skill and with due regard to the numerous possible sources of error.

THE BIRMINGHAM MEETING OF THE BRITISH ASSOCIATION.

THE arrangements for the Birmingham meeting (September 10–17) are almost completed. In order to avoid the competition for places at the various functions, which so often causes inconvenience to visitors, the local secretaries intend to obtain beforehand from members an indication of their wishes with regard to the general meetings, lectures, entertainments, and excursions; and a circular for that purpose will be issued shortly.

A new arrangement has been made for the convenience of the delegates of corresponding societies. Thanks to the council of the Birmingham Natural History and Philosophical Society, the meeting-room and library at 55 Newhall Street is to be placed at the disposal of the delegates for the display of their publications, and also to act as a meeting-ground for the representatives of these corresponding societies during the meeting. The addresses to the delegates will be given in the Technical School, Suffolk Street.

The lectures to citizens, which were inaugurated at Dundee last year, will be given on a more extended scale this year at the Digbeth Institute, Birmingham. Five lectures have been arranged by the council of the association. The first of these—"The Decorative Art of Savages"—will be given by Dr. A. C. Haddon, F.R.S., on Thursday, September 11, at 8 p.m. Other lectures will be "The Panama Canal," by Dr. Vaughan Cornish; "Heredity in relation to Man," by Dr. Leonard Doncaster; "The Microscopic Structure of Metals," by Dr. W. Rosenhain; "Radio-activity," by Dr. F. Soddy, F.R.S. These lectures are arranged for that section of the public which is interested in the progress of science, but cannot take part in the meetings of the association. They are not intended for members or associates. The chief points in the programmes of the sections are described below.

Section A (Mathematical and Physical Science).—The section meets this year under the presidency of Dr. H. F. Baker. It is expected that greater interest will be taken in the proceedings of the pure mathematics subsection than in former years. There is a possibility of a discussion on non-Euclidean geometry, which will be of interest to many in addition to the pure mathematicians. In the full section the chief item after the presidential address is a discussion on radiation, arranged for the Friday morning, which will be opened by Mr. J. H. Jeans. Profs. H. A. Lorentz and E. Pringsheim have accepted invitations to be present at the meeting, and will add greatly to the interest and value of this discussion. Prof. Planck may also possibly be there. Of the English scientific men who will be there, Profs. Love and Rutherford will take part in the discussion. Two other discussions have been arranged in conjunction with other sections. With the Engineering Section a joint meeting will be held at which reports of a committee which has been investigating problems of stress distribution will be discussed. The other meeting is with the Geography Section, at which problems of geodesy and mathematical geography will be considered. One paper of great interest to many will be presented by Capt. H. Winterbotham, on the accuracy of the principal triangulation of Great Britain.

Amongst the papers to be contributed to the section, one, by Prof. Barkla, on the nature of X-rays, will be of considerable interest, and will probably give rise to an animated discussion. This paper will probably be read in full section immediately after the presidential address at eleven o'clock on Thursday morning.

The meeting will be of special interest because of the close association of the president of the association, Sir Oliver Lodge, with the section. It is expected that a large number of leading English scientific men will be present, and already the published list of papers shows that a stimulating session may be expected.

Section B (Chemistry).—The programme of this section has been framed so as to appeal as widely as possible to chemists, as many as five different subjects being down for discussion. Taking first those which have a practical bearing, the subject of the economical use of fuel is of national importance. The chemist can emphasise the wasteful nature of present practice and describe alternative and more economical practices, free from the bias of the commercial advocate. It is hoped to present at the meeting the views of authoritative speakers on all branches of the subject; the details will be announced later. The subject of metallurgy is of particular interest in Birmingham, and a number of papers are promised by Prof. Cohen, Prof. Turner, Dr. Desch, Dr. Rosenhain, Dr. Holt, and others, which will deal from the scientific side with problems of practical interest. Turning to pure chemistry, the discussion on optical activity should prove of particular value, as all the workers in this country who are specially competent to speak on the subject are expected to be present. The ground has been prepared by Prof. Frankland's summary in his presidential address to the Chemical Society, whilst new light has been thrown on it by the recent work of Prof. Armstrong and Mr. E. E. Walker. Although of a far more speculative character, the discussion on radio-active elements and the periodic law, which Prof. Soddy is to open, should attract a large audience. For the benefit of its biological followers, the section will cooperate with the Physiological and Agricultural Sections for a discussion of some of the elusive processes included in the title fermentation.

SECTION D (ZOOLOGY).—The programme of the proceedings of Section D contains many items of considerable interest. In addition to delivering his presidential address, Dr. Gadow will open a discussion on convergence in the mammalia; Prof. J. Versluys (Giessen) and Dr. Chalmers Mitchell will also take part, and the palæontological side will be represented. There are several entymological papers which will form an introduction to a discussion on mimicry, to be opened by Prof. E. B. Poulton.

There will be a joint session with the Physiological and Botanical Sections for a paper and demonstration by Prof. Benjamin Moore on the synthesis of organic matter by inorganic colloids in the presence of sunlight, considered in relation to the origin of life. A novel feature will be a demonstration in the Cinema Theatre by Prof. H. Braus (Heidelberg), "Mikrokino Aufnahmen von lebenden Kulturen embryonaler Herzen." These films have previously been shown in Berlin and Vienna, but not in this country. The same author is communicating a paper on the homology of the gills in the light of experimental investigation. Another paper by a distinguished foreign visitor is one on the carapace of the Chelonia, by Prof. J. Versluys.

The afternoon lecture will be given by Prof. E. A. Minchin, who will deal with "Some Aspects of the Sleeping Sickness Problem." An excursion will be made to Burbage, on the invitation of Major C. C. Hurst, to view a number of extremely interesting experiments in inheritance, but the number of members whom it is possible to accommodate must necessarily be strictly limited.

SECTION F (ECONOMIC SCIENCE AND STATISTICS).—After the presidential address by the Rev. P. Wicksteed, the discussion will be concentrated on certain subjects. One of these will be "The Cost of Living," which will be introduced by papers from Prof. Irving Fisher, of Yale, Prof. Bowley, Mrs. F. Wood, and Mr. Cuthbertson. The attitude of trade unions to profit-sharing and co-partnership will be dealt with by Dr. C. Carpenter and Mr. B. C. Kershaw. There will be an important discussion on inland waterways. Papers will be read by Lord Shuttleworth, Sir J. P. Griffith, Mr. W. M. Acworth, and Mr. R. B. Dunwoody; amongst the speakers will be Mr. Neville Chamberlain, Mr. Frank Impey, Mr. J. A. Sauer, Mr. Fred Morton, and Sir J. Brunner. Other papers of a more miscellaneous character will be read by Prof. Chapman, progressive taxation; Prof. Muirhead, the economic order; Mr. A. J. Kenny, on mathematical methods; Prof. Oldham, study of business organisation; Prof. Kirkaldy, the Panama Canal; Mr. C. R. Enoch, human geography and industry planning; Mr. F. Tillyard, towns in the nineteenth century.

SECTION H (ANTHROPOLOGY).—In this section the programme will, as usual, cover a wide field. It includes a number of communications of considerable interest and importance, especially in connection with the study of religion. Dr. W. H. R. Rivers will read a paper entitled "Sun-cult and Megaliths in Oceania," Dr. G. Landtman will give an account of the ideas of the Kiwai Papuans regarding the soul, and Mr. J. H. Powell will describe, with lantern illustrations, the ceremony of hook-swinging in India, while Mr. W. J. Perry will present to the section the results of an examination of the custom of orientation in Indonesia. Major Tremearne will deal, in two separate papers, with the Bori ceremony of the Hausas of Tunis and the magic of the Nigerian Hausas. Semitic medical magic and folklore, as exemplified in a number of unpublished formulæ from the inscriptions, will form the subject-matter of a communication from Mr. R. Campbell Thompson, who will also submit for the consideration of the section his suggested decipherment of the Hittite inscriptions. Egyptian archæology will be represented by papers from Prof. Flinders Petrie and others. Prof. Petrie also proposes to describe the results of an anthropometric examination of the skeletal remains found in his excavations during the past season. Among the remaining archæological communications may be mentioned Dr. Capitan's description of recent discoveries of paintings in the Palæolithic caves of France, and papers by Dr. Ashby on Italian archæology.

An interesting topic which has not been under discussion in the section for some considerable time will be touched upon in papers by Mr. T. W. Thompson, on gipsy tabus and funeral rites, and by Dr. Rivers and the Rev. G. Hall, on gipsy pedigrees.

Finally, mention must be made of a paper by Prof. Fleure and Mr. T. C. James on the ethnology of Wales, which is of a special importance not only on account of its conclusions, but as an example of a statistical method.

SECTION I (PHYSIOLOGY).—The main feature of interest in the Section of Physiology is that, for the first time, there will be a subsection of psychology in connection with the above section. This subsection ought to be very attractive, as a large number of papers have been promised. One meeting will be devoted to a joint sitting of the whole section to hear papers of interest to both physiologists and psychologists. During the rest of the meeting, however, the subsection will meet independently.

A discussion on the physiology of reproduction will be held jointly with the Section of Agriculture on Monday, September 15, and Dr. F. H. A. Marshall will open this discussion.

The address of the president of the section will open the meeting, and the reports of research committees will, as usual, be taken early in the meeting. The report of the committee on anæsthetics should lead to some discussion, as Sir Frederic Hewitt wishes to raise the subject of legislative restriction of the employment of anæsthetics. Another subject of interest will be a paper which Prof. B. Moore is giving before a joint meeting of zoologists, botanists, and physiologists, on the synthesis of organic matter by inorganic colloids in presence of sunlight, in relation to the origin of life.

SECTION L (EDUCATIONAL SCIENCE).—The sectional programme is unusually full and interesting. After the presidential address a joint meeting with Section H will discuss "The Educational Use of Museums," in which Dr. Hoyle, of the National Museum of Wales, Mr. Chubb, of the Liverpool Museum, Sir Richard Temple, Prof. Newberry, Dr. Harrison, and others will take part. On the following day a question of national importance is down, viz. "The Function of the Modern University in the State." As the academic heads of several of the universities concerned have promised to speak, the meeting should be a large one. Amongst others, Sir Alfred Hopkinson, Sir Harry Reichel, Dr. Hadow, Dr. Alex. Hill, Dr. H. A. L. Fisher, Miss Tuke, Sir James Yoxall, Mr. Alfred Moseley, Sir George Kenrick, and Miss Burstall are expected to take part. The president of the association will also come, unless Section A proves too attractive.

Following its custom of recent years, the section, meeting jointly with the Psychological Subsection, will give Monday to the consideration of psychological investigations, so far as they illuminate educational practice. Dr. Kimmins will read a paper on the need for educational research, which will be followed by a discussion, and papers on the psychological processes involved in learning to read and spell will be read. On Tuesday a demand for the registration of schools will be raised by Mrs. Bryant, Bishop Welldon, and Bishop McIntyre; and Mr. P. B. Ballard, Mr. T. S. Usherwood, and Mr. W. F. Fowler will present the case for handwork as a factor in education. On Wednesday, Sir George Fordham will read an important paper on the working of the Act of 1902. This should provoke considerable interest in view of coming legislation. Other papers to be read include one on "The Use of Suggestion in Discipline and Training," by Mrs. Meredith, and the Montessori method, by Dr. Jessie White.

SECTION M (AGRICULTURE).—As usual in the agricultural section, a special feature is being made of joint discussions with other sections. An important meeting is being held with the botanists, when prolificness of barley is to be discussed. The chief British authority, Mr. E. S. Beaven, is giving an account of his extensive trials, and Messrs. Hunter, Hackett, and Bennet are describing the experiments made by the Irish Department of Agriculture. Another meeting is arranged with the physiologists to discuss the factors influencing sterility and fecundity in live-stock. Dr. F. H. A. Marshall is opening the discussion, and Messrs. K. J. J. Mackenzie, L. Doncaster, G. W. Smith, and others are expected to take part. The section is also participating in the biochemical discussion on fermentation.

A number of papers of very general interest are promised. Sir Richard Paget is dealing with the possibility of partnership between landlord and tenant. Prof. Fraser Storey describes the German forestry methods, and Mr. Walter Collinge is to deal with a curious disease of cereals. Considerable attention is being devoted to soil problems. Mr. T. Goodey is giving a summary of his investigations at Rothamsted on the protozoa of the soil, and Dr. Hutchinson and Mr. McLennan are describing experiments showing that soil may be partially sterilised by means of caustic lime. Mr. C. T. Gimingham is presenting an account of ammonification and nitrification in pasture soils.

Ecologists will be interested in Dr. Winifred Brenchley's summary of the relationships of weeds to arable land. Miss Taylor is dealing with certain fruit problems, and Messrs. Barker and Gimingham with Bordeaux mixture. The foreign guest is Prof. Sörensen, from Copenhagen, who will be very generally welcomed by men of science in this country.

Altogether the programme promises to be of considerable interest. Among the excursions is a visit to the Burbage Experimental Station, where Major Hurst's breeding experiments are to be seen.

NOTES.

WE announce with great regret that Prof. Francis Gotch, F.R.S., Waynflete professor of physiology in the University of Oxford, died on July 15 at sixty years of age.

WE REGRET to announce the death on July 3, in his fifty-sixth year, of Dr. R. Lendlmayr von Lendenfeld, professor of zoology and rector of the German University at Prague.

PROF. A. FOWLER, F.R.S., has been awarded the Valz prize of 450 francs by the French Academy of Sciences for his investigation of the principal series of hydrogen lines and other contributions to astronomical physics.

DR. HANS BUSCH has taken over the editorship of the *Physikalischen Zeitschrift*, and it is requested that contributions for that journal be addressed to him at Göttingen, Friedländerweg 61.

THE death is reported, in his seventy-first year, of Dr. Charles Greene Rockwood, who was professor of mathematics and natural philosophy at Bowdoin College from 1868 to 1873, professor of mathematics and astronomy at Rutgers College from 1873 to 1877, and professor of mathematics at Princeton from 1877 to 1905. Prof. Rockwood was a member of the Princeton Eclipse Expedition to Colorado in 1878, and contributed a large number of articles on seismology to American scientific periodicals.

THE science section of the R. Accademia di Bologna has issued a circular relating to the first biennial prize of 3000 lire from the fund given by Prof. Elia De Cyon for the encouragement of scientific research. Memoirs are invited on a number of subjects, including the functions of the cardiac and vasomotor nervous systems, the functions of the thyroid and pineal glands, and of the labyrinth of the ear. The memoirs may be written in Latin, Italian, French, or English. The award will be made on March 1, 1915. Full particulars can be obtained from the secretary of the academy, Mr. Ercole Giacomini, at Bologna.

MR. JOHN MUIR, the American naturalist, is appealing to nature-lovers throughout the United States to use their influence to save the Yosemite National Park from spoliation. The city of San Francisco is trying to rush through Congress a Bill permitting it to acquire the Hetch Hetchy Valley as a site for a reservoir. The proposed scheme would turn this valley into a lake, and would close to the public the Grand Canyon of the Tuolumne, a river which at this point is a succession of waterfalls of every variety of height and beauty. This would mean depriving the rest of the United States of 500 square miles, or more than one-half the total area of the present National Park. Mr. Muir supports his protest by showing that this destructive scheme is not really essential to meeting the needs of San Francisco, which could find other, if more expensive, sources of water supply. He quotes the report of an advisory board of army engineers in support of this contention.

UNTIL quite recently the discovery of pygmy flints, established in England by Rev. R. A. Gatty, had not been confirmed in Scotland. Mr. R. M. Leslie Paterson, in *Man* for July, now reports the discovery of flints of this type near the confluence of the river Feugh with the Dee, on the 10-ft. terrace level. This district abounds in stone circles, and contains burial-places and pottery of the Bronze age, thus showing that it was continuously occupied by prehistoric man. The present discoveries include pygmy flints of various types—rough knives, duck-bill and thumb scrapers, borers, and a saw. But, curiously enough, not a single arrow-head has yet been found.

It has hitherto been believed that the Maori religion represented a cult of the powers of nature, with ancestor worship; that they had no conception of a Supreme Being, and that their deities were malevolent, to whom no true invocations were offered, but merely rude charms and incantations. In *Man* for July Mr. Elsdon Best, on information received from an old member of the tribe, describes the cult of one of the late Mr. Andrew Lang's "High Gods of Low Races," in the worship of a deity known as Io, whose name was deemed so sacred that it was never uttered in public. The priest is said to have performed his devotions in a secluded spot in the forest, or he used to enter a river in a state of nudity, and stood waist-deep in the water, having first immersed the upper part of his body. The account of this remarkable cult is full, and apparently authoritative, however it may conflict with our preconceived views of the religious beliefs of the Maori people.

We are indebted to the author, Mr. L. M. Lambe, for a copy of a paper from *The Ottawa Naturalist*, vol. xxvii., p. 21, on the bones of a fore-limb of an iguanodont dinosaur of the genus Trachodon from the Edmonton formation of Alberta, Canada.

In vol. ix., No. 11, of *The South African Journal of Science*, reference is made to the discovery in the Lower Cretaceous marls of Bushman's River—the locality where the type skull of Owen's *Anthodon serrarius* was obtained—of the broken femur of a reptile fully as large as the corresponding bone of Diplodocus, and, when complete, measuring about 5 ft. in length. Whether it belongs to Anthodon, now believed to be a dinosaur, remains to be proved.

Since the publication of Mr. Boulenger's volume on the reptiles and amphibians in the "Fauna of British India," two new species of land tortoises, namely *Testudo travancorica*, of the Western Ghats, and *T. baluchiorum*, from Baluchistan, have been added to the Indian list, while *T. latinuchalis* and *T. horsfieldi* have been shown to range into the British Indian area. A third new species, *T. parallelus*, from the Singhbhum district of Chota Nagpur, is described by Dr. Annandale in the second part of vol. ix. of Records of the Indian Museum. In the same paper Dr. Annandale also describes a new species of terrapin from Chota Nagpur, under the name of *Geoëmyda indopeninsularis*, which is of interest as showing that the genus Nicoria is inseparable from Geoëmyda, in the sense in which these terms are used in the "Fauna." This obviates much confusion in nomenclature, as it renders superfluous the name Heosemys, proposed by Dr. Stejneger to replace Geoëmyda, as employed by Mr. Boulenger.

The co-existence of man with extinct animals in South Africa forms the subject of an article by Dr. R. Broom in vol. xii., part 1, of the Annals of the South African Museum. The most convincing evidence of this is afforded by a layer of peat at Haagenstad salt-pan, about thirty miles north of Bloemfontein. Below the upper layer of pure peat, 8 to 10 ft. thick, is another layer, of about the same thickness, composed of peaty sand, and beneath this is a bed of broken bones, burnt bones, and human implements. Although most of the implements were unfortunately dispersed, a stone spear-head and knife secured for the Bloemfontein Museum amply attest their human origin. Among several species of extinct and existing mammals, special interest attaches to the frontlet and horn-cores of a gnu (*Connochœtes antiquus*), which are stated to be almost exactly intermediate in character between those of the white-tailed gnu (*C. gnu*) and the brindled gnu (*C. taurinus*). The same issue contains six papers, some by Dr. Broom, others by Mr. S. H. Haughton, and others by both writers, on new and other vertebrates from the Permo-Triassic beds of South Africa.

Dr. Hans Preuss has published (*Schriften der naturforsch. Ges.*, Danzig, Band 13) an elaborate account of the vegetation of the Baltic coast of Germany (Schleswig-Holstein, Mecklenburg, Pomerania, West and East Prussia), his paper of 213 pages being illustrated by sixty-two photographs. This important paper is of great interest to ecologists in Britain, since the maritime vegetation of the North German coast presents considerable general resemblances to that of our shores, apart from its greater richness in species and the presence of such groups as the "Pontic" forms, which have doubtless migrated from the warmer regions of Central Europe along the river valleys to parts of the Baltic littoral.

Prof. V. Arcichovskij has forwarded reprints of five recent papers appearing in various German and Russian journals. Two of these give descriptions of methods for experimental work with seeds freed from micro-organisms; in one of these the author describes and figures a modification of Hansen's sterile chamber, adapted for investigations with sterilised seeds and for pure cultures of higher plants. A third paper deals with the culture of higher plants in a simple air-chamber improvised from an ordinary flower-pot; excellent results were obtained in the cultivation of bean plants in moist air, the nodules being unusually large and numerous, as well as with other species, and the author advocates this method in preference to the use of water or sand cultures, in which access of air to the roots is hindered by the excess of water used.

Mr. J. F. Dastur, of the Agricultural Research Institute, Pusa, has published (Memoirs Dept. Agriculture in India, vol. v., No. 4) an account of a new disease of the castor-oil plant caused by *Phytophthora parasitica*, n. sp. In his introduction the author gives a brief account of the cultivation of the castor-oil plant in India, and the varied uses to which the oil is put besides that due to its medicinal properties. Though so widely distributed, this plant has hitherto been regarded as immune from serious fungus pests, except the castor rust, but at Pusa the crop has been attacked by two serious pests, the new Phytophthora now described and a species of Cercospora, to be dealt with later. The former destroys seedlings by causing "damping off," and also attacks leaves of older plants, and is the most injurious of the fungal parasites of castor. The structure and life-history of the fungus are fully described and illustrated by means of ten excellent plates, one being coloured to show the characteristic brown leaf spots which form the first external indication of the disease.

TECHNICAL BULLETIN No. 16 of the Michigan Agricultural College Experiment Station deals with the grain-size and moisture content of soil in relation to bacterial activity. Aëration and thickness of the moisture film may be considered to be the important physical factors of the soil in relation to the activity of aërobic bacteria. Aëration increases as the square of the grain-size, while the increase of the moisture film is directly proportional to the grain-size. A coarse soil is therefore of advantage to the aërobic bacteria. The grain-size in cultivated soils is generally so small that the optimum moisture film is reached only in the waterlogged state.

IN the Bulletin of the Imperial Earthquake Investigation Committee (vol. v., pp. 109–37), Prof. Omori again directs attention to the small slow movements of the ground which he calls pulsatory oscillations. The period of these oscillations ranges from about four to about eight seconds, and Prof. Omori shows that the period at a given moment is identical even at Tokyo and Osaka, which are nearly 250 miles apart, not only in its mean value, but also in its variation from day to day. The amplitude of the oscillations is much greater on soft than on hard ground, and Prof. Omori suggests that the oscillations are produced at some depth in the solid crust and magnified when transmitted to the soft soil of the alluvial plains. A remarkable feature of pulsatory oscillation is their complete dissimilarity at stations only a few miles apart, it being impossible to identify the different maximum groups even at two observatories in Tokyo. This indicates that pulsatory oscillations are not the results of a progressive disturbance like an earthquake. Prof. Omori regards them rather as the results of underground disturbances originating at an infinite number of points, due probably to volcanic activity or to changes in the internal pressure caused by the transit of a deep barometric depression or by the existence of heavy ocean swells.

MR. R. C. MOSSMAN (Argentine Meteorological Office) has contributed to *Symons's Meteorological Magazine* for June the third of his useful articles on southern hemisphere seasonal correlations. During the months January to March a remarkable parallelism is pointed out since 1897 in the curves of mean temperature at Alice Springs (Australia) and Cordoba (Argentine Republic), both stations being located in a continental situation. In eleven out of fourteen years discussed (1897–1910) the departures from the means for the period have the same sign. But previous years (1879–96) show no definite agreement. During the same months an opposition is generally shown in the mean temperature curves at Perth (Western Australia) on one hand, and at Valparaiso and Santiago (Chile) on the other; for Valparaiso data for only nine years (1901–9) were available. There is also an opposition between the mean temperature at Santiago and the thickness of the ice at Duluth (Lake Superior). These results, as Mr. Mossman remarks, are of interest as they indicate an interrelation between the action centres governing the conditions during the period in question in Australia, South America, and the United States.

A WELL-ILLUSTRATED article in the Journal of the Franklin Institute for May reproduces an address given before the institute in January by Mr. E. A. Sperry, president of the Sperry Gyroscope Company, and deals with the engineering applications of the gyrostat. It appears that the gyroscope has been successfully applied to the stabilising of the United States steamer *Worden*, and that the application has enabled a more complete study of the effects of rolling of vessels on the power necessary to propel them to be made. To the gyrostatic compass we have directed our readers' attention previously. The application of the gyrostat to the control of the wings and rudders of an aëroplane has now been successfully carried out, and we have, in addition, recorders of the rolling and pitching of vessels and artificial horizons depending on the gyrostatic principle, all working satisfactorily.

THE report of the Advisory Committee for Aëronautics for the year 1912–13 gives a general account of the work accomplished. The construction of the new four-foot wind channel at the National Physical Laboratory has been undertaken in the light of numerous experiments, and the pulsations in the flow which are the chief cause of difficulties in air-channel experiments have been so much reduced that the accuracy of individual measurements can be relied on in general to within one-half per cent. This channel replaces one of the same size, but a new 7-ft. channel is projected, and the necessary sum for its construction will be included in the estimates for 1913–14. In this respect the laboratory will be provided with means for experiments on fully rigged models of complete aëroplanes, an acceptable addition to its resources too long delayed. Amidst a number of interesting and important researches carried on, the investigation of the stability problem will command most attention, alike from mathematicians, physicists, and from those who have to trust themselves to their incessant vigilance to keep their frail craft upon an "even keel" in the air, and we therefore are glad to note that great advance has been made in the study and investigation of this problem, though sufficient time has not elapsed to put the knowledge so derived to the test of practical application. The close relationship between the work carried on at the Royal Aircraft Factory and that at the laboratory gives reason to hope that the inevitable divergence between laboratory and full-scale experiments will be ascertained and allowed for, and we are glad to note the cooperation that exists to forward the experiments. We hope to return to the work of this department of the laboratory when the technical report of the committee is ready.

IN a paper published in the *Gazzetta Chimica Italiana* (vol. xliii., i., 38) Prof. F. Angelico and Mr. F. Catalano have brought forward additional evidence in support of the generally accepted view that traces of formaldehyde are present in the foliage leaves of plants during the period of active assimilation under the influence of sunlight; they show, moreover, that formaldehyde is absent when the same plants are kept in darkness so as to suppress the chlorophyllian function. Parasitic plants, such as *Psalliota campestris* and Coprinus, which do not contain chlorophyll, also fail to give any indication of the presence of formaldehyde. The authors made use in their experiments of the glucoside atractylin, which is present in *Atractylis gummifera*; this substance they find to be the most delicate test yet devised for minute traces of formaldehyde; a solution obtained, for example, by adding three drops of 40 per cent. formaldehyde to one litre of water gives, under suitable conditions, a distinct violet coloration with the reagent. This behaviour is quite specific, no other aldehyde or substance responding in the same way.

THE report of the meeting of the Swiss Scientific Association held last autumn at Altdorf includes accounts of the many permanent commissions which the association has instituted. One of the most notable is in charge of the definitive edition of Euler's works; five volumes, including the "Algebra," "Dioptrica," and "Mechanica," have been published since 1911. The work of the geological commission and the glacier commission is prolific in measurements, maps, and observations. The nature protection commission, instituted in 1906, is successfully carrying out the project of a *grande réserve*, or national park, in the Grisons (the commune of Zernetz). Newly instituted is the commission for the study of atmospheric electricity. Among the papers read, a comprehensive study of the mountain structure of central Switzerland, by Dr. P. Arbenz, is one of the most considerable. Mr. Weiss discusses recent research in molecular physics, and his own work on magnetons. "Radiation and Matter," by von Kowalski, includes investigations in atmospheric electricity; Mr. R. Chodat describes the problems of plant-coloration and his own important experiments in this difficult subject. Mr. Pictet shows that the flight of insects in relation to artificial light is not a case of tropism. Very interesting conclusions on the effects of storms upon forests are drawn by Mr. van Ufford from the destruction of the forest at The Hague in 1911. Mr. Mirimanoff carries further than Poisson and Oettinger the mathematical theory of the game *trente et quarante*. The sixty-nine papers read at the meeting are well distributed among the various sciences, and deal in many cases with significant and important research.

PROF. J. WALKER, F.R.S., of Edinburgh University, is just completing a "Text-book of Organic Chemistry for Students of Medicine," which will shortly be published by Messrs. Gurney and Jackson, London, and Messrs. Oliver and Boyd, Edinburgh.—Dr. Reinheimer is about to issue through Messrs. Kegan Paul, Trench, Trübner and Co., Ltd., a volume entitled "Evolution by Co-operation: A Study in Bio-Economics."—"The Living Plant," a description and interpretation of its functions and structure, by Dr. W. F. Ganong, will be published shortly by Messrs. Constable and Co., Ltd.

OUR ASTRONOMICAL COLUMN.

A METEORITE SEEN TO FALL AND FOUND.—It is not often that a meteorite is actually seen to fall to the ground, but this was the case with the specimen described by Messrs. Masumi Chikashige and Tadasu Hiki, in the Memoirs of the College of Science and Engineering, Kyoto Imperial University (vol. v., No. 1, September, 1912). It was at 6.30 on the morning of April 7, 1904, that the meteorite fell at the village of Okano, in the neighbourhood of the town Sasayama, in the province of Tamba, Japan. The white glowing mass was observed by a peasant, and when he came to the spot he found a stone which looked like a block of iron with the long point upwards, and imbedded about 80 cm. A teacher 30 km. to the north observed the meteorite also as a white glowing mass, at an altitude of about 70°. The chemical analysis, which is given in the paper, is as follows, in percentages:—Iron, 94·85; nickel, 4·44; cobalt, 0·48; copper, trace; phosphorus, 0·23. Thus nickel-iron amounted to 98·52 per cent., and phosphor-nickel-iron 1·48 per cent. This result is very similar to that obtained in the De Sotoville meteorite, namely nickel-iron 98·71 per cent., and phosphor-nickel-iron 1·29 per cent. The authors complete their monograph with three excellent plates showing the external appearance of the meteorite and sections before and after treatment.

MEASURES OF PROPER MOTION STARS.—The Carnegie Institution of Washington has just issued another large volume (No. 168), the contents of which in this case consist of the valuable series of measures of proper motion stars made by Mr. Burnham with the 40-in. refractor of the Yerkes Observatory in the years 1907 to 1912. Attention may be directed in the first instance to the promptitude of publication of such a mass of valuable data, for this large volume, containing no fewer than 311 pages, includes measures so recently made as last year. The total number of measures made in the present work is about 9500, and all places are given for 1880 unless otherwise mentioned. The original places as given in the General Catalogue of Double Stars have been retained, and the stars in part i. reduced to the same epoch. The measures are published in two parts. The larger number of stars selected for measurement are given in part ii. of this volume, and are taken from the General Catalogue of Double Stars for reasons stated in the notes and observations in that work. Part i. includes all other stars for which prior observations with the micrometer have been made. The small stars from zone 26° of the Oxford Astrographic Catalogue were compared with one or more fainter stars in the field. Mr. Burnham has added three more stars, namely 37 Tauri, 55 Tauri (OΣ 79), and OΣ 82, to the list of Boss's thirty-nine bright stars, principally in Taurus, which appeared to have a common proper motion of approximately 0·10″ in the general direction of about 100°.

THE TOTAL SOLAR ECLIPSE OF AUGUST 30, 1905.—In a beautifully got-up portfolio measuring about 20×25 in., just issued by the Hamburg Observatory, Prof. R. Schorr publishes a series of nine reproductions illustrating the photographs of the corona he and his party secured during their expedition to Souk-Abras, in Algeria, in August, 1905. Perfect weather was experienced on this occasion, and the programme was carried out in its entirety. When it is stated that the diameter of the moon on these plates measures 7·5 inches, the scale of the reproductions can be better understood. The main object of the expedition was to obtain the structure of the inner corona by means of photography, and for this purpose a horizontal telescope of 20 metres focal length was used, fed by a cœlostat. The objective itself was by Zeiss, and of 160 mm. aperture, and achromatised for wave-lengths 531·7 and 405·1 $\mu\mu$, the resulting solar image being 19 cm. in diameter. In the introduction to these plates Prof. Schorr gives details as to the kind of photographic plates used, and the details of exposure. Great pains seem to have been taken to make the reproductions as representative of the original negatives as possible, and the result is remarkably successful. Each plate is accompanied by a celluloid sheet over it, on which the correct orientation and prominent features are marked. The last plate is a reproduction of a drawing by Dr. Graff of the structure of the inner corona, in which are combined the details shown in all the negatives. Fortunately, on the occasion of that eclipse the corona was fully of quite extraordinary detail, especially in form, and this record is therefore of particular interest. The atlas is a valuable outcome of a most successful expedition.

KELVIN MEMORIAL WINDOW.

THE memorial window to Lord Kelvin, subscribed for by engineers in Great Britain, Canada, and the United States, was dedicated at a special service in Westminster Abbey on Tuesday. The window is in the east bay of the nave on the north side. The light from it falls upon the graves of Kelvin and Isaac Newton, and immediately beneath it are the graves of Darwin and Herschel. The window, which was designed by Mr. J. N. Comper, is chiefly ecclesiastical and historical in character. The lights contain two large figures under canopies; and in front of the pedestals of these two figures are tablets held by angels, containing the words:—"(1) In memory of Baron Kelvin of Largs, (2) engineer, natural philosopher, b. 1824, d. 1907." Beneath these again are the arms of Lord Kelvin and of Glasgow University.

The Dean of Westminster, in the course of an address, is reported by *The Times* to have said that forty years ago there were at Cambridge an extraordinary constellation of great men of mathematical genius—Adams, Clerk-Maxwell, Cayley, and Stokes—occupying professorial chairs. Of the four, two had been justly commemorated in the north aisle of the Abbey. Another Cambridge man, William Thomson, was destined to surpass his four friends. In originality, in range of study, in ingenuity and resource, Kelvin was pre-eminent. It was said by Goethe that to make an effort in the world two conditions were essential—a good head and a good inheritance. Lord Kelvin and his four friends had both. The new world of electricity had been already discovered. They entered into that inheritance and transformed its glories for the practical utility of mankind. It was Kelvin who subdued the whole province of the new realm of science. All through his life, in the face of a strong prevailing current of materialism, Kelvin preserved the simplicity of his early Christian faith. He wrote in 1892: "The real phenomenon of life infinitely transcends human science." He spoke with the humility of a great man, and many could look back with gratitude to the example which the religious belief of a man of his gigantic intellect furnished to those of a younger generation. His name was one of the most epoch-making in the domain of natural philosophy.

The chairman of the Memorial Committee then offered the window to the Abbey, and it was gratefully accepted by the Dean on behalf of himself and the Chapter.

THE EXETER MEETING OF THE ROYAL SANITARY INSTITUTE

AT the twenty-eighth congress of the Royal Sanitary Institute, held at Exeter on July 7–12, many useful papers were contributed, one or two of which dealt with research work of scientific interest.

Mr. James Crabtree contributed a paper which embodied some experiments on the lines of those carried out by Dr. E. J. Russell and his co-workers on the part played by protozoa in soils, the experiments here recorded relating to sewage disposal beds. From these experiments it is evident that the fauna of the bacteria bed play an important part in keeping the bed open and porous; it seems probable that they play a further part by the actual digestion of some of the more easily resolvable colloidal matter precipitated on the beds. The conclusion arrived at is that the animal population of the bacteria (contact) bed is entirely advantageous in maintaining the capacity of the bed, probably in keeping down extraneous bacteria, and thus assisting purification to some extent, and also by bringing about some actual digestion of colloidal deposited matter.

Dr. Gilbert G. Fowler and Mr. E. Moore Mumford contributed an interesting paper on the bacterial clarification of sewage. The area and cost of sewage filter beds depends mainly upon the amount of colloidal matter present in the sewage, and some confusion of ideas is probably due to the fact that the ordinary sewage filter is called upon to do two entirely different things at the same time, namely on one hand to oxidise, granulate, and finally discharge as humus the colloidal matters present, and, on the other, to oxidise and nitrify substances in true solution. If this oxidising and coagulating process could be brought about by suitable open-tank treatment before the filtration process, it is obvious that the latter could be enormously accelerated, if not dispensed with altogether; and the whole operation of sewage treatment could be conducted on a much smaller area.

In the course of a research on another matter, one of the authors had occasion to study the reactions of an organism occurring in nature in pit-water impregnated with iron. This organism is a true facultative organism, preferably an aërobe, and it exercises a specific action on iron solutions. The action of the bacillus on iron solutions proceeds in two stages, in which the aërobic and anaërobic actions appear to be symbiotic, at any rate under the conditions occurring in nature. The aërobic action is to precipitate ferric hydroxide from iron solutions; while the anaërobic action is to transform the hydroxide thus precipitated into bog ore, with partial reduction of the iron to a ferrous state. It was found that in order to precipitate the iron sufficiently the organism required a certain proportion of albuminoid organic matter. It was, therefore, natural to expect that ordinary sewage matter could be utilised in this way. Experiment, in fact, showed that a previously sedimented sewage effluent could be effectively clarified in this way when acted upon by this organism in presence of small quantities of ferric salts, aërobic conditions being maintained in the liquid by means of a current of air. An experimental plant has been erected at the University of Manchester, which will permit of accurate observations of this process and the collection of further detail.

Mr. F. Southerden has extended the investigations made at Leeds, Glasgow, and London, upon atmospheric pollution, to the atmosphere over the city of Exeter and its immediate surroundings. He finds that rain-water collected less than a mile from the centre of the city is very noticeably superior to that collected more centrally, the proportion of dissolved solids and sulphate reaching only about one-half, but there is no marked difference as regards the chlorine or ammonia, and so he concludes that these are derived in the main from sources other than coal smoke. The experiments make it clear that the atmospheric pollution of Exeter, though less in amount, is similar in its nature to that in larger towns.

Mr. Southerden also gave the results of his investigations upon the effect of coal smoke on the stonework of Exeter Cathedral. The stonework consists of limestone of varying quality and texture, and the oxy-acids of sulphur derived from the combustion of coal convert the calcium carbonate of the stone into soluble calcium sulphate, and the surface of the stones slowly crystallises and expands in such a way that disintegration results. The author concludes that the exact conditions which lead to scaling are not simple, but the extent of sulphate formation appears to be an important factor, and the destructive influence of sulphuric acid is doubly important, for in the more sheltered situations it leads to disintegration by scaling, and in exposed positions calcium sulphate is formed and dissolved away, thus hastening the destruction brought about by more natural agencies, such as frost, wind, and rain. The blackening which is very noticeable on portions of the stone structure is due to a thin film of soot, from which it has been possible to extract a small amount of tar.

REPORT OF THE ADVISORY COMMITTEE ON FORESTRY.

A FEW weeks ago was issued a Blue-book of general interest, the Report of the Advisory Committee on Forestry for the period July to October, 1912 (Cd. 6713, price 6*d*.). The Advisory Committee on Forestry comprises such well-known names as Sir E. Stafford Howard, Sir S. Eardley-Wilmot (late Inspector-General of Forests, India), Sir D. Prain (director of Kew), Sir William Schlich (the Oxford professor of forestry), and Prof. Somerville, of the Oxford School of Rural Economics, who is perhaps as well known for his writings on forestry as for those on agriculture; and Mr. E. R. Pratt, president of the Royal English Arboricultural Society. Of the ten members of the Committee only four are professional foresters, so that the professional element is not even in a majority. Mr. R. L. Robinson, the chief of the forestry branch of the Board of Agriculture and Fisheries, fulfills the office of secretary to the Advisory Committee, and is apparently the author of the two chief appendices to the report, though one of these is not signed. These appendices, on forest research and development, contain a mass of technical information and interesting general observations, which will well repay perusal by those interested in British forestry.

The Blue-book contains the advice of the Forestry Committee on three questions submitted to it for opinion by Mr. Runciman.

The first of these questions relates to forest surveys, which it is advised should be divided into two classes: (*a*) preliminary or flying surveys, (*b*) detailed surveys.

The surveys proposed should bring together much useful information, and supply a long-felt want in the cartography of these islands. We have excellent geological, topographical, meteorological, and other maps; but he who wishes to see what is the extent and value of the woodlands must be satisfied with the ordinary ordnance maps and a few forest maps. The ordnance maps give no indication of the quality, and are often misleading as to the quantity, of the forest. Yet few of the special maps that exist have the importance of a forest map, with the national issue of 30,000,000*l*. yearly sent out of the country for timber and forest produce, which could be produced easily in these islands! The extension of forest surveys is therefore an excellent scheme, which should meet with universal approval.

When, however, we go on to read that surveys of both types are necessary "*as a preliminary step towards the inauguration of afforestation operations*," the forest surveys assume a sinister aspect. If they are to be taken as an excuse for postponing the commencement of practical forestry, the country will be better without them. This, perhaps, is why Mr. Munro Ferguson adds his rider to the report: "I am of opinion that 2000*l*. is a sufficient sum to apply for survey work for the next two years, after which the expenditure could be reviewed in the light of experience." In the estimate at p. 50, the total cost of the surveys is given at 35,000*l*., and the time at eleven years; and this is for a partial survey, not embracing the whole of the seven areas mentioned in the report of the Advisory Committee. These seven areas for the forest surveys are:—

1. South Wales.
2. North Wales.
3. Westmorland, Cumberland, and Northumberland.
4. Kent, Surrey, and Sussex.
5. Berks, Hants, Wilts, and Dorset.
6. Derby, Lancashire, and the West Riding.
7. Lincoln, Norfolk, Suffolk, and Essex.

It is recommended that surveys be begun in districts 1, 3, 4, and 7, and that in conducting these preliminary surveys use should be made to the fullest extent of the knowledge which local owners, foresters, and agents possess. The cooperation of the Royal English Arboricultural Society and of local committees is also invited. This is excellent.

The report expresses doubts as to the advisability of publishing these forest surveys. It is not clear wherein lies the difficulty of doing so, but obviously they should be of much general utility, both to the public at large and the student of forestry.

The second question on which the advice of the Forestry Committee has been asked relates to "demonstration areas." These have figured largely in British forest literature of recent years, and the Advisory Committee states that "it has received their very careful consideration" (though, indeed, this phrase is repeated in the answer to each question). It seems possible that forest demonstration areas are one of those side issues which during the last three years in British forestry have served to distract attention from the main question—the inauguration of practical forestry by the acquisition and planting of ground on a large scale. Here Mr. Munro Ferguson has added another rider which will receive the hearty approval of every forester—"I agree with paragraph 6, that the Forest of Dean, with the adjoining Crown woods, is well suited to meet the requirements imposed by a demonstration forest, and am of opinion, therefore, that the whole area should be removed from the control of the deputy-surveyor and placed under a trained forest officer." Some years ago, when the post of deputy-surveyor of the Forest of Dean became vacant, some 600 applications were received for the vacant post, one of them actually being a worthy minister of a local Methodist connection. This shows the loose manner in which forest appointments had come to be regarded in this country. At that time there were probably not a dozen quite qualified foresters available in the whole of Britain.

Rules are framed for the maintenance of experimental plots in private forests. It is possible that in some cases useful purposes may be served by these rules; but it may be anticipated that most frequently we shall find the private forest owner conducting useful experiments in his own forests; and the forest officers, with their wider facilities, carrying on their own experiments in the State forests.

The third reference relates to the training of woodmen, both foremen woodmen and the more fortunate men whose lot it is to work with their own hands. Those who have had experience of the excellent training given in the Government school in the Forest of Dean would endorse all that is here said in its favour. The two forest schools, in the Forest of Dean and in the Chopwell Woods (county of Durham), provide for the training of about fourteen men yearly. We heartily endorse the recommendation that increased provision should be made for the training of men of their type. The census of 1901 returned 12,035 woodmen employed in England and Wales.

The appearance of this Forestry Blue-book is opportune; it shows that Mr. Runciman is actuated by an earnest wish to break away from the difficulties and delays that have so long beset British forestry. It is indeed time that the first sod in practical British forestry were turned. While the Development Commission, with its grant of 500,000*l.* yearly, has been running for three years, no beginning in practical State forestry has yet been made in Britain.

It is not evident from a perusal of the Blue-book why there should be further delay. The obvious course to be followed now is at once to open negotiations for the acquiring of land—either by direct negotiation, or by purchase as it comes into the market; and, so soon as an area has been secured, to depute the competent forest officials in the Whitehall Forest Office to proceed with the planting, in consultation with local opinion and experience. The examination of sites for State forests seems to offer scope for the energies of the five forest advisors recently appointed to the five forest areas into which England and Wales have been divided. These forest advisors are stationed at Oxford, Cambridge, Cirencester, Bangor, and Newcastle.

Following the practice of other countries, the State forest nurseries referred to in the Blue-book should be initiated, as early as may be; not only for the supply of young trees at economical rates for planting in the State forest, but for *free issue to private forest owners*, and to such municipal or other public bodies as may be disposed to undertake forest planting on their own account. The private forest owner in Britain has had a hard time these last years, with falling prices for timber and underwood, and increased taxation. The woodlands that he maintains are a national benefit, and he may well ask that the State should now help him with something more substantial than good advice in forestry!

A somewhat pressing question that the Advisory Committee has not yet touched upon is what monetary contribution, if any, should be allowed to municipal (or other corporate) forest planters by way of grant-in-aid, in the case of loss on their forest planting. India and Cape Colony are, in State forestry, some thirty years ahead of this country and the other British Colonies. For many years in Cape Colony municipal and other non-private planting has been aided on the 1*l.* for 1*l.* principle; that is to say, to every 1*l.* of approved forest expenditure Government has added another 1*l.* With this contribution the State retains certain guarantees for the proper management of the forest or trees planted.

It is, as we have seen, now three years since the Development Commission obtained the grant of half a million a year for developing the natural resources of the country in various ways, the most lasting and far-reaching of these ways being forestry. During the first year provision was made for the planting of about ten square miles of forest in Ireland; but in Great Britain to this day no decided step has been taken in practical State forestry. We may therefore express the very earnest wish that, useful though the contemplated forest surveys may be, they will not be allowed to delay, for one day, the initiation of State forestry in Britain.

In the present season of the year, England is beautiful, almost in proportion to its woodedness! Every consideration of sentiment and hard fact demands the beginning, without further delay, of practical afforestation.

ORNITHOLOGICAL NOTES.

IN view of persistent reports as to the marked decrease, or even disappearance, of the landrail, or corncrake, as a breeding bird in many parts of the country, more especially the eastern and south-eastern counties, the editors have issued with the June number of *British Birds* a schedule of inquiries on this matter. In a covering note Dr. Ticehurst points out that answers should be strictly limited to the presence or absence, now or in the past, and the relative numbers and changes in numbers, of breeding birds in different districts.

A beautifully illustrated article on the albatrosses of Laysan Island, in the South Pacific, appears in the April number of *The American Museum Journal*, based on a visit paid to that wonderful bird-resort by Mr. H. B. Dill in 1911. In spite of periodical raids by plumage-hunters, the albatrosses still retain their original lack of fear, parties of them walking up to a visitor as if to greet him. Some idea of the vast numbers of sea-birds on the island may be gathered from an estimate that their daily product of guano is about 100 tons. Some years ago a company was started to work this guano, but the venture was not a success, owing to the fact that the frequent rains wash out a large proportion of the ammonia from the deposits.

To the April number of *The Emu* (vol. xii., part 4) Dr. R. W. Shufeldt contributes an illustrated article on the osteology of the Cape Barron goose (*Cereopsis novae-hollandiae*). Although the skull presents certain well-marked peculiarities, the rest of the skeleton is that of a typical goose. The genus has been assigned to a special subfamily, but the affinities of the bird are clearly with the snow-goose (*Chen hyperboreus*).

According to *The Christian Science Monitor*, Boston, Mass., of May 29, Mr. R. C. Murphy has returned to New York from an ornithological expedition to South Georgia, bringing with him 500 skins and skeletons of large sea-birds, while others are to follow. These are to be divided between the American Museum of Natural History and the Brooklyn Institute of Arts and Sciences. Mr. Murphy states that on a small island a mile in diameter he has seen 4000 pairs of birds nesting on the ground. The principal specimens represent albatrosses, petrels, and three kinds of penguins. R. L.

GREAT ADVANCE IN CRYSTALLOGRAPHY.[1]

TWO pictures of the actual apparatus employed (one of which is produced in Fig. 7), and an explanatory diagram of it (Fig. 8), will enable the precise nature of the experiment to be grasped. A plate, 1 cm. square and 0·5 mm. thick, was cut from a good crystal of zinc blende parallel to a cube face, and

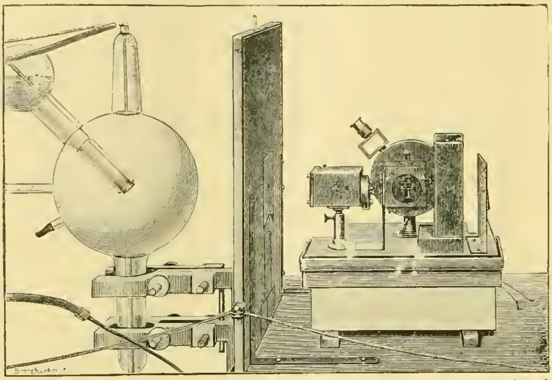

FIG. 7.—Apparatus of Friedrich, Knipping, and Laue for passing X-rays through crystals and photographing the effect.

adjusted on the crystal holder of a goniometer in the path of a very narrow pencil of X-rays from the bulb, isolated by their passage through a succession of lead screens (lead being impervious to X-rays) pierced by small holes. The last screen, which gave the final form to the pencil of rays, was a plate of lead 1 cm. thick, pierced by a cylindrical hole 0·75 mm. in diameter, and fitted with a delicate means of adjustment so that the axis of the boring could be brought

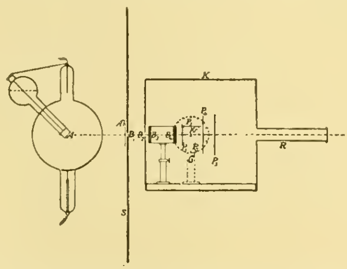

FIG. 8.—Diagrammatic representation of apparatus of Friedrich, Knipping, and Laue. A, Antikathode of X-ray bulb; B_1, B_2, B_3, B_4, diaphragms of lead; K, leaden box-screen with tubular termination R; S, large leaden screen; G, goniometer; P_1, P_2, P_3, P_4, P_5, photographic plates; Kr, Crystal; Al, aluminium plate.

exactly perpendicular to the crystal plate. The beam of pure X-rays of circular section, after passing normally through the crystal plate, was received on a Schleussner-Röntgen photographic plate, which was afterwards developed with rodinal.

The developed plate showed an intense circular spot at the centre, caused by the direct X-rays, and a considerable number of other spots of elliptical shape, arranged in a geometrical pattern. Three of these original photographs are exhibited on the screen (and two are also reproduced in Figs. 9 and 10). If a series of such photographic plates be used, at different distances from the crystal (as for Figs. 9 and 10), the fact is revealed that the spots are formed by rectilinear pencils of rays spreading in all directions from the crystal, and some of them inclined more than 45° to the direction of the incident rays. These deflected beams show similar properties to the original X-rays, ionising air and helium just like the latter, and with the same degree of variation with the pressure. Hence, there can be no doubt that the character of these deflected rays issuing from the crystal is that of unaltered X-rays, and that they are due to the deflection of X-rays by planes situated at different angular positions in the interior of the crystal. In short, we are in face of reflection of X-rays from planes of atoms in the crystal.

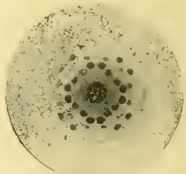

FIG. 9.—Spot photograph afforded by zinc blende. Incident X-rays perpendicular to a cube-face, and parallel to a tetragonal axis of symmetry.

Now a study of the spots reveals the further interesting fact that the pattern shows the full symmetry (that of class 32) of the cubic system to which the

crystal belongs, although zinc blende exhibits the slightly lower symmetry of the hexakis-tetrahedral class (31), one of the formerly so-called hemihedral classes of the cubic system. This clearly proves that it is the planes of similar and similarly situated (same-

[1] From a discourse delivered at the Royal Institution on Friday, March 14, by Dr. A. E. H. Tutton, F.R.S. (continued from p. 494).

ways orientated) atoms in the crystal that are producing the reflections; in other words, the planes of the space-lattice.

At first Laue, who published a separate memoir on the theory of the experiments, considered that it was the space-lattice due to similarly situated zinc atoms which afforded the spot patterns, as he had been engaged with Prof. Summerfeld in experiments relating to the action of zinc on X-rays. But there appears no reason why the sulphur atoms should not be similarly capable of producing reflections of these extremely fine vibrations of corpuscles, and as the space-lattice is the same for both elements, according to all versions of the geometrical theory of crystal structure, there is really no reason why we should not consider the reflections as due to the general space-lattice of zinc blende. Laue considered the "molecules" of the crystal to form a three-dimensional grating—that is, a Raumgitter—and that each molecule is capable of emitting secondary vibrations when struck by incident electromagnetic waves from the X-ray bulb; also that the molecules are arranged according to the simple cube space-lattice (No. 1). The incident waves being propagated parallel to one of the cube axes (edges), the wave-surfaces will be parallel to the plane of the other two cube edges. He then considers the spots to be interference maxima of the waves scattered by the orderly arrangement of the molecules in the crystal. The equations of condition were next found for interference maxima of direction cosines α, β, γ, and for incident wave-length λ, and from the position of each spot the direction cosine of the pencil of rays which formed it was calculated, assuming all the transmitted pencils to come from the centre of the crystal. Thirteen spots in each quadrant were investigated, and in every case Laue's equations were satisfied; hence, the conclusion that the spots are due to interference of secondary Röntgen radiation appears to agree with the positions of the spots, provided only radiations of certain definite wave-lengths are present in the incident rays.

The lecturer pointed out, in an article in NATURE of November 14, 1912, that the structure of zinc blende was probably not so simple as had been assumed by Laue, and that the space-lattice with a point at the centre of each side of the cube (No. 3) was the more probable one, the structure being that assigned to it by Barlow and Pope, as already described in this lecture.

A satisfactory explanation has since been advanced by W. L. Bragg, which does accord with this structure and with other essential conditions referred to by the lecturer, altogether avoids the assumption of only a few wave-lengths, and agrees with a simple reflection of unchanged X-rays from the planes of points of the general space-lattice of zinc blende. He regards the incident radiation as composed of a series of independent pulses, which, falling on a number of atoms definitely scattered in a plane, are separately reflected, each atom acting as a centre of a secondary wave, and the whole building up a wave-front. The interference maximum is thus due to the reflection of the incident pulses from a system of parallel planes of similar atoms, that is, from one of the parallel series of planes of the space-lattice. Now besides the principal planes of the space-lattice, the cube planes, the points of the space-lattice also lie in a considerable number of other planes, all of which are possible crystal faces corresponding to rational indices. For instance, the octahedral planes are very easily traced, as also those of the rhombic dodecahedron. A minute fraction of the energy of a pulse traversing the crystal will be reflected from each parallel plane in succession, and the corresponding interference maximum will be produced by a train of reflected pulses. The crystal thus actually manufactures rays of definite wave-lengths, just as a diffraction grating does, the only difference being here in the extremely short length of the waves, which is the very reason why X-rays can penetrate in this manner into the Raumgitter structure. Each incident pulse produces a train of pulses, resolvable into a series of wave-lengths, λ, $\lambda/2$, $\lambda/3$, $\lambda/4$, &c., where $\lambda = 2d \cos\theta$, d being the shortest distance between successive identical parallel planes in the crystal, and θ the angle of incidence of the primary X-rays on the plane of points of the space-lattice. The intensity of any spot depends on the energy in the spectrum of the incident radiation characteristic of the corresponding wave-length, and this varies considerably so that certain parts of the spectrum are much more pronounced than others. Also it depends on the number of reflecting atoms in the plane—that is, on the reticular density of the possible crystal face corresponding to the plane. Hence, the greater the reticular density, the more intense the spot produced in the photograph. As reticular density is also proportional to importance of face, the primary faces having the greatest reticular density, it follows that the most important facial planes reflect the intensest spots, a fact which may prove of great value in enabling us to discover the real primary planes in doubtful cases. Each spot reflected by a plane (considered as passing through the origin and two other points) lies at the intersection of two ellipses, and the figure on the screen, showing an analysis of one of the spot photographs, exhibits this clearly. Indeed, the plane of atoms corresponding to any spot can be found from the two ellipses; for each ellipse is the section of a cone by the plane of the photographic plate, the axis of the cone being the line joining the origin (centre of the triaxial system, and considered as one of the three points determining the plane) and the particular atom (the second or third point of the three, of definite coordinates), and the generator of the cone being the incident beam.

The interesting results of Bragg are in full accord with the assumption of the centred-face cubic space-lattice (No. 3), but not with either the simple-cube or the centred-cube space-lattice (Nos. 1 and 2). They also account for the elliptical shape of the spots. The amount of ellipticity depends on the distance of the photographic plate from the crystal. When the two are very close the spots are round, but they become more and more elliptical as the plate is receded (compare Figs. 9 and 10). The phenomenon is due to the fact that the initial rays are not strictly parallel, and the effect will be clear from the next slide. The vertically diverging rays striking the reflecting planes of the upper part of the crystal meet them at a less angle of incidence than those of the lower part, and so the reflected rays converge. Horizontally diverging rays, however, diverge still more on reflection. Hence the section of the reflected beam is an ellipse with major axis horizontal.

It is of importance to note that the centred-face cubic space-lattice is characteristic both of the arrangement of identically (sameways) orientated and environed atoms of the same element, zinc or sulphur, and of the atoms of both elements regarded as equal spheres in contact. In the slide already shown (Fig. 5), of Barlow and Pope's model, the spheres of sulphur are coloured yellow to distinguish them from the grey-coloured spheres of zinc. If we ignore the colour and consider them as similar spheres, we see that they form the centred-face cubic arrangement. The hemihedral nature of zinc blende is, however, very likely connected with some real difference of volume between the atomic spheres.[5] As the spot figure is holohedral it would appear to be due to the space-lattices of similarly placed atoms of either (but in each lattice only one) element, rather than to the spheres of the combined system of atoms.

This latter conclusion is further borne out by the result of the new work by Laue on quartz. The photograph now shown, so kindly sent by Prof. Laue, exhibits the trigonal nature of the symmetry very clearly, and Prof. Laue informs me that the same figure is afforded by both right and left quartz, so that it does not reveal the hemihedral character of quartz, but possesses the full holohedral symmetry of the trigonal space-lattice, and exhibits the threefold nature of the axis of symmetry which is perpendicular to the plate and along which the X-rays were directed.

Prof. Laue has also experimented with the crystals of a number of other cubic substances, and, like zinc blende, they all show holohedral symmetry about a tetragonal axis.

W. L. Bragg has found that stronger photographs of the same nature can be obtained from mica, using nearly grazing incidence, and it is by use of this fact that Mosely and Darwin have been able to study the reflected rays electrically, and found them to resemble ordinary X-rays. By the kindness of Mr. Bragg, a diagram of his apparatus and a positive lantern slide of one of his mica spot photographs are exhibited on the screen.

Incidentally these experiments appear likely to throw light on the much-debated question of the nature of the X-rays. As all the experiments unite in indicating that a fraction of the X-rays suffers reflection at the planes of atoms parallel to the more important possible crystal faces, all being planes of atomic points of the space-lattice, it would appear that the X-rays are some type of wave-motion, or at any rate some kind of pulse with an extended wave-front. Yet after reflection they retain the same corpuscular character which Prof. W. H. Bragg has shown they possess. For the liberation of a high-speed electron from an atom traversed by the X-ray cannot be explained, according to Rutherford, unless it be supposed that the energy of the X-ray is concentrated over a minute volume, and can be given up in an encounter with a single atom. Hence these experiments show that the X-rays possess at the same time the apparently opposite properties of extension over a wave-front and concentration in a corpuscular point.

It appears to the lecturer that the simpler explanation is that we are truly dealing with waves, but that the wave-lengths of the X-rays are excessively short, approaching atomic dimensions, and that the amplitude of the effective waves is actually smaller than the reflecting atom. This view that the X-rays are waves is further supported by the results of some experiments just completed by Barkla, in which a diverging pencil of X-rays was directed on a crystal of rock-salt, and the issuing rays received on a photographic plate in the same manner as in the experiments already described. The developed plate shows a new phenomenon, namely, striation of the spots obtained by reflection from the planes of atoms of the space-lattice, especially in the reflections from the cubic cleavage planes. The striations are, in fact, true interference bands, due to interference of the reflections from equally spaced parallel planes of the space-lattice. By the kind courtesy of Prof. Barkla, two of these interesting photographs are projected on the screen. On the assumption that the X-rays are waves, and that the reflecting plane is one passing through corresponding portions of single NaCl molecules—which agrees with the choice of a representative point from each simple molecular grosser unit, or of a similarly situated atom of one of the two chemical elements present in each molecule NaCl to act as such representative point of the space-lattice—Barkla has calculated that the wave-length is the one hundred and sixty millionth of a millimetre, $0{\cdot}6 \times 10^{-8}$ mm. If the grosser unit be polymolecular, the wave-length works out larger, being proportional to the cube root of the number of atoms in the molecule. If eight molecules form the grosser unit of sodium chloride crystals, as suggested by some chemists, the wave-length is found by Barkla to be twice this value, namely $1{\cdot}2 \times 10^{-8}$ mm.; and if sixteen molecules of NaCl are comprised in the grosser unit, as would be the case if Barlow and Pope's structure for the cubic binary compounds be correct (the space-lattice in the case of rock-salt being that of the simple cube, No. 1), the wave-length would be still longer, about the seventy millionth of a millimetre, $1{\cdot}5 \times 10^{-8}$ mm. Now it is very interesting that these values are of the same order as those derived from determinations of the velocity of electron ejection, which varied from 1 to 2×10^{-8} mm.

The most trustworthy recent estimations of the size of a molecule of rock-salt indicate a diameter about 3×10^{-7} mm. Hence the diameter of a crystallographic molecule 8NaCl would be 6×10^{-7} mm., and of 16NaCl about $7{\cdot}5 \times 10^{-7}$ mm.

It should be emphasised, in concluding the account of this fascinating new field of research, that all these reflections occur in the body of the crystal, and are not surface effects. Cleavage planes usually afford stronger results merely because they are generally primary planes of high reticular density. The effect is sometimes heightened by conducting the X-rays at nearly grazing incidence; but this is by no means necessary, and in Laue's experiments several of the planes were inclined as much as 30° to the incident rays.[6]

The experimental proof of the existence of the space-lattice imparts all the more confidence in approaching the other great advance which has lately been achieved. The completion of the four-volume catalogue of crystallographically measured substances by Prof. von Groth provokes the question: What more is needed in order to enable a crystallised substance described in this book to be recognised by means of a few measurements on the goniometer? For it is now proved up to the hilt that, except in the cases of cubic crystals identical in angles in accordance with their perfect symmetry, every solid crystallisable substance is characterised by its own peculiar crystalline form and interfacial angles. This is quite true, even to the last minute of angular measurement, when the conditions of crystallisation are ideal. When thus perfect, even isomorphous sub-

[5] Prof. T. W. Richards shows (*loc. cit.*) how four molecules of ZnS, each composed of an atom of zinc and an atom of sulphur of very different volumes, can form the cubic crystal unit of an edifice possessing cubic systematic symmetry, the different volumes of the two kinds of atoms causing it, however, to exhibit hemihedral class-symmetry.

[6] Since this lecture was delivered, the following further experiments with X-rays and crystals have been described in NATURE (1913, vol. xci., pp. 111, 135, and 161). H. B. Keene has obtained with crystals of galena, mica, and rock salt analogous results to those of Laue, Friedrich, and Knipping, the spot diagrams corresponding to the holohedral systematic symmetry in each case. T. Terada has found that the transmitted rays may be rendered optically visible by means of an ordinary fluorescent screen, provided the pencil of rays be from 5 to 10 mm. in diameter and the crystal adequately transparent to the rays; this latter he found to be the case with crystals of alum, borax, cane-sugar, fluorspar, mica, rock crystal, and rock salt, in thicknesses of 4 to 10 mm. M. de Broglie has obtained spot diagrams similar to those of Laue, Friedrich, and Knipping with fluorspar, magnetite (using an octahedron face), and rock salt; but all the spots were striated with parallel fringes. Finally, Owen and Blake have obtained what appears to be a line spectrum of X-rays by using the surface of a crystal of gypsum as a diffraction grating. The lines were always the same with different crystals, using the same X-ray bulb, but the different lines varied in intensity with the hardness (degree of vacuum) of the bulb. The evidence from the action of crystals on X-rays is thus accumulating that the X-rays are waves of exceedingly short wave-length.

stances show differences among themselves to the extent of a definitely measurable number of minutes. But such perfection of growth is not easy to attain, and, in ordinary crystallisation without special precaution against disturbance, is rarely found. The essential crystallographic measurements can, however, be made in an hour's time, provided use be made of the two- or three-circle form of goniometer, such as the excellent one devised by Dr. Herbert Smith. This form of goniometer enables all the needful measurements of the interfacial angles to be made with a single setting of the crystal on the wax of the holder. But practical difficulties have hitherto still stood in the way. Excellent as is von Groth's classification—and the most suitable for a work of reference of the full and comprehensive character of this permanent monument of the master's industry and wide knowledge of chemistry, related compounds being arranged and compared in close proximity—the very nature and size of such a work renders it unsuitable for the purpose of discovering rapidly the chemical composition of a substance from its geometrical elements. An index of substances arranged in the order of their symmetry and the numerical values of the crystal constants within the system is what is needed, and this has now for the first time been drawn up for the ten thousand measured substances by Prof. von Fedorow.

Another difficulty then presents itself. It often entirely depends on how a crystal is held in space, that is, which direction in it is regarded as the vertical axis, which the right-and-left axis, and which the front-and-back axis, as to what the nature of the crystal constants (elements) will be. Moreover, even if two different observers choose these similarly, they may select a different parametral plane (a fourth face other than the three faces parallel to the axes, and cutting off unit lengths from the latter) to determine the axial ratios. Hitherto, beyond a few arbitrary rules —for instance, that the right-and-left axis of a rhombic crystal shall be longer than the front-to-back axis —there has been no definite guiding principle for the determination of the setting. Prof. von Fedorow has now given us one, by means of which we can be sure which are the real vertical faces (prismatic or pinakoidal), which is the basal plane (the pair of top and bottom faces), and which set of pyramid faces are the important ones fixing the relative axial lengths. The true setting has been determined by Prof. von Fedorow for every one of the substances in his index, and the crystal elements for such setting calculated.

The mode of classification adopted in this index-catalogue is based on the values of the five fundamental angles which, in general, characterise the crystals of any specific substance. A cubic crystal has definite angles which are entirely fixed and rendered invariable by reason of the perfect symmetry. At the other extreme come triclinic crystals, the general case, in which all five fundamental angles are different and quite independent of each other. On monoclinic crystals there are three independent angles, from which the other two can be calculated. Rhombic crystals have only two independent angles, which, if measured, enable the other three to be calculated. Hexagonal, tetragonal, and trigonal crystals possess only one angle independent of the symmetry, determinative of the relative length of the unique axis of hexagonal, tetragonal, or trigonal symmetry.

The first object of von Fedorow in order to arrive at the correct setting is to decide which are the primary axial-plane and parametral faces; and he is wonderfully aided here by the discovery of the fact that the faces most extensively developed under ideal conditions of growth are those over which the points of the space-lattice are most densely strewn. Hence, von Fedorow tries to discover the faces of greatest reticular density, the primary faces, by calculation. For it is a well-known fact that the most diverse habits—due to different faces being most prominently developed under different conditions of environment—are shown by the crystals of the same substance.

Having thus determined the correct setting, and measured the principal angles, including the five fundamental angles, the results are recorded in the index-table in an abbreviated symbolic form if the substance be a new one, or, if it has previously been measured, and therefore appears in his index-table, he discovers the fact at once by the identity of the elements found with those of a substance given in the table. The average time occupied in all this by Prof. von Fedorow or one of his skilled assistants is about two hours. Mr. T. V. Barker, who studied with Prof. von Fedorow before acting as demonstrator of mineralogy at Oxford, has been of considerable help in submitting the new method to a very severe test, from which it has emerged with flying colours. He collected, at Prof. von Fedorow's suggestion, fifty specimens of substances which had been crystallographically examined in this country and described in the recognised publications. Five of these were furnished by the lecturer, six others by Prof. Armstrong, with the aid of Messrs. Colgate and Rodd, others by Drs. Chattaway and Drugman and Mr. Marsh at Oxford, and the remainder by Mr. Barker himself. Each specimen was only marked by a number, no name or formula being given, on its dispatch to St. Petersburg. The result was that Prof. von Fedorow identified without any difficulty forty-eight of the fifty substances. The crystals of one of the two others were too imperfectly developed to be of use, and the fiftieth specimen was that of a substance which it was afterwards discovered had never hitherto been measured, a fact which was first indicated by its elements not tallying with those of any substance mentioned in the table. This latter occurrence confers even greater confidence in accepting the new method.

It thus appears that in Prof. von Fedorow's hands, or those of his pupils, the method is practically infallible, provided the crystals are well developed and not of cubic symmetry. If the latter perfect symmetry be developed, reference must be made to the optical properties, which the lecturer has always insisted have been far too much neglected, and are here seen to be indispensable. The optical methods themselves, moreover, as regards their use with small crystals on the polarising microscope, have been further perfected by von Fedorow, his universal stage placing the rapid methods of two- and three-circle goniometry at the disposal of the microscopist. It must also be remembered that Prof. von Fedorow's method does not discriminate between the members of isomorphous series, as the crystals usually available are not of the high degree of perfection requisite in order clearly to substantiate the last few minutes of any particular angle; for the differences of angle between the members of series formed by metallic family analogues have been shown by the lecturer to be very minute, although unmistakable given the most perfect crystals, and have also been found to obey the law of progression according to the atomic weight of the metal. For instance, ammonium zinc sulphate was simply returned by Prof. von Fedorow as a member of the isomorphous series of monoclinic double sulphates and selenates crystallising with $6H_2O$. Qualitative analysis would be necessary after all, in order to discover the actual member of the series present. Moreover, there are certain features of Prof. von Fedorow's own peculiar version of the theory of crystal structure, such as his idea about pseudo-cubic and pseudo-hexagonal types, and his dealing in consequence with many substances as being deformations of a higher symmetry than they actually show, which to the lecturer appear unnecessary complications likely to discourage the use of the new method. But these defects can, and doubtless will, be eliminated as the method becomes practically applied. That crystallochemical analysis will ever entirely replace qualitative chemical analysis, however, is neither to be expected nor desired, even if alone on the ground of the admirable training and experience in chemical operations and principles which chemical analysis affords.

In conclusion, it must be obvious that a great advance has really now been made in crystallography. For the geometrical conception of crystals as homogeneous structures, based on the fourteen space-lattices as the grosser structures and the 230 point-systems as the ultimate atomic structures, has been not only theoretically perfected, but proved by direct experiment to represent the actual fact, by the epoch-making work of Laue, Friedrich, and Knipping. The descriptions and chemical relationships of all the ten thousand measured substances have been brought together in the great book of Prof. von Groth, and the material further sifted, reduced to correct setting, and arranged according to symmetry and elements by Prof. von Fedorow, in a tabular form immediately available as a reference index for identification purposes, thus providing the material for a true crystallochemical analysis. The science of crystallography is thus now placed on a secure foundation, supported equally by mathematics, geometry, and experiment, and its natural data are rendered available for chemists and physicists alike.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. C. W. Dyson Perrins, a former member of Queen's College, has offered to give the sum of 5000*l*. towards the erection of the proposed new chemical laboratory, if such sum is required after the expenditure of the 15,000*l*. granted for the purpose by the trustees of the Oxford University Endowment Fund.

THE honorary degree of LL.D. was conferred on Mr. W. Botting Hemsley, F.R.S., on July 8 by the University of Aberdeen.

DR. W. C. MCCULLAGH LEWIS has been apppointed to the chair of physical chemistry in the University of Liverpool, in succession to Prof. F. G. Donnan, F.R.S.

THE following honorary degrees were conferred by Queen's University, Belfast, on July 9:—*D.Sc.:* Prof. Norman Collie, F.R.S.; Sir Joseph Larmor, M.P., F.R.S.; Sir Arthur Rücker, F.R.S. *LL.D.:* Sir Donald MacAlister.

AMONG the bequests of the late Lord Avebury is one of 1000*l*. to the University of London to found a prize in mathematics or astronomy in memory of his father, Sir John William Lubbock, first Vice-Chancellor of the University.

DR. J. RITCHIE, superintendent of the laboratory of the Royal College of Physicians, Edinburgh, has been appointed to the new chair of bacteriology instituted in the University of Edinburgh, under the bequest of Mr. Robert Irvine, Royston, Granton.

AMONG recent appointments at University College, London, are:—Dr. Marie Stopes, lecturer in palæobotany for three years; Miss Winifred Smith, lecturer in taxonomy for three years; Dr. Paul Haas, demonstrator in organic and applied chemistry and in chemical physiology, and Mr. H. Terrey, demonstrator in chemistry to medical students; Mr. N. F. Kelsey, demonstrator in mechanical engineering, and Mr. D. W. Fletcher in graphics.

THE following official announcement referring to the Education Bill has been issued on behalf of the Government:—"The measure which will shortly be introduced by Mr. Pease in the House of Commons, although it is technically described as an Education Bill, is in reality only a one-clause measure designed to enable the Government to afford a limited amount of immediate relief to education authorities. It will, when introduced next week, form a not inappropriate peg upon which to hang a statement of the Government's policy in the development of a national system of education."

AT the annual graduation ceremony at St. Andrews University on July 10 honorary degrees of LL.D. were conferred on Lieut.-Col. Sir C. H. Bedford and Dr. G. A. Boulenger, F.R.S., among others. In addressing the graduates the principal, Sir James Donaldson, said that both France and Germany have come gradually to form an exact notion in regard to university work. Their idea is that after the culture obtained in the secondary schools the students who are to proceed to degrees should spend three years at the university and should devote themselves to the original study of certain subjects in which they find their interest. There must be entire freedom for the student to form his own plans and studies and entire freedom for the professor to search for the truth for its own sake in disregard to consequences. The Germans have kept to that idea since 1815, and the French have now come to the same conclusions. We are in many respects far behind this ideal, and we cannot expect to be a match for those nations in the great conflicts of the world, but it is the duty of young and old to look into the question, particularly at this time, and see if we cannot do something to put ourselves on an equality with Germany and France.

THE recommendations made in the second report of the Advisory Committee on the distribution of Exchequer grants to universities and university colleges, which was issued last February, having been approved by the Board of Education, the Committee proceeded with a further consideration, in conjunction with the universities and colleges, of the federated superannuation scheme adumbrated in the second report. In its third report the committee outlines a federated scheme of superannuation for professors and other members of the staffs of colleges. Two problems were debated; first, the selection of a limited number of insurance companies to undertake the contracts involved by the superannuation system; and secondly, the drafting of a suitable form of legal agreement between the institution and the members of the staff which when adopted by colleges concerned would give practical effect to the principles set out in the second report. The form of agreement indicates, by means of alternative readings, the various forms which will be necessary to meet different cases. In practice institutions will probably find it convenient to have separate forms of agreement to meet different types of cases. The superannuation scheme itself expresses in legal terminology the principles outlined in the second report, and in order to secure interchangeability it seems essential, the third report points out, that this part of the legal document should be adopted without amendment by every institution cooperating in the system. A pamphlet has been prepared setting out the main features of the options available and the precise terms offered by the selected insurance companies; it also embodies the detailed arrangements with the companies, and copies will be furnished on request by the companies concerned.

FROM time to time attention has been directed in these columns to the recent successful endeavours to develop the University of Hong Kong. The prospectus for the session 1913–14, and a pamphlet providing details concerning the faculty of engineering, have reached us, and an examination of the arrangements made shows that there is likely to be much useful work done in the next few years in the spread of higher scientific education in China. A resolution adopted by the Court of the University says: "It is resolved that the objects of the University are (*inter alia*) to afford a higher education, more especially in subjects of practical utility, such as applied science, medicine, &c. Similarly, in a dispatch from the Viceroy of Canton, we read "the teaching of applied science, including civil, mechanical, and electrical engineering and surveying, meets the present and most urgent need of our country." The University possesses spacious laboratories for experimental work and is assured already of excellent equipment. In the first year of the University fifty-three students applied for admission in the faculties of engineering, medicine, and arts, and of that number thirty-eight elected to take instruction in engineering. When the University commenced instruction in engineering science it was stated definitely that no student would receive a degree unless he attained the same standard as that required by the London University. To that policy the faculty of engineering is committed, and the regulations have been framed with that object in view.

THE eighth report has been published (Cd. 6871) of the Rural Education Conference, which was constituted by minutes of the Presidents of the Board of Agriculture and Fisheries and of the Board of Education in 1910. The conference has had under consideration the following reference received from the Board of Agriculture and Fisheries last November:—"To inquire into the methods which local education authorities adopt with the object of promoting efficiency in the performance of manual processes, *e.g.* ploughing, hedging, ditching, sheep-shearing, milking, and basket-making, and to advise as to any further action that may appear to be desirable for the purpose of developing skill in workmen employed in agriculture." After the examination of eleven expert witnesses representing farmers and educationists, the conference drew up a number of recommendations which may be summarised very briefly. To develop skill in agricultural employees it is recommended that instruction in certain manual processes of agriculture should be provided for the elder boys and girls attending elementary schools in rural districts; local education authorities should regulate the holidays in country schools so as to leave the boys free to work on the land at a time when their work is most useful; classes in manual processes for men employed upon the land should be conducted so as to be more in the nature of assistance to, rather than the formal instruction of, those who attend; instruction in manual processes should be provided more generally throughout the country, present instruction should be made more thorough, and practical instruction be encouraged in every possible way.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 7.—M. F. Guyon in the chair.—Paul **Appell**: Developments in series proceeding according to the inverse of given polynomials.—J. **Boussinesq**: The equations of dynamic equilibrium of the superficial layer separating a liquid from another fluid.—A. **Lacroix**: The rhyolitic and dacitic rocks of Madagascar, and in particular those of the Sakalave region. Complete analyses of twenty-one rocks are given, and the distribution of the rocks in the area discussed.—A. **Müntz** and E. **Lainé**: Studies on the irrigation of soils. The minimum irrigation gives the best cultural results; it depends on the slope of the land, the nature of the vegetation, and the dimensions of the distributing channels.—G. **Charpy** was elected a correspondant for the section of chemistry in the place of the late Louis Henry.—Ch. **Platrier**: Meromorph solutions of certain linear integral equations of the third species.—M. **Barré**: Helicoids of the second species.—Th. **Got**: The symmetries of the reproductive groups of indefinite ternary quadratic forms.—A. **Romieux**: Contribution to the study of the terrestrial deformation.—C. G. **Bedreag**: Electrification by the X-rays. The charge depends on the pressure, the nature of the metal of the electrode, difference of contact potential between the electrode and the surrounding walls, and ionisation of the gas. In the present communication a special study is made of the function of the metal. André **Chéron**: A new arrangement for the examination of stereoscopic photographs.—Henri **Labrouste**: The visibility of traces of foreign substances deposited on a surface of pure water. The method described permits of the thin layers being detected by optical means without the use of any special apparatus. Mlle. Cécile **Spielrein**: The equilibrium of lithium sulphate with the alkaline sulphates in presence of their mixed solution at 100° C.—Ruby **Wallach**: The thermal analysis of clays. The double galvanometer of Le Chatelier-Saladin with a thermocouple was applied to the examination of various kaolins and clays, the heat absorption due to the volatilisation of water being shown by well-marked depressions on the curve. A slight heat evolution between 900° C. and 1000° C. was also observed in some cases, an effect probably due to a transformation of alumina.—André **Job** and Paul **Goissedet**: The cerium acetylacetonates. Ceric acetylacetonate has been prepared and analysed.—M. **Dumesnil**: Diketones obtained by the action of the xylylene dibromides on the sodium derivative of *iso*-propylphenylketone and their decomposition by means of sodium amide. Roger **Douris**: The addition of hydrogen to some secondary α-ethylenic alcohols in presence of nickel.—Marcel **Baudouin** and Louis **Reutter**: The analysis of the contents of some Gallo-Roman vases and of a flask of perfume, found in a vault at la Vendée. These vases date probably from the third century. Styrax, turpentine, resin, asphalt, or Judean bitumen, and incense were found. These prove indirectly the existence of commercial relations between France and Asia Minor, Somaliland and Judea.—J. **Durand**: A layer of aragonite crystals in the marls attributed to the Upper Trias in eastern Corbières.—C. **Gaudefroy**: The dehydration figures of different types obtained in the same crystals.—A. **Guilliermond**: The rôle of the chondriome in the elaboration of the reserve products in fungi.—A. **Marie** and Léon **MacAuliffe**: The anthropometric study of 200 Madagascans.—E. **Gley** and Alf. **Quinquaud**: The influence of the suprarenal secretion on the vasomotive actions dependent on the splanchnic nerve.—A. **Barbieri**: The difference in chemical composition between the great sympathetic system and the axial nervous tissue of the cranial and spinal nerves.—E. **Bourquelot** and M. **Bridel**: The synthesis of β-geranyl-glucoside with the aid of emulsin; its presence in plants. The glucoside can be synthetised from geraniol saturated with water and glucose in presence of emulsin; a larger yield is obtained in aqueous acetone solution. The presence of this glucoside was proved in *Pelargonium odoratissimum*.—P. Noël **Bernard** and J. **Bauche**: The influence of the mode of penetration (cutaneous or buccal) of *Stephanurus dentatus* on the localisations of this Nematod in the organism of the pig and on its evolution.—E. **Pinoy**: The necessity of a bacterial association for the development of a Myxobacterium, *Chondromyces crocatus*.—F. **Picard** and G. R. **Blanc**: Coccobacillary infections in insects.—F. **Kerforne**: The Devonian iron minerals of Brittany.—Antonin **Lanquine**: The presence of layers containing Witchellia, of the lower Bajocian, at some new points of the Var.—Alfred **Angot**: A new barometric formula. The barometric formula communicated to the last meeting is equivalent to Babinet's formula. The latter in its original form is more easy to memorise.—Ladislas **Gorczynski**: The reduction in the solar radiation for 1912 from pyrheliometric measurements made in Poland.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2282, VOL. 91] THURSDAY, JULY 24, 1913 [PRICE SIXPENCE

Registered as a Newspaper at the General Post Office.]

THURSDAY, JULY 24, 1913.

CAMBRIDGE IN THE NINETEENTH CENTURY.

"J.": a Memoir of John Willis Clark. By A. E. Shipley. Pp. x + 362. (London: Smith, Elder and Co., 1913.) Price 10*s.* 6*d.* net.

TO anyone who had a share in Cambridge life in the latter half of the century that closed with 1910, J. W. Clark, either as superintendent of museums or as registrary, was a familiar and striking figure. The many who knew him intimately called him "J.," and all will welcome the biography with that title which the Master of Christ's, in more ways than one "J.'s" successor, has produced with the assistance of a number of friends. The book itself is rather gossipy. "We respected him as a man of learning and weight, and still more as a man of the world," says one of the contributors; and it is largely with "J." as a man of the world that the book deals. From the point of view of the casual reader, it reminds one somehow of the hundred and nineteenth psalm. The kaleidoscope is shaken through some 300 pages, but the same constituent elements occur on every page: "J.'s" friendliness, waywardness, temper, as well as his interest in society, travel, theatres, museums, buildings, architecture, books and libraries; and the serious part of the book, which deals with the development of the study of the natural sciences at Cambridge, finds accommodation in two appendices. But, by the same token, those who read the book with some knowledge of local colour will find it an epitome of Cambridge in the nineteenth century, opportunist, casual of purpose, wayward, but effective and progressive.

Look at the beginnings. "J.'s" father, William Clark, the second son of a Newcastle doctor, was sent to Trinity in 1804, became a scholar in 1807, seventh wrangler in 1808, fellow of Trinity in 1809, "having especially impressed the examiners by a brilliant rendering of a passage of Pindar into English verse." He "walked the hospitals" in London, was admitted to holy orders, and at the age of twenty-six became a candidate for the "professorship of anatomy." The election was *more burgensium.* Lord Byron was a distinguished supporter. Clark failed on the first occasion, but succeeded later, and became professor of anatomy in the University at the age of twenty-nine—a fine instance of casualness of purpose, waywardness, and effectiveness on the part of the University.

At that time the domination of the colleges over the University was complete. The heads of the seventeen colleges were the governing body; pairs of colleges took it in turn to "police" the undergraduates, and to examine them all for their degrees. The head was "the only permanent officer of the college"; indeed, the other offices were mostly held at his pleasure. It is a common misunderstanding to suppose that the matrimonial restriction operated to prevent fellows marrying; its real effect was to restrict the college appointments to what would now strike us as extreme youth. A few confirmed bachelors who had taken holy orders lingered on in residence, and sometimes even attained old age, but they soon became superannuated for college work and fossilised. Lecturers were often Bachelors of Arts, and an appointed tutor has had to wait for the completion of his M.A. degree before he could fufil all his functions. Veritable history speaks of a college don who, having passed through all the range of college offices, was regarded as quite past work, and only waiting until it should please Providence to call him to his rest, and who, on inquiry, proved to have attained the ripe age of thirty-five years. He is, however, still in this world of care, again enjoying a well-earned rest, though he has some thirty years of service in a country living to add to the record which forty years ago was regarded as complete.

Thus when "J.'s" father took up the duties of professor of anatomy, the permanent staff of the University and colleges made up a small and select society of seventeen heads and twenty-five professors, with a registrary and librarian, three bedells, and eleven "cormorants," members of the senate *commorantes in villa.* The selectness and closeness of that society are still the subject of many Cambridge anecdotes, some of which are included in "J.'s" charming reminiscences, reprinted from the *Cambridge Review,* in the volume before us; but what is forgotten is that there must have been a yawning gulf of age between the average college don and the permanent society which, as years went by, had necessarily to rely more and more upon its dignity rather than its activity for the respect of the rising generation. The social amenities of college life naturally remained mediæval, and to a certain extent they are so yet. It is still an accepted principle that the simple labour of the bedmaker is to be preferred to the devious machinations of the plumber for carrying bath-water to and fro.

Into this close society "J." was born in 1833, with one of the twenty-five professors as father, and another, Robert Willis, as uncle; the biography does not say what he thought of professorships, but he never developed that respect for headships of colleges which continues to be the keystone of the structure of Cambridge society.

He was sent to Eton, where he was not very happy, and then passed on to Trinity. As an undergraduate he wrote with characteristic exaggeration: "Really, I cannot but think it quite monstrous that everyone is to waste four-and-twenty years of their life in learning two dead languages which can never be of the slightest use to them"; but he obtained a place in the first class of the Classical Tripos in 1856, and his exertions were rewarded by a fellowship in 1858. Vacancies were not so scarce then as they are now; the average tenure was, no doubt, much shorter. "I never ought to have got a fellowship, but there happened to be eight vacant that year, and they gave me one."

It was the same all through his life—things happened. After obtaining his fellowship, he proceeded to amuse himself with foreign travel and otherwise. "He took an active part . . . especially in the A.D.C.," and so he became for many years stage-manager of the University for dons and men, and the drama was his hobby. When his fellowship lapsed, in 1866, he retained his rooms in Trinity because he was supposed to be engaged upon the college records, and he was deputy junior bursar in charge of the buildings, and deputy librarian in charge of the books. He only returned the muniments which gave him a title to rooms, duly "calendared," forty-four years later, but he soon became the leading authority on college buildings and the care of books. His father included comparative anatomy in the subject which he professed, and collected specimens in illustration. When he grew old, his classical son helped with the "museum," and so, when his father resigned, became superintendent of the Museum of Comparative Anatomy, while human anatomy went to G. M. Humphry, and a new professorship of zoology was created. The attitude of the new professor to the Museum of Zoology and Comparative Anatomy is characteristic of himself and of one side of Cambridge.

"The prevalent belief, I take it to be, is that the professor of zoology ought to look after the museum. I need not say how absurd this is. . . . One notion that underlies it all is that your salary (!) may be saved to the University, which, of course, is false, because I should never, under any circumstances, take on me such additional duties without an equivalent."

The appointment as superintendent and the lapse of his fellowship, since "J." was not in "orders," occurred in the same year; and, at the same time, he became a member of the newly formed Museums and Lecture Rooms Syndicate, and later he became secretary. The history of this syndicate, now at an end, is neither more nor less than the history of the development of the study of the natural sciences in Cambridge, and it nearly all "happened" while "J." was secretary. How it all happened, perhaps no one can say; new statutes and a Royal Commission, a few far-sighted dons, and private benefactors had something to with it, but "J.," without professing anything, or being what one could call a don, was there all the time, a sort of nucleus for growth. That "J." was a Trinity man goes without saying, but, perhaps more than anyone else, he stood for the University as distinguished from the colleges. Of his college he became auditor, a sort of external guardian, but of the University he was so much a part that the statutory offices of librarian and registrary, for which the colleges had never claimed a right in rotation, seemed his own. Popular election gave him the latter in 1891, and in that he served the University until close upon his death in 1910.

In 1873, when his position in Cambridge was established, "J." happened to propose to, and marry, Miss Frances Matilda Buchanan, whose father was at the time British Ambassador at Vienna. According to his biographer, this was the best thing he ever did, and certainly he owed to it no small part of his success as a man of the world. The book abounds with stories and letters of affectionate family life, of deep and lasting friendships, and of unconstrained sociability with all men of proper tone, quite irrespective of age or academic standing. "J." was a very helpful friend, but he never patronised.

Thus "J." made the most of a very fortunate opportunism; he never set out deliberately to be a zoologist, or a man of books, or an archæologist, and he certainly did not try to be a social success; yet he was all these things because they came in his way.

How like to his University! While "J." lived his life, Cambridge, out of the rivalry of her colleges, developed from her "tripos" a scheme of examination which has overspread the Civil Service and the whole educational system of the country, without any more motive than to "doe the nexte thyng." It has somehow added study to study, laboratory to laboratory, museum to museum until it has obtained a magnificent establishment for the University, as distinct from the colleges, and the old close society has become absorbed in a larger life. Those who remember the material provision which the University had in the early 'seventies for Maxwell, Stokes, Foster, Liveing, Dewar, and compare it with the scientific palaces that are now to be found there.

about, will naturally look for some well-laid scheme for fostering all the subjects that are called scientific. They will find something *à propos* in the action of the Commissioners of 1877; but, so far as the spontaneous action of the University is concerned, it is all very much "as it happened." Other universities may set out to rear proconsuls, and succeed therein, but Cambridge leaves her actions to define her ambitions. If she prepares for nothing, there is nothing which she is not prepared for, if only opportunity offers.

Like "J.," if there are museums to be tended, she is a zoologist; if there are books to be cared for, she learns about libraries; if there are buildings to think about, she is an archæologist, or at least an architect. One is reminded of the person whom Mark Twain once set to music in words like these:—

> Whate'er this man is sot to do
> He'll do it with a zest;
> No matter what his training is,
> He'll do his level best.

There are, indeed, few things in this world that the well-trained Cambridge man has no opinion about; he generally knows at least how they ought to be done. A few weeks ago a typical Cambridge man, confronted for the first time with an elaborate contrivance, the result of years of effort, for eliciting some of the secrets of nature, gave expression to his admiration by suggesting that it was probably based upon an erroneous principle. The danger of the Cambridge opportunism is that the opportunity of doing the same things over again, but, of course, better, is such a tempting by-path leading away from the object for which the things are done at all.

The Cambridge man has the examiner's instinct in his bones; he is so accustomed to examining everything that his first impulse is to assign marks —but not too many. "I should give 75 per cent. for the sort of answer I would have written myself," as a colleague examiner once said. It may be that, in the same way, the instinct of the sister university, on being confronted with a new fact, would be to write an essay about it (which might come in useful sometimes), but Cambridge still holds by "Mr. Tripos," and cannot help beginning the consideration of any subject by a "nego majorem," if possible.

One ought not to omit the biography of Sedgwick, written in conjunction with Prof. McKenny Hughes, but "J.'s" chief contributions to our knowledge were his four monumental volumes of the architectural history of the University and colleges of Cambridge, begun by his uncle, Robert Willis, his dramatic work, and his numerous books and pamphlets on libraries and the care of books, while his ostensible business in life was the Museum of Zoology and Comparative Anatomy. According to his own account, had Frank Balfour lived, he would have devoted himself to science, but, unfortunately, Balfour perished. Here, again, through him we see his University. With its seventeen colleges it now includes a vast staff of persons of the highest competence, whose ostensible duties are to teach, but how many of them become known to fame for their teaching? One hears more often of their attaining eminence as "good business men," and, indeed, the curious art of expert management of affairs by unpaid syndics seems likely to overspread the land like the examination idea. Perhaps Rhodes might have had some opinion on the subject; he might have thought, with some justice, that the syndic was apt to take out his value in time, as there was no question of money. It may be either pious or profane to say it, but in its indirectness of purpose Cambridge is distinguished from the great world outside, and the Cambridge man is apt to carry with him the opportunist idea which abounds on the Cam, that his chance of distinction lies in making and using opportunities to do something else.

Dear "J."; one wonders what he would have said at his biography being made a spyglass to look at his University with; something forcible, no doubt, if not polite. It was not any sublime absence of human failings that endeared "J." to successive generations of Cambridge men. His jaunty walk, the suggestion of being on good terms with himself and all the world, the air of possession when some purpose happened to have become his own, and the natural conclusions to be drawn from the fact that, whatever happens, one has to dine somewhere, made his society a real addition to the joy of life.

And, after all, if one takes out "J.," and writes Cambridge instead, there would be nothing much to alter. Alma Mater Carissima! you are provokingly irresistible. How can we but adore you when, in reply to the suggestion that with a scheduled income of some 300,000*l.* a year you might easily present the magnificent spectacle of a self-governed world speeding onward towards the light, you say (and really think), "Tut-tut—it's all a misunderstanding; we are really seventeen sisters and a mother, old and very poor, as poor as can be, especially the mother." *Hinc lucem et pocula sacra!* yet you are very human, and by taking advantage of this opportunity and that, you have surely moved onward in the last century more than any of your sons would have thought possible.

To the presbyopic eye, looking backward over the dim years, it seems that it must have been the people of "J.'s" type in Cambridge who have really counted in the revolution of the nineteenth century. "All the world's a stage," and a born stage-manager has, perhaps, as much to do with the success of a play as the "stars" themselves.

THE FLEUR-DE-LYS.

The Genus Iris. By W. R. Dykes. With Forty-seven Coloured Drawings by F. H. Round, One Coloured Plate of Seeds by Miss R. M. Cardew, and Thirty Line Drawings by C. W. Johnson. Pp. 245. (Cambridge University Press, 1913.) Price 6*l*. 6*s*. net.

NO more fitting tribute could have been prepared to the memory of Sir Michael Foster than a monograph of the group of plants he loved so well and studied with so deep an interest, and the volume produced by Mr. Dykes would without doubt have evoked Sir Michael's warmest approbation.

The genus Iris, like Crocus and so many other monocotyledonous genera, offers a particularly fascinating field of study from the beauty of form and colour displayed and the remarkable diversity of the species. Mr. Dykes is to be congratulated in having cultivated the majority of the species in his own garden, and with such success that the illustrations, with but one exception, have been prepared from the plants grown by him at Godalming. These illustrations, by Mr. F. H. Round, are elegant works of art which have been very faithfully reproduced in colour, and form a valuable addition to the volume. The Cambridge Press deserves a special mention in this connection, both for the beauty of the plates and for the style in which the monograph has been published.

Mr. Dykes has spared himself no pains in searching English, Continental, and American herbaria for his material, and, in particular, Kew, with its herbarium and library, proved to be a mine of wealth. He has wisely studied the type specimens with the original descriptions of all the "species" of Iris, and has thereby been able to arrive at a definite idea as to the actual number of such "species" as are really worthy of specific rank. By ignoring the records of species in local floras, unless they could be verified by actual specimens, Mr. Dykes may have left some gaps in the distribution tables of some of the species, but he has certainly avoided many possible sources of error.

Irises are not only plants of interest to the gardener, but they are also of interest to the plant-breeder for the facility with which they may be hybridised. In this direction the late Sir Michael Foster was, of course, an expert, and the hybrids he produced were always a source of the keenest pleasure to him.

In addition to the ease with which hybridisation may be effected, variation is also characteristic of many species, and it is owing to this tendency that so much confusion as to the limits of species has arisen. Mr. Dykes has constant occasion to allude to this fact, for not only do the plants vary in their wild state, but they show themselves particularly prone to manifest variations under cultivation. Mr. Dykes, however, has been in no hurry to rush to conclusions, but has taken time thoroughly to digest the mass of material which he has studied, and botanists, we feel sure, will agree that they owe him a deep debt of gratitude for the sound and careful work he has done.

The early pages of the monograph are occupied by general matter dealing with the literature of the iris, structure, distribution, and cultivation, followed by outlines of the different sections of the genus. The species are then described very fully under their respective sections, with full citations of specimens and detailed setting-out of their geographical distribution, followed by useful notes on the affinities of each species.

It is not possible to attempt any criticism of this the essential part of the book, and its merits can only be adequately realised by one working over the material. It may, however, safely be said that Mr. Dykes has produced a work with much care and sound judgment, the value of which will increase as years pass by.

THE CHEMISTRY OF FATS AND ALLIED SUBSTANCES.

Chemie der Fette, Lipoide und Wachsarten. By Dr. W. Glikin. Erster Band: pp. xvi + 789; Zweiter Band: pp. xi + 788. (Leipzig: Gebrüder Borntraeger, 1913.) Price, 2 vols., 72 marks.

A NOTABLE feature of this work is the amount of consideration given to the physiological chemistry of the fats, and to the general chemistry of the lipoids. The question of the origin of fat in the animal body is of much interest and importance; and in the earlier chapters of the first volume Dr. Glikin gives an account of the experimental evidence on which arguments have been based to show that the fat of the animal body may be produced from fat ingested as food, or elaborated from proteid substances, or from carbohydrates. Doubtless the accounts of the experiments are often ancient history, going back, as they do, to researches of Hoppe-Seyler in 1859, of Pettenkofer and Voigt in 1869, and to various controversies in subsequent years. They serve, however, to give a connected survey of the whole matter.

The lipoids, it should perhaps be mentioned, are substances more or less closely associated with the fats, and extractible by organic solvents from various parts of animals and plants. Some—the phosphatides—contain both phosphorus and nitrogen; others contain nitrogen, but not phosphorus; others, again, contain neither of these elements. They are of much physiological importance, and during recent years have been much studied by Windaus, Diels and Abderhalden, Cousin, Rosenheim, and other workers. Cholesterol, phytosterol, lecithin, and cerebrin may be mentioned as some of the best-known representatives of the group. The author gives a full description of this class of substances and their compounds, though he regrets that lack of space prevents his discussing the behaviour of lecithin under hæmolysis.

The general chemistry of the fats and waxes is treated at considerable length. Besides the usual descriptions of the acids, alcohols, and glycerides which compose the oils, fats, and waxes, the text includes discussions of the constitution of some of the principal fatty acids, and of the properties of their salts and other compounds.

The remainder of the first volume is devoted to a description of the methods in vogue for the analysis of oils, fats, and waxes. An alphabetical order is adopted in tabulating the various physical and chemical data; this plan is convenient for ascertaining the characteristics of a known oil or fat, but for help in classifying an unknown article it might well be supplemented by a table arranged according to the values of the iodine number.

In the second volume the preparation and examination of the individual oils, fats, and waxes are dealt with. For each article an outline of its origin, method of preparation, and properties is given, followed by tables of the physical and chemical constants appertaining to the substance and to the fatty acids separable from it. The closing chapters are concerned with various manufactures allied to the fat industry, such as the making of soap, varnish, glycerin, and stearin.

The author's aim has been to produce a connected treatment of the whole subject, and his book is probably the most complete work of the kind yet published. C. S.

OUR BOOKSHELF.

Weights and Measures Act, 1904. Board of Trade Notices Annotated. By H. Cunliffe and G. A. Owen. Vol. i. Pp. viii+199. (Smethwick: H. Cunliffe, 1913.) Price 5*s*. net.

This work is intended for inspectors and others interested in the administration of the Weights and Measures Acts. Under the Act of 1904 the Board of Trade was empowered to examine as regards material and principle of construction such patterns of weights, measures, weighing or measuring instruments as might be submitted to it, and to issue certificates in cases where the patterns were found not to facilitate fraud. From time to time the Board issues notices setting forth its decisions with respect to such submissions, and the writers of the present volume have collected together the first fifty of these notices and publish them with criticisms and explanatory notes.

The authors are inspectors of weights and measures of considerable experience, and their book appears likely to be useful to persons preparing for the Board of Trade examination for certificates of qualification as inspectors, as well as to such acting inspectors as may find difficulty in identifying patterns from the information given in the Board of Trade notices. It is usual for the inspectors' examination to include a question requiring a description of the functions of the various parts of a pattern illustrated in one of the notices, but owing to the fact that some of the patterns represent instruments which have never been put on the market, or are in very restricted use, such information is rather difficult for a candidate to obtain.

The descriptive letterpress which accompanies the notices in this work is very complete, the annotations and detailed explanations as regards the various weighing instruments considered being particularly good. A few blemishes are noticeable here and there: for example, there is an omission on p. 6 in the citation of section 5 (*a*) of the Act, which renders some of the remarks on p. 8 not readily intelligible. The interpretation of instruction 35 given on p. 12 is forced and misleading. On the whole, however, the work appears to have been prepared with great care. The authors propose to deal with later issues of the notices in a subsequent volume.

Text-book of Zoology. By H. G. Wells and A. M. Davies. Sixth edition. Revised by J. T. Cunningham. Pp. viii+487. (London: W. B. Clive, University Tutorial Press, Ltd., 1913.) Price 6*s*. 6*d*.

The supplement which Mr. Cunningham added to the fifth edition of this popular text-book has now been incorporated in the body of the work, and the section dealing with the Invertebrata has been rearranged so that the types follow in general the descending order in classification. Important additions have been made explaining the facts and theories of most importance to modern biologists in relation to the problems of evolution.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

"Cheiropleuria bicuspis" (Bl.) Pr.

Through the influence of the Rajah of Sarawak and the activity of the director of the museum there, to both of whom my grateful thanks are due, I have recently received an ample supply of specimens, dried and preserved in alcohol, of the uncommon Malayan fern, *Cheiropleuria bicuspis* (Bl.) Pr. As some considerable time must elapse before its details can be worked out, I think it will be well to state briefly certain points of interest in relation to it.

The creeping rhizome, which is covered with hairs, not scales, bears long petiolate leaves at intervals, which are variable in the form of the lamina. Some, especially those of the smaller plants, have an ovate acuminate outline, others may be two- or three-cusped, or in large plants the number of lobes may be four or five. In these cases there is an obvious bifurcation of the lamina, a point well shown in Sir W. Hooker's illustration of the species, quoted as Fig. 175 in Engler, u. Prantl., i., 4, p. 337. The relation of the leaf and its venation to that of Dipteris is very marked in the larger examples. There can be no doubt that the nearest affinity of Cheiropleuria is with the Matonineæ.

The fertile leaves appear to be always simple, and of narrow form. Their lower surface is covered by a dense mass of sporangia and hairs, in an Acrostichoid manner. The sporangia themselves have an oblique annulus, and the various ages of them are intermixed.

As against these rather advanced characters, the anatomy presents surprising features of simplicity. The rhizome appears in the Bornean specimens to be constantly protostelic, with much parenchyma, not solenostelic, as stated by Christ ("Farnkraüter," p. 128). The leaf-trace comes off as a single mesoxylic strand, which soon opens out and becomes semilunar, and then divides into two equal strands. These characters indicate, on one hand, a greater similarity to Mertensia in the mature stock than is shown by any Matonioid fern; on the other an advance on Matonia and Dipteris, both in the anatomical and the soral condition of the leaf. The effect of these facts upon the comparative position will be, on one hand, to strengthen the relation of the Matonioid series to the Gleicheniaceæ; on the other, to illustrate a further step in advance in foliar character than any of them show. The relation to Platycerium has been definitely indicated by Diels ("Naturl. Pflanzenfam.," i., 4, p. 336). It will remain for more detailed inquiry into the structure and development of both of these genera to show how far Cheiropleuria approaches Platycerium. Conclusions on this point must be deferred for the present, though certain facts appear provisionally to support such an alliance.

Cupriferous Sandstones at Exmouth.

Observations made last winter upon the lithological characters of the Red Marls, with intercalated sandstones, exposed in the cliff-section running eastwards from Exmouth towards Straight Point, disclosed some interesting facts which may serve to remove doubts as to these rocks having been formed under conditions contemporaneous with, and similar to, those prevailing during the deposition of the German Rothligendes in Permian times.

The sandstones consist of very smooth and rounded grains of quartz, and what appears to be cornelian, together with copper and manganese, consolidated by a calcareous and dolomitic cement. The copper occurs as a green carbonate derived from the decomposition of minute particles of copper pyrites present in the rock. Vivid green patches and specks of this copper carbonate are very conspicuous on the surfaces of bedding-planes and other places where water has percolated freely. Mr. F. Southerden, of the University College, Exeter, kindly analysed some of the specimens, and an average sample yielded about 1 per cent., and a richer specimen more than 3 per cent., of the carbonate. None was found in any of the marl, nor in the *red* sandstones of Rodney and Orcombe Points.

The manganese is very widely distributed, both in the red and the buff sandstones, as minute black specks, frequently rudely dendritic in arrangement, and as films coating the grains of quartz. Occasionally large areas become quite black with it. Where copper is present manganese is always present also, but manganese is frequently present without the association of copper.

The grains of quartz composing the bulk of the sandstone are remarkable for their roundness and smooth surfaces. Much research in reference to sands leads me to believe that they were originally rounded by wind action, and subsequently polished by water holding finer matter in suspension. The natural disintegration of this type of sandstone produces a sand which, when sifted by wind and wave on the sea-beach, should be musical, but it was not until May last, after many visits, that I found several very musical patches on the beach between Rodney and Orcombe Points, and also under the "High Lands of Orcombe."

In places along the foot of the cliffs the lime in the cliff-springs cements the beach material into solid masses of sandstone and conglomerate, and dry sand, blown from the beach against wet places on the cliff-surfaces, eventually becomes consolidated into great cakes of sandstone for the same reason.

Cecil Carus-Wilson.

A Fresh Feature of the Large Larch Saw-fly Outbreak in the Lake District.

In the Lake District plantations, and elsewhere throughout the country, those interested in the welfare of the larch have viewed with no little apprehension, for some time past, the yearly ravages of the large larch saw-fly (*Nematus erichsonii*). As direct methods of control are out of the question over most of the affected areas, interest has been centred upon those natural agencies which in any way tend to limit the indefinite multiplication of this saw-fly, and it has been recognised that the atmospheric conditions, several of the common insectivorous birds, voles, certain insects, and parasitic fungus, are all capable of exercising a considerable if variable influence upon the numbers of the pest. To a combination of forces such as these must be attributed such respite as the trees have gained in certain of the infested areas, and in those cases where accurate observation of the facts was possible it was found that cessation of the saw-fly attack coincided with an overwhelming increase in the numbers of one of its insect enemies, an ichneumon, hitherto unknown to science, *Mesoleius tenthredinis*, Mor. This parasite, by eventually accounting for more than 70 per cent. of the larvæ within the cocoons, undoubtedly in these instances played a very large part in the reduction of the pest.

As *M. tenthredinis* was known to be present in most of the districts where the larch saw-fly was making itself felt, and as none of the other parasitic hymenoptera or diptera recovered from the cocoons from year to year showed signs of attaining to anything like its efficiency as a parasite, it was felt that the eventual control of the pest possibly depended largely upon the future activities of this one species. Hence the following observations made during the present season may be of interest in so far as they indicate the probability of other of the parasites attaining to a like importance.

Shoulthwaite plantation at Thirlmere, the first in that area to suffer from attack, endured during several summers the severest defoliation, until in 1910, owing to the good offices of *M. tenthredinis*, the ravages of the pest abruptly and almost entirely ceased. In 1911 it was impossible to obtain from there any further cocoons for the purposes of the investigation owing to the scarcity of the saw-fly. In 1912, however, this plantation was invaded by a vast swarm of adult saw-flies, which there was reason to believe came from a badly infested plantation some three miles away. Owing to a period of very unfavourable weather, and perhaps to other causes, the defoliation that ensued was not at all so extensive as it was feared it would be; however it was distinctly noticeable, and the consequences of this reinfection of the area were looked forward to with some anxiety. Would the trees, weakened by the old outbreak, have to submit to renewed defoliations, until such time as *M. tenthredinis*, re-emerged Cincinnatus-like from its obscurity, regained sufficient strength to overcome the progeny of the invaders? An examination of the parasites that have emerged this year from cocoons collected in this area revealed a quite unexpected state of affairs. Scarcely 2 per cent. of the cocoons proved to be parasitised by *M. tenthredinis*, but some 25 per cent. yielded specimens of an ichneumon which had hitherto played quite an insignificant part as a parasite of the large larch saw-fly (a species of Mesoleius, as yet undetermined). From approximately 24 per cent. emerged tachinids belonging to the species *Zenillia pexops*, B. and B. (Mr. C. J. Wainwright, who kindly identified it for me, informs me that he knows of but one other record of its having been taken in Britain.) It seems highly probable that both these parasites have followed in the wake of the invading saw-fly, particularly as observation of material from the locality from which it was suspected that the latter had flown has shown that the tachinid at all events is exceedingly abundant there.

It is impossible as yet to have direct proof of the efficacy of these two parasites in warding off defoliation in the areas in which they have so opportunely appeared, but it is very reasonable to suppose that, here and elsewhere, they will prove to be important enemies of the large larch saw-fly.

Mackerel and Calanus.

REFERRING to Prof. Herdman's interesting observations upon the above (NATURE, July 17), I may perhaps mention that the mackerel-drifters, when fishing upon the usual grounds around Scilly and in the Bristol Channel, are largely influenced in their selection of a suitable position by the finding of so-called "yellow water." This condition of the sea in the area under consideration arises from the presence of vast shoals of Calanoids—*e.g. Calanus finmarchicus*, *Pseudocalanus elongatus*, &c.—which impart a yellowish tint to the surface of the water. The sporadic distribution of such copepods, moreover, is often somewhat remarkable; the fishermen state that it is possible at times to observe the entire extent of a "splat" of "yellow water."

The presence of mackerel is generally to be expected in water of this character, but heavy catches are not invariably made in it.

THE FUTURE OF OIL FUEL.

THE position of liquid fuel has increased in importance far beyond any expectations its most enthusiastic advocates of but little more than a decade ago ever dreamed, due to the rapid advances made in its use in internal combustion engines. The success of engines of the Diesel type, which can employ crude oil or heavier residues after the lighter fractions of the crude oil have been removed for other applications, has furnished the completing link in the use of oil in such engines. With the petrol engine, slow-speed oil engines working on ordinary burning oil (kerosene), and the Diesel and semi-Diesel engines, high efficiency is now assured with any fraction of the natural oil.

The importance of liquid fuel and the certainty of its more extensive use in the Navy rendered it imperative that the whole question, especially that of supply, should receive consideration, and led to the appointment of the Committee now sitting. The advantages of oil fuel for steam raising were dealt with fully in these columns so far back as 1902 (vol. lxvi., p. 186), when oil fuel was in its early trial in the Navy.

The present general position and future policy of the Admiralty were outlined by Mr. Churchill in a reassuring speech before the House of Commons on Thursday last. Whilst the crude oil output for last year was nearly 50,000,000 tons, Naval requirements were met by fewer than 200,000 tons, and the Admiralty have assured themselves of obtaining all requirements in time of war, so long as British command of the sea is maintained.

This necessarily involves obtaining supplies by suitable contracts, and drawing specially upon supplies under British control, which is now possible from the Mexican fields. A far-reaching step in national policy is the further proposal to establish an oil refinery, so that crude oils may be dealt with as they come cheaply into the market. It is not only essential to have some measure of control of the supply at its source; it is equally essential to provide ample storage and transport facilities. The former has been arranged for on a large scale in this country and throughout the Empire, and by the end of 1914 the Admiralty will possess thirteen transport steamers, the five largest of which have a carrying capacity considerably greater than the quantity of oil fuel consumed throughout the fleet last year.

In connection with the subject of oil fuel, three Cantor lectures recently delivered by Prof. Vivian B. Lewes before the Royal Society of Arts[1] are of especial interest. The first lecture was

[1] Journal of the Royal Society of Arts, May 23, 30, and June 6, 1913.

devoted principally to theories on the formation of petroleum, and to the composition of natural crude oils. In the second lecture methods of combustion for steam raising, and, briefly, its use in internal combustion engines, were considered. Particular interest attaches to the possible high efficiency attainable when utilised for steam raising by Prof. Bone's surface combustion system. It is, however, in the third lecture that we find the all-important questions of supply discussed. Euthusiastic advocates of the advantages of oil fuel—advantages which are admitted—often forget that, with small exception, liquid fuel must always be an imported fuel in this country, and that the questions of supply and price must depend on a variety of factors, not the least important being that of transport. Prof. Lewes rightly emphasises the fact that trusts and rings are by no means wholly responsible for the recent high price of petrol; there is the big question of enormous increase in consumption with nothing like a corresponding increase in production Referring to this high price, Prof. Lewes says :—

The way to keep the price of petrol within reasonable bounds is not by letting the imagination run riot on the subject of trusts and rings, but to develop steadily all processes that will increase the supply, not only of petrol, but petrol substitutes, always bearing in mind that with the present consumption ever increasing, petrol itself cannot supply the market for even another ten years, and will probably be a rarity as a motor fuel before the end of the century.

This naturally leads to a reference to processes for "cracking" heavier oils to produce lighter fractions by the breaking down of the heavier hydrocarbons, and a description is given of one of these processes in which oil mixed with water is sprayed through heated iron retorts filled with iron turnings.

Referring to sources of supply other than petroleum oils, it is shown that shale distillation in this country can yield only an infinitesimal fraction of the petrol consumed. Benzene (benzol), obtained from coal-gas and coke-oven tars, being a native product of proved value as a motor fuel, is discussed. Prof. Lewes says that if the whole of the benzol from the 32 million tons of coal annually coked in coal-gas and coke-oven practice were recovered, a very considerable supply would be assured, but under existing conditions less than half the coke is obtained in recovery plant (it may be noted that the use of recovery ovens is extending rapidly), and most of the benzol goes abroad. Prof. Lewes appears to advocate removing the tax on petrol and the imposition of a tax on export benzol as a means of obtaining an important addition to our supplies of motor fuel.

Heavy fuel oils, suitable for steam raising and for internal combustion engines, constitute 50 per cent., or even more, of the crude oil. Prof. Lewes anticipates no such shortage in supplies of these oils in the future as has existed for some time past, for "the distillation of every available supply to yield petrol must result in enormous volumes being thrown on the market." The present shortage is ascribed to the better price of petrol giving it preference for shipment during a period when there is great lack of transport facilities. With the increase in the number of tank steamers (many yards are busy with such vessels) he anticipates that the enormous stocks held in many fields will become available.

IS CANCER INFECTIVE?

NOTWITHSTANDING that no analogy has been shown to exist between cancer and any known form of infective disease, the contrary is often asserted without proof, as a kind of creed, by well-meaning and enthusiastic students of the disease. A recent lecture illustrates the importance of the influence the latter view may come to have upon the public in general. Whether it is wise to put forward such views before a non-critical lay audience is open to doubt, even if they are told "there is no risk of direct infection, although it is better to avoid direct contact by kissing, by using in common table porcelain, clothing, or beds."

In a popular lecture[1] delivered at the Urania, in Berlin, Dr. V. Czerny, the famous surgeon, gives a clear account of the reasons why, after forty years' experience in surgical practice, he still holds that cancer is an infective disease. According to him it is communicable, not directly, but through an intermediate host. Once the infection is conveyed, the normal cells become changed, they destroy the organism not only by disturbing functions vital to life, but also because, like real parasites, the cancer-cells withdraw necessary foodstuffs, as well as secrete abnormal products of metabolism, viz. toxins which poison the organism. Czerny supports his view by arguments as to the varying frequency of the disease in different countries and in different districts of the same country, the alleged occurrence of epidemics of cancer, of the eyelid in cattle, of the thyroid in trout, and of cage epidemics in mice; but he neither points out the statistical and pathological fallacies that underlie the assertions of the authors whom he quotes, nor takes cognisance of the explanations more cautious authors have given of the apparent differences and "epidemics" upon which he depends. Every precaution necessary for the statistical study of cancer in man applies with even greater necessity to animals, since the data obtainable from an animal population can be controlled at will by the investigator. Unless these precautions are taken, weight may not be attached to reasoning from such imperfect data without important reservations.

Bugs, mucors, mites, worms, cockroaches, bilharzia, filaria, acid-fast bacilli, &c., are alleged as possible intermediate hosts of "the ubiquitous cancer parasite," which may be a protist, but more likely is an ultramicroscopic organism "which constantly secretes a chemical irritant. If one

[1] "Ueber die neuen Bestrebungen, das Los der Krebskranken zu verbessern." By Dr. Czerny. *Himmel und Erde*, Heft 7, April, 1913. Also published separately by B. G. Teubner, Leipzig and Berlin

conceives of these micro-organisms being adapted to the diseased cells and disseminated along with them by the lymph and blood-streams, a satisfactory explanation of the features of cancer in man is obtained. It is conceivable that there are a number of different micro-organisms which produce these irritating substances, and that there is not a single cause of cancer." The "ubiquitous parasite" finds entrance into the body by the openings made in the case of X-ray ulceration, chronic inflammation of all kinds, *e.g.* of the breast, the ulceration of the tongue following on the irritation of a jagged tooth, catarrh of the stomach due to alcohol or tobacco, ulcer of the stomach, ulcer or catarrh of the large intestine due to constipation; entrance for the parasite may even be made possible by congenital anomalies, &c., &c.

Although no evidence is adduced in support of these conceptions, any alternative to such an infective causation, involving as it does the further hypothesis of symbiosis of the parasite and the cancer-cell, is ruled out of court by Czerny. He says: "On account of the numerous errors made in the past, many pathologists have given up the search for a cancer parasite, and content themselves with some ingenious cellular theory, which suffices for instruction, but does not yield actual practical applications." Surely no practical application can yet be made of the infective hypothesis of the cause of cancer, although the taking of quite fallacious cancer censuses has been based upon it. The importance actual observation has given to chronic irritation has long since justified legislative measures for the protection of workers engaged in various occupations from enhanced liability to the disease.

Czerny reviews optimistically recent attempts to influence the growth of tumours by radium, X-rays, fulguration and chemical means, sera, &c., but his forty years' personal experience as a distinguished surgeon of international fame adds greater weight to his important announcement: "Unfortunately, the first beginnings of cancer are often so insidious that they do not attract the attention even of the patient himself, who first seeks medical advice when ulceration, a palpable tumour, pain—that faithful guardian of health—long-lasting digestive troubles, wasting, and bad looks warn him. Nevertheless, early diagnosis and removal of a condition *long remaining localised*, is the best means of restoring to complete health and avoiding the sad chain of consequences of the advancing disease. Therefore, with the assistance of anæsthesia and asepsis the surgeon has gradually sought out tumours in all organs of the body, even in the brain and spinal cord, and removed them. Naturally cancer comes under operation later, and therefore in less favourable circumstances the more inaccessible its situation. If success for tumours of the brain and spinal cord is rarer, still in the case of the skin 80–90 per cent. of cures can be depended upon. Complete cure in the case of the breast is obtained in 40 per cent., *i.e.* living and controlled five years after operation. For the stomach and intestine, 20–30 per cent. of success can be calculated on."

Since the first vague statements of the cure of transplanted cancer in mice by chemical means were made there has been a rising flood of similar announcements in scientific journals. According to the experience of the writer the greater number of these communications had better never have been published. The results claimed as cures have been for the most part nothing of the kind, but due to errors, sometimes arising in the properties of the tumour unknown to the "curer," at other times due to the observer being unaware of the behaviour of transplanted tumours in general and of the behaviour of a particular tumour obtained from some other laboratory, the observer being inexperienced both of how to obtain uniform growth and of the numerous fallacies he has failed to avoid. Shots in the dark, by those inexperienced in the growth both of experimental and natural tumours in animals, are, however, to be expected until more is known of the nature, chemistry, and metabolism of cancer, and certainty is attained as to whether or not it is an infective disease. But it would be a grave misfortune if the increasing flood of alleged cures of transplanted cancer in animals led to an augmentation of the number of persons who, disdaining or fearing surgical advice and treatment, prefer "treatment" by some other less efficacious or even useless method, or by some of the new chemical preparations already prematurely placed upon the market.

E. F. BASHFORD.

PLANKTOLOGY ON THE PACIFIC COAST.

THE school of marine planktologists at the University of California and the biological station of La Jolla (San Diego) is doing notable work on the Pacific under the expert guidance of Profs. Ritter and Kofoid. We now welcome a recent contribution on the classification and vertical distribution of the Chætognatha of the San Diego region, by Ellis L. Michael (University of California Publications in Zoology, vol. viii., no. 3). To begin with, the material is evidently very abundant. The locality in question shows seven out of the eighteen valid species of Sagitta, two of the three species of Eukrohnia, and one of the two species of Spadella. The author has done good work in redescribing and elucidating those species, and is to be congratulated on having failed to discover any new ones. The work has been confined to a comparatively small area, but it is evident that no pains have been spared to make it complete.

The author states: "We are convinced that direction and velocity of currents, temperature and salinity of water, wind, clouds, fog, rain, light and darkness all affect the distribution of plankton *even within a very small area*. The influence of all these conditions must be known to solve any problem concerning the quantitative distribution of plankton." All these influences have been very fully investigated.

The systematic part of the work contains a most useful revision of the known species of Chætognatha with a detailed key giving brief diagnoses of the genera and species, as well as a fuller statement of characters, with measurements of many specimens in the case of most species.

In the very full discussion of the problems of distribution, illustrated by many tables, we find that our author considers that his data contain numerous examples illustrating lack of uniformity in distribution. Some of these examples are as follows: In two hauls of the same net in the same region on the same day the number of *Sagitta bipunctata* varied from fifteen at 6.20 a.m. to one at 7.20 a.m. per unit volume of water. On another day, under similar conditions, the number varied from twenty-five to one, and on another day similarly from one to fifty-six, and on still another occasion from 135 to one. "Other instances might be cited, but enough have been given to show that the surface-distribution of *S. bipunctata* is not constant for any length of time, even in very small areas. The objection will be made that hydrographic and meteorological conditions change rapidly near the coast, but remain constant on the high seas. I doubt the validity of such an objection. In the first place, owing to variations in wind, rain, light, barometric pressure, heat, &c., it is very improbable that hydrographic and meteorological conditions even approach constancy on the high seas. In the second place, some of the above examples show that *S. bipunctata* varied in abundance even when these conditions, so far as known, remained constant during the period within which the contrasted hauls were made."

The author finds himself in agreement with similar observations that have been taken in recent years in the Irish Sea, and comes to the conclusion that "we are therefore compelled to acknowlege a very definite causal relation between rate of reproduction and variations in the quantity of plankton." He discusses the influence of other organisms on the abundance of plankton, and illustrates it by the effect of "red-water," due to the presence of enormous numbers of the dinoflagellate Gonyaulax, and recognises, consequently, that to estimate adequately the quantity of plankton in a given area of the sea we must consider far more than the physical and chemical conditions, and must not omit the biological influences involving the effects of growth, reproduction, food-relations, and other activities of the organisms concerned. As Kofoid (1903) has demonstrated, there are variations in the quantity of plankton which are nearly, if not entirely, independent of hydrographic and meteorological conditions.

Mr. Michael shows that *Sagitta bipunctata*, the commonest species that he deals with, is "epiplanktonic," and, moreover, migrates towards the surface at night and into deeper zones in the day. In the surface-nets this species attains its morning maximum within an hour after sunrise, and its evening maximum within an hour after sunset. He considers that it is probable that the species in its diurnal migrations is constantly moving towards that zone of water in which "twilight conditions" are to be found. The effects of salinity and temperature are also investigated in detail, and the conclusion that our author arrives at is that "probably light has more pronounced effect on vertical distribution than temperature or salinity, because its variations are more regular and periodic."

It is interesting to find that in a later paper in the same series from the University of California, viz., C. O. Esterly on the distribution of the Copepoda of the San Diego region, precisely the same general conclusions as to irregularity of distribution of the plankton are arrived at. In speaking of the absence of any uniformity, the author of this later paper says: "Instances of this could be given almost without number in regard to the distribution of the Copepoda of this region." The marine biologists of the Californian coast are clearly to be congratulated on the thoroughness with which their investigations are being carried out, and on the sound conclusions at which they are arriving. W. A. H.

PROF. FRANCIS GOTCH, F.R.S.

THE phenomena of life and their cessation at death present varied interests attracting to their investigation minds of very diverse type. Thus when the foremost ranks of physiology show a new-made gap, and a distinguished service of some one particular kind is at an end for ever, the loss to the science is not readily repaired. It is then too clear that the gifts which have vanished have differed from those that are left more than in degrees of excellence. Thus deeply at the present time physiology suffers by the death of the late Prof. Francis Gotch. His name is significant of a world-wide reputation. His personality was obviously individual, and in its peculiarities excellent.

Nothing that can be said in the near future can add to or detract from his established reputation. A master of the technique in one particular line, his measurements stand until that technique undergoes unforeseen developments and improvements. In that branch of the subject which he had made his own he had contributed to knowledge a long series of very precise data, placed with great skill at points of salient interest. Feeling no need for the incentives provided by explanatory hypotheses, testing no particular form of speculation, he has patiently and with great ingenuity assisted in a fundamentally essential survey of the physical evidences of life as studied in nerve, muscle, the retina, the special organs of electrical fishes, and in the central nervous system. Further than this, he was a distinguished authority upon the literature of this subject, and a writer of valued summaries and lucid historical articles.

Judged from his writings, he was what I have thus too briefly stated, namely, a dispassionate contributor, and a cold analyst, of evidence. Strange as may seem the contrast, to his students he was a magician, a marvellous weaver of deft words, a master of dramatic effects, who, with a sure hand, shaped before their eyes a brilliant texture of knowledge, ending always by laying down a finished carpet on which they might walk with reposeful security towards their own looms. His excellence in teaching the general groundwork of the subject was unique. Backed, as it was, by admirable practical classes, in which the niceties of technical skill required for the collection of evidence were instilled, and a whole field of evidence of a particular type displayed, it provided an educational basis of unsurpassable value. No one acquainted with his work will scent exaggeration in the statement that in this matter he was superb.

Outcome as this excellence was, in part, of unstinted effort and elaborate pains, and of a fully-developed desire to satisfy a genuine ambition for success in such teaching, it was also largely the result of native temperament and talent. A cheerful and courteous man, kindly to the core, generous to a fault. Humble with a knowledge of his own limitations, reverently serving undiscussed ideals, alight with enthusiasm. Of wide sympathy, singularly well-informed, of great culture, and most refined taste. Qualities such as these, and an evident sincerity in his devotion to his subject, necessarily won home to receptive and humane minds.

If at any time his manner caused irritation, then I take it this may be attributed to an excellent and uncommon quality, which was at times of great public service. He was essentially æsthetic, exquisitely sensitive to every light and shade in the inanimate, and in the animate character of his surroundings necessarily seeking harmonies, and as necessarily, therefore, arranging them. Neither inviting admiration nor in any way impelled towards dominance, nevertheless he was always quietly to the front to make certain that the scene was set, the players grouped, and a satisfying *ensemble* produced. Wherever such initiative was welcomed, as often in social matters where it is most rare, he was admirably successful. Arriving in Liverpool in 1891 as the first occupant of the newly endowed Holt Chair of Physiology, the complete sincerity of these qualities enabled him to give invaluable support to those able men who were then watchfully tending the growth of the university spirit within its boundaries. There, with his wife, he gained a great social success without underlying thought other than to give his best, and to obtain the best from others. His accomplished predecessor, citizens of great importance and benevolence, colleagues and students, he turned into grateful friends not of himself alone, but into mutual friends. That he was so signally capable of assisting in an obviously large and progressive movement, the development of university ideals of freedom in thought, in work, and in teaching, within a great and typical centre of commercial industry, must have had a reflected influence on his own character, and given him an added courage and skill in dealing with public affairs.

Leaving Liverpool in 1895 to occupy the Waynflete Chair of Physiology in Oxford, he returned to scenes already familiar. He was frankly pleased with this great and different opportunity; thinking it no small thing that he was entrusted with the banner carried so loftily by his distinguished master, whose influence had been largely responsible for the shaping of his career. If it is right to regard as ambition the desire to win complete recognition in a life-work not chosen from motives of dominance or gain, then it was his ambition which was now completely satisfied. In return for this satisfaction he endeavoured to perform the duties of this post of honour with anxious care and unflagging industry, shirking no responsibility. That he has proved equal to the task is evident from the continued success of the Oxford school of physiology, and from the value and numbers of its alumni who have passed out into, and maintain with credit, positions of great importance.

To his personal friends who have tramped through the mists of Cumberland fells, or wandered through the picture galleries and churches of foreign towns, with a companion so brimful of cheer and interest, or who have heard him tell the tale of his one participation in a cavalry charge in Zululand, or have listened to his renderings of Devonshire songs, his death has brought an intimate sense of loss.

To his wife and family, the centre of so much mutual love and understanding, we can do no more than offer sincere sympathy.

J. S. Macdonald.

NOTES.

Dr. R. von Lendenfeld, professor of zoology and rector of the German University of Prague, who died on July 3, aged fifty-six, had many friends and acquaintances in this country, where he resided for a time. He began his scientific career by travelling in Australia, where he studied chiefly marine sponges and cœlenterates. The results of his investigations were published, partly in English, as "A Monograph of the Australian Sponges," and other papers in the Proceedings of the Linnean Society of New South Wales, and partly in German, as a series of memoirs, entitled "Ueber Cölenteraten der Südsee." After his Australian trip he was for a time assistant in the zoological department at University College, London, and while in England produced, besides other works, his "Monograph of the Horny Sponges," published by the Royal Society, based chiefly upon material collected in Australia. Much of his earlier work was somewhat Haeckelian in the method of treatment, and later investigation has failed to confirm the accuracy of many of his statements, notably the existence of a nervous system in sponges alleged by him. Subsequently he published some works on sponges jointly with Prof. F. E. Schulze, of Berlin, and later, after he obtained the chair of zoology at Czernowitz, he published a monograph of the sponges of the Adriatic in a series of memoirs. When called to Prague he continued to publish, from time to time, systematic monographs upon the sponges collected by various expeditions. In addition to his zoological work he was a keen mountaineer, and contributed articles to various Alpine journals.

THE Dogs (Protection) Bill, which has for several weeks been before a Standing Committee of the House of Commons, but reached a deadlock on July 16, provides that it shall be unlawful to perform any experiment of a nature likely to cause pain or disease, with or without anæsthetics, upon dogs. The Bill would thus prevent, in this country, all experiments on dogs, not only all experiments under anæsthetics, but all inoculations. We may all of us be agreed that a dog has more claim on our regard than a rat or a guinea-pig; but we have to consider whether the Bill, in the long run, would lessen the sum of pain, disease, and death, in the world; and the answer surely is that it would not. Indeed, it would inflict far more than it would avert. For it would hinder in this country the proper and complete investigation, not only of human diseases, but also of canine diseases. Among human diseases, it would hinder the study of diabetes, and perhaps of kala-azar and of cancer. Looking back a few years, we can say that the Bill would have prevented, if it had been in existence, the discovery of the best vaccine against distemper in dogs, and the best treatment of malignant jaundice in dogs. Looking forward, we cannot foresee what the Bill would be preventing; but all experience goes to show that it would be preventing work useful either to man or to dogs. Experiments on dogs in this country are jealously restricted already by the Home Office; and the Bill is a move in the wrong direction. Some useful pamphlets on this subject can be had on application to the Research Defence Society.

MR. L. W. KING, assistant in the Department of Egyptian and Assyrian Antiquities in the British Museum, has been appointed to the post of assistant-keeper in that department.

CAPT. P. J. MARETT has been appointed to a Beit Memorial Research Fellowship to carry on further research as to the nature of the virus of sand-fly fever, a disease which is the cause of much sickness in the ships of the Mediterranean Squadron and among the troops stationed at Malta and in certain parts of India and elsewhere. The Army Council has approved of Capt. Marett, who has already published several papers on the subject, undertaking this research in addition to his military duties at Malta.

THE council of the Royal Society of Arts attended at Buckingham Palace on July 18, when his Royal Highness the Duke of Connaught, president of the society, presented to his Majesty the King, for nine years president and now patron of the society, the society's Albert medal for the present year, "in respectful recognition of his Majesty's untiring efforts to make himself personally acquainted with the social and economical conditions of the various parts of his Dominions, and to promote the progress of arts, manufactures, and commerce in the United Kingdom and throughout the British Empire."

THE Institution of Mechanical Engineers will meet at Cambridge on Tuesday, July 29, and Wednesday, July 30, in the Senate House of the University. The papers to be read and discussed are:—A new method of cooling gas-engines, Prof. Bertram Hopkinson; modern methods of measuring temperature, R. S. Whipple; modern pumping machinery for the drainage of the fens, R. W. Allen; the drainage of the fens, R. F. Grantham; the drainage of the River Ouse basin, E. G. Crocker; modern flour milling machinery, R. B. Creak; and a few notes on engineering research and its coordination, G. H. Roberts.

A SCHEME for the establishment of an Oriental Research Institute in India has been put forward tentatively by the Government of India, with a suggestion that an expression of the views of the provincial Governments be invited. Meanwhile the Royal Anthropological Institute has taken the opportunity of addressing the Secretary of State with a plea for the inclusion of anthropology in the course of studies at the institute. In his reply the Secretary of State observes that he is alive to the importance of anthropological research, and thanks the institute for its offer of cooperation, which is being conveyed to the authorities in India. But he points out that in the present state of the question it would be premature to discuss the exact scope of the proposed Research Institute.

WE understand that excavations in the base-beds of the Red and Coralline Crags of Suffolk have now been proceeding for some months under the direction of Mr. J. Reid Moir. Worked flints of various forms, consisting of the well-known rostro-carinate type, pointed implements for use in the hand, pounders, rubbers, round-ended and other scrapers, borers, hammer-stones, and flakes, affording evidence of a complete sub-Red Crag "industry," have been recovered. Extensive diggings at various sites have brought to light a small but very excellent series of humanly flaked flints, some of which have barnacles of the Red Crag Sea attached to their worked surfaces. With the exception of one small ridged flake, no humanly struck flints have as yet been found beneath the Coralline Crag.

THE KING has recently placed on loan for exhibition at the British Museum a large and valuable collection of gifts received by him from the Dalai Lama of Tibet. It includes a very sacred relic, a royal saddle, said to be 500 years old, and used by the first Dalai Lama who entered Lhasa; a set of Tibetan armour with a steel helmet, the armour being of a type spread over western Asia; a fine sword of the shape still used by the Khambas, the most warlike Tibetan tribe, which was probably made at Derge, and exhibits remarkable handwork. Tibetan Buddhism is represented by seven gilt images of the Seven Gems, which have been fully described by Dr. Waddell in his classical work, "The Buddhism of Tibet," and the Eight Glorious Emblems and Offerings. Among smaller objects is a model of a Chor-ten or shrine, charm-boxes, and a complete costume of a Tibetan lady, the gown of bright colours on a dark purple-brown ground, the boots of green and red cloth, embroidered in green and red.

The new Natural History Department of the Birmingham Museum and Art Gallery was formally opened on July 17 by Alderman W. H. Bowater (Deputy Lord Mayor), in the absence of the Lord Mayor through illness. The museum, which forms a part of the Council House extension, is situated on the upper floor of the building facing Congreve Street, and comprises four galleries, one of which is not yet opened, having been reserved for the Beale Memorial collection, which is to consist of nesting groups of British birds. The collections, which have been arranged by Mr. W. H. Edwards, contain representatives of most sections of natural history, and though birds, shells, and insects predominate at the present time, the committee hopes now the museum is started that generous donors may be forthcoming to supply some of the deficiencies. An interesting feature is a large case arranged on somewhat original pictorial lines, and illustrating a British marine topographical group. Sea-birds, some with their eggs, are mounted on a large rock, others are shown in flying positions, whilst the lower portion of the case represents a depth of 18 in. of sea-water, in which various fishes, an octopus, cuttle-fish, crabs, lobsters, &c., are shown as in a state of nature amongst seaweeds or resting on the sandy bottom. Special mention must be made of an extremely fine collection of British birds, including many very rare species, arranged in cases with their natural environment, and in various states of plumage. These have been lent by Mr. R. W. Chase, and occupy the whole of one of the galleries.

Aphides form the subject of the two chief articles in the July issue of *The Journal of Economic Biology*. In the first Prof. F. V. Theobald reviews the British representatives of the genus long known as Siphonophora, or Nectarophora, but for which the author employs the earlier title, Macrosiphum. Inclusive of twelve described as new, the British list comprises fifty-five species. In the second article Mr. T. R. Hewitt records the occurrence of a woolly aphis (*Schizoneura lanigera*) in the core of an apple, and suggests that such infestation may occasionally assist the dissemination of the species.

According to the July number of *The Entomologist's Monthly Magazine*, the greater part of the magnificent collection of butterflies and moths (including hundreds of type specimens) formed by the late Mr. Herbert Druce has been acquired by Mr. J. J. Joicey, of The Hill, Witley, Surrey. The representatives of the Lycænidæ and Hesperiidæ have, however, been retained by Mr. Hamilton Druce, and Mr. Druce's first collection of butterflies is now in the Natural History Museum. In communicating this information Mr. Joicey states that his portion of the collection is available for study to entomologists.

In *Spolia Zeylanica* for June Mr. E. E. Green describes, with coloured illustrations, a case of mimicry by spiders of the genus Cœnoptichus of the wingless forms of wasps of the family Mutilidæ, including those of the type genus. The general effect of the resemblance is most striking, the cephalo-thorax of the spiders having the red dorsal surface characteristic of many of the wasps, while in both groups the abdomen is conspicuously spotted with white or yellow. The spiders belong to one species, but mimic the whole group of wasps, and not any particular kind, protection being doubtless the object of the resemblance. Other Ceylon spiders belonging to the same family (Attidæ) mimic ants.

In *The Field* of July 12 Mr. Boulenger directs attention to the description by Mr. P. A. Ouwens in the *Bulletin du Jardin Botanique de Buitenzorg* for 1912 of a gigantic monitor lizard from the Isle of Comodo, between Flores and Sumbawa. The type specimen, described as *Varanus komodensis*, measured 7 ft. in length, but a second example is reported to have reached 13 ft., and there are stories of others with a length of from 19 ft. to 23 ft. The species appears to be related to the North Australian *V. giganteus*, which grows to 7 or 8 ft., but it has the muzzle less pointed and brown in colour, while the tail is proportionately shorter. That this giant of its tribe is distinct from all the other living representatives of its genus is certain; but Mr. Boulenger suggests that it may prove to be inseparable from *V. priscus*, of the Pleistocene of Queensland, the vertebræ of which appear to indicate a reptile at least as large as the biggest reported individuals of the Comodo monitor.

The latest publications of the Fisheries Branch of the Department of Agriculture and Technical Instruction for Ireland include a paper by Messrs. E. W. L. Holt and L. W. Byrne, on the fishes of the Irish Atlantic slope. Some species belonging to the families Stomiatidæ, Sternoptychidæ, and Salmonidæ are described and figured. The same part of the report also contains a paper by Mr. C. L. Boulenger on the luminous organs of the stomiatid fish, *Lamprotoxus flagellibarba*. Mr. R. Southern, in a further report, describes a collection of Gephyrean worms from the coasts of Ireland. Twenty-three species in all are recorded, and six of these are described as new to science. Five species are added to those previously known to exist in the British area. The author advances reasons for regarding *Golfingia macintoshii* of Lankester as synonymous with Blainville's *Phascolosoma vulgare*, and *Thalassema lankesteri* of Herdman as synonymous with Müller's *Thalassema gigas*.

Prof. O. Schmeil's "Naturwissenschaftliches Unterrichtswerk" series has enjoyed an extraordinary vogue in Germany, and when recently revising the botanical portion of the series the author found it necessary to omit certain branches of the subject in order to avoid undue extension of the general botanical volume, intending to write a special work on foreign economic plants. This has now appeared as a separate volume by L. Oberwalter, "Ausländische Kultur- und Nutzpflanzen" (Quelle and Meyer, Leipzig, price 2.40 marks), with an introduction by Prof. Schmeil. This book, uniform in plan with the other volumes in Schmeil's well-known series of manuals, is illustrated by fifty-nine figures, and forms an excellent introduction to economic botany.

One of the most important and difficult questions in connection with the maintenance of railways in India is the supply of suitable sleepers, and in a recent issue of *The Indian Forester* (vol. xxxix., No. 4) Mr. R. S. Pearson discusses the reasons why the forests of India, covering about 25 per cent. of the country, cannot apparently at present fully meet the demands of the railway engineers, who seem inclined to fall back on iron in default of a supply of suitable wood. On the railways running through the desert tracts, with climate ranging from severe frosts in winter to fierce dry heat in summer, and salt winds laden with sand, iron sleepers have proved unsatisfactory, since all kinds of iron become spongy under such conditions, and wooden sleepers last much longer. With the extension of railways in India the demand for sleepers is increasing, and for lack of suitable native wood large quantities of the Australian hardwoods have been imported during recent years; these answer fairly well in the damp climate of Bengal, but elsewhere have failed owing to inability to resist the attacks of white ants. The best sleeper wood in India and Burma is teak, but this is now used for other purposes, for which a much higher price can be paid, and Indian foresters are devoting considerable attention to the whole question of a suitable timber or timbers, and the equally important matter of suitable treatment to make the wood more resistant and durable.

In the June number of the Journal of the Board of Agriculture, Dr. Winifred E. Brenchley gives a survey of a season's work on weeds and their relations to the soils of Norfolk. Compared with results of similar work in Bedfordshire and the western counties, a greater number of species was observed in Norfolk, and this is attributed partly to greater diversity of the Norfolk soils (which are of drift origin) and partly to the larger area covered by the investigation. Some of the weeds are proving to have a real association with different types of soil, while others show decided local differences. The relative richness of sand and sandy loams in calcium carbonate is reflected in the flora, such "acid" plants as Rumex and spurrey never being found on these soils. Few species have a decided preference for heavy land, and practically none can be designated as absolutely symptomatic of clay, though a few are certainly characteristic; of these the chief are field foxtail, cut-leaved geranium, hogweed, and corn crowfoot. The occurrence of certain weeds with definite types of crop was also observed.

The Bulletin of the Philippine Weather Bureau for October, 1912 (recently received), contains particulars of four typhoons in that month, three of which crossed the archipelago. The most noteworthy was one which passed over the Visayas, or central group of islands, on October 15 and 16, and named the Leyte and Cebu typhoon. As the observations from Yap (Western Carolines) gave no indication of its existence it is supposed to have originated rather near the Philippines, probably about long. 132° E., lat. 10° N.; the Manila Observatory was, however, able to give timely warnings of its approach. The Rev. J. Coronas, S.J. (assistant director), states that the storm must be classified as one of prime importance, both on account of the lowness of the barometer in the neighbourhood of the vortex, 707 mm. (27·84 in.), and the consequent violence of the winds (seventy to eighty miles an hour), as well as on account of the torrential rains which caused inundations, more particularly in the south of Leyte and north of Cebu. All towns within a radius of twenty miles from the storm centre describe their losses as incalculable, and several interesting photographs are given showing the destructive effects of the typhoon. The great loss of life in Cebu is partially due to the facts (1) that little attention was paid to the warnings, and (2) that the vortex passed near midnight, whereas in Leyte it passed during the daytime.

The Electrician for July 4 contains a description of a method devised by Mr. G. B. Burnside for sealing metallic conductors, *e.g.* copper into glass directly. The essential feature of the method consists in the repeated immersion of the glass and metal, immediately the fusion in the usual way has been effected, and the glass has cooled to a red heat, into a slightly heated bath of oil or fat for a second or two, the extent of the immersion being increased each time. For currents up to 15 amperes solid conductors may be used, but above that it is advisable to fuse in tubular conductors. The author has experienced no trouble with these joints, and has found that a copper tube capable of carrying 100 amperes fused into glass in this way may be heated to 100° C. without the joint showing any signs of deterioration. The method solves a difficult problem, and obviously has a wide range of applications.

Two recent Memoirs of the College of Science and Engineering, Kyoto Imperial Observatory (vol. iv., Nos. 1, 2), show that the Japanese are prepared to follow up their previous excellent work in connection with geodynamics and latitude variation by some other thorough-going researches. The volume for which Prof. Toshi Shida is mainly responsible, contains an interesting account of preliminary horizontal pendulum experiments conducted at the Kamigamo Geophysical Observatory. The results of these experiments so far confirm the larger value for the effective rigidity of the earth found by Herglotz from the Chandler period of free nutation. This is about twice the value derived from the results of tidal observations and deflections of the plumb-line. Hecker's Potsdam observations have been analysed by Messrs. Shida and Matsuyama for the lunar diurnal term. The results confirm the idea that Hecker's observations, at any rate for one pendulum, were either seriously affected by some local disturbance (*e.g.* pumping in the well) or else represent some abnormal behaviour locally of the earth's crust. Another interesting communication from Prof. Shida is his discussion of volcanic tremors. His attempt to deduce the Chandler period from the time distribution of volcanic eruptions is interesting if not convincing. It gives the value 431·45 days. The z-term in the variation of latitude—or the Kimura term as it is known in this country—comes in naturally for discussion in a Japanese memoir. Prof. Shinzo Shinjo enters into a careful discussion of possible physical explanations, and ascribes it to anomalies in zenithal refraction. In this view he is in agreement with Dr. Frank E. Ross. Without being able to give any accurate numerical result, he suggests that in periodic changes in the refraction may be found in part the explanation of the discrepancy between the values of the aberration constant derived from the solar parallax and that given by Talcott's method. Further work can alone elucidate the point.

Engineering for July 18 gives an account of investigations made by the United States Bureau of Mines on the ignition of mine-gas by glow-lamps. That all types of glow-lamps are not equally liable to cause ignition of explosive gas was known from previous experiments, conducted chiefly in Belgium, France, and Germany. The American investigators come to the following chief conclusions:—The naked carbon filaments of standard types of lamps, burning at rated voltages, will invariably ignite explosive gaseous mixtures. If the gas can reach those filaments without breaking them, or without producing partial combustion within the bulbs, the gas is sure to be ignited. Several, but not all, sizes of standard lamps (carbon and metallic filaments) and of miniature lamps (small lamps for miners) will ignite the gas when smashed while burning at rated voltages; those lamps which do not cause ignition usually, may do so if the broken pieces of the filament produce a short circuit when the lamps are smashed. Reviewing the results, all the lamps tested must be considered unsafe, though some specimens of a class might not cause ignition. Alternating or direct current, and coupling in series or parallel, made little difference.

MESSRS. J. and A. CHURCHILL have nearly ready for publication the seventh edition of "The Microtomist's Vade-Mecum," by A. B. Lee; the sixth edition of the late Prof. J. Campbell Brown's "Practical Chemistry," edited by Dr. Bengough; and the third edition of "A Text-book of Physics," edited by A. Wilmer Duff.

THE publication of a new series of books, entitled "The Cambridge Technical Series," and edited by Mr. P. Abbott, is being undertaken by the Cambridge University Press. The series will be comprehensive and will include the whole sphere of technical work in the widest sense. Among the subjects arranged for are:—Automobile engineering, electro-technical measurements, chemistry and technology of oils and fats, mining geology, and domestic science.

A COPY of their new list of wireless apparatus and accessories has been sent to us by Messrs. F. Darton and Co., 142 St. John Street, Clerkenwell, London, E.C. This firm has a long-distance installation at work at its factory, and makes a practice of explaining the most efficient methods of using the apparatus supplied to customers. The list is well illustrated, and full particulars of many forms of transmitting and receiving apparatus are supplied.

OUR ASTRONOMICAL COLUMN.

PERIODIC SPECTRUM OF α CANUM VENATICORUM.—Prof. A. Belopolsky publishes in *Astronomische Nachrichten*, No. 4664, the epochs of maximum intensity of the dark line $\lambda = 412{\cdot}993$ $\mu\mu$ in the spectrum of α Canum Venaticorum. Fifty hours is stated to be the length of time of the visibility of this line, and the periodicity very near 5·50 days. Other lines become faint at these epochs.

STARS HAVING PECULIAR SPECTRA.—The observations carried out by Miss Cannon for the Revised Draper Catalogue have added already ten stars to those known to have bright lines in their spectra, and twenty-four new composite spectra. Details of these are given in Harvard Circular 178. The bright-line stars have spectra belonging to classes ranging between B3 and Oe. The latter shows the bands $\lambda\lambda$4633 and 4688 bright, whilst Hβ is seen bright in the rest, one also showing Hγ as a bright line. Of the twenty-four stars showing composite spectra only four are included in Burnham's General Catalogue of Double Stars.

In the same circular it is remarked that a photograph of the spectrum of Nova Geminorum No. 2 secured on April 5, 1913, shows only slight changes since November 9, 1912, when the brightest band was at λ4363. Between $\lambda\lambda$4686–5007 the spectrum resembles that of the prevailing type of gaseous nebulæ, but differences occur in other portions of the spectrum.

THE ORIGIN OF THE PLANETS.—In a memoir communicated to the American Academy of Arts and Sciences (vol. xiv., No. 1) Prof. P. Lowell arrives at some interesting conclusions regarding the genesis of the solar system. Inquiring into the causes of a striking commensurability exhibited between the mean motions of adjacent planets some of the deductions he makes are:—(1) The planets grew out of scattered material; (2) each brought the next one into being by the perturbation it induced; (3) Jupiter was the starting point, and is the only one of the planets that could have had a nucleus at the start.

Prof. Lowell enunciates the following law:—"Each planet has formed the next in the series at one of the adjacent commensurable-period points, corresponding to $\frac{1}{2}$, $\frac{2}{5}$, $\frac{1}{3}$, and in one instance $\frac{3}{5}$ of its mean motion, each then displacing the other slightly sunward, thus making of the solar system an articulated whole, an inorganic organism, which not only evolved but evolved in a definite order, the steps of which celestial mechanics enables us to retrace."

On the basis of this law he makes some predictions regarding "the nearest trans-Neptunian planet"; thus it should have a major axis of 47·5 astronomical units, and a mass comparable with Neptune, though probably less.

THE HULL MEETING OF THE MUSEUMS ASSOCIATION.

THE annual conference of the Museums Association was held at Hull last week, under the presidency of Mr. E. Howarth. There was a large attendance, including representatives from abroad, as well as from numerous places in the British Isles.

As his presidential address, Mr. Howarth gave a helpful and suggestive discourse on the scope, function, and development of museums, using the word in its most comprehensive sense. He pointed out that though the universe could not be represented in a museum, yet even the provincial institution was doing work of a national character. It would be foolish to attempt to reproduce the British Museum in every town, but the principles dominating it were applicable to the smallest village museum. Museums should hold a recognised position in the scheme of national education from its base to its summit, and each museum, whether its teaching be general or specific, should do more than merely provide object-lessons. It should focus attention upon the progress of human knowledge and achievement. This cannot be done by punishing the visitor with endless series of specimens of interest only to the specialist. It must be accomplished by selecting a strictly limited number of objects, and so displaying them as to endow them with an intensely human interest. The gathering together of objects of local significance should be the primary duty of the curator, and their effective display his greatest achievement.

In a paper entitled "Methods of Collecting," Mr. T. Sheppard gave a brief account of the growth of the Hull museums. As evidence of continued development it may be mentioned that at the association dinner it was announced that Colonel G. H. Clarke had determined to purchase and present to Hull the Mortimer collection of prehistoric antiquities, geological specimens, and other relics, at present housed in the museum at Driffield. The announcement was received with the greatest enthusiasm, for the collection is renowned as one of the best series of Yorkshire prehistoric antiquities in existence, and its value is enhanced by the careful and scrupulous records kept by Mr. Mortimer.

The most novel paper of the conference was probably that given by Mr. J. A. Charlton Deas, of Sunderland, "How to Show our Museums and Art Galleries to the Blind." In essence this was a report of experiments made by Mr. Deas at the Sunderland Museum and Art Gallery, where demonstrations have lately been given to parties of blind people, both adults and children. Blind visitors in the museum were taken in hand by guides. They handled certain specimens, and each feature was explained at the moment of touch. Attached to each specimen was a carefully drawn-out descriptive label, which was read by the guide, and great care was taken in leading the hands or fingers of the blind to the important features. Mr. Deas emphasised the need for conscientious guiding of the blind person's hands, and said that where possible there should be a guide for each blind visitor. The blind children of the council school were also taken in this way through the museum and art gallery. Some remarkable models were made, after the examination of the specimens, by children between eight and fifteen years of age, none of whom had any special knowledge of modelling. In fact, in some cases they were a first attempt. The models, though rough, showed in many cases remarkable spirit.

Prof. Roberts Beaumont, of Leeds University, read a paper upon the organisation of a textile museum, in which he said that the subject, though a large one, had not received that full attention which those connected with the textile arts considered it should have. He insisted upon the importance of illustrative models being technically correct, and effective for the demonstration of the purpose and function for which the machines were originally invented. Nor is it enough to furnish the student with specimens illustrating the history of textile ornament. Such analyses should accompany the specimens as would make them increasingly suggestive to those who viewed them and increasingly inspiring. A textile museum should set forth the history of manufacture and the process and sequence of invention, typifying the nature, scope, and function of each department of the industry, exemplifying each phase of woven art, stimulating research, and proving a veritable storehouse of classified knowledge.

Mr. J. W. Baggaley described a simple and efficient gelatine and glycerine cement by means of which he had been able to mount zoological specimens in spirit.

The association was honoured by the presence of Prof. F. Rathgen, chemist to the Royal Museum at Berlin, whose experiments and writings on the treatment and preservation of antiquities are so well-known to all curators. He gave a paper on the decay and preservation of antiquities, which aimed at giving an outline of the various causes underlying the disintegration of antiquities after excavation, due to the changes which have taken place during varying periods and conditions of interment.

Mr. Cecil W. C. Hallett and Mr. J. H. Leonard, official guides at the British Museum, Bloomsbury, and the British Museum (Natural History), South Kensington, gave accounts of their personal experience in conducting parties of visitors around these great national institutions. Arising out of this experience they were able to give many valuable hints as to the precautions to be taken to ensure successful and enjoyable demonstrations. Some of the difficulties which present themselves—such as noise, interruption from visitors not belonging to the party, &c.—were admittedly difficult to remedy, but, as public appreciation and the powerful advocacy of such friends of museum work as Lord Sudeley seem destined to bring this mode of spreading knowledge of our potentialities into vogue, it is essential that they should be overcome.

Mr. Reginald A. Smith, of the British Museum, gave a paper on curators and the Stone age. He directed attention to the fact that Britain was rapidly showing itself to be a much richer field for discovery in this direction than we have hitherto believed, and that the subject has now attained such public prominence as to call for close attention on the part of the curator. Stone-age archæology may now be described as being in the melting-pot, and it is our duty to see that we assimilate the new and far-reaching ideas which emanate therefrom.

The paper part of the meeting concluded with some interesting remarks by Dr. F. A. Bather, F.R.S., on fittings and preparations noted during a recent visit to the museum of the Institut Océnographique at Monaco, and a message from the Rev. Prof. Henry Browne emphasising the need for assistance from museums in the furtherance of classical studies.

The business meeting had several matters of special interest to consider, foremost amongst which was the question of grants by the Board of Education in aid of the purchase of scientific specimens for provincial museums. These grants have been in abeyance for several years, but the advisory council for the science museum has now taken up the matter, and a sub-committee recently received a deputation from the association in a most understanding and sympathetic spirit. The outcome is that the Museums Association has been asked to submit its views as to the direction in which grants would be helpful and appropriate, and as to the conditions which should accompany them.

The following resolutions were passed:—

"That this association desires to direct the attention of the Board of Education to the great value to provincial museums of the collections sent out by the Victoria and Albert Museum, and trusts that, now that the circulation department has been made a self-contained section of the museum, with no power to circulate any of the specimens in the general museum, the collections available for circulation will be augmented to meet the requirements of the provincial museums, which steadily increase in number, and are undoubtedly attaining a higher level of artistic excellence."

"The Museums Association, at its annual conference in Hull, 1913, declares itself in cordial sympathy with the proposal to make provision in the grounds of the Crystal Palace for a British Folk-Museum on the open-air plan, and expresses the hope that the Right Hon. the Lord Mayor of London will use every endeavour to carry the proposal into effect."

The conference concluded its business by electing Mr. Charles Madeley, director of the Warrington Museum, to be president for the 1914 meeting, which is to be held at Swansea.

THE ELECTRIC FURNACE SPECTRUM OF IRON.

IN NATURE for April 24 (p. 200) we gave a brief account of the researches carried on by Mr. A. S. King, of the Mount Wilson Solar Observatory, upon the variations of the spectrum of titanium in the electric furnace. Mr. King has now concluded an investigation of the variation with temperature of the electric furnace spectrum of iron, an account of which is published in No. 66 of the Contributions from the Mount Wilson Solar Observatory.

This communication, like others of his on a similar subject, is of great interest, because it shows that the spectrum of a substance is not the same for any temperature. By knowing what spectrum is given at a known temperature it is possible to determine the temperature of stars or portions of the sun, and so utilise these laboratory researches for stellar and solar spectroscopy.

While a great amount of work has already been done in the case of iron, one of the earliest being the differentiation of temperatures by the short- and long-line method of Lockyer, Mr. King has all the advantages of the latest form of furnace and method of determining accurately the varying temperatures for the lower stages of temperature.

One of the great problems in these investigations is to determine whether the changes described are due to temperature or to electrical or chemical conditions which are present in different degrees in the sources of heat.

In a brief summary like this it is not possible to state all the conclusions which the research has led Mr. King to deduce, but the more important may be briefly summarised. In the first place, he has been able to divide into six classes the relative intensities of the iron lines in the visible spectrum for three furnace temperatures and the arc, basing them on the temperature at which a line appears in the furnace, and its rate of growth as the temperature increases. In passing from the furnace to the arc the changes in relative intensity may generally be accounted for by a difference in conditions equivalent to a large temperature difference. The ultra-violet was found a rich region for lines, and it was noted that increase of temperature corresponded to an extension of the line spectrum towards shorter wavelength. The increase in intensity of lines from the outer vapours into the core of an iron arc was found usually to resemble the rate of growth shown by the same lines with rising furnace temperature, and this the author suggests renders it unlikely that chemical reactions in the outer vapours affect the relative intensity of arc lines in any large degree.

So far as the visible region is concerned the enhanced iron lines are above the furnace stage, no lines being observed in the furnace spectrum. The furnace spectra at low and medium temperatures were found, except perhaps in the ultra-violet, to be very similar to those of the several flames.

The author concludes that while there is no definite proof that temperature radiation in a strict sense takes place, the position of temperature as the exciting and regulating agent in furnace phenomena seems to be clear.

ANTARCTIC LICHENS.[1]

LICHENS form a quite exceptional group of plants with many peculiar features, the chief among which is the fact that they are compound organisms, a lichen consisting of a fungus individual and numerous alga individuals—the fungus with its branched and interlacing threads has grown around the alga cells and enclosed them in a nest. The result is that the lichen can grow in places which would be quite unsuitable for the independent existence of either the fungus or the alga of which it is composed. Algæ grow in water or in moist places, while most fungi are extremely sensitive to cold and drought, but lichens can thrive in the bleakest positions and in the most severe climates, as on bare mountain rocks and in the farthest circumpolar regions reached by explorers—provided that the land surface is not covered by perpetual snow. In alpine and arctic regions, lichens do important pioneer work, helping to break up the hardest rock surfaces and prepare soil on which other plants can grow; while on steeply inclined and bare rock, lichens, along with minute algæ, are in general the first colonists.

These pioneer lichens are of the flat crustaceous and foliose types, the former attached closely to the substratum by their entire underside, the latter clinging more loosely, and being therefore detachable without chipping off bits of the rock itself in order to obtain specimens. On less steeply inclined parts, where the vegetation is older, the shrubby or fruticulose lichens are added; these are fixed at the base only, and show much greater variety of form than is found among the encrusting and leafy types.

In his report on the lichens of the Swedish Antarctic expedition, 1901–3, under Dr. O. Nordenskjöld, which has recently been published, Dr. O. V. Darbishire adds to his descriptions of the new species an interesting summary and discussion of the distribution of lichens in the arctic and antarctic regions generally. Unfortunately the good ship *Antarctic* was crushed by ice in January, 1903, and a large portion of the plants collected during her cruise along the coast of Graham Land had to be abandoned when she sank a month later; but though doubtless a considerable amount of material was lost in this disaster, a rich harvest was brought back by the botanical members of the Swedish expedition. This includes no fewer than 145 species of lichens, of which thirty-three are new.

An analysis of the results of antarctic expeditions up to and including Charcot's (1905) shows that at present 106 lichen species are known from the land which lies strictly within the antarctic limits, and that of these thirty-two also occur in subantarctic America, twenty-five in New Zealand, and sixteen in South Georgia, showing a very close affinity between the antarctic lichen flora, on one hand, and the American and New Zealand floras, on the other—the difference to the disadvantage of the latter being accounted for by the greater nearness of the subantarctic American region to the extreme limit of the southern drifting pack-ice. The lichens of subantarctic America and New Zealand are also very nearly allied, for out of 133 lichens in the former flora, 113 are found in New

[1] "The Lichens of the Swedish Antarctic Expdition." By Otto Vernon Darbishire. Wissensch. Ergebn. der schwedischen Südpolar-Expedition. 1901–1903. Band iv., Lief. 11. Pp. 1—73+3 plates. (London Dulau and Co., Ltd., 1912.) Price 8s. (Subscription price 6s.)

Zealand, 32 in the Antarctic, and 31 in South Georgia, the latter being evidently, from the phytogeographic point of view, a half-way house on the road from subantarctic America to the true antarctic area. Moreover, practically half of the antarctic species are common also to the arctic regions.

Of the 106 antarctic lichens, sixty-nine are crustaceous, eighteen foliaceous, and nineteen fruticulose species; of these, the numbers found in subantarctic America are respectively sixteen, five, and eleven. Of the sixty-seven species found only in the true antarctic area, forty-nine are crustaceous, ten foliaceous, eight fruticulose. The subantarctic American lichen flora includes 366 species, while 740 species have been enumerated for New Zealand; of the species common to the two regions 50 per cent. are fruticulose, 30 per cent. foliaceous, and only 20 per cent. crustaceous. The affinity of the subantarctic American and New Zealand lichen floras lies mainly in the fruticulose lichens, which are the oldest and probably the least variable forms. The encrusting species are more variable and have adapted themselves more readily to local conditions, thus giving rise to new species. An interesting point arises from a comparison with northern lichen floras. The arctic area had nearly 500 lichens, of which 72 per cent. are found in Tyrol. Thus the relation of arctic to alpine lichens is much greater than that of subantarctic American to New Zealand species, indicating that the latter are further from the point of common origin.

Dr. Darbishire raises the interesting question of the resistance of cold by lichens, and suggests some simple experiments which might be made on lichens in the very coldest regions. For instance, it would be of the greatest importance to determine the amount of water contained in the lichen thallus at various times and seasons. In what condition are lichens during the long winter? At what temperature does assimilation commence? It is of little use to try experiments on plants in warmer climates, if we wish to ascertain how these small plants can live under the adverse conditions prevailing in the arctic and antarctic regions.

Lichens are found everywhere on the outer limits of vegetation, and their chief ecological distribution factor is their power to become quite dry and yet remain alive. No doubt it is this property which enables them to spread slowly but surely into the bleakest and most inhospitable regions. They are making their way towards the north and south poles, and so far they have been beaten in their race only by the perpetual covering of snow. There is little doubt that if bare rocks are found in the neighbourhood of the poles themselves, lichens will be found growing there.

Dr. Darbishire's memoir is illustrated by three double plates of beautifully reproduced photographs, depicting the new species brought back by the expedition.

F. C.

APPLICATIONS OF POLARISED LIGHT.[1]

ON November 30, 1812, just above 100 years ago, the French physicist Biot communicated to the Institute of France a memoir "on a new kind of oscillation which the molecules of light experience in traversing certain crystals." In this paper, which extends over 371 pages of the printed memoirs, the phenomenon of "rotatory polarisation" was described for the first time. This phenomenon depends on the property which certain substances possess of taking a beam of polarised light and imparting a twist to the plane of polarisation: the beam of light enters with all the vibrations compressed, say, into a vertical plane; it emerges apparently unchanged, but careful examination shows that the component vibrations are no longer vertical, but inclined either to the right or to the left. The importance of this discovery to physicists and to crystallographers was immediately obvious. In our own generation its fertility has been realised also by chemists, who have found in the polarimeter an instrument which promises to render to the science services not less notable than those which have been accomplished with the help of the spectroscope.

[1] Discourse delivered at the Royal Institution on Friday, April 18, by Dr. T. M. Lowry.

A.—*Sources of Polarised Light.*

If one were to ask what progress had been made in the facilities for applying polarised light to the study of chemical and physical problems, the answer would be twofold. On one hand it must be acknowledged that the "Iceland spar," by means of which Huyghens in 1678 first detected the polarisation of light, is still the best substance for producing this effect. But the increasing demand for the spar has not been accompanied by any corresponding increase in the supply, and large clear pieces of the mineral are becoming increasingly difficult to procure. It may indeed be doubted whether large polarising prisms such as those which have been handed down as heirlooms at the Royal Institution could now be purchased at any price, in view of the "spar-famine" which has prevailed for some years.

Considerable advance has, however, been made in the direction of improved methods of illumination. The solar light, which figured so largely in the experiments of the earlier workers, is too precarious to satisfy the ardent worker of to-day, and in any case could render no direct assistance in illustrating a Friday evening discourse. When Faraday, on Friday, January 23, 1846, delivered his discourse on the magnetisation of light to an audience of 1003 persons, the source of light in the experiments which he described was an Argand gas-burner. Prof. Silvanus Thompson in 1889 was able to use the electric arc, which was then just beginning to come to the front as a commercial illuminant. With this unrivalled source of light he was able to show for the first time in a public lecture a large number of the properties of polarised light which had been reserved hitherto for individual observation in the laboratory. The remarkable effects which are seen when light of one single colour or wave-length is substituted for white light were shown by Spottiswoode in 1878, with the help of a powerful sodium-lamp which had been devised by Sir James Dewar. His lecture was aptly described as "A Nocturne in Black and Yellow."

During several years I have taken a special interest in seeking to discover other sources of monochromatic light for use, in experiments on polarisation, and have been particularly concerned to proclaim the merits of the mercury arc as an illuminant for everyday use in optical investigations.

The Mercury Arc.

The spectrum of the light produced by passing an electric discharge through mercury vapour was described by Wheatstone in 1835 in a report to the British Association on the prismatic decomposition of electric light; but it was not until twenty-five years later that a real mercury-lamp was invented by Prof. Way. This consisted of an intermittent jet of mercury which was directed into a cup half an inch below. The current from a battery of Bunsen cells was passed through the jet and developed an intense light. The spectrum of the light was examined by Dr. J. H. Gladstone, and described in a paper on the electric light of mercury, published in the *Philosophical Magazine* of 1860 (vol. xx., pp. 249–53).

The first use of the mercury arc as a source of light in polarimetry appears to have been made just ten years ago by two German workers, Disch and Schönrock, working independently (Disch, *Ann. Phys.*, 1903 (IV.), vol. xii., 1155; Schönrock, *Zeit. Vereins Deutsch. Zuck. Ind.*, Tech. Part, 1903, vol liii., 652). Through the personal kindness of Mr. Bastian, I was enabled about three years later to make use of the same source of light in what is still, perhaps, its most convenient form. The glass Bastian lamp was designed to burn with the coils of the arc in a horizontal plane, and was arranged to light automatically in this position. It was with great delight, therefore, that I discovered that, in spite of all warnings to the contrary, the lamp would continue to burn for any length of time with the coils raised into a vertical plane; in this position one of the straight portions of the arc could be focussed by a condenser directly on to the slit of a spectroscope, and so used to illuminate the field of a polarimeter. The lamp consumed very little current, and could be connected directly to the ordinary lighting circuits without any risk of "blowing" the fuses; it was cheap to purchase, and as the resistances formed part of the holder of the lamp there was no need for any auxiliary apparatus whatever. In view of its special suitability for polarimetric work, it is to me personally a matter of some regret that this pioneer lamp has been displaced completely by the more powerful arcs, encased in refractory silica glass, which now adorn the exteriors of so many places of amusement.

When using the mercury arc as a source of violet light, account must be taken of the greatly reduced sensitiveness of the eye to light of such short wavelength. It is here that the silica mercury lamp has proved of such great utility. I am indebted both to Mr. Lacell, of the Silica Syndicate, and to the Brush Electrical Engineering Company for allowing me, for experimental purposes, to distort their well-considered designs for commercial mercury arc lamps. Here, for instance, is a horizontal lamp which has been altered so that the arc can be seen at its greatest intensity in an end-on position. At first the light was liable to be obscured by globules of condensed mercury. But by recessing the window it was kept sufficiently hot to prevent condensation, and this difficulty was effectively overcome. Even then, however, the arc was not so convenient as one arranged in a vertical plane, like the upturned Bastian lamp. It was at this stage that I persuaded the Brush Company to modify for me their "Quartzlite" lamp by twisting one of the terminal **U**-tubes into such a position that it did not empty itself when the lamp was raised into a vertical plane. The "end-on" lamp and the vertical "Quartzlite" lamp have been described in the Transactions of the Faraday Society (1912, vol. vii., pp. 267–70), and were exhibited at the Optical Convention of June, 1912. The lamp shown in Fig. 1 has not been described previously. It combines the merits of both of the preceding patterns, and can be used either horizontally or vertically, and either in a side-on or in an end-on position.

The "Pinch Effect."

One feature of the silica mercury-lamps is sufficiently remarkable to deserve attention. When the arc is first struck by tilting the lamp it fills the whole of the bore of the half-inch tube which encloses it; but, in accordance with Faraday's observation that currents travelling in the same direction attract one another, the parallel threads of current are drawn together until finally, as you see, the arc is "pinched" together into a thread occupying only about one-third of the diameter of the tube. This pinching together of the arc contributes substantially to its efficiency as an illuminant in polarimetric and spectroscopic work; but it is not a suitable form for projection, which demands, as a condition for successful work, a powerful point-source of light.

If the current in the mercury arc is increased, the pinching effect may extend to the point of breaking the threads of current completely and so extinguish the arc.

It may be of interest to refer here to the well-known fact that the "pinch effect," which I have exhibited on a small scale in a mercury-lamp, is of great importance in the electrical melting of steel on a large commercial scale. In that case a current of great magnitude, flowing through a mass of molten steel enclosed in a circular channel, sometimes causes the metal to pinch together to such an extent that the circuit is actually broken. The "pinching" apart and running together of the mass of molten metal produce a somewhat thrilling display.

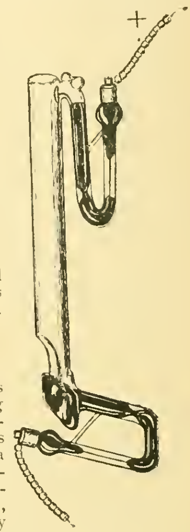

FIG. 1.—Mercury lamp for use in a horizontal or vertical, side-on or end-on position.

The Mercury Spectrum.

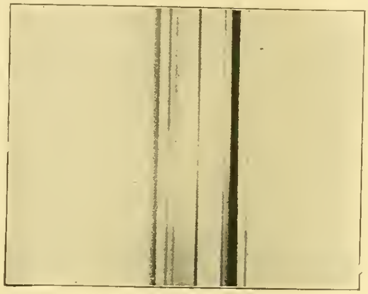
The mercury arc differs from the carbon arc in giving an extremely simple line-spectrum, the chief features of which are a yellow, a green, and a violet component. The yellow component contains two lines, separated by about twenty units of wave-length as compared with six units for the yellow sodium doublet; it shows up well in the spectrum, but on account of its duplex character it is not suitable for use in exact measurements.

By means of powerful high-resolution apparatus, such as the echelon spectroscope, the green line of the mercury spectrum has also been shown to be complex (Fig. 2); but in this case the components are so close together that they do not in any way reduce the value of the line as a source of monochromatic light. The extreme brilliancy of this green line, its high spectroscopic purity, and the ease with which it can be produced, have given to it an unrivalled position amongst the various sources of monochromatic light which are now available for polarimetric work. I can say with confidence that no one who has worked with the mercury-lamp will ever wish to return to the sodium flame, which it is rapidly displacing both in scientific and in technical laboratories.

Dr. Gladstone directed special attention to the strength of the violet lines in the spectrum, of one of which he said that "this ray is situated far beyond what is ordinarily considered the limit of the luminous spectrum." This deep-violet component contains two lines which are clearly visible in the spectroscope; but they lie so near to the limit of visibility that their presence can be shown most clearly with the help of a fluorescent screen. The bright violet line is, from the scientific point of view, one of the most valuable features of the mercury spectrum. The main line is accompanied by two satellites of greater refrangibility; But these are so close to the principal line, and are of so much smaller intensity, that they do not diminish appreciably the unique value of this line, which still remains the most powerful source of monochromatic light for work at the violet end of the spectrum. Actual measurements in which the violet line has been used, both with and without the satellites, have shown that the errors introduced by the presence of the latter do not exceed one part in 10,000 on the readings of a polarimeter. This error would, therefore, be quite inappreciable in the case of all readings of less than 100°.

The visible spectrum does not by any means exhaust the usefulness of the mercury arc. The powerful series of ultra-violet lines, which are freely transmitted by the glass of the silica lamps (Fig. 3), are of value for a number of scientific purposes, and have found an important technical application in the sterilisation of water.

At the other end of the spectrum, the magnificent though invisible line at wave-length 10,140 has proved to be of unique value as a starting point for calibration work in the infra-red. It will also be remembered that some of the longest waves of light that have yet been detected were discovered by Rubens in the radiation from a mercury lamp.



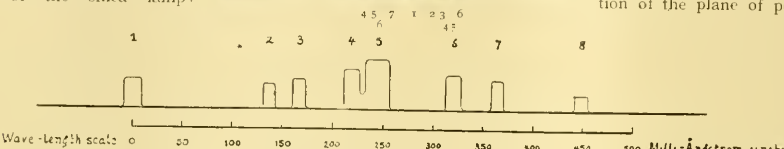


FIG. 2.—Resolution of the mercury-green line by the echelon spectroscope. The actual distribution of the components is shown by the diagram. (*By courtesy of Prof. Stansfield.*)

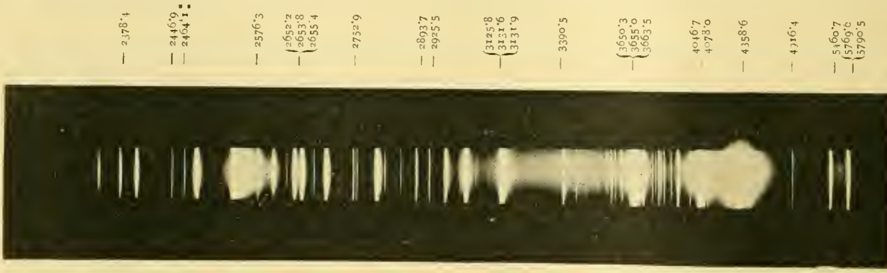

FIG. 3.—The ultra-violet spectrum of mercury. (*By courtesy of Messrs. A. Hilger, Ltd.*)

Resolution of the Mercury Spectrum.

One merit of the mercury arc as a source of light consists in the readiness with which the three main components may be separated. A direct vision prism of quite moderate dispersive power, placed in front of the eyepiece of a polarimeter, produces a separation of the three images which is sufficient for most purposes. The lines may also be separated by means of coloured screens prepared from gelatine films stained with suitable dyes.

B.—*Rotatory Polarisation.*

The phenomenon of rotatory polarisation was first discovered in the case of quartz. Arago in 1811 (Mem. Inst., 1811, pp. 93–134) found that a plate of quartz interposed between a polariser and analyser was capable of depolarising the light in such a way that transmission took place where previously there had been complete extinction. When plates of suitable thickness were used the transmitted light was no longer white, but beautifully tinted, the colour of the light varying with the thickness of the plate. Thus with increasing thickness we have progressively yellow, orange, rose-red, violet, blue, and green.

These colours were shown by Biot to be due to a rotation of the plane of polarisation, which increased (*a*) with thickness of the plate, (*b*) with change of colour from red to violet. It is therefore impossible when a beam of polarised light has passed through a quartz plate to extinguish all the colours simultaneously.

The tints which Arago observed were due to the selective extinction of light of different colours by the mirror which he used as an analyser. This selective extinction may be shown by inserting a direct vision spectroscope in front of the apparatus: the plate which produces the pale yellow colour has rotated the violet light through 180°, so that it is extinguished exactly as if no quartz plate were present; the yellow tint is the complementary colour to that extinguished. As the thickness of the plate increases, the same effect is produced with light of longer wave-length; as the extinction moves from violet to red the complementary colour changes from yellow to orange, red, blue, and green. When the bright yellowish-green is extinguished a grey "neutral tint" is produced which is extremely sensitive to small rotations of the plane of polarisation, and was at one time used very largely in polarimeters illuminated with white light.

When monochromatic light is used—as, for instance, when a green screen is placed in front of the mercury arc—the light can be extinguished completely even after it has passed through a very long column of quartz. Using green light purified by a spectroscope and rods of quartz cut from a crystal of extraordinary beauty, I have obtained a perfectly sharp extinction with a column of quartz half a metre in length, giving an actual rotation of 12,789·20° ± 0·01°. I have also been making experiments with the same material to determine accurately what rotation is produced by quartz in light of different wave-lengths, not only in the visible spectrum, but also in the infra-red and ultra-violet regions; but as the work is still incomplete, I will not attempt to describe it, but pass on at once to other ways in which rotatory polarisation may be produced.

Three years after his discovery of rotatory polarisation in quartz Biot was astonished to find that the same property was possessed by certain liquids, turpentine and laurel-oil rotating the plane of polarisation to the left, and oil of lemon and camphor (dissolved in alcohol) rotating it to the right.

In the case of quartz, Biot had attributed the rotation of the plane of polarisation to the crystalline structure of the material. The correctness of this view was proved when it was shown that rotatory polarisation no longer took place when the crystalline structure of quartz was destroyed by melting it or by dissolving it in alkali. In the case of liquids this explanation was no longer possible. Rotatory polarisation must here be attributed to some lack of symmetry in the structure of the molecule rather than of the crystal. It is in such cases that the polarimeter has proved its supreme value in the investigation of molecular structure. In this connection it will be sufficient if I refer to the classical researches of Pasteur, van't Hoff, and le Bel, and to the brilliant contemporary work of Pope, Kipling, Smiles, and Mills in our own country, and of Meisenheimer and Werner on the Continent. In each of these investigations the development of "optical activity" has been accepted as a conclusive proof of molecular asymmetry, and no firmer basis for theories of molecular structure has yet been found than that which rests upon the use of the polarimeter to detect rotatory polarisation.

C.—*Mutarotation.*

In 1846, thirty years after Biot had discovered that rotatory polarisation might occur in liquids as well as in crystals, a remarkable discovery was made by the French chemist Dubrunfaut in reference to the rotatory power of aqueous solutions of grape-sugar or glucose. Dubrunfaut found that by using freshly prepared solutions of the sugar he could observe a transient rotatory power which was twice as great as that observed in solutions which had been prepared a few hours previously. To this remarkable phenomenon he gave the name Birotation.

The same phenomenon, which is now generally known as mutarotation, has since been observed in the case of nearly all the "reducing" sugars. Many explanations were given to account for so mysterious a change, but nothing in the way of proof could, as a rule, be offered in support of these suggestions. In 1890, however, Emil Fischer discovered that similar changes of rotatory power occurred when gluconic lactone was dissolved in water and thus partially hydrolysed to gluconic acid—

$$\underset{\text{Gluconic lactone}}{C_6H_{10}O_6 + H_2O} \rightleftharpoons \underset{\text{Gluconic acid.}}{C_6H_{12}O_7.}$$

He therefore suggested that a similar explanation might be given of the mutarotation of glucose, thus—

$$\underset{\text{Glucose.}}{C_6H_{12}O_6} + H_2O \rightleftharpoons \underset{\text{Glucose hydrate.}}{C_6H_{14}O_7.}$$

Mutarotation of Nitrocamphor.

In 1896 a happy accident led to the discovery that very marked changes of rotatory power occur in freshly prepared solutions of nitrocamphor. But, unlike the case of glucose, these changes could be observed in a large range of solvents. The change varied greatly in the numerical values involved, but was always in the same direction—from left towards right.

The cause of the mutarotation was not difficult to discover. It could not be due to hydration, nor indeed to any direct chemical action of the solvent, but must be attributed to some change of structure in the molecule of the nitrocamphor itself. In view of the fact that the nitro-compound is able to simulate the properties of an acid, giving rise to strongly dextrorotatory salts, there could be little doubt that the change of rotatory power was caused by a partial conversion of the nitrocamphor into its acidic form—a conversion which can be rendered complete by the addition of alkali. This view was immediately confirmed by the discovery of a dextrorotatory anhydride, which could be prepared from nitrocamphor merely by evaporating its solutions on a water-bath.

This interconversion of isomeric compounds, which we have called dynamic isomerism, could also be used to explain the mutarotation of glucose, of which two isomeric forms are known; but there is good reason to believe that the hydrolysis suggested by Fischer is also an important factor when aqueous solutions of the sugar are under consideration.

In the case of π-bromonitrocamphor two isomeric forms of the substance can actually be isolated, thus affording direct evidence that the mutarotation observed in the case of this compound is due to a reversible isomeric change.

Form of the Curves.

In most cases the change of rotatory power proceeds according to a very simple law, the rate of change being directly proportional to the distance still remaining to be traversed.

But I have recently found a number of cases in which the curves are far more complex. In such instances it is necessary to assume a series of successive isomeric changes; but this assumption presents no difficulty, as the substances in question can all be formulated in at least five different ways.

Acceleration by Catalysts.

The mutarotation of glucose is accelerated to a moderate extent by acids and very largely indeed by alkalis. Similar observations have been made in the case of nitrocamphor. Piperidine added to a solution of nitrocamphor in benzene produces a remarkable acceleration which can be detected even at a concentration of N/10,000,000, *i.e.* 1 part in 100 million or 1 centigram per ton. Aniline is 100,000 times less active.

Arrest of Isomeric Change.

The fortunate selection of chloroform as one of a series of solvents led to the discovery of one of the most important facts that have come to light in the course of fifteen years' work on mutarotation. In the very earliest stages of the work it was found that solutions in chloroform behaved in a very irregular and surprising way; the mutarotation in this solvent seemed sometimes to "hang fire" until set going by some accidental stimulus. These observations were evidently important as proving that isomeric change was not spontaneous, even after the nitrocamphor had been dissolved. But for ten years no explanation was forthcoming to show why this phenomenon was observed in chloroform and in chloroform only. About five years ago, however, an arrest of isomeric change was again observed in the case of chloroform solutions to which a trace of acid had been added. These solutions (the rotatory power of one of which "held up" absolutely during twenty-four days) acquired a pungent and horrible odour, and had evidently undergone marked decomposition. It was not long before the odour was recognised as being due to carbonyl chloride—a well-known and (in anæsthetic chloroform) a dangerous impurity, formed by oxidation of the chloroform according to the equation—

$$CHCl_3 + O = COCl_2 + HCl.$$

This substance has the property of attacking ammonia and organic bases, such as piperidine, and converting them into neutral ureas, as shown by the equations:—

$$COCl_2 + 2NH_3 = CO(NH_2)_2 + 2HCl,$$
$$COCl_2 + 2NC_5H_{11} = CO(NC_5H_{10})_2 + 2HCl.$$

The next step was obviously to try to arrest the isomeric change by the addition of carbonyl chloride to a solvent which did not naturally contain it. This was done with marked success. A solution of nitrocamphor in purified ether showed a change of rotatory power extending over about a day; by the addition of carbonyl chloride the period was increased to eighteen days in a glass vessel, and to sixty-one days when a silica vessel (free from alkali) was used to contain the solution. In the case of benzene, to which acetyl chloride was added, the period was increased from sixteen days to sixty-four days in glass, and to two years in a silica vessel. Finally, by the addition of carbonyl chloride to a solution of nitrocamphor in benzene contained in a silica vessel the period was increased from sixteen days to six years.

Action of Light.

A convenient method of studying the effect of light on isomeric change has recently been devised in which the polarimeter plays a leading part. The solution to be studied was enclosed in a silica tube, surrounded by a silica water-jacket, and exposed to the light from a silica mercury-lamp. In seven cases out of nine, however, no acceleration whatever could be detected as a result of this extremely powerful "insolation."

I have attempted to give some account of a few instances in which polarised light has been applied to the solution of chemical and physical problems. In each case the observations have taken the form of measurements of rotatory polarisation. Measurements such as these have supplied to the chemist a key which has enabled him to unlock the strong-room in which many of the secrets of molecular structure were stored. The physicist, too, following in the footsteps of Faraday, has found in rotatory polarisation a link between the sciences of magnetism and optics, and has obtained valuable hints as to the way in which light is propagated through matter. The hundred years which have elapsed since Biot announced his great discovery have therefore served only to enhance its brilliancy, and to reveal it as one of the most illuminating disclosures even of the splendid period in which it was made.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—At Emmanuel College the following awards have been made for post-graduate research:—Studentships: W. N. Benson (petrology), 75*l*., for half-year only; J. Macdonald (the development of Plato's ethics), 120*l*.; G. Matthai (continuation of research on the comparative anatomy of corals), 150*l*. Grants from the research studentship fund: R. T. Beatty (the energy of Röntgen rays), 25*l*., for one term only; J. H. Burn (biochemistry), 50*l*.

Leeds.—Mr. E. L. Hummel has been appointed professor of mining. Mr. Hummel is a son of the late Prof. Hummel, and was educated at Leeds and in Austria. He has had much practical experience in the Yorkshire coalfield and in South Africa with the Vereeiging Estates Company.

Mr. Walter R. Crawford, of Tullyhogue, co. Tyrone, Ireland, has been appointed live stock officer for Yorkshire under the scheme for the improvement of live stock which has been inaugurated by the Board of Agriculture, with the aid of funds set aside by the Development Commissioners. Mr. Crawford has been a chief inspector under the live stock improvement scheme of the Department of Agriculture for Ireland, and is an authority on the breeding of shorthorns and on the work of milk record associations.

London.—An important correspondence between the University authorities and Lord Haldane with reference to the new site for University headquarters has been published. Lord Haldane, in a letter dated June 6, states that he is willing to try again to interest the donors who were prepared in March to acquire the Bedford Estate (British Museum) site for the University. In reply, the Vice-Chancellor raised the questions of the provision of funds for rates and taxes, and for buildings, and of securing an option for additional land in the neighbourhood for extensions. He also inquired whether it would be possible to close the central road between the buildings to traffic. Lord Haldane, in a letter dated July 13, was able to give satisfactory assurances on these points. The sites committee of the University have decided to postpone further consideration until a conference is arranged with the London County Council.

At the meeting of the Senate on July 16, the D.Sc. degree was granted to Mr. J. C. Chapman (King's College) for a thesis on secondary Röntgen radiation; to Dr. G. C. McK. Mathison (University College) for a thesis on the action of asphyxia upon nerve centres; and to Mr. J. Johnstone for a thesis entitled "Tetrarhynchus Erinaceus, van Beneden I., Structure of the Larva and Adult Worm."

Sir Harry Waechter has offered 300*l*. a year for five years for a department for the treatment of disease by vaccine therapy at University College Hospital.

Grants amounting to 375*l*. for 1913–14 have been made to the following out of the Dixon Fund, for the assistance of various researches:—The Brown Animal Sanatory Institution, Prof. G. Barger, Mr. Morley Dainow, Mr. P. E. Lander, Miss Constance Leetham, Dr. Martin Lowry, Dr. Geoffrey Martin, Mr. J. W. McLeod, and Mr. J. A. Pickard.

Prof. John Laird, professor of logic in the Dalhousie University, Halifax, Nova Scotia, has been appointed to the chair of logic and metaphysics in the Queen's University, Belfast, in succession to the late Prof. Park.

An anonymous donor has given 500*l.* to the South-Eastern Agricultural College, Wye, for the extension of the research department, and the Development Commission is recommending a grant of 6000*l.* for the completion of the new college buildings. The governors have decided upon the erection of the buildings at the Fruit Research Station at Malling, the land for which (twenty-two acres) has been purchased by the Kent County Council.

The following benefactions, among others, we learn from *The Times,* have been left to the British Academy by the late Miss Henriette Hertz:—2000*l.* for an annual lecture, investigation, or paper on a philosophical problem, or some problem in the philosophy of Western or Eastern civilisation in ancient and modern times bearing on the phenomena of life in relation to eternity; 1000*l.* for an annual public lecture on some master mind, considered individually with reference to his life and work, specially in order to appraise the essential elements of his genius, the subjects to be chosen from the great philosophers, artists, poets, musicians; and 1000*l.*, the income of which is to be used to promote the publication of some philosophical work or to reward some meritorious publication in the department of philosophy. Miss Hertz also left the sum of 1500*l.* to Girton College, the income to be used for the endowment of archæological research.

The Board of Agriculture and Fisheries has awarded research scholarships in agricultural science of the annual value of 150*l.*, tenable for three years, to the following candidates, viz.:—E. W. Barton (Wales), economics of agriculture; W. Brown (Edinburgh), plant pathology; Miss E. C. V. Cornish (Bristol), dairying; F. L. Engledow (London), genetics; E. J. Holmyard (Cambridge), plant nutrition and soil problems; R. C. Knight (London and Bristol), plant physiology; F. J. Meggitt (Birmingham), agricultural zoology; H. Raistrick (Leeds), animal nutrition; G. O. Sherrard (Dublin), genetics; T Trought (Cambridge), genetics; G. Williams (Wales), animal nutrition; S. P. Wiltshire (Bristol), plant pathology. The Board has also awarded Miss T. Redman (London), a scholarship in dairying, tenable for two and a half years, to fill a vacancy caused by the resignation of a former scholar. The scholarships have been established in connection with the scheme for the promotion of scientific research in agriculture, for the purposes of which the Treasury has sanctioned a grant to the Board from the Development Fund; they are designed to provide for the training of promising students under suitable supervision with a view to enable them to contribute to the development of agricultural science.

The May issue for this year of the *Johns Hopkins University Circular* takes the form of the University Register for 1912–13. The volume contains an interesting historical introduction, which points out that the Johns Hopkins University was founded by a merchant of Baltimore, Johns Hopkins, who bequeathed the greater part of his estate for the establishment of a university and a hospital. The University was incorporated on August 24, 1867. Instruction began in 1876, in which year President D. C. Gilman, from the University of California, was appointed first president, and remained in office for twenty-five years, being succeeded in 1901 by President Remsen, who resigned last year. The original endowment of the University amounted to somewhat more than 600,000*l.* This has been supplemented by several gifts, including the Endowment Fund of 1902 (200,000*l.*), the John W. McCoy Fund (100,000*l.*), and the Garrett Fund of 60,000*l.*, in addition to many other large sums. The income-bearing funds have a book value of more than 1,000,000*l.*, and the real estate and buildings, books, scientific apparatus, and general equipment are valued at more than 450,000*l.* The assets of the University have thus a total value of a million and a half sterling. By Act of the Legislature of Maryland, at its session of 1912, the sum of 120,000*l.* was granted for the purpose of constructing and equipping buildings for a school of technology as a department of the University, with an annual appropriation of 10,000*l.* for maintenance.

The Government's education policy was outlined by Mr. J. A. Pease, President of the Board of Education, in introducing in the House of Commons on Tuesday a "Bill to amend the law in respect to grants in aid of building, enlarging, improving, or fitting up elementary schools." In the course of his remarks, Mr. Pease said that the defects of our so-called national system of education are two—it is not national and it is not a system. The age at which compulsory attendance at school ceases under the existing law is too early; and to allow children to leave school at the age of from twelve to fourteen years, and leave them to forget what they have learned, is to neglect national responsibility. One main purpose of the Government is to organise intermediate education—that is, all classes of education from the elementary school and the university—by extending the powers and duties and adding to the resources of local education authorities. Further duties of these authorities must be accompanied by further and substantial assistance from the State. Out of 29,834,000*l.* spent on education in 1911–12, 14,186,000*l.* was obtained from the rates and 13,648,000*l.* from Exchequer grants. The increase in expenditure since 1905–6 has been 3,500,000*l.* drawn from the rates and 1,000,000*l.* from grants, or out of every additional 9*l.* required in the last six years 7*l.* had been found by the ratepayers and 2*l.* by the taxpayer. The demand which the ratepayer has for further relief for the taxpayer must, therefore, be admitted. As regards higher education, there will be no interference with the independence of the universities or with the government of training and technical colleges. The principles of the proposed legislation will be the arbitrary provision of intermediate education for all who desire it, placing it within the reach of all classes, and the coordination of such provision between authorities to prevent overlapping. Local authorities will have the duty imposed upon them of affording children during the latter years of elementary-school life opportunities of obtaining such instruction of a more advanced character than that given in the ordinary public elementary schools as may be thought suitable to the circumstances of the children. For this purpose the limit imposed by the Act of 1902 on the amount that might be raised by way of rates for the purposes of higher education will be removed. To give effect to the proposals of the Government, will require a large and substantial addition to the sum at its disposal, which will rise progressively from the first, second, third, and subsequent years. The forecast, of which no details can yet be given, includes provision for the universities, provision for the reconstitution of London University, and provision for the maintenance of increased secondary and technical schools.

SOCIETIES AND ACADEMIES.

Dublin.

Royal Irish Academy, June 23.—Dr. F. A. Tarleton in the chair.—**H. Ryan** and Rev. **J. M. Dunlea**: Unsaturated diketones. I. By the condensation of cinnamic ester with acetone, acetophenone, methyl-ethyl-ketone, and isopropyl-methyl-ketone, the unsaturated β-diketones, cinnamoyl-acetyl-methane, cinnamoyl-benzoyl-methane, cinnamoyl-propionyl-methane, and cinnamoyl-*iso*butyryl-methane were synthesised, and their structural properties examined.—H. **Ryan** and J. **Algar**: Unsaturated diketones. II. Although benzylidene-acetone does not condense to a β-diketone with benzoic ester in the presence of sodium it reacts readily with dimethyl oxalate. Similarly anisylidene-acetone condenses to a β-diketone with dimethyl oxalate. The diketones formed isoxazols with hydroxylamine hydrochloride, and behaved as weak mordant dyes.—G. H. **Carpenter**: Aptera, in connection with the Clare Island Survey. Eighteen species of Collembola and two of Thysanura are recorded from Clare Island, and the apterygotan fauna is found to present, on the whole, an Arctic and American facies. One of the commonest insects on the island and neighbouring mainland is *Petrobius maritimus*, Leach. Some details of the external anatomy of this species are given, and it is shown that the Dutch shore-haunting bristle-tail described by Oudemans, and called *Machilis maritima*, is entirely distinct from the British and Irish insect named by Leach.—W. M. **Tattersall**: Amphipoda, in connection with the Clare Island Survey. The number of species recorded in this paper from the Clare Island marine area is ninety-five. No new species are described, but nineteen species are added to the Irish list for the first time, and fifty-four species are new to the area under review. The Amphipoda of Clare Island include thirty-three Arctic species and sixty-two non-Arctic. Of the former, fourteen extend to the Mediterranean and twelve to the coasts of America. Of the non-Arctic forms, twenty-five are found in the Mediterranean, a further twenty-one are confined to the Atlantic coasts of Europe from Norway to France. Six species are common to the British area and the Mediterranean, but do not extend to Norway. A further ten species are confined to the waters of the British area and neighbourhood, and are unknown from both Norway and the Mediterranean.—R. **Southern**: Nemertinea, in connection with the Clare Island Survey. The total number of species found in the Clare Island area was thirty-one. Of these, two species, *Lineus acutifrons* and *Prostoma beaumonti*, were described as new. *Tubulanus banyulensis*, Joubin, was added to the British fauna, and seven other species were obtained which had not previously been recorded from Ireland. The Nemertean fauna as a whole closely resembles that found in the south-west of England.

Royal Dublin Society, June 24.—Prof. H. H. Dixon, F.R.S., in the chair.—Miss M. C. **Knowles**: Maritime and marine lichens of Howth (Dublin Bay). Altogether 180 species are recorded from the Howth coasts in this paper, of which three are now described for the first time, and twenty-three are new to Ireland. An attempt has been made to give an account of the lichen vegetation from an ecological as well as from a systematic point of view, and the various species are described as growing in the following succession of belts from the top of the cliffs to low-water mark:—(1) The Ramalina belt; (2) the belt of orange lichens; (3) the Lichina vegetation; (4) the *Verrucaria maura* belt; (5) the belt of marine Verrucarias. The composition of each belt is given in detail.—Prof. G. H. **Carpenter**: Injurious insects and other animals observed in Ireland during the year 1912. The very hot, dry summer of 1911 led to an excessive abundance of insects in the spring of 1912, from the depredations of which orchards and fruit-trees suffered heavily. "Greenfly" on apple-trees were especially abundant, and two distinct kinds of Aphis occurred in many parts of Ireland. Referring to the "woolly aphid," or "American blight," attention was directed to a new mode of wintering for the insects—inside the cores of apples, several of which, imported from America and sold in Dublin, were found to be infected in this way. Introduction of the pest into fresh localities might thus be brought about.—W. R. G. **Atkins**: Oxydases and their inhibitors in plant tissues. The distribution of oxydases seems to point to their being concerned in the production of cork and sclerenchyma. The guard cells of stomata and the cells abutting on them are particularly rich in "epidermal" oxydase, while the abutting cells may also contain the bundle oxydase of Keeble and Armstrong. The leaf-saps of *Iris germanica* and *Aspidium Filix-mas* contain powerful reducing substances which inhibit oxydase reactions. Precipitation of the enzymes by alcohol or removal of the reducing substance by dialysis permits of the detection of oxydase. The colours of the perianth of Iris are due to the presence of a yellow plastid pigment or of a purple anthocyan chromogen which arises by the action of the epidermal peroxydase on a chromogen. The reducing substance may inhibit colour production.—Dr. W. E. **Adeney**: The "streaming" of dissolved atmospheric gases in water. Part i. In this communcation there are given the results of an experimental investigation of the rates at which atmospheric nitrogen and oxygen are dissolved by the exposed surfaces of quiescent columns of de-aërated fresh- and sea-water, and the rates at which the dissolved gases are transmitted downwards through the columns under the conditions: (1) when evaporation can freely take place from the exposed surfaces of the columns, and (2) when it cannot, the columns of water being maintained at a uniform temperature. The determinations have been made for temperatures varying between 8° and 20° C. Descriptions of special apparatus for the rapid extraction of the dissolved gases from water, and for their analysis, are also given.

EDINBURGH.

Royal Society, June 2.—Sir William Turner, K.C.B., president, in the chair.—Sir William **Turner**: Contributions to the craniology of the people of the Empire of India. Part iv. The author described and compared a number of skulls from the Bhils, frontier tribes of Burma and Pakkoku, South Shan tribes, and Tibetans.—Dr. J. H. Harvey **Pirie**: Scottish National Antarctic Expedition, glaciation of the South Orkneys. This was a full account of a careful survey made by Dr. Pirie when wintering at the South Orkneys. These glaciers are either of the "ice-foot" or of the "Spitsbergen" type, according to Nordenskjöld's classification. Their movement and erosive powers are very slight, and they are at present much less extensive than at former times.

June 16.—Dr. B. N. Peach, vice-president, in the chair.—Dr. J. G. **Gray**: New models of gyrostats. When large rotational speeds are employed, the fly-wheels must be perfectly balanced. Some of those exhibited could be run up to 30,000 revolutions per minute. The largest size, when spun at 15,000 revolutions per minute, continued to revolve for forty-five minutes. Among the many curious devices shown was the model of a motor-car running on two wheels placed in tandem. The car was stable, both when at rest or when in motion. When in motion the car derived its stability from the propelling system. The gyrostat detected any tendency to tilt over and immediately applied to, and obtained from, the propelling system just the forces required to correct the tendency. This force disappeared precisely when its existence was no longer needed, so that the contrivance was entirely free from gyrostatic oscillations. The model was shown moving slowly about the room under the direction of an electromagnetic driver seated on the car and controlled by a switch on the lecture table. The driver could also be operated by wireless transmission.

July 7.—Dr. J. Horne, vice-president, in the chair.—S. D. **Carothers**: Plane strain in a wedge with application to masonry dams. The equations of equilibrium for plane strain were applied to a sector of an infinite right cylinder bounded by two planes through the axis, when the plane faces were subject to various conditions of pressure, which was either constant or varying as the distance from the axis. The several appropriate solutions were combined with the solution appropriate to the case in which the body forces were considered so as to obtain a solution applicable to the case of a masonry dam. The displacements were worked out for one case.—Prof. J. Stanley **Gardiner**: The corals of the Scottish National Antarctic Expedition. Five species were described, of which one, referred to genus Madracis, was new. It was dredged off the Abrolhos Bank.—Dr. W. M. **Tattersall**: The Schizopoda, Stomatopoda, and non-Antarctic Isopoda of the Scottish National Antarctic Expedition. Of Schizopoda twenty-four species were recorded, including one new species of Boreomysis. The Stomatopoda were represented by one species of Squilla and three larval forms of Lysiosquilla; and of the eighteen species of Isopoda recorded, three were new, two of Exosphæroma, and one of Antarcturus.—Dr. J. H. **Ashworth**: Some pseudo-hermaphrodite examples of *Daphnia pulex*. The specimens were undoubted females, but in each the antennule of one side resembled that of a male, and in one case also one of the valves of the carapace had a configuration similar to that of a male. In all other features, both external and internal, the specimens exhibited female characters. The offspring of two of the specimens were available for examination, and proved to be entirely normal—that is, the structural peculiarities of the antennule were not transmitted.

PARIS.

Academy of Sciences, July 15.—M. F. Guyon in the chair.—J. **Boussinesq**: The theory of Savart's retractile liquid sheets.—Armand **Gautier** and P. **Clausmann**: Fluorine in the animal organism, brain, glands, muscles, blood, milk, excretions. Fluorine exists in all animal organs and tissues, but in very varying proportions. Excluding organs not completely formed in very young animals, and the excretions, there is a relation between the amounts of fluorine and phosphorus present; the two increase together without being proportional. The dental enamel has the highest proportion of fluorine, 180 to 118 milligrams in 100 grams of dry material; muscle has the smallest amount, 0·6 to 0·15 milligram in 100 grams of dry material. In man about 1 milligram of fluorine is excreted per day, and as the fluorine taken with the food is considerably greater than this figure, the difference represents epithelial desquamation, hair and nails, &c.—H. **Block**: The energy of nebulæ and Carnot's principle. A discussion of the theory of Arrhenius and an extension of some recent calculations on this subject by Schwarzschild.—Kr. **Birkeland**: The general magnetism of the sun.—M. **Robinson**: Systems of partial differential equations.—Th. **Anghelutza**: A generalisation of Riemann's summation.—M. **Ariès**: Remarks on a form of the velocity of propagation of sound in a homogeneous fluid.—Thadée **Peczalski**: New forms of the characteristic equations of gases.—Marcel **Boll**: The influence of the wave-length on the velocity of a photochemical reaction. A formula is given, based on experimental results, expressing the velocity of a reaction as a function of the thickness of the layer, concentration, coefficient of absorption, power and frequency of the incident radiation. The wave frequency acts in a manner analogous with temperature in ordinary chemical reactions.—M. **Blanchetière**: Oxidation and luminescence. A large number of substances have been examined for the production of luminescence on oxidation. The phenomenon was marked with lophine, amarine, hydrobenzamide, extracts of meat, urine, tea. The question as to the exact nature of the organic complex the oxidation of which results in luminescence was not solved.—S. **Wologdine**: The heats of formation of some silicates of iron and manganese.—Paul **Braesco**: The baking of clays.—Victor **Henri** and René **Wurmser**: The action of ultra-violet rays on solutions of hydrogen peroxide. The velocity of decomposition of hydrogen peroxide in monochromatic light is proportional to the concentration, to the incident energy, and to the energy absorbed. Einstein's law of photochemical equivalence does not apply to this reaction. The energy which is absorbed by the decomposition of a gram-molecule of hydrogen peroxide is sensibly equal to the energy evolved by the decomposition of the same quantity in the dark.—Daniel **Berthelot** and Henry **Gaudechon**: Addition reactions between carbon monoxide and other gases under the influence of the ultra-violet rays. Carbon monoxide, under the action of ultra-violet light, combines with chlorine, oxygen, water, ammonia, but not with bromine, iodine, sulphur, sulphuretted hydrogen, phosphine, arsine.—Léo **Vignon**: The formation of methane by catalysis, starting with carbon monoxide and water vapour. Details of experiments with iron, nickel, copper, and their oxides, silica, alumina, and magnesia, as catalysers at temperatures ranging from 300° C. to 1250° C.—H. **Gault**: The lactonisation of the α-ketonic esters.—Paul **Lebeau** and Marius **Picon**: The action of sodammonium on the true acetylenic hydrocarbons of the fatty series, and on a mode of formation of ethylenic hydrocarbons. Sodammonium reacts with the acetylenic hydrocarbons of the fatty series, giving the sodium derivative of these hydrocarbons and the corresponding ethylenic hydrocarbon in the proportion of one molecule of the ethylene to two molecules of the sodium derivative. The products of the reaction are very pure, and no secondary reactions were observed.—L. **Bounoure**: The influence of the size of insects on the production of chitin. The mean thickness of the chitin layer is constant, or the quantity of chitin is proportional to the secreting surface.—Edouard **Chatton**: *Orchitosoma parasiticum*, a parasite with three rudimentary leaflets of *Paracalanus parvus*.—E. **Faure-Fremiet**: The action of the ultra-violet rays on the egg of *Ascaris magnalocephala*.—Charles **Nicolle**, A. **Conor**, and E. **Conseil**: Intravenous inoculation of some living typhoid bacilli.—Gabriel **Bertrand** and Robert **Sazerac**: The favourable action exercised by manganese on the acetic fermentation. The power of the organism of transforming alcohol into acetic acid is strongly accelerated by the addition of a certain proportion of manganese; the acceleration increases at first as the amount of manganese increases, then passes a maximum.—R. **Fosse**: The presence of urea in the invertebrates and in their excretion products.—Jules **Ventre**: The influence of the yeasts and the initial constitution of the musts on the acidity of fermented liquids.—André **Mayer** and Georges **Schaeffer**: Researches on the lipocytic constancy. The proportion of lipoids containing phosphorus in the tissues.—M. **Repelin**: The geology of Sainte-Baume.

CALCUTTA.

Asiatic Society of Bengal, July 2. F. F. **Laidlaw**: Note on the dragonflies of Syria and the Jordan Valley. The dragonflies of Syria and the Jordan Valley are still imperfectly known, but at least two geographical elements may be distinguished among them a Mediterranean element, and a tropical one, African in its main features, but also showing certain affinities with the Oriental fauna.—Dr. N. **Annandale** and S. W. **Kemp**: The Crustacea Decapoda of the Lake of Tiberias. Three species of Decapoda are known from the Lake of Tiberias and its immediate vicinity, viz. the crab *Potamon potamios*, and the prawns *Atyaëphyra desmarestii* and *Typhlocaris galilea*. The last occurs only in one small isolated pool, and is remarkable on account of its degenerate eyes and uniform white coloration, as well as for certain structural characters which separate it from all other Caridea.

PROF. PERRY'S PRACTICAL MATHEMATICS.

Elementary Practical Mathematics. With Numerous Exercises for the Use of Students, and especially of Mechanical and Electrical Engineering Students. By Prof. John Perry, F.R.S. Pp. xiv + 335. (London: Macmillan and Co., Ltd., 1913.) Price 6*s.*

DURING the past ten or fifteen years a great deal of work has been done by mathematical teachers in wiping old scores off the slate and redeveloping their teaching on more sensible and rational lines. It is well known that this revolution owes its success largely to the indefatigable exertions of Prof. John Perry. We cordially agree with many of the remarks contained in the preface to the present book. It is impossible to quote the whole of the author's attacks on the old-fashioned drudgery in algebra which has disgusted many would-be mathematicians in the past, and made it quite impossible for the present reviewer ever to appreciate anything but applied mathematics. We can only quote the first few lines:—

"Academic methods of teaching mathematics succeed with about five per cent. of all students, the small minority who are fond of abstract reasoning; they fail altogether with the average student. Mathematical study may be made of great value to the average man if only it is made interesting to him."

Now one difficulty that most teachers have experienced in developing mathematics on more rational lines has certainly been the difficulty of constructing suitable exercises, examples, and examination questions. It is not that it is intrinsically more difficult to construct practical questions than it was to devise the old "pretty" question to the effect that "if tweedledum" (meaning one jumbled mass of symbols) "shew" (never show) "that tweedledee" (an equally meaningless formula). Still, to stock a book with practical intelligent questions is so difficult a task that the author's statement, "In many cases each of the questions has taken several hours, and in some cases several days, to construct," will be well understood by everyone who has worked or tried to work on similar lines.

If Prof. Perry had only published his collection of questions under the title "Exercises in Practical Mathematics," we should have given the book our unqualified praise. Unfortunately, however, when he comes to deal with *bookwork*, we fail to find much difference between his "practical" mathematics and the old-fashioned "academic" mathematics, except that his methods are less logical, less interesting, and less convincing than those now adopted by our best teachers.

In fact, most of the bad features of our existing methods of teaching, which the author so violently attacks in his preface, will be found reproduced in his own text. The book, to some extent, resembles a recent volume which might be called "The Fool's Calculus," and which justified this title from the way the author had made an easy subject appear difficult. Let us now examine a few points in detail.

Prof. Perry is quite correct in saying that "when calculating from observed quantities it is *dishonest* to use more figures than we are sure of," although, perhaps, this mistake might be rather described as "unmathematical inaccuracy," than as dishonesty. But the only remedy he can suggest in the case of contracted multiplication is to multiply by 8651 when he wants to multiply by 1568. Very few teachers adopt this absurd and unnecessary method. A boy who has any common sense ought to learn not only to multiply numbers the right way round, but to be able to fix the position of the decimal point in any line of the products.

His definition of a logarithm is as follows:—

"If $a^n = N$ then $n = \log_a N$ and we read this as 'n is the logarithm of N to the base a.'"

Now the average schoolboy ought to learn to multiply and divide by means of a table of logarithms long before he knows what is the meaning of a^n. Besides, the definition is not a logical one unless n is a positive integer, because the very existence of quantities with fractional indices depends for its proof on the existence of a system of logarithms. By making up successive integral powers of 1·01 or 1·0001 or 1·0000001, we can prove the existence of logarithmic scales capable of performing numerical calculations to any required degree of accuracy, and these lead to the conception of the natural scale. Prof. Perry then says that "in many important calculations we need to use Napierian logarithms, whose base is 2·71828." "Why 2·71828?" asks the intelligent student. No answer is given; and this is what Prof. Perry calls "practical mathematics." We should call it cram. But the author continues to drag in this apparently useless and meaningless symbol e throughout the book, and when it occurs in such examples as the following (p. 30):—

"If $\log_e \frac{853}{493} + 0{\cdot}9 \times \frac{836}{853} = \log_e \frac{677}{493} + \frac{961}{677}x$, find the value of x to three significant figures"

Z

—we fail to see the superiority of Prof. Perry's questions over the worst examples of the old Cambridge school.

A very few lines of explanation, based on the definition as a limit, would make the student take an intelligent interest in e. But having started on the wrong tack, Prof. Perry, on p. 150, fails to find a satisfactory proof of the differentiation formulæ involving e without assuming the exponential series, and by the time he uses the formulæ, on p. 189, it is too late to exhibit the significance of this important limit. An intelligent boy ought to be able to understand the compound interest law and the ordinary differentiation formulæ long before he learns how to differentiate the infinite series employed in Prof. Perry's proof. Take next the formula for the belt slipping on the pulley (p. 37). The formula $N/M = e^{\mu\theta}$ conveys no meaning to the student of average intelligence, and it is not the method that anyone with common sense would employ in experimental work. What he would do would be to use the formula $N/M = c^n$, where c is a constant and n the number of turns, c being found by experiment.

The same mistake is made with the radian. Prof. Perry (p. 62) expects his students to be as ready to *think* in *radians* as in degrees, but he conspicuously fails to impress his readers sufficiently with the *utility of the radian* in connection with the relation between angular and linear velocity and differentiation formulæ.

The chapter on algebra is a good feature, if for no other reason than the fact that existing text-books on algebra are still so unsatisfactory. The proper method of introducing algebra is in connection with the *use of formulae*, and the converse use of formulæ naturally leads to the problem of *solving an equation*. In the conventional treatment the utility of the subject is completely ignored, and the study is presented in the form of hateful drudgery. But here, again, Prof. Perry lays stress on such problems as, "Divide a number into two parts," or "A father is 3·5 times as old as his son," of which we have had too many already.

In the chapters on mensuration, squared paper, and important curves, Prof. Perry is working on what is now well-known ground; at the same time his treatment is in many respects unsatisfactory, particularly in connection with curves. Thus we all know the importance of the cycloid in geometry, mechanics, and physics. But all that Prof. Perry does is to make the student plot this curve on squared paper by means of the equations $x = a(\phi - \sin\phi)$ and $y = a(1 - \cos\phi)$. When this is done the student knows nothing whatever about what a cycloid really is. An intelligent boy should learn to plot curves not only from their equations, but from their geometrical definitions; and, further, he should be trained to plot envelopes as well as loci. The mere drawing of graphs may easily degenerate into unintelligent drudgery quite as objectionable as any of the old algebraical drill of our schooldays. What is the use of asking boys such questions as the following?

"Find a value of x to satisfy

$$5{\cdot}3\, e^{0{\cdot}104x} \sin^2 0{\cdot}8x + 0{\cdot}78x^{1{\cdot}52} \cos x - 2{\cdot}126 = 0.$$

"The student must remember that $0{\cdot}8x$ is in radians, and must be multiplied by 57·296 to convert it into degrees. Ans. $x = 0{\cdot}74$."

In the sections on the calculus there is not very much fault to find with the practical illustrations, and, indeed, most of them are based on fairly reasonable views. But when the author comes to establishing differentiation formulæ he falls into the error of defining a differential coefficient as the limit of

$$\frac{f(x+\delta x) - f(x)}{\delta x},$$

instead of regarding it as the limit of

$$\frac{f(x_2) - f(x_1)}{x_2 - x_1},$$

when x_2 and x_1 both approach a common limit x, which may or may not be taken to be equal to either x_2 or x_1. Consequently he introduces higher powers of δx, which he afterwards has to neglect, and which ought never to have come in. The alternative definition here suggested leads at once to Lagrange's remainder theorem in the form,

$$f(x_2) = f(x_1) + (x_2 - x_1)f'(x),$$

where x has some value between x_1 and x_2.

The result is that in differentiating x^n Prof. Perry assumes the binomial theorem plus certain other assumptions not stated, whereas any pupil ought to differentiate x^n long before he has heard of the binomial theorem. In speaking of limits Prof. Perry says:—

"The plain man of common sense finds no difficulty in catching the idea. Two thousand years ago neither he nor a small boy would have had a difficulty in understanding that a hare would beat a tortoise in a race; it is the mathematical philosopher who makes a difficulty about such matters, and in these days he says that this fundamental idea of the calculus can only be comprehended by a mathematician. This would not matter if these philosophers were not entrusted with the education of youth, a trust for which all their training has unfitted them. When they come to explain the essential idea of the limiting value of $\delta s/\delta t$, they talk foolishly."

Readers of "Elementary Practical Mathematics" will have no hesitation whatever in endorsing this statement!

While a great many notions are introduced into the text in such a way as to make them appear useless, uninteresting, and unintelligible, many of the most important points in a rational system of mathematical education receive little or no attention. Take the broad, general notion of a function, so simple that it can be explained to anyone who is sufficiently unmathematical to understand common sense. It is well illustrated in the case of the senior wrangler who entered the Stock Exchange and began to apply algebraic methods to the money market. He failed because he had omitted to take account of political considerations. Here was a case where the result was a function of a number of variables, and he treated some of these variables as constant. The senior wrangler was not sufficient of a mathematician. The mere failure to enumerate all the variables in a function occurring in everyday life represents a national loss of millions per annum. Prof. Perry says:—

"I must confess, however, that the compilers of modern school algebras must make the gods laugh over the uses to which they put this plotting of functions."

They certainly will do so when they read this book.

All this is a very great pity. Most modern matnematical teachers are only too glad to get "formula" questions for their pupils dealing with beams, expansion of steam, flow of water through pipes, electrical resistances, and other practical considerations which familiarise the student in the use of algebraic formulæ and equations. We believe they *can* get the questions they want from this book, and, on the other hand, when it comes to methods of teaching, every teacher naturally prefers his own. But if the substance of the text is a fair indication of what is meant by "practical mathematics," we agree with Prof. Perry's remark (p. xiii.), which, when quoted without its context, reads to the effect that

"The subject of practical mathematics is, I am happy to say, a subject which is not likely to commend itself to such institutions, nor are such text-books likely to be of much use to real students."

Evidently neither "academic" nor "practical" mathematics supplies exactly what is wanted. They both have one fault in common, namely, that they place difficulties before the student without any rhyme or reason. Mathematics is not in itself difficult or uninteresting; a child of three can invent a theory and notation for minus quantities without any assistance, help, or encouragement whatever. What we want is a subject that might be better described as "common-sense mathematics." Teachers are striving after this ideal, and it is very valuable and important to see clearly, as this book shows, that for the attainment of this ideal something more than "practical" mathematics is necessary.

G. H. BRYAN.

AN EGYPTIAN DESERT.

The Geography and Geology of South-eastern Egypt. By Dr. John Ball. (Survey Department of Egypt, Cairo.) Pp. 394. With Maps and many Illustrations.

THE area described in this latest monograph issued by the Geological Survey of Egypt is the southern part of the Eastern Desert—a district little known, and inhabited only by nomad Arabs of the Ababda and Bisharin tribes.

From north to south, this country is intersected by a mountainous axis which rises to heights of from 3000 to more than 5000 feet, and consists mainly of granite, diorite, gabbro, and other plutonic rocks. Eastward from this axis a series of Wadys run down, somewhat steeply, to the shores of the Red Sea on the east, these shores being almost everywhere bordered by coral reefs, which render the coast one of the foulest in the world for shipping. Westward from the mountain axis another series of Wadys lead down more gradually to the basin of the Nile. Dr. Ball, who is an accomplished surveyor as well as a geologist, has been able to add much to our knowledge of the physiography and scenery of this almost unexplored country. While devoting his chief attention to the geological features of the district—his discussion of the petrology being especially full and well illustrated—the author has been able to supply much new and interesting information concerning the antiquities, the plant and animal life, and the inhabitants—their languages, industries, and customs.

From a very early period the district has been credited with the possession of considerable mineral wealth, especially famous having been its gold-mines and emerald workings. Dr. Ball's researches, however, do not give much support to the belief that the district may in the future become a great mining centre.

It is true that very numerous small workings scattered all over the country show how wide and persistent has been the search for gold within the area. There do not appear to have been any alluvial workings, but numerous quartz veins, intersecting all the crystalline rocks of the district, sometimes containing calcite with ores of copper and iron, yield minute quantities of gold, the particles of which are seldom visible. In small handmills of diorite this quartz appears to have been ground up and the gold extracted from it, but this appears to have been only profitable when done by convict labour. Prospectors in modern times, guided by the presence of these old workings, have attempted to carry on the extraction of the gold on a larger scale by modern methods, but only in a few cases has it been found that this can be done with profit, and most of the concessions have been surrendered.

The once-famous emerald-workings of Zabara and Sikait in this district are opened in masses of mica-schist, which alternate with gneiss, and contain crystals of tourmaline and beryl—the clear green varieties of this latter mineral constituting the valuable gem emerald. It would appear, however, that the ancients were satisfied with specimens which, owing to their clouded or flawed characters, do not appeal to the jewellers of the present day, and, extensive as the old workings undoubtedly were, there appears to be little chance of the industry being revived.

At several points on the Red-Sea coast, deposits of gypsum and anhydrite, with pockets of sulphur, occur, and concessions for the working of the latter mineral have been granted.

One successful mining industry, however, would appear to be in full operation in the little island of Tuberged, or St. John's, lying out in the Red Sea, forty or fifty miles from the coast. Here, in the midst of serpentine rocks, numerous beautiful crystals of peridot (oliome) are obtained, and the work of exploitation is being successfully carried on.

But although the expectations that this desert region might become a centre of a great mining industry do not seem likely of fulfilment, the district is not devoid of interest to the man of science. The rocks of the country exhibit, as shown by Dr. Ball, a very great variety and not a few remarkable characters, and the book before us, with its abundant photographic and other illustrations, is well worthy of the attention which it cannot fail to attract. J. W. J.

THE PROBLEM OF A PURE MILK SUPPLY.

The Milk Question. By Prof. M. J. Rosenau. Pp. xiv+309. (London: Constable and Co.; Boston and New York: Houghton Mifflin Co., 1913.) Price 7*s.* 6*d.* net.

THE milk question is very much to the fore at the present time, and the appearance of this work is therefore opportune, and, although it embodies American views and practice, a great deal of it is applicable to our conditions. The author is well known as the present professor of hygiene at Harvard, and former director of the Hygienic Laboratory, Public Health and Marine Service, U.S.A., who has contributed much to the scientific investigation of milk and its bacteriology. From the sanitary point of view the book is sound, but, in addition, its author shows a knowledge of the subject from the producer's point of view, a side of the question which is frequently overlooked by sanitary reformers in this country. Written in simple language, it is a book for the educated public generally, and many striking cartoons and diagrams and terse sayings serve to drive home the views enunciated, *e.g.*—

"It (milk) requires scrupulous care from pasture to pail, and from pail to palate."

"The milk problem starts with the cradle, and ends with the grave. Sometimes it leads to an untimely grave."

One or two considerations may be quoted as illustrating the author's appreciation of the producer's point of view. As regards the question as to where the blame lies for an unhygienic milk supply, the author says the tendency is for the consumer to blame the producer, for the producer to blame the consumer, for the middleman to blame both of these, and for the health officer to blame all three. Really, society must blame itself; we are suffering the inevitable penalties we must pay for modern conditions of life, and of all those concerned the farmer is least to blame for the situation as it exists, and the consumer in the city should be ever mindful that he has largely brought the conditions upon himself.

While expressing the opinion that bottled milk is the ideal method of distribution, Prof. Rosenau fully recognises its dangers and difficulties—difficulties in the cleansing and handling of the bottles and in transportation, which, he points out, is expensive, bulky, the breakage is considerable, and the return freight adds to the cost. He looks forward to the time when milk will be dispensed in some form of cardboard non-returnable package.

On the mixing of milk from several cows, this the author says is desirable, as it furnishes a more uniform product, and tends to dilute infection if present; this the framers of Bills in this country might note.

On the cells present in milk, it is stated that normal milk has relatively few or no leucocytes, and, when critically examined, the majority of cells distinctly differs from leucocytes.

The author would ascribe from 5 to 7 per cent. of all human tuberculosis to infection with the bovine bacillus, but he is careful *not* to suggest that this is necessarily derived from milk, and quotes Weber's observations (made for the

German Imperial Board of Health), which seem to show that the risk of infection from tuberculous milk is surprisingly small.

Clean milk, and methods of producing and controlling it, are dealt with at some length, and some interesting details are given respecting certified milk.

A long chapter is devoted to pasteurisation of milk, and this process is strongly advocated, under proper safeguards, such as labelling with the time, temperature, and date of pasteurising, as a general method for treating the milk supply if a pure milk cannot otherwise be guaranteed.

Singularly little is said respecting infants' milk depôts. In view of the comparison made by some between the United States and this country in this respect, we should have expected more information had this method of dealing with infant mortality the importance which some would ascribe to it. Altogether the book is a valuable one, and one to read, ponder, and digest.

R. T. HEWLETT.

OUR BOOKSHELF.

Theoretische Astronomie. By Dr. W. Klinkerfues. Neubearbeitung von Dr. H. Buchholz. Dritte verbesserte und vermehrte Ausgabe. Pp. xxxviii + 1070. (Braunschweig: F. Vieweg und Sohn, 1912.) Price 50 marks.

THE claims of Klinkerfues and Buchholz are readily admitted by all acquainted with the calculation of orbits. The classical treatises of Oppolzer and Watson having run out of print, it was most fortunate that this, the practical, side of gravitational astronomy was taken up by Buchholz, who extended the original work of Klinkerfues to make it fit to take the place of the former works. The plan of dividing the subject-matter into lectures (*Vorlesungen*) is still continued, although much is unsuitable for verbal exposition. Lecture 14, for example, extends to ninety pages, and gives, besides the general theory of the earth's rotation, all the formulæ necessary for the reduction of observations.

The greater part of this edition agrees exactly with the last, but the additions are well worthy of attention. The new preface runs to twenty pages, and gives a historical treatment of recent advances in the theory of orbits. Although Gyldén's work in no way enters into the subject treated in the work, Buchholz has described at some length the claims of the great Swedish astronomer. We believe that posterity will give to Gyldén the place which is due to one who did much for the cause of dynamical astronomy as applied to real, in contrast with merely ideal, problems. The criticisms of Bauschinger and others have led to Harzer's method not being developed, but the vector method of Willard Gibbs is retained. We are glad to see that Leuschner's method has been introduced. The method is carefully explained, the formulæ are collected, and a considerable number of examples are worked out. The necessary new table is given, and Oppolzer's M- and N-tables have been reproduced.

An appendix gives the known errors in the works of Bauschinger and Oppolzer on the determination of orbits.

The greatest fault of the book is its bulk. For a work intended to assist in the numerical calculation of orbits it is almost essential that the auxiliary tables should be easily manipulated. This work could with advantage be divided into several volumes.

J. JACKSON.

New Contour Map of the Near and Middle East (The Land of the Five Seas). (London: G. W. Bacon and Co., Ltd.) Price 7*s.* 6*d.*

THIS wall-map includes the empires of Babylon, Persia, Parthia, Egypt, and Rome. It shows the routes of Alexander the Great, Pompey, and St. Paul, and illustrates classical history from the earliest times. The scheme of ten colours makes it possible to show with impressive clearness the close relation between land configuration and the spread of civilisation. The scale of the map is ninety-five miles to an inch. In the bottom left corner an inset orographical map of Palestine is provided. The size of the map as a whole—40 by 30 in.—will indicate that it is scarcely large enough for use in big classes, but it should prove of service to individual students in the higher forms of secondary schools.

The Tarn and the Lake. Thoughts on Life in the Italian Renaissance. By C. J. Holmes. Pp. xi + 48. (London: Philip Lee Warner, 1913.) Price 2*s.* 6*d.* net.

THIS essay of Mr. Holmes forms very pleasant reading; originally designed as an introduction to a few studies of Italian painting and sculpture, it overran its intended bounds and became eventually the present little volume. Entertaining analogies are drawn between certain communities of fish and certain societies of men, and though the appeal is more directly to anglers, all readers who appreciate literary expression will enjoy the essay.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Pianoforte Touch.

THE question as to whether what is known as touch is due to any peculiarity, apart from the energy, with which the hammer strikes the strings, and, consequently, with which the fingers strike the keys, would appear to be determinable by direct experiment. Personally I have always held, probably with the majority of people, that touch is dependent on such peculiarities, but the evidence seems to be decidedly against it. A note was struck one hundred times in succession so as to produce sound of as nearly as possible the same intensity; on half these occasions it was struck in a pressing, or caressing, manner; in the other cases it was struck sharply; the different kinds of blows were intermingled irregularly, and according to a list previously drawn up, and the damper was held up while the note was being struck. As each note was struck a verdict as to its quality was given by a person sitting out of view of the piano, and this verdict was compared with the character of the blow given. The observer, it should be mentioned, was not a trained musician, but was exceptionally appreciative of what is called touch.

Discarding all cases where the note had accidentally been more or less loud than the average, it was found that in 49 per cent. of the cases of uniform loudness the effect on the auditor coincided with the character of the blow given, in 51 per cent. the reverse. In another series of 100 notes the values were 51 and 49 respectively. It is evident, therefore, according to this, that different quality of touch produces no difference in the quality of the sound produced. No doubt further evidence should be obtained by a repetition of such experiments with other performers and other observers, and a further test would be obtained by having two performers alternately striking the same note, and ascertaining whether the observer could detect the difference.

Even if the independence of "touch" on the character of the stroke is fully established, there is no difficulty in explaining the apparent difference in touch of a performance with the fingers and one with a piano-player. At least seven factors may be specified as determining touch:—(1) Differences in loudness of a note (or notes) as compared with that of the preceding notes, (2) deviation from the theoretical value, according to the score, of the duration of the note as compared with that adopted for the preceding and succeeding notes (*i.e.* different degrees of *staccato* or *legato*); (3) variations in time as compared with that of the preceding notes; (4, 5, and 6) similar differences in loudness, duration, and time of one note in reference to its nominally contemporary notes; (7) the use of the loud pedal. The use of the soft pedal is so specialised that it need not be considered; it is used more for modifying a whole passage than for modifying individual notes, and it practically gives the performer the command of a second instrument; but, perhaps, an eighth factor of a general character should be included, namely the extent to which the above means of emphasising notes is made to harmonise with the rhythm and sense of the music.

Now, in the piano-player we have the means, either by moving levers or by pressure on the bellows, of altering the loudness (1) or time (3) of a note as compared with that of preceding notes, but such alterations are gross and sluggish in comparison with those possible in finger playing; the inertia of the mechanism has to be overcome, and the result depends directly or indirectly on the pressure of air in the bellows, which cannot be altered instantaneously. The least unsatisfactory operation is a retardation of the time. The duration of the note as compared with that of its neighbours (2), or of its fellow-notes (5), as well as the loudness of it as compared with its fellow-notes (4), can only be accomplished by modifications in the slots of the roll, and they are, therefore, stereotyped and always the same; this produces a very unsatisfactory result.

When hearing for the first time a well-played piece with the air strongly brought out in this way, the impression produced is decidedly favourable, but at the second hearing a sense of irritation is felt; we know exactly the degree of emphasis which is going to be placed on each note of the air, and the monotony is even more trying than where no emphasis is attempted. It is a case similar to that of a beautiful landscape which never changes; the charm of music lies largely in its imperfections, or, at least, in the varying and unexpected degree in which its beauties are brought out. An alteration in the time of contemporaneous notes (6) is, I believe, attempted on some rolls, but the effect, I should imagine, would be even less satisfactory than in the other cases. The use of the loud pedal is a potent defect in the piano-player. Needless to say, this pedal is not used in good finger playing only to produce loudness, but more generally to produce softness, and a smooth flow of sound. In a slow movement a good performer will often depress and raise the pedal for nearly every note, and the effect produced depends entirely on the correct timing of these movements with the depression of the keys; this is impossible unless the messages from the brain to the fingers and to the feet are simultaneous. This cannot be so with a piano-player, where the sound is produced by a separate mechanism; this sound (either of the particular note in question or of its predecessor) must travel to the brain, which then has to interpret it, and to send a message to the finger which controls the pedal lever; the performer is conscious of an act of thought being necessary in using the pedal of a player, whereas in finger playing its use appears as if it were instinctive. With the player it is practically only used for producing loudness.

I believe that the thud of the air on the keys is another defect in the player. When in the same room as the instrument, it seems possible to decide after hearing one bar whether the player or fingers are being used, and this is certainly so, as I have ascertained by trial, and apparently more easily so, when one is in a distant room, the reason of this being that the thud penetrates the walls more easily than the note, and hence attains more relative predominance. I have an instance of this in a striking clock, of which the note is inaudible in the next room, while the thud can be distinctly heard.

No doubt many of the defects of the piano-player will be diminished in time, especially by such devices as those of Prof. Bryan. Already one of the best piano-makers is putting on the market an instrument which is a great advance on its predecessors, the chief feature of it being a reduction in the size of the bellows, which admits of much greater control over the sound production. Still, it is a case of playing with the feet, instead of with ten independent fingers.

When the damper is allowed to act in the ordinary way, it is possible that the effect produced (touch) may be modified by the character of the blow given to the keys, for this blow results in the damper being raised, as well as in the hammer striking the strings, and these two actions may not synchronise to the same extent with blows of different character.

SPENCER PICKERING.

A Danger of so-called "Automatic Stability."

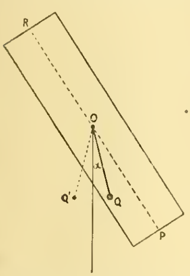
FROM time to time devices have been proposed for securing "automatic stability" in aëroplanes by means of a suspended weight or "pendulum," which operates on rudder-planes governing the motion of the machine. A similar device is also in actual use for governing the motion of torpedoes in a vertical plane, in conjunction with a further device for maintaining the torpedoes at a constant depth below the surface, or more strictly at a level where the hydrostatic pressure is constant. "Pendulum" arrangements for automatic stability of aëroplanes have frequently figured in the pages of such journals as *The Scientific American*, and it must be admitted that such devices are calculated to appeal strongly to the imagination of readers whose knowledge of dynamical principles is limited in range or *nil*.

The statement, which stands in my name, to the effect that such a device increases the number of degrees of freedom of the apparatus with an accompanying increase in the number of possible oscillations and of conditions necessary for stability is, I believe, incontrovertible. One form of dynamical instability that may result in such cases is the setting up of violent oscillations, ever increasing in amplitude, in the pendulum itself, accompanied by flapping of the control planes, in which case this particular method of control becomes worse than useless.

The remedy which naturally suggests itself, in such circumstances, is to damp down the oscillations of the pendulum by means of frictional or other resistances, and it is probable that few university graduates who have taken first-class honours in mathematics would think that such a contrivance could possibly be wrong. The following test case will show how very dangerous it is to attempt to draw conclusions from general considerations.

For the aëroplane or torpedo, we substitute a heavy, rigid body POR, free to rotate without resistance about a horizontal axis through its centre of gravity O, perpendicular to the plane of the paper, and therefore, in the absence of other causes, in neutral equilibrium, and we assume that the moment of inertia of this body is considerable.

We next imagine a light, small pendulum OQ to be fixed in bearings in the body POR, so that it can turn about the same axis, but we suppose that a frictional couple is called into play between the large body and the pendulum at these bearings. The pendulum being light, this frictional couple exerts no appreciable effect on the large body POR, but the friction is sufficient rapidly to damp out the oscillations of the pendulum itself. The effect of a rudder plane controlled by the pendulum we represent by the assumption that the pendulum operates some mechanism which impresses on the large body a couple proportional to the angle QOP, tending to make it revolve towards OQ, the object of this couple being to bring that body into a position of rest in which OP is pointing vertically downwards.



When the large body is rotating in the counterclockwise direction (as in the figure) the small pendulum assumes a position of equilibrium OQ on the right-hand side of the vertical, and inclined to the vertical at a certain angle α, the moment of its weight then just balancing the frictional couple. When the body begins to swing backwards the pendulum swings with it until both have described an angle 2α, so that the pendulum occupies the position OQ′, now making an angle α on the opposite side of the vertical. During this portion of the motion the controlling mechanism impresses on the body a constant angular acceleration, because the angle QOP remains constant. Consequently in the new position the body is rotating with a certain angular velocity set up by this acceleration. In the subsequent motion the pendulum remains at rest in the position OQ′, and the body performs a simple harmonic rotation about OQ′, but owing to its initial angular velocity it does not come to rest until its angular distance from OQ′ is greater than the angle QOP. It follows by this reasoning that the oscillations increase in amplitude, and this effect owes its existence to the frictional couple.

G. H. BRYAN.

The Structure of the Diamond.

WE have applied the new methods of investigation involving the use of X-rays to the case of the diamond, and have arrived at a result which seems of considerable interest. The structure is extremely simple. Every carbon atom has four neighbours at equal distances from it, and in directions symmetrically related to each other. The directions are perpendicular to the four cleavage or (111) planes of the diamond; parallel, therefore, to the four lines which join the centre of a given regular tetrahedron to the four corners. The elements of the whole structure are four directions and one length, the latter being, in fact, $1{\cdot}52 \times 10^{-8}$ cm. There is no acute angle in the figure. These facts supply enough information for the construction of a model which is easier to understand than a written description.

If we proceed from any atom, using only standard directions, to the next but one, the straight line joining the first to the last is a diagonal of a face of the cubical element of structure; if we move in the same way through four stages, using all four standard directions in turn, the straight line joining the first and the last is a cube edge. Starting from any atom we can return to it after six stages, using three standard directions twice each. In this way we always link together rings of six carbon atoms.

If the structure is looked at along a cleavage plane it is seen that the atoms are arranged in parallel planes containing equal numbers of atoms, but separated by distances which alternate and are in the ratio 3 : 1 (actually $1{\cdot}52 \times 10^{-8}$ cm. and $0{\cdot}51 \times 10^{-8}$ cm.). It is a consequence of this arrangement that no second order spectrum is reflected by the (111) planes, although spectra of the first, third, fourth, and fifth orders are found. It was this fact that suggested the structure described above. Several other tests, however, may be applied, and all are satisfied.

Zincblende appears to have the same structure, but the (111) planes contain alternately only zinc and only sulphur atoms. In this way the crystal acquires polarity and becomes hemihedral.

Artificial Hiss.

REPLYING to the inquiry of Lord Rayleigh (in NATURE of May 29, vol. xci., p. 319) as to the way in which an artificial hiss may be produced with a moderate pressure of air, I suggest that a current of air directed against a sharp edge of a knife held somewhat obliquely may answer his purpose.

In this connection it is interesting to note that for the formation of the hissing sound in our mouth the presence of saliva seems necessary. If I dry the tongue and the other parts which are needed for the pronunciation of the hissing "s," it is almost impossible to produce an audible "s," and the tongue—instinctively, as it were—makes an effort to gather some saliva and to wet itself.

I would therefore suggest that Lord Rayleigh wet the end of the rubber tube with which he experimented.

FRED J. HILLIG.

Kioicho 7, Kojimachi, Tokyo, July 1.

IT had occurred to me also that the moisture of the mouth might play a part in the production of a hiss, but I do not find that such drying as I can give makes an important difference.

I have to thank several correspondents for suggestions. In particular, Mr. G. Beilby sent me two pipes suitable for a 4 in. water pressure, which gave a better effect than anything I had then tried, but still, in my estimation, much short of a well-developed hiss. I doubt much whether any pure tone gives the full impression of an "s," having often experimented with bird-calls of about the right pitch. Perhaps a rapid *change* of pitch is essential. RAYLEIGH.

Prof. Armstrong and Atomic Constitution.

In the April number of the quarterly journal called *Science Progress* appears an article signed H. E. A., in which that distinguished chemist at length accepts, though not without hesitation and sustained scepticism, some of the results deduced by physicists from the phenomena of radio-activity; but he takes the opportunity of restating and reinforcing his opinion that the inert gases—helium, for instance—are not really monatomic—an opinion expressed by Prof. Armstrong soon after the discovery of argon.

To maintain this rather strained position in face of experimental facts, a considerable amount of what seems to me gratuitous hypothesis is required; and since it is desirable to come to a better understanding of this matter, I propose to criticise his attitude, in a friendly way, in the October number of the same journal. OLIVER LODGE.

Distribution of Amphidinium.

BIOLOGICAL readers of NATURE will perhaps recollect the record of the finding of the dinoflagellate, *Amphidinium operculatum* (previously unknown in Britain), on the beach at Port Erin a couple of years ago. Since then it has been present in great abundance at Port Erin on many occasions; Mr. R. D. Laurie has found it at Hoylake, near Liverpool, two of our young Liverpool zoologists (R. J. Daniel and J. E. Hamilton) now at the Belmullet Whaling Station, co. Mayo, inform me that they have noticed it on the shores of Blacksod Bay, and now I have to-day found it here in abundance, staining slightly in patches and streaks the beautiful white shell-sands of Iona.

Both the forms found at Port Erin—viz. the shorter discoid (the typical *A. operculatum*) and the larger more ovate form which I have described from Port Erin—occur here, associated with a few Naviculoid diatoms.

It seems probable that this curious dinoflagellate, known in the living state so far as I can ascertain to very few biologists, and previously recorded from only three or four far-distant localities, is really very generally distributed, and might be found by careful searching on many sandy beaches.

W. A. HERDMAN.

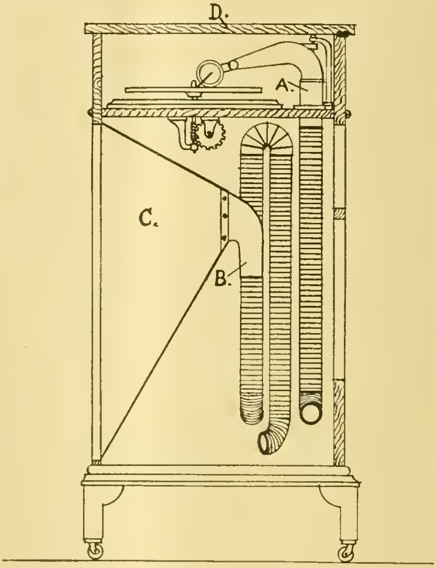
Gramophone Improvements.

I HAVE greatly improved my gramophone, at any rate for use in rooms of moderate dimensions, by applying to it both the long tube arrangement for eliminating scraping noises—described by Mr. Ernest De la Rue in NATURE of November 14, 1912—and also the "donkey's ear" form of trumpet, devised by Mr. Sidney G. Brown, which I have the latter's permission to describe.

The accompanying illustration shows an elevational section through the instrument as altered. From the sound-box, the sound passes through the usual movable arm and the socket A into one end of about 14 ft. of 2 in. flexible steel pipe, arranged in six vertical lengths, of which four are shown in the illustration; the other end of the pipe, B, being connected to the trumpet C. As in the case of Mr. De la Rue's machine, the bends in the pipe are made of zinc, and it seems that it is chiefly these bends that almost entirely eliminate the scraping noise due to the friction of the needle on the record.

The "donkey's ear" trumpet devised by Mr. Brown is shown in section at C. It is made of four flat pieces of three-ply Birch fretwork wood of about $\frac{1}{8}$ in. total thickness. It has an oblong mouth, and its special feature is that, like the ears of donkeys and many other animals, it is shaped with a top and bottom of unequal lengths so as to resonate comparatively equally to sounds of widely different pitch.

It has been found desirable to put a felt seating for the lid D to rest on, as though previous to the alteration the amount of scraping noise that came



out through the trumpet was so considerable that it made very little difference whether the lid was closed or open; with the new arrangement this scraping is eliminated to so great an extent that until the felt was inserted quite an appreciable amount of noise was found to come out round the lid.

Though the instrument is not so loud as previously, the reproduction of sounds of all descriptions seems now much more accurate than before, while the objectionable scraping noise has been virtually done away with. A. A. CAMPBELL SWINTON.

66 Victoria Street, London, S.W., July 24.

The Maximum Density of Water.

I FEAR Mr. W. B. Croft will get few to agree with him in supposing that it would make little difference in the conditions existing on the earth whether water was at its maximum density at 0° or at 4° above it (NATURE, July 17). If water was densest at 0° there would be little surface ice, as water does not change to ice at 0° unless in the presence of ice crystals or other solids. The ice-cold water would therefore, after sinking, freeze when it came in contact with the solid bottom, and we would have much anchor ice and but little on the surface. The small margin of only 4° does not seem to be quite enough entirely to prevent anchor ice; still we have reason to be thankful for these few degrees.

JOHN AITKEN.

THE UNPUBLISHED PAPERS OF J. J. LISTER.

A LARGE parcel of miscellaneous papers by J. J. Lister, and some pieces of apparatus, were left to the Royal Microscopical Society by the late Lord Lister. The papers were eventually submitted to me for examination, and this resulted in the discovery of the important paper on the limit of defining power in vision with the unassisted eye, the telescope, and the microscope now published in the society's journal.[1]

The underlying remarkable experiments were made, and a first—still existing—MS. prepared in 1831–2, shortly after Lister had published his famous paper on the improvement of the achromatic compound microscope (Phil. Trans., 1830, pp. 187–200). The manuscript was entirely rewritten, practically as now published, in 1842–3, and again revised in 1853; but although the author lived until 1863, he never published this excellent piece of work, which is interesting and instructive even now, fully eighty years after the doing of it and just fifty years after the author's death.

The original paper is now so easily accessible, and is so well worth reading, that instead of giving a detailed account of the contents I propose discussing more particularly those of Lister's results which are either of real interest even at the present time, or open to criticism as to their validity.

The most striking feature of the work—and undoubtedly so intended by the author—is its absolute homogeneity; for precisely the same objects were used in experimentally determining the limit of resolving power of the naked eye with full aperture and through circular apertures down to 0·00059 in. diameter, of telescopes of various apertures up to 4 in., and of a large number of good microscope objectives covering a wide range of angular apertures.

The objects, which are still in existence, being included among those now in the keeping of the Royal Microscopical Society, were very accurately made coarse gratings, produced by sticking paper on glass plates, cutting parallel lines through it, and removing strips at equal intervals. There was also a similarly produced chess-board pattern on glass, the separation from line to line or square to square being of the order of 1/10 in. This coarseness of the objects leads to the principal point worth discussing; for, as only 400 ft. distance was available, the objects could not be observed directly, even in the telescopic experiments, a diminished image of the actual object in a convex mirror having to be used instead.

In the microscopic observations a very greatly diminished image was employed which an auxiliary objective of higher power and wider angular aperture than that to be tested projected in the common focal plane of both. To most people this will appear as a perfectly legitimate proceeding involving only the most elementary optical assumptions and therefore not open to objection. But a crude method of carrying out this process with the microscope by observation of the small images formed by air-bubbles or fat-globules in a watery liquid has been severely criticised by Abbe for two reasons: first, because such images, when received by microscope objectives of wide aperture, must be affected to such an extent by aberrations as to render any calculation as to their size and nature utterly futile. Little can be said against this, but it does not apply to Lister, as he takes great care to state that the projecting lens was a perfectly corrected and carefully adjusted microscope objective. But Abbe raised a second objection of more serious aspect:—

"Even supposing that a perfectly corrected projection-system be used, the observation is not really a microscopical one at all; it is a quasi-telescopic observation of the actual object by an instrument giving erect images, consisting of the projecting system and the real microscope, which latter acts merely the part of an erecting eyepiece."

There is no answer to this argument *so far as it goes*. But it really misses the crucial point, the only point of interest, altogether. And if we concentrate our attention on this, the question to be answered becomes this: Does the light received by the microscope from a perfectly corrected projecting lens differ in any essential respect from that which it would receive from a real object similar in every respect to the large one actually used, but diminished in size according to its distance from, and according to the focal length of, the projecting system?

The only answer to this question seems to me to be that there is no essential difference, and that Lister's results are perfectly valid. For on the older theory, which assumes that objects may be treated as if they were self-luminous, each point in the real object will send out spherical waves towards the projecting system, which turns them into perfectly spherical waves converging towards the conjugate point of the aërial image, from which they expand again so as to form, at a little distance, perfectly spherical waves *from* the same conjugate point as a centre, precisely as if the conjugate point itself were the true origin. The complicated interference phenomena which arise close to the focal plane, in what the late Dr. Johnstone-Stoney so aptly called the region of turmoil, have no effect on the form of the waves beyond that region. And if we adopt the Abbe theory we are led to substantially the same conclusion, for by the combined effects of the principle of equal optical paths between conjugate points and of the optical sine-condition we can easily show that the diffracted waves received by the projecting system are turned into such directions as to correspond exactly in every respect to those which would be sent out by an actual object of the size and structure of the ideal image of the real object.

We may indeed say that Lister not only gained the advantage of absolute homogeneity by his procedure, but that he avoided a very grave objection which, in fact, renders open to doubt,

[1] Journ. R. Micr. Soc., 1913, pp. 27–55.

if not absolutely futile, much of the work done by amateur theorists—namely, that observations for theoretical purposes must be made on objects of a structure which is perfectly known by some independent method, as otherwise we are moving in a "vicious circle." It is clear that in the case of the higher powers of the microscope this difficulty cannot be avoided with delicately marked natural objects examined directly.

The numerical results obtained by Lister are still of great value.

For the naked eye he finds that there is practically no gain in resolving power when the pupil is opened beyond 0·095 in.; that the difference in keenness of vision of different individuals rapidly decreases when smaller and smaller apertures are placed before the eye, and that with apertures below about 0·025 in. all reasonably normal eyes have the same resolving power which corresponds to his general formula. In this section we find a remarkable instance of the accuracy of his observations; for he records the fact that—contrary to his preconceived idea—two or three lines are more easily separated than a larger number; this has in recent times been theoretically confirmed!

The telescopic section is the shortest, owing to difficulties from unsteady air and bad light. But it includes interesting measurements of the diffraction rings of the spurious star-disc. The limit of resolution arrived at is 4·33 seconds of arc divided by the diameter of the object-glass in inches.

Probably the most remarkable results are those recorded in the microscopical section, which also contains the most surprising proof of the extraordinary accuracy of Lister's observations. For these enabled him to deduce that the resolving power of microscope objectives did not increase in proportion to the angle of aperture, but to the chord of that angle—in modern language, to what Abbe, forty years later, called numerical aperture. When it is considered that the widest angle accessible to Lister was one of 80°, and that even for that the ratio of chord to angle is merely that of 10 : 13, it will be realised that this was a very creditable feat.

The limit of resolution for the microscope arrived at by Lister, when translated into modern terms, is 95,240 lines per inch for N.A. 1·00. It should, however, be stated that although there are a very few observations reaching or slightly exceeding the figures finally adopted in the paper, these are not the *mean* of all the observations. Unlike some modern microscopists, Lister understood the meaning of the word limit as a practically unsurmountable barrier which should only be closely approximated under extremely favourable conditions, and he adopted his final numbers accordingly.

In conclusion I should like once more to advise those interested in instrumental optics to read this extremely interesting paper *in extenso*.

A. E. CONRADY.

THE ANCIENT ARTISTS OF SOUTH-WESTERN EUROPE.

THE attention of readers of NATURE has been directed from time to time to the numerous and interesting archæological discoveries in the caves and rock-shelters of central and southern France and northern Spain, which are due to the energy and skill of Prof. l'Abbé H. Breuil, MM. L. Capitan, E. Cartailhac, Prof. H. Obermaier, E. Piette, and others. During the last two or three years similar investigations have been made in other parts of Spain, mainly by the indefatigable Abbé Breuil with the co-operation of Juan Cabré Aguilo, Pascual Serrano Gomez, and Gomez Moreno, and we should like to take this opportunity of congratulating the Spanish archæologists on pursuing this fascinating line of inquiry, which already has led to important results.

The epoch-making monograph "La Caverne d'Altamira," by E. Cartailhac and H. Breuil (1906), is being followed by the publication of equally sumptuous memoirs on the more important French caves. These, together with the numerous papers and smaller memoirs that have already appeared (mainly in *l'Anthropologie*), prove that central and southern France and Spain north of the Cantabrian Mountains constituted an area throughout which the later stages of Palæolithic culture were spread with remarkable uniformity. This sequence consists of the Aurignacian, Solutrian, Magdalenian and Azilian industries, with their accompanying manifestations of glyptic and pictorial art.

The earliest phases of the art of the Franco-Cantabrian area are characterised by rude statuettes of the human figure, which are followed by beautifully executed carvings of animals in the round or in relief, and by large numbers of engravings on bone, ivory, and stone. The earliest engravings are linear scrawls, and even rude but vigorous drawings of animals on clay surfaces. The walls of numerous caves were also decorated with engravings and paintings of animals, of which the following sequence has been established.

First phase: the engravings consist of broad deep incisions; many of them are unrecognisable; some are profile representations of animals with but two legs drawn; the paintings have a similar character, but the earliest efforts were simple impressions in colour of the human hand and timid attempts at linear designs and grouped dots. Second phase: the incisions are still broad and deep, but the drawings are more lifelike; the four legs are shown, and hair is often indicated; the clever brush outlines of the earlier part of this phase are replaced by monochromes, some of which are beautifully shaded. Third phase: the engravings are now in thin lines; they vary in excellence, but some are real masterpieces; the paintings are deplorable, owing to an excessive use of pigment. Fourth phase: the engravings lose their importance, and in some cases are merely employed as subsidiary to painting; the artists try to regain by the use of various colours the modelling lost in the preceding phase; at first they are timid, the animals are outlined in black and the paint laid on in masses, but they soon obtain a mastery of the technique, and produce wonderful shaded polychrome paintings of bisons, boars, and other animals in various positions. Fifth phase: there is no longer any mural engraving; nor are there paintings of animals, but merely painted bands, branched designs, dots, and so forth. With this decadence that marks the

FIG. 1.—Group of red animals on a rock at Cogul: stag surrounded by hinds; to the right an ox and elk. Behind the ox is a black head of a hind of earlier date. Length of panel, 0·75 m.

Azilian period comes the close of the Palæolithic age.

The question naturally arises, whether the simple decoration and absence of naturalistic drawings of the Azilian period are due to a degeneration of the Magdalenian art, or whether they reflect a movement from elsewhere. The evidence certainly points to the latter explanation, as the implements are also different from the Magdalenian and agree with those from pre-Neolithic sites in Italy, Sicily, Tunis, Algeria, and south Spain.

In various other parts of Spain pictographs have been found in rock-shelters and on rocks in the open; these form an eastern and a southern group. The rock-paintings in the lower valley of the Ebro at Cretas were first noted in 1903, but not studied till 1908, while those at Cogul were discovered in 1907 (Fig. 1). In every case they are in full daylight and often exposed to the weather, whereas all those previously considered are in the deep recesses of dark and usually tortuous caves. The paintings of the Dordogne include bears, lions, mammoths, rhinoceroses, horses, bisons, wild oxen and goats, deer, and reindeer. The reindeer and mammoth scarcely occur in the caves of the French Pyrenees, while in those of Cantabria the reindeer is entirely absent, and there are two elephants and one bear. Throughout the whole region representations of human beings are practically absent.

In the frescoes of eastern Spain the deer, primitive ox, and wild goat are very abundant; there are also a few wolves, one horse, one male elk, some fallow deer, and a bison. We are here in a different zoological area. With the exception of two very diagrammatic deer at Cogul (Fig. 2), all the animals are depicted with the same artistic feeling that is exhibited in the Magdalenian art of France and Cantabria; there is the same ability to seize forms and attitudes, the same certainty of execution. The number of human beings that are drawn marks a sharp contrast to the art of the north. At Cogul there was found a remarkable fresco representing a group of nine partially clothed women apparently dancing round a small nude male figure—doubtless a representation of a ceremony that may have had fecundity for its object; 300 kilometres south of Cogul, near Alpéra, two very similar women were painted in the midst of a wonderful assemblage of men and animals. The men are always nude, often they wear feather head-dresses and tasselled leglets; they are drawn in various attitudes, and the majority of them are shooting with bow and arrows at deer and other animals (Fig. 3). The investigators have satisfied themselves that the paintings belong to the Magdalenian period, and now we have indisputable evidence that at all events in the latter part of the Palæolithic age the bow was a common weapon in Spain; its presence has not yet been proved in the Franco-Cantabrian area, but we know that the spear-thrower was employed by the French Magdalenians. Two large male figures at Alpéra in a dancing attitude, wearing a feather head-dress and flourishing a bow and arrows, have doubtless a ceremonial significance, and may represent magicians.

There is nothing to show whether the above-mentioned schematic figures at Cogul were earlier

FIG. 2.—Hunting scene painted in red on the rock at Cogul: man shooting a deer; the figure to the right is a dead deer lying on its back with legs in air. Length of fresco, 0·75 m.

or later than the other naturalistic paintings, for assuredly they were not done by the same artists. The same style reappears at Alpéra, in the eastern area, where it is easy to see that it is later than the fine style.

At Batuecas, in west-central Spain, enormous panels are covered with dots, rows of lines, branched, scaliform, pectiform, and other signs, circles, and rayed figures, together with very schematic men and animals (Fig. 4), which are later than certain more naturalistic drawings. Precisely similar diagrammatic signs occur in profusion in Andalusia, and below a few of them l'Abbé Breuil has found small, poorly executed, but realistic figures of the same kind as those at Batuecas. The signs agree with those that are found superimposed on Magdalenian drawings in the Franco-Cantabrian area, so there is little doubt that they characterise the Azilian culture.

FIG. 3.—Hunting scene painted in a brownish red, older than the very diagrammatic red signs (in cross-hatching) and later than the light red hind in the centre. Scale, about ⅙.

Prof. Breuil has given in *Rev. Arch.*, xix., 1912, p. 193, a large number of sketches from central and south Spain which are evidently degraded representations of the human form.

In the same article he points out that, so far as is known, the art of the Franco-Cantabrian area developed *in situ* throughout a considerable period during which the climate, vegetation, and fauna were modified several times, while migrations of peoples, all of whom were hunters and collectors, took place in different directions. The realistic representations of animals by the Aurignacians continued through Solutrian to the end of Magdalenian times, and until the extinction of the reindeer in France and central Europe. Human figures, as we have seen, were rarely portrayed except at the beginning of this series of cultures. Then an invasion from the Italian and Iberian peninsulas brought other peoples to north-west Europe, who painted schematic and geometric forms, often very like those painted on rocks in south and west Spain.

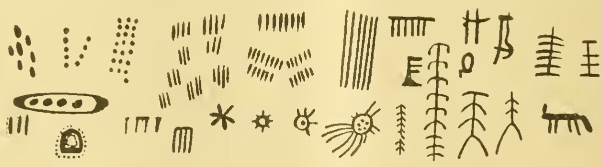


FIG. 4.—Azilian signs at Batuecas (Salamanca) which recall the coloured pebbles and petroglyphs of Andalusia.

These latter seem attributable for the most part to peoples who, while in the Palæolithic stage of evolution, did not progress through the Aurignacian-Solutrian-Magdalenian line of evolution that extends from Cantabria to Poland, but advanced in the direction of the industries termed "Capsian" by de Morgan and "Getulian" by Pallary. The eastern Spanish art may have been derived from north of the Pyrenees or influenced by it, at the same time undergoing a local development. On the other hand, Breuil notes that influences of the schematic art of the south-west were felt in the Magdalenian art of Cantabria and even of the Pyrenees, and that a cave in Ariège also shows pictorial influence from the artistic province of east and north-east Spain.

"As a result of the arrival of Neolithic man in the south of the Iberian peninsula, the Capsians flowed over the Magdalenian world, substituting their schematic art for the realistic art of the Magdalenians; borrowing from them some slightly modified industrial objects, like the harpoon, they spread not only to Gascony and Aquitaine, but to Dauphiné, Switzerland, Bavaria, and even to Scotland. On the other hand, some Capsians of Andalusia and Murcia seem to have rallied to the new state of things, since certain painted rocks represent 'idols' known only in the ancient Neolithic age in these regions, and certain Portuguese dolmens preserve a mural decoration conceived in their style. Perhaps other Capsian groups, driven from Morocco by the newcomers, migrated into central Sudan, unless the strange analogy of the paintings found there with those of Andalusia be purely fortuitous."

A. C. HADDON.

EXPERIMENTAL CANCER RESEARCH.

EXPERIMENTAL cancer research can be undertaken with two main objects in view: (1) The investigation of the origin of cancer; (2) The study of the properties and life-history of the developed tumour. In regard to the first of these objects the staff of the Imperial Cancer Research Fund has confined its attention to the question of heredity. In the present report [1] there is a summary of observations on this point which confirm the conclusions previously published. In mice with recent cancerous ancestry, 20 per cent. of all deaths were due to cancer, while in those with remote cancerous ancestry the ratio was 11·6 per cent. It will be interesting to see whether further research in this direction will reveal any relation between the types of tumour in the ancestors and their progeny, and whether there will be any appearance of the Mendelian phenomenon.

The main efforts of experimental cancer research are, however, directed towards an investigation of the properties and life-histories of spontaneous and propagated cancer. In this direction the record is one of steady progress; the scope of investigation is continually expanding, and new problems are constantly offering themselves for solution.

Perhaps the most striking phenomenon in experimental cancer research is the appearance of a sarcoma during the propagation of a carcinoma. Recent work brings out the interesting fact that the power of inducing sarcoma formation is not necessarily a permanent property of a particular carcinoma, but may be only transitory. Two tumours have been previously observed to have this property. In one of these, sarcoma formation was irregular, and was promoted by rapid repetition of transplantation. In the other, sarcoma formation occurred with remarkable regularity if the tumours were allowed to grow for about two months before transplantation, but did not occur if transplantation was effected rapidly. The recent history of these tumours has shown that the first has completely lost the power of inducing sarcoma formation. Of the second tumour four carcinomatous substrains have been kept growing. In one of these, sarcoma development has occurred earlier at each transplantation until it has occurred so early that it has been impossible to retain the carcinoma in propagation, and this strain has become purely sarcomatous. In another strain the appearance of sarcoma has become progressively later until the power of inducing sarcoma formation has been lost. In the other two strains the same process is apparently going on.

In this phenomenon of sarcoma formation there thus await consideration not only the problem, What causes the production of a sarcoma during the propagation of a carcinoma? but also the problems, Why does a tumour which at one stage of its propagation shows the power of inducing sarcoma formation subsequently lose this property? and What is the explanation of the variability in this power displayed by different strains of the same tumour? All we can say at present in answer to these problems is that the sarcoma formation is not due to any filterable virus or other material derived from the carcinoma cells, but requires the presence of living cells for its induction.

The curious variability of the properties of mouse-cancer is also shown in other directions. In some tumours the structure remains constant during propagation for several years, while others show great variability. An acinous carcinoma may become alveolar in type; a tumour originally showing keratinisation, sebaceous transformation, or glycogen formation may lose these properties temporarily or permanently. Similarly in its power of growth a tumour may show constancy or variability. From a single tumour two strains may be isolated, one of which constantly disappears after a short period of growth, while the other regularly grows progressively and gives rise to metastases. The power of growth in a particular tumour depends inversely on its power of inducing in the host resistance to its own growth.

In all these cases of variability the question arises, Does the variability reside in the tumour-cells, or in the tissues of the host? The available evidence goes to show that the variability centres in the tumour itself. When, for instance, a slow-growing tumour arises from one which grows rapidly, when the structure of a tumour changes in the course of propagation, or when a sarcoma arises during the propagation of a carcinoma, the changes must be ascribed to variations in the tumour-cells, the transplantation subsequently effecting the isolation of the different characters evolved. It is well to note that this variation is not always in one direction. The change in the tumour-cell is not always from one of lower to one of higher differentiation and *vice versâ*. Also tumours showing high differentiation are not necessarily the most constant, nor those of low differentiation the most variable.

One important point should be noticed; that is, the increasing evidence as to the identity in nature of the mouse-cancer with the human disease. Every feature of cancer in mice finds its parallel in man. Squamous-celled carcinomata in mice sometimes show the formation in them of cysts lined with typical squamous epithelium, and this property may remain constant during propagation. The same feature is frequently found in human squamous-celled carcinomata, and is repeated in the metastatic growth. Similarly sarcoma formation may take place in human carcinoma, as it does in propagated and spontaneous carcinoma in mice. Again, in man the structure of the primary tumour is often repeated with great constancy in the metastatic tumours, whereas in some cases there may be great variability, and tumours of the same structure in man may show great differences in the power of growth, one

[1] Eleventh Annual Report of the Imperial Cancer Research Fund. Presented July 24.

confining its growth locally, and the other early giving rise to metastases. In these respects, as in many others, the similarity in nature between mouse-cancer and cancer in man is placed on a firm basis, and the importance of experimental cancer research in relation to human cancer established.

Experimental research continues to throw discredit on the hypothesis that cancer is caused by a specific parasite.

NOTES.

It is announced that the Admiralty has accepted a tender for the construction of a large laboratory, which is to be built on the high land at Crombie and used for purposes of chemical research in connection with the ordnance works there.

Prof. W. A. Bone, F.R.S., has been awarded the Howard N. Potts gold medal for distinguished work in science or the mechanic arts by the Franklin Institute of Philadelphia, in recognition of his work upon surface combustion. Prof. Bone lectured before the institute upon this subject in October, 1911.

The King decorated the members of the British Antarctic Expedition on July 26 with the Antarctic medal and clasp. The medals and clasps awarded to those who lost their lives were presented by the King to the widows, and in other cases to the mothers. Chief Stoker W. Lashley, R.N., and Petty Officer T. Crean, R.N., were decorated also with the Albert Medal of the Second Class for gallant conduct in connection with the heroic saving of the life of Commander Evans, with the details of which readers of Nature are already familiar.

A correspondent of *The Birkenhead News* directs attention to the submerged forest at Leasowe, lying north-west of that city. Numerous relics, including coins, have from time to time been discovered, and it has been suggested that these are remains of an ancient port now submerged. It is much to be desired that this important archæological site should be thoroughly examined, and the suggestion that a committee of local geologists and archæologists should be formed for the purpose will meet with general approval. The local archæological and scientific societies might with advantage cooperate in the proposed inquiry.

A demand for a Royal Commission on the subject of venereal disease has been issued by the leaders of the medical profession. It is pointed out that the State has compelled local authorities to provide asylums for the insane, it has insisted on the notification of many infectious diseases, it has undertaken the inspection of school children, it has introduced an elaborate system to ensure the purity of food, and is building up a vast system of public health legislation. Yet the subject of venereal disease has been left severely alone. In London alone the disease claims 40,000 new victims every year, innocent members of the public are sometimes infected, it is transmissible from the parent to the offspring, and the effects of the disease are dire and widespread.

A committee, including the names of Sir H. Read, Profs. Haverfield, Ridgeway, and Dr. M. R. James, provost of King's College, Cambridge, has issued an appeal for funds to be devoted to the excavation of the Romano-British city of Wroxeter, which stands beside the Severn, five miles east of Shrewsbury. In its first phase it was a legionary post intended to watch the Welsh hills; but on the removal of the Roman troops to Chester there sprang up on the site a Romano-British town, which flourished for some three centuries, and became the capital of the Canton of the Cornovii. The city was laid out like Caerwent and Silchester, in Roman fashion, with a forum and baths, and streets crossing at right angles; but the area within its walls was more spacious than Silchester and Caerwent together. At the close of the Roman period it was destroyed by barbarian invaders, and since then has remained practically undisturbed. The excavation promises to throw much light on the later Roman period. The work will be carried on by an experienced archæologist, Mr. J. P. Bushe-Fox, with the aid of Oxford and Cambridge scholars. The scheme may be confidently recommended to the liberality of English antiquaries.

The Secretary of State for the Colonies has nominated a Committee to report:—(1) Upon the present knowledge available on the questions of the parts played by wild animals and tsetse-flies in Africa in the maintenance and spread of trypanosome infections of man and stock; (2) whether it is necessary and feasible to carry out an experiment of game destruction in a localised area in order to gain further knowledge on these questions, and, if so, to decide the locality, probable cost, and other details of such an experiment, and to provide a scheme for its conduct; (3) whether it is advisable to attempt the extermination of wild animals, either generally or locally, with the view of checking the trypanosome diseases of man and stock; (4) whether any other measures should be taken in order to obtain means of controlling these diseases. The Committee is constituted as follows:—Lord Desart (chairman), Mr. E. E. Austen, Dr. A. G. Bagshawe, Dr. Andrew Balfour, Sir John R. Bradford, F.R.S., Mr. E. North Buxton, Dr. W. A. Chapple, M.P., Sir Mackenzie D. Chalmers, Lieut.-Col. Sir W. B. Leishman, F.R.S., Sir Edmund G. Loder, Dr. C. J. Martin, F.R.S., Mr. J. Duncan Miller, M.P., Dr. P. Chalmers Mitchell, F.R.S., Prof. R. Newstead, F.R.S., Mr. H. J. Read, the Hon. L. Walter Rothschild, F.R.S., and Sir Stewart Stockman. Mr. A. C. C. Parkinson, of the Colonial Office, will act as secretary.

In the House of Commons on July 24 Mr. Runciman was able to give a very satisfactory account of the work of the Board of Agriculture during the past session. Energetic steps have been taken to stamp out animal disease, and the result is that the country is now freer from disease than any other in Europe. For a time last year there were outbreaks, and the export of pedigree live-stock ceased, but the foreign ports are now open to us again, and the result has been an unprecedented export during June, the total value of the animals sold being nearly 62,000*l.*, against 28,000*l*., the highest previously reached. Arrangements have been made for research on agricultural subjects to be carried on at a number of centres, including Rothamsted, Manchester, Birmingham, Oxford, Cambridge, the Royal Veterinary College, Leeds, Wye, Bristol, and Kew, and grants amounting to 20,000*l*. a year have been made for the purpose. In addition, 3900*l*. has been given for special investigations lying outside the scope of the programme of the special institutes. All these investigations have reference to the great fundamental problems lying at the root of the agricultural and horticultural work of the country; the work is wholly scientific. In order to bring the scientific results into the region of practical farming a number of advisers have been set up whose function it is to advise farmers or county organisers in the light of the results of the scientific knowledge that is gained. A grant of 9000*l*. per annum has been made towards the salaries of these advisers.

Now that we are at the end of the second month of summer some anxiety is being felt as to the general character of the weather to be experienced during August. June was a fair month with a generally deficient rainfall, but the conditions were mostly seasonable. July has had many shortcomings. During the early part of the month the weather was very unsettled, and the rainfall in the first three weeks was equal to the average for the whole of July except in parts of the Midlands and in the south-west of England. The special feature of the weather has been the persistent absence of bright sunshine and the consequent low day temperatures. At Greenwich there were only eight days to July 28 with a temperature of 70° or above, and there was only one day in the four weeks with the maximum day temperature above the average, the highest reading during the period being 76°. In July, 1910, the maximum temperature for the month was 76°, and in 1888 July had no higher reading than 74°. According to the average of the past seventy years July has twenty-two days with a temperature of 70° or above. The aggregate sunshine at Greenwich to July 27 is sixty-six hours, and the least sunshine for July previously since sunshine records were established, rather more than thirty years ago, is ninety-six hours in 1888, the next lowest record in July being 113 hours in 1910. July this year bids fair to be the least sunny July on record. There were only four days to July 27 with more than five hours' sunshine, whilst in 1911 July had twenty days with more than ten hours' sunshine, and the total duration for the month was 335 hours at Greenwich.

The Institute of Metals will hold its first foreign meeting on August 28 and 29 at Ghent. Prof. A. K. Huntington will preside. The congress will commence with an official welcome of the members on behalf of the University and the municipality of Ghent. A number of important scientific papers will be read and discussed. The second report to the corrosion committee by Dr. G. D. Bengough and Mr. R. Jones will be presented. The report indicates not only the causes of the corrosion of condenser tubes, but how such corrosion may be eliminated. Among the papers arranged for the meeting the following may be mentioned:—Mr. H. Garland, "Metallographical Researches on Egyptian Metal Antiquities"; Dr. W. M. Guertler (Berlin), "The Specific Volume and Constitution of Alloys"; Prof. S. L. Hoyt (University of Minneapolis), "Copper Rich Alloys"; Dr. T. K. Rose, "The Annealing of Gold"; Dr. W. Rosenhain, F.R.S., and Mr. D. Ewen, "The Intercrystalline Cohesion of Metals—Second Paper"; Mr. J. H. Chamberlain, "A Further Study of Volume Changes in Alloys"; Dr. C. H. Desch and Mr. S. Whyte, "The Micro-Chemistry of Corrosion: I., Some Copper-Zinc Alloys"; Mr. F. Johnson, "A Method of Improving the Quality of Arsenical Copper"; Prof. A. A. Read, "The Influence of Phosphorus on Some Copper-Aluminium Alloys"; and Mr. T. West, "The Determination of Oxygen in Copper and Brass." Visits will be paid to factories of importance, and numerous social functions have been arranged. Those who desire to attend the meeting should communicate with the secretary of the Institute of Metals, Mr. G. Shaw Scott, Caxton House, Westminster, S.W.

The Brighton meeting of the British Medical Association was held on July 22–26, the scientific business being conducted in sixteen sections. Among these the majority was of purely technical interest, all important problems of medical practice in its various branches having been ventilated. The section of State medicine dealt with questions regarding the Insurance Act, the importation of disease into seaports, school hygiene, and popular education in hygiene. The section of medical sociology held discussions on eugenics (Dr. E. Schuster, Dr. J. Scott, and many others), on hospitals in relation to State, public, and medical profession (Prof. B. Moore, Mr. C. F. Masterman, M.P., and various authorities, including foreign guests). Questions of general scientific interest were raised and discussed in the sections of medicine (the internal secretion in disease, by Prof. G. R. Murray), the section of electro-therapeutics (on secondary X-ray radiations in medicine, by Prof. C. G. Barkla, F.R.S.), the section of bacteriology and pathology (general pathological, experimental, bacteriological, and clinical aspects of anaphylaxis, by Profs. W. G. Dixon and G. Sims Woodhead, and Drs. Thiele, Embleton, G. W. Goodall, and H. H. Dale), the section of neurology and psychological medicine (discussion on sleep and sleeplessness, by Sir George Savage and others), and the section of tropical medicine (discussion on filariasis, by Dr. G. Low and others). We hope next week to give a descriptive article dealing in more detail with some of these discussions of general importance. The Brighton meeting was very largely attended, and was a great success in spite of the International Congress of Medicine to be held in London next week.

On account of the deadlock reached by the Committee of the House of Commons considering the Dogs (Protection) Bill, referred to last week (p. 536), it was decided at the meeting of the Committee on July 23 not to proceed with the Bill. The question of the exclusion of dogs as subjects of all experiments in this country—not only experiments under anæsthetics, but all inoculations—has given rise to an interesting correspondence in *The Times*. Mr. John Galsworthy urged that the affectionate relationship existing between the dog and man gave dogs claims to consideration over those possessed by other animals. But, as Mr. Stephen Paget pointed out, 30,000 dogs are put to death annually at the Battersea Home for Lost Dogs, whereas the total number used for experiments of all kinds in Great Britain and Ireland is only 500. Nothing can be learned, nothing can be gained, by the killing of these 30,000 dogs; and they suffer neither more nor less than dogs anæsthetised for an experiment and killed under the anæsthetic. The physiologist is so often pictured as a man who has no tender or sentimental feelings that a letter from Sir E. A. Schäfer, published in *The Times* of July 26, is particularly appropriate to the discussion. Sir E. A. Schäfer is not prepared to let Mr. Galsworthy have it all his own way in the matter of ethics and sentiment. He says:—"I also love my dog even more, I confess, than many of my own kind. If the question arose of sacrificing my dog to save my own life I might hesitate. But if it were a question of choosing between the life of my dog and that of my wife, or child, or friend; nay, even between the life of any man, woman, or child—were it the meanest beggar in the street—and that of my dog, I should not hesitate to sacrifice the dog. This I would do—and I believe Mr. Galsworthy also would do the same—to save even a single human life. And when I consider that the employment of a few uncared-for animals, which would otherwise have been uselessly sacrificed for the mere sake of getting rid of them, has been the means of saving the lives and mitigating the sufferings of many thousands of our fellow-beings, it seems to me to be beyond a doubt that both ethics and sentiment are on the side of science."

The *Scientific American* for June 14 contains an illustrated article by Dr. Bolduan entitled "Bacteriology and Your Health," in which antitoxins and other curative serums, vaccine treatment, and bacteriological methods for the diagnosis of disease conditions are dealt with in a popular manner.

To Vol. xxxv., No. 2, of Notes from the Leyden Museum Mr. R. Van Eecke communicates an article, illustrated by four plates, on variation in the beautiful "long-tailed" Indo-Malay butterfly, *Actias maenas*, of the family Saturniidæ. Four varieties, or races, are indicated, which exhibit a complete transition in the matter of colouring from dark-brown to greenish-yellow, the females of one race being more advanced in this respect than the males. In Java the females, which differ markedly from the males, are more numerous than the latter, whereas in Celebes the reverse of this condition obtains.

In connection with experiments to find parasites capable of successfully combating the spread of the gipsy moth, the Entomological Bureau of the U.S. Department of Agriculture has issued a pamphlet, by Mr. P. H. Timberlake, on the life-history of *Limnerium validum*, an hymenopterous parasite normally attacking the fall web-worm (*Hyphantria cunea*). This parasite will attack caterpillars of the brown-tail and gipsy moths, as well as the tent-caterpillar, but will only undergo its full transformation, and then but seldom, in the last. It is, therefore, a failure in the matter of checking the gipsy moth.

From the Imperial Department of Agriculture for the West Indies we have received a copy of a pamphlet on the insect pests of the Lesser Antilles, by Mr. H. A. Ballon. The work, which is well illustrated, describes in popular language the chief species of insects, mites, and ticks injurious to plants and animals. It is interesting to note that, with the great increase of cotton-growing which has taken place of late years in the West Indies, "insects which were not previously recognised as pests, and in some cases even were not known to science, have assumed an important position as serious pests."

In a report on calf-feeding experiments (North of Scotland College of Agriculture, Bulletin 17), Prof. Hendrick discusses the use of separated milk and oils as substitutes for whole milk. The data obtained from three series of experiments show that separated milk with either cod liver oil or cottonseed oil may be substituted for whole milk with good results. The average cost per pound of increase was found to be 1·83, 1·85, and 4·77 pence respectively up to the time of weaning, and both in regard to health and quality of carcase at the age of two years, the different sets of animals were indistinguishable. Although the stock which received whole milk were slightly heavier than those fed on substitutes, this difference was not great, and would be more than counterbalanced by the reduced cost of rearing.

In the current number of *Bedrock*, Prof. Punnett replies to Prof. Poulton's article on mimicry, mutation, and Mendelism, which appeared in the April number of that publication. The main point of difference between the two writers is stated by the former to be concerned with "the conception of the function of natural selection with regard to these [mimetic] resemblances." "Both of us," he says, "are agreed as to the reality of natural selection," but while Prof. Poulton believes in the establishment of mimetic resemblance by the accumulation of small variations, Prof. Punnett holds that the mimicking form has in all cases suddenly arisen as a definite "mutation." This mimetic form, he allows in theory though apparently not in concrete instances, may when once produced be "conserved" by natural selection. To Prof. Poulton's argument from the existence of transitional forms, as in the females of *Papilio dardanus*, Prof. Punnett replies that apparently continuous transitional series may occur in cases of strict Mendelian inheritance.

The Buenos Aires *Handels-Zeitung* (No. 1297) of May 3 discusses the recent discoveries of petroleum in the northern districts of Argentina, and reports the presence there of oil-bearing horizons for a distance north and south of 300 kilometres, and beside a series of moderately inclined anticlinals. This discovery is the more valuable as analyses show that the petroleum is rich in light illuminating oils, whereas that previously found in the Argentine Patagonia is rich in heavy oils. The article discusses the geological relations of the oil-fields; it points out that those in Patagonia are connected with great transcontinental fracture lines. The northern oil-fields are connected with the middle part of the South American Pacific coast, which is dominated by the great subsidence that causes the sudden change in the course of the coast near Arica. The author of the article connects this subsidence to the antipodal disturbance of the western coast of the Pacific on the Gulf of Tongking.

Though it had long been known that sudden displacements take place during strong earthquakes, the first case in which such displacements were established by geodetic measurements was that of the Sumatra earthquake of May 17, 1892. The movements of the crust were then entirely horizontal. Though no trace of any fault is visible at the surface, Prof. H. F. Reid shows (Bulletin of the Seis. Soc. of America, vol. iii., pp. 72–9) that the measured displacements imply the existence of a fault trending N.N.W. and S.S.E., and that the crust on the west side was shifted towards the north, and that on the east side towards the south. The total relative slip of the two walls of the fault amounted to 3½ or 4 metres, or about the same as that of the San Andreas fault during the Californian earthquake of 1906. As in that earthquake, also, the displacement diminished rapidly as the distance from the fault increased. Judging from the great displacements at the limits of the measured area (about 55 km. apart), Prof. Reid estimates that the ruptured part of the fault may have been from 150 to 200 km. in length.

In *Symons's Meteorological Magazine* for July Dr. Mill refers to the message recently received from Dr. Mawson at the winter camp of the Australian Antarctic Expedition and to the "interesting and remarkable fact" that daily meteorological reports are being received in Melbourne from Commonwealth Bay and from Macquarie Island. He remarks:—"No more striking advance in the study of world meteorology has ever been made than this inclusion of the Antarctic regions within the system of daily meteorological weather reports; and meteorologists must pay a tribute of gratitude to Dr. Mawson for his triumphant realisation of what, a very short time ago, would have been held to be a fantastic dream."

A pamphlet on the "Démonstration du théorème de Fermat," by Prof. E. Fabry (Paris: A. Hermann et Fils, price 1.50 francs), does not contain what its title seems to indicate. Assuming that all the details of the analysis are correct, the net conclusion is that if $x^p+y^p+z^p=0$, with p an odd prime, has an integral solution for which x, y, z, have no common factor, one of these integers must be divisible by p^2. But although this result is not much in itself, M. Fabry's tract deserves study, and may suggest some new way of attacking this famous problem. Another recent attempt by M. de Bouffall is of no value at all, as the author assumes that two equations are identical, when all that he has proved is that they have a common root.

The June number of the Proceedings of the American Academy of Arts and Sciences contains a contribution from Prof. B. Osgood Peirce, of the Jefferson Physical Laboratory of Harvard, on the maximum value of the magnetisation of iron. The recent measurements of Sir R. Hadfield and Prof. Hopkinson, by what is known as the "isthmus method," gave 1680 as the maximum. By building a large solenoid capable of giving a magnetic field of 5000 units, Prof. Peirce has been able to obviate the uncertainties which attach to the determinations of the magnetising field in the isthmus method, and has arrived at results for twenty-five examples of commercial iron which vary from 1735 for American ingot iron to 1533 for a sample of drill-rod iron. Curves are given for a number of these materials which all show how closely the reciprocal of the magnetic susceptibility of any specimen is a linear function of the magnetising field for fields above about 50 units.

Part 6 of each of the two sections—Physics and Electrical Engineering—of Science Abstracts has reached us. Each part extends to sixty-three pages, and the average length of an abstract in the Physics Section is one-third, and in the Electrical Engineering Section one-half, of a page. The engineering abstracts are in many cases accompanied by figures which are not invariably so clear as they might be. The greater length of these abstracts seems to be due to the descriptive details of apparatus and machinery on which the interest of the articles abstracted in many cases depends. So far as the dates of the articles abstracted are concerned, a glance through the two sections shows that the great bulk of them are of February, March, and April, so that the periodical is reasonably up to date. The Institution of Electrical Engineers and the Physical Society of London have earned the thanks of all workers in these two fields for their enterprise in maintaining so useful a publication.

The July number of *Science Progress* (No. 29) marks the commencement of a new volume, and a change of editorship. Sir Ronald Ross will in future guide the destinies of this well-known journal. The present number contains several articles of a wide general interest, of which the following may be named:—Enzymes as synthetic agents, by Prof. J. H. Priestley; the seats of the soul in history, by Dr. D. Fraser Harris; and scientific national defence, by Colonel Charles Ross. Drs. M. S. Pembery and O. A. Craggs cross swords on the vexed question of woman's place in nature, and Prof. H. E. Armstrong destructively criticises recent experimental work on the perennially interesting subject of the corrosion or rusting of iron, which, it is maintained, cannot possibly be brought about by the action of pure water and pure oxygen only.

In *The Biochemical Journal* (vol. vii., p. 268) Mr. E. Ashley Cooper describes the isolation from animal tissues, such as horseflesh, or ox-heart, of a substance which rapidly cures polyneuritis in birds induced by a diet of polished rice; it can be precipitated from the fats and lipoids present in an alcoholic extract of the tissue by means of ether, and, thus obtained, is extremely active. Ordinary quinine and cinchonine exert a temporary curative action upon birds affected with polyneuritis, but as this action is destroyed by heating the alkaloids at 125°, it is probable that the curative properties are due to the presence of traces of an anti-neuritic substance derived from the cinchona-bark, which is destroyed by this treatment. The same number of *The Biochemical Journal* also contains an account by Dr. R. H. A. Plimmer of a very useful method for quantitatively separating tyrosine from cystine by means of absolute alcohol saturated with hydrogen chloride, which converts the former into its ester, whilst the cystine does not undergo esterification.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR AUGUST:—

August 1. 1h. 44m. Neptune in conjunction with the Moon (Neptune 4° 59′ S.).

4. 0h. 0m. Mercury in inferior conjunction with the Sun.

12. 16h. 29m. Jupiter in conjunction with the Moon (Jupiter 4° 52′ N.).

14. 18h. 9m. Uranus in conjunction with the Moon (Uranus 3° 28′ N.).

22. 1h. 0m. Mercury at greatest elongation west of the Sun (18° 25′).

24. 5h. 23m. Mars in conjunction with Saturn (Mars 1° 9′ N.).

25. 18h. 54m. Saturn in conjunction with the Moon (Saturn 6° 53′ S.).

,, 20h. 29m. Mars in conjunction with the Moon (Mars 5° 43′ S.).

28. 11h. 43m. Venus in conjunction with the Moon (Venus 5° 25′ S.).

,, 13h. 38m. Neptune in conjunction with the Moon (Neptune 5° 0′ S.).

29. 12h. 38m. Venus in conjunction with Neptune (Venus 0° 18′ S.).

31. 8h. 52m. Sun eclipsed, invisible at Greenwich.

NOVA GEMINORUM No. 2.—Among recent references to Nova Geminorum No. 2 may be mentioned a communication by Herr C. Wirtz (*Astronomische Nachrichten*, No. 4667, p. 219), who gives the values derived from his observations of its magnitude. The observations extended from March 14 to May 12 of last year, from the time when the star was about 3·5 mag. to that when it had diminished to about 7·0 mag.

Another communication in the same number of the *Astronomische Nachrichten*, by Mr. F. P. Leavenworth, gives the position of the nova from photographs taken at the University of Minnesota, the arithmetical mean of eleven observatory positions being given as—

R.A. 6h. 49m. 11·793s. Decl. +32° 15′ 5·65″.

Another excellent series of magnitude observations of this nova is one which appears in the *Memorie della Società degli Spettroscopisti Italiani* (disp. 6, vol. ii., ser. 2, p. 105), by Dr. E. Guerrieri, at the Royal Astronomical Observatory at Capodimonte. These observations cover the period March 28, 1912, to April 29, 1913, and are accompanied by a chart. The curve shows the curious fluctuations which the light of the nova was undergoing during its gradual diminution in brilliancy.

VARIATION OF LATITUDE.—No. 4665 of the *Astronomische Nachrichten*, p. 161, contains the provisional results of the International Latitude Service of the north parallel for the period 1912·0 to 1913·0, communicated by Prof. Th. Albrecht. The author states that the method for the determination of the path of the pole is the same as that employed in his previous publications, and he gives here the mean values of the latitude of the six stations according to group on which his values are based. In one table he shows the values of the variation in latitude, and in another the values of an expression from which the variations in azimuth and longitude can be computed for every 30° of longitude from 1912·0 to 1913·0. The paper is accompanied by a chart of the now well-known form showing the polar track from 1906·0 to 1913·0. During these years the amplitude is small at first and then increases up to 1911, afterwards decreasing rapidly up to the last-mentioned year.

THE INTENSITY DISTRIBUTION OF INDIVIDUAL LINES IN STELLAR SPECTRA.—Those familiar with the lines in the spectra of new stars know that at some stages of development the lines, such as those of hydrogen, have a complicated structure, the intensity distribution being very far from uniform. Herr K. F. Bottlinger has recently taken up the study of the question of the intensity distribution of lines in many of the type stars, and communicates his results to the *Astronomische Nachrichten*, No. 4662, p. 117. The spectra were secured at the Astrophysical Observatory at Potsdam, and measured with a Hartmann's microphotometer. The investigation chiefly consisted in the study of Hγ and a few other lines in the spectra of the following stars:—α Can. maj., α Cygni, η Leonis, ζ Orionis, δ Orionis, and γ Cassiopeiæ. The paper is accompanied by a series of curves showing the form of the distribution, and brings out the fact that a systematic study on a more extensive scale might lead to important conclusions.

RECENT WORK OF THE GEOLOGICAL SURVEY OF GREAT BRITAIN.

THE memoirs here referred to bear witness to the publishing activity of the Geological Survey during 1912 and the present year. In explanation of Sheet 299, H. J. O. White describes the country around Winchester and Stockbridge (1*s.* 6*d.*), where the broad stretch of chalk is cut by the valley of the Test. Though Crawley stands out isolated on its dome, few of our Upper Cretaceous areas show more clearly the dependence of the villages on permanent streams. It is interesting to notice that the pre-Eocene denudation of the Chalk has not entirely removed the zone of *Belemnitella mucronata* (p. 40). On the accompanying map, the unusual feature of knolls of calcareous tufa, some 5 or 6 ft. thick, is represented in the valleys of the Itchen and the Test.

The description of Devon and Cornwall is continued in three memoirs. Numerous authors are associated in "The Geology of Dartmoor" (2*s.* 3*d.*), accompanied by Sheet 338 of the one-inch map. The great mass of granite, penetrating Carboniferous strata, occupies almost all the area. Its upper surface probably lay at no time much above the present undulating surface of the moor. The Culm-Measure rocks on its margins are regarded as representing the Millstone Grit, and perhaps the higher zones of the Avonian Series. Chapter vii. directs attention to the probability that the valleys of the small streams, with a general north-westerly and south-easterly trend, are controlled by earth-fractures. The rapid deepening of the valleys during the Pliocene uplift is illustrated (p. 70) by the case of the Dart, which lowered its floor below the general platform of the country by 700 ft. The freshness of the rock on such valley-sides is in marked contrast with the depth of decomposed rock found (p. 27) across the moor. So well-written a memoir on a district visited by thousands of tourists would gain much in popularity if it were illustrated by views of scenery. Wistman's Wood (p. 60) in its desolate surroundings is a geographical feature in itself. Such appeals to the general taxpayer seem, however, to be largely the privilege of the Scottish branch of the Survey, and, as we have remarked on previous occasions, England, with all its rich associations, still awaits adequate illustration.

A considerable step, however, is made in this direction in W. A. E. Ussher's memoir on Ivybridge and Modbury (3*s*.), in explanation of Sheet 349, and by J. S. Flett and J. B. Hill in dealing with Sheet 359, the Lizard and Meneage area. In the former, we see the romantic crag of the Dewerstone, and in the latter the purple rocks of Kynance Cove and the folded schists on Lizard Head. The Lizard memoir (5*s*.) naturally has immense petrographic interest. New analyses are given of rocks that serve as types to English students, and the changes are traced from massive intrusive bodies to foliated schists (p. 97, &c.). The Kennack Gneisses (p. 129) afford a clear example of the penetration of a dolerite by a granitic magma, the gneissic structure being due (p. 140) to "injection foliation." Sedimentary schists are also present in the south and in the north-east of the area (pp. 34 and 167), and in the latter district, near Manaccan, they appear to belong to the Ordovician kiilas series. At Lizard Head, however, they strike north-north-west, and this is taken as strong evidence of their pre-Cambrian age. To mention quite another feature among the many described in this important memoir, on Crousa Down a gravel of blocks of vein-quartz resting on gabbro is regarded (p. 231) as probably a marine deposit of Pliocene age. It is now 364 ft. above the sea. The map (1*s*. 6*d*.), covering the country from Constantine to the Lizard, will surely accompany all future scientific visitors.

W. Gibson, in a special memoir (1913, price 1*s*. 6*d*.), describes the concealed coalfield of Yorkshire and Nottinghamshire, with a map showing by contours the depth of the Coal-Measure surface below the Triassic and Permian covering. North-east of Leeds 5000 ft. of Upper Carboniferous strata were removed by denudation before first Permian beds were laid down (p. 27).

FIG. 1.—Fluvio-glacial erraces, Glen Glass, eastern Ross-shire. Terminal moraine beyond. (Reproduced by permission of the Controller of H.M. Stationery Office.)

The Scottish branch deals in Memoir 93 (4*s*.) with a moorland district, where Ben Wyvis rises as a flat-topped relic of an old plateau of metamorphic rocks. The maps of the Scottish Survey (2*s*. 6*d*. each) cover individually a much larger area than those of England, and the work on Sheet 93 must have often seemed monotonous. The glacial and other superficial deposits are shown by stippling over the colour-printing used for "solid" rocks, and we no longer have the anomaly of peat and alluvium represented in colour and boulder-clay and glacial gravel omitted altogether. Fresh-water alluvia, however, still receive a separate colour. The contributions by J. S. Flett contain, as usual, much original matter. A riebeckitegneiss is described (p. 91) from Carn Chuinneag, containing ægirine and albite, and albite-gneisses occur near it, with streaks of magnetite and cassiterite. Scyelite, the remarkable biotite-hornblende-peridotite, occurs at Carn Cas nan Gabhar, two and a half miles north of the head of Loch Morie. Its exposures are almost too small to appear upon the map. Both the foliations in the great mass of igneous "augen gneiss" (why not "eye-gneiss"?) of Carn Chuinneag are attributed to pressure-metamorphism (p. 55).

In glacial times the ice moved from west to east across this area, Ben Wyvis forming an obstacle that was not completely overtopped. Ice, however, descended from it in the general easterly direction. The fluvio-glacial terraces of Glen Glass, east of the mountain, are finely illustrated in plate viii. (Fig. 1).

G. Barrow and E. H. Cunningham Craig, in Memoir 65 (2*s*. 6*d*.), describe a varied district centring in the granite mass of Balmoral Forest. The accompanying map, with its bands of quartzite and amphibole-schists folded with the Caledonian trend, shows clearly how the main granites are of later date than the earth-movements that made the Highlands. There remains some difference of opinion as to the extent to which these granites are responsible for the development of the contact-silicates present in the adjacent schists, and also (p. 26) as to the succession in the schists themselves. The remarkable boulder-bed, representing so continuous a horizon of erosion, is accepted by both authors as being near the summit of the series.

The same authors, with L. W. Hinxman, have explored the adjacent region of Upper Strathspey and the Forest of Atholl (Memoir and Sheet 64, 2*s*. and 2*s*. 6*d*. respectively). The huge granite domes of the Cairngorm Mountains lie in the north-east of the map, and the central high-road from the Grampians descends through Kingussie on the north-west. Glen Tilt, memorable for the researches of Hutton, Playfair, and Macculloch, between 1785 and 1816, on the contact of granite and limestone, occupies the south-east corner. Here, then, is a country full of inspiration for the geologist. The phenomena of river-capture are naturally interesting on the Grampian watershed; the case of the Feshie (p. 7) is notable, where it draws off the head-waters of the eastward-running Geldie Burn. On the map it appears that a preliminary capture was made of the Eidart, descending from the Cairngorm range, and that the increased flow enabled the stream to reverse the drainage at the east end of Srôn na Ban-righ. Is it, however, quite right to suggest, as is done in the memoir, that the upper part of the Feshie, at 1800 ft. above the sea, has "practically reached the base-level of erosion"?

The glacial features, including the formation of hanging valleys and dry gaps, are described in chapter ix.

In conclusion, we note that a new geological language is developing in the north. Are we to accent "calc-flintas," "hornfelses," and "kamiform"? After all, we have absorbed "taluses" and "volcanoes."

G. A. J. C.

ORNITHOLOGICAL NOTES.

A PAPER on the Plumage Bill in relation to the British Empire was read by Mr. James Buckland at a meeting of the Royal Colonial Institute on June 13. This Bill proposes to forbid the sale, hire, or exchange of the plumage or skin of any species of wild bird inhabiting, during the whole or part of the year, any region of the British Empire or Protectorates, outside the United Kingdom. Ostriches, game-birds, domestic pigeons and poultry, are excepted from the operation of the Bill, as well as skins for museums. The effect of the measure would be, by prohibiting importation, to cut off a large proportion of the plumage supplies that now reach the London market. Mr. Buckland argues that the protection of wild birds throughout the British Empire would be of immense value to agriculture and forestry, in tending to keep down injurious insects, and that the wealth thus gained would enormously overbalance the loss necessarily sustained by the comparatively small number of merchants interested in the feather trade.

The proceedings at the annual meeting of the Royal Society for the Protection of Birds, presided over by Earl Curzon of Kedleston, covered practically all the subjects and objects in which the society interests itself. Foremost among these was the plume trade carried on in order that women may decorate their hats with the plumage of the most beautiful birds in the world. Despite what has been done in some countries beyond the seas to stop this trade, it seems to flourish here exceedingly—humming-birds and birds of paradise being sold by the tens of thousands —and we seem as yet far off getting the only law which will stop the destruction, viz. a law to prohibit the wearing by women of feathers of this description. Another important subject which came before the meeting was the protection of migrating birds from the dangers they incur at lighthouses through being attracted by the brilliant lights, and flying round until they become exhausted and fall to the ground, the gallery, or the sea. To prevent this it is proposed to fit up round the lights an apparatus, newly invented, on which the birds can perch and rest. This has been tried with good result on the Frisian coast. Funds for this special purpose are required by the society, and a considerable sum has been raised. Other subjects treated of by the speakers included sanctuaries for birds, nesting boxes, reserves for wild birds, the pole-trap in Norway, and the watchers' fund, which enabled the society to see that protective legislation was carried out. The society has more than twenty watchers spread over the country from Shetland to Cornwall. This society issues quarterly its very interesting publication, called *Bird Notes and News*, and the sixth number of vol. v. contains much that concerns the bird protector. The frontispiece gives a view of St. Catherine's Lighthouse, which has now been fitted with racks and perches for the use of migrating birds, as before mentioned. There are two short articles on the plume trade from which much may be learned.

A serious falling-off in the supply of guano from the islands off the coast of Peru induced the Peruvian Government to enlist the services of Dr. H. O. Forbes, the well-known naturalist, with a view to the suggestion of remedial measures. Dr. Forbes, who reached Peru at the commencement of 1912, but was unable to get to work until late in that year, has recently returned to this country, and an account of his experiences and investigations appeared in *The Times* of July 25. The guano-islands form a chain of more than 1000 miles in length, commencing with the Lobos Islands in the north to a point off Mollendo in the south. In the breeding season they are the resort of countless thousands of gannets, cormorants, pelicans, and other sea-birds, the two most important species from a commercial point of view being Bougainville's cormorant (*Phalacrocorax bougainvillei*) and the pelican known as *Pelecanus thagus*. Each of these voracious birds consumes from 8 to 10 lb. of fish *per diem*, and the production of guano from the whole assemblage is consequently enormous. Dr. Forbes succeeded in calculating the product of each pair of birds and their offspring in a season, from which he was enabled to form an estimate of the amount for a period of, say, four years. "From that estimate he divided up the whole of the guano-archipelago into zones. He made certain practical suggestions for the protection of the birds with a view to allowing them to deposit and to have a rigorous close-season, and also a period of rest in each of four years. Only one zone would be worked every year, thus leaving a period for recovery." A remarkable event occurred just before Dr. Forbes's visit, almost the whole of the birds having deserted the islands in November, 1911, and not returning until February or March, 1912, leaving their young to perish from starvation. An unusually severe earthquake shock is considered by Dr. Forbes to have been the probable cause of the exodus, and he surmises that the birds may have betaken themselves northwards to the Galapagos Islands.

The supreme importance of birds to the agriculturist, as being in the main the only effective check on most of the insects by which crops are ravaged, is perhaps more fully and more generally recognised in the United States than in this country. Evidence of popular interest in this matter among our American cousins is afforded by the first article in the June number of *The National Geographic Magazine*, which is a reprint of a "Farmers' Bulletin," issued some years ago by the Agricultural Department, containing an account of fifty species of birds commonly frequenting American farms and orchards. In its new guise the article contains a coloured illustration, printed in the text, of each of these fifty species. Although small, the figures are beautifully executed, and form a striking instance of journalistic achievement.

In an illustrated article on national bird-reservations in the United States, published in the May number of *The American Museum Journal*, Prof. T. S. Palmer points out that, in addition to protected breeding places, refuges have been established in the west for birds while on passage. A reservation of this type "comprises merely a narrow strip of land bordering the reservoir, and is set aside to afford the birds a resting place on their journeys north and south. Some of these reservations were created before construction work was completed and before there was any water to attract the birds, in order to afford protection as soon as the reservoirs were filled and the birds began to visit them."

In an article on the velocities of migratory birds in the July number of *The Zoologist* Mr. F. J. Stubbs disputes the belief that migrants prefer to fly in the teeth of the wind, and likewise that they do so in order to escape the inconvenience of the wind ruffling their plumage by blowing obliquely through it from behind. The fact that head-winds undoubtedly bring most migrants has been a main argument in support of the former belief, but it is urged that such winds stop migration, and that birds flying under these conditions are really retarded. The "feather-ruffling" theory, on the other hand, is stated to be based on a misinterpretation of the fact that such birds as lapwings constantly stand head-to-wind in rough weather, and that if they happen to turn ruffling of their feathers ensues. For the author's arguments in support of his views, our readers must be referred to the article itself.

In an account of a recent visit to Phillip Island, published in *The Victorian Naturalist* for June, Mr. J. Gabriel states that sixty species of birds were identified, of which sixteen are sea or shore species, leaving forty-four as residents on the island, an excess of eight over a previous record. Protection, it is urged, is sorely needed for the mutton-bird and the little penguin, the numbers of which are rapidly diminishing owing to incessant persecution.

BLOOD-PARASITES.[1]

YOU will remember that Mephistopheles, when he insists upon the bond with Faust being signed with blood, says, "Blut ist ein ganz besondrer Saft" ("Blood is a quite special kind of juice"). Goethe would probably not have used the word "Saft" had he been writing "Faust" to-day instead of in 1808, for at that time the cellular elements of the blood—although they had been seen and described by Leeuwenhoek in 1686—were believed to be optical illusions, even by so distinguished a person as the professor of medicine of that time at the Sorbonne. The incredulity of scientific men as to what they see is proverbial and astounding, fortunately; but it is probably because science is really quite sure of nothing that it is always advancing.

I have the privilege this evening of trying to show you the barest outlines of our present knowledge of the parasitology of the blood. It is a subject of great practical and economic importance, as many grave diseases of man and beast are caused by these parasites, which, on account of their minuteness, enormous numbers, and very complex life-histories, are very difficult to eradicate or to deal with practically. On this account there is a good deal of the enthusiasm of the market-place mixed up with this subject, which, although a new one, has advanced with great rapidity, and has revolutionised pathology, and medicine so far as possible. From our point of view it began in 1880 with the discovery by Laveran, in the military hospital of Constantine, of the parasite which causes malaria. This caused the protozoa, to which order most of these parasites belong, to oust bacteria from the proud position they then occupied of being the cause of all the ills we have to bear, and to reign in their stead; not an altogether desirable change; for when you have seen what I shall show you, you will agree with me that sufficient unto life is the evil thereof. It has had all the disadvantages of a new subject, and since that time floods of work have been poured into journals, annals, proceedings, &c., some of it of the best, with much of it that is indifferent, temporary, and bad; so that at times it seems as if this branch of science were in danger of being smothered in the dust of its own workshop, or drowned in the waters of its own activity. We do not, nowadays, keep our ideas and scraps of work to ourselves until they are either established, or, as is more likely, dissipated, so we have a huge mass of what is called "literature," filled with many trivial, fragmentary, and doubtful generalisations, many of which we have with pain and trouble to sweep into the dust-bin: nature's blessed mortmain law taking too long to act. You remember Carlyle complained—to use a mild term—of Poggendorff's *Annalen*, and I feel sure that, if he had had to study blood-parasites now, he would have said that it was a much over be-Poggendorffed subject. Blood-parasites are afflicted, too, with terrible names, and with large numbers of them; some have as many as ten or even fifteen different names, perhaps on the Socratic principle, that naming saves so much thinking. And they are in Latin, too, so that the terminology of this subject is a perfect museum of long Latin and hybrid-Latin names. The terminology generally of our later biology is, as one has said, "the Scylla's cave which men of science are preparing for themselves, to be able to pounce out upon us from it, and into which we cannot enter." This will be my excuse if I should use words you do not understand.

I will just remind you of the structure of the blood, that it consists of an extraordinarily complex fluid—

[1] Abstract of a discourse delivered at the Royal Institution on Friday, May 2, by Mr. H. G. Plimmer, F.R.S.

the plasma—which holds in suspension living cellular bodies, called cells or corpuscles. These are of two kinds, red and white corpuscles. The red are by far the more numerous, and in man there are about 5,000,000 of them to a cubic millimetre of blood, but this number varies enormously under the influence of parasites. To these red corpuscles is due the red colour of the blood, and they are the carriers of oxygen, acquired by the aëration of the blood in the lungs, to the tissues. We breathe in order that they may breathe, for we only care about oxygen in so far as they care about it.

The other kind of corpuscles are the white, or leucocytes, and of these in health there are about 7500 per cubic millimetre. A few years ago it was enough to know that there were red and white corpuscles, but now we have to know more. Through the work of Ehrlich we know that there are at least five different kinds of leucocytes in normal blood, which I will just indicate to you.

(1) Lymphocytes.—These are the smallest cells, and contain a relatively very large nucleus.

(2) Large Mononuclears.—These are large, and are called macrophages, as they possess the power of being able to absorb and digest parasites and other foreign bodies.

(3) Polynuclears.—These are characterised by the irregular, moniliform aspect of their nucleus, and they are called microphages for the same reason that the large mononuclears are called macrophages. Both of these are also called generally, phagocytes, on account of their power of ingesting and digesting foreign bodies.

(4) Eosinophiles.—These are characterised by a bilobed nucleus, and by granulations which colour deeply with eosin and other acid colours.

(5) Labrocytes or Mastzellen.—These are rare, and are characterised by large granulations which stain with basic colours.

In parasitic diseases these corpuscles are profoundly modified and altered, numerically and morphologically, and other new elements may make their appearance in the blood.

The blood is essentially the same in all animals, but it varies within certain limits. For instance, the red corpuscles are not of the same size and shape in every animal, and in birds and fishes they are nucleated; in us they are only nucleated in fœtal life and in disease. The mononuclear and polynuclear leucocytes are really separate organisms living in us, and they have qualities which it is very difficult to call anything else but consciousness; so that it is a subtle distinction to draw the line between the parasites—which these leucocytes are, in a way—which are part of us, and those that are not. When the balance of power is well preserved amongst our leucocytes, when they are working well together, then all is well with us; if we are ill, it is because they are quarrelling with themselves or with an invader, and we send for Sir Almroth Wright to pacify or chastise them with his vaccines.

So that, as Darwin said: "An organic being is a microcosm, a little universe, formed of a host of self-propagating organisms, inconceivably minute and numerous as the stars in heaven"—as we ourselves are but parts of life at large.

The three main functions of the blood are: that it is a means of respiration, a means of nutrition, and a defence against invading organisms.

And now to these latter. A blood-parasite proper is a living being, vegetable or animal, passing part or the whole of its existence in the blood of another living being, upon which it lives, this being obligatory and necessary to its life-cycle.

It was in 1841 that the first blood-parasite was seen by Valentin in the blood of a fish, and two years later Gruby gave the name trypanosoma to an organism he found in the blood of a frog. But since Laveran's discovery of the malarial parasite in 1880, we have learnt to differentiate many other parasites as causal agents of such diseases as I shall mention later in connection with the various parasites. But we know as yet dangerously little about most of them, so that we have strenuously to resist the temptation to make our account of them sound too harmonious, before we have found half the notes of the chord we are trying to play. We speak, as it were, with authorised uncertainty, and there are parts of our science which, after all, are only expressions for our ignorance of our own ignorance. These parasites have a very complicated life-history; part of their life-cycle is passed in the blood of man or beast, and part in various parts of the body of some blood-sucking invertebrate, such as a fly, mosquito, or tick, which transfers the parasite to another animal whilst feeding from him. It was thought formerly that blood-parasites would be a restricted order, but the work of recent years has shown that they have an enormous distribution both geographically and as regards their hosts. For instance, during the last five years I have had the opportunity of examining all the animals (in the large sense of the word) which have died in the Zoological Gardens. I have examined the blood of more than 8000 animals, coming from all parts of the world, and I have found parasites in the blood of 587 of them, that is in about 7 per cent., and in 295 species of animals I have found them for the first time. I mention this just to give you some numerical idea of their occurrence and distribution.

It will be better to take first those parasites which live in the plasma, and then those that live in the corpuscles, rather than to attempt to take them in their, at present rather uncertain, biological order; and I will begin at the bottom, biologically speaking, that is with the bacteria which are plants. These only require mention, since they do not live in the blood as parasites proper, but only as accidental parasites—that is, parasitism is not necessary to their life-cycle; they get into the blood in the later, or in certain, stages of certain diseases.

An example is the blood of a Senegal turtle-dove which died in twenty-six hours from fowl cholera. This bacillus was discovered by Pasteur, and is interesting, as it was his work upon it which led to his discovery of the attentuation of a virus, and of its transformation thereby into a protective vaccine.

The first parasites proper I shall mention are the Spirochetes. These have at present rather an insecure position in our idea of nature; they were formerly classed close to the bacteria, but now they are placed tentatively among animals, and they are not yet quite sure of their place. But they, nevertheless, although insecure of their place in the books, produce grave diseases, such as relapsing fever, tick fever of man, the spirochetoses of horses, oxen, and birds, syphilis, and yaws. They, with the exception of the last two, are carried by, and developed in, ticks and bugs; and in tick fever the parasite is also found in the nymph form of the tick, and this is one of the rare instances of heredity of a parasite.

The spirochete of relapsing fever in man was discovered by Obermeier in 1868, and he died from inoculating himself with the blood of a patient with the disease. He was one of the first scientific martyrs; he established our knowledge of the cause of this disease at the expense of his own life.

We will now take a long jump to the Filariæ. These are nematode worms, the embryo forms of which live in the blood; the parent forms, being too large to get through the capillaries, live in many other parts of the body. The larval form lives in the body of some invertebrate—in a few known cases in a mosquito, or in a crustacean. The microfilariæ were discovered by Demarquay in 1863. Many of them show a remarkable periodicity, some appearing in the blood at an exact hour at night, and some in the day, for which phenomenon there is at present no satisfactory explanation.

Some are short, and some long, and some are encapsuled, others not. Filariæ cause various diseases, probably elephantiasis, and certainly enormous varicosities of the lymphatics, chyluria, chylous dropsy, Calabar swelling, and certain tumours.

We now come to the trypanosomes. They are flagellated organisms, which are the cause of many deadly diseases in men and animals, such as sleeping sickness, nagana (or tsetse-fly disease), surra, mal-de-caderas, dourine, and others. They are transferred from animal to animal by biting flies, fleas, lice, and leeches, in which the sexual part of their life-cycle takes place. The first one was seen in the blood of a frog by Gluge in 1842.

A type example is *T. lewisi* in the blood of a rat. This was discovered by Lewis in 1878, and is found in about 25–29 per cent. of wild rats. Some die, but most recover and become immune; it is a very specific parasite, and cannot be transferred to any other kind of animal.

The *T. brucei*, causing nagana or tsetse-fly disease, probably exists in the wild game of South Africa, much as the *T. lewisi* does in the wild rats, but when it is carried by the tsetse-fly to domesticated animals it kills them one and all in enormous numbers.

The *T. gambiense*, which causes sleeping sickness, was first seen by Dutton in 1902, and is carried by another species of tsetse-fly.

Nature attempts to fight against these invaders by phagocytosis. The parasites, however, multiply so rapidly that this method of attack is not very effectual; it can only be so in very early infections, and probably it then often is, that is, before the parasite has had time to start dividing. At the present time the question of trypanosomosis amongst man and animals is, for many countries which have colonies, of the greatest economic importance, so that a great deal of work has been done in the attempt to find a cure. A great many drugs, new and old, have been tried, and some good has been done. The first drug which was found to be of service was arsenic, first in simple and then in complex combination, and the subcommittee of the Royal Society, formed for the purpose of supervising experiments in this direction, suggested the trial of antimony in these diseases, on account of its near chemical relationship to arsenic.

This has given better results than arsenic, and a commission is at present at work in Africa, in the Lado district, trying its effects on a large scale. We found that the salts of antimony were too rapidly eliminated from the body to be successful in the larger animals and man, and so we devised a very finely divided form of the metal itself which we put directly into the circulation, and this has given, so far, the best results. The leucocytes eat it up and transform it slowly into some soluble form, taking, in a horse, for instance, four days to dispose of one dose, and the effect of this is much more profound and lasting than that of the salts. But some trypanosomes always escape, since one dose is never sufficient for cure. In rats with nagana, in which the trypanosomes by the fifth and sixth day may number 3,000,000 per cubic millimetre of blood, the minimum number of doses for cure has been found to be four, and with this dosage it is possible to cure 100 per cent. of rats. So there is still some hope.

It is interesting in this connection to remember what Bacon, whose death, you know, was due to an experiment he undertook to prove the preservative action of intense cold upon animal bodies, says, "Laying aside therefore all fantastic notions concerning them, I fully believe, that if something could be infused in very small portions into the whole substance of blood . . . it would stop not only all putrefaction, but arefaction likewise, and be very effectual in prolonging life." His vision was prophetic!

The bird trypanosomes are very much larger than the mammalian variety, are very dense, and move much more slowly.

An example of an organism very closely allied to the trypanosomes which is found only in fishes' blood is the trypanoplasma. It has two flagella, and the micronucleus is very large. This organism is probably transferred by leeches, but very little is yet known of it.

There are other flagellated organisms which may appear in the blood and live there as accidental parasites. There is a kind of inflammation of the intestines in reptiles (in the large sense) which causes the mucosa of the intestine to become permeable, so that some of the organisms which live in the intestine are able to get into the blood and live there. The only mention of these organisms in the blood is by Danilewsky, who in 1889 found hexamitus in the blood of a frog and tortoise. When in the blood they appear to excite a general œdema and ascites. I have found them now in nine cases. These are interesting as showing the power of adaptation to new surroundings possessed by these parasites.

I now come to the intracellular parasites.

Schaudinn thought that the bird trypanosomes had an intracellular stage, and if this were so they would form a bridge between the extra-cellular parasites, of which I have shown you types, and the intracellular parasites we are about to consider. But Schaudinn seemed, with his very brilliant attainments, to want a little more ballast of medical earth-knowledge. His work on this point has not been confirmed, and he was probably misled by a double, or even treble infection, so that we must think of these intracellular parasites as quite distinct from the others.

I will take first the *Plasmodium praecox*, the cause of the malaria in birds, as this parasite is of great historical interest; for it was Ross's work on this organism and his discovery of the rest of its life-cycle in the mosquito, which enabled him—on account of the great likeness between this and the parasite causing human malaria—to deduce from the one the etiology of the other, which was confirmed by Grassi and others. The *Plasmodium praecox* is, in many stages, so like human malaria that it can only be differentiated by the presence of the oval nucleus of the bird's red corpuscles. The life-cycle is very complex, part taking place in the blood of the bird, and another part (sexual reproduction) in the body of a mosquito. This parasite was first seen by Grassi in 1890; it is very widely distributed, and is very deadly to birds.

Human malaria has been known for centuries. Varro, who knew a good deal about what we should now call hygiene, more than a century B.C., thought that malarial fevers were due to invisible animals, which entered the body with the air in breathing, and Vitruvius, Columellus, and Paladius were of the same opinion. Now we know that the mosquito is again the carrier, and that the sexual part of the parasite's cycle takes place in it, but whether the mosquito alone can account for all the phenomena of malaria is not yet quite certain.

There are three varieties of malaria in man—the tertian, quartan, and quotidian; in the tertian the cycle of the parasite in the body takes forty-eight hours, and in quartan seventy-two hours, and in pernicious malaria the fever is very irregular, but continuous. Whether there are three different parasites, or only one, which is altered according to its environment of host, climate, &c., is still apparently uncertain. Laveran and Metchnikoff believe in the specific unity of the parasite, whereas some observers want as many as five different species.

Just as in human malaria the pernicious form is distinguished by the elongated form of its gametes, so in birds there is a parasite which is distinguished, in the same way, from *Plasmodium praecox* by its very elongated gametes. This parasite is called *Haemoproteus danilewski*. Its development is unknown; it begins as a tiny, irregular body in the red corpuscles of the bird, then it grows in the long axis of the cell and turns round the end of the nucleus. It is possible in these parasites to follow the process of impregnation, which normally takes place in some insect. By taking the blood when full of the long, fully-grown gametocytes, and keeping it for a time outside the body, this process can be followed.

First of all, the gametocytes escape from the blood-corpuscles and roll themselves up into a ball. Some of these remain quiet—the females, curiously, the macrogametocytes—whilst in the microgametocytes active movements are seen; then tailed processes are seen projecting from its surface, which at last get free and wander about in the blood, this constituting the origin of the microgametes from the microgametocyte. They then find a macrogamete, and penetrate into it and fertilise it. This fertilised macrogamete then alters its shape and becomes an oökinete, with the remains attached containing the pigment. It may enter a red corpuscle, but it usually breaks up, because it finds it is not in the stomach of the insect it intended to be in, but between two pieces of glass.

From Hæmoproteus it is easy to pass to a rare and undetermined parasite of the blood of birds called a Leucocytozoon. It occurs in the blood in the form of a long, spindle-shaped, unpigmented body. Very little is known of it except that it is found in its sexual forms. The earliest observers of this parasite—Danilewsky and Ziemann—believed the host-cell to be a leucocyte (hence the name), but Laveran has shown that it is a red corpuscle.

We now come to a group of parasites of great practical importance, the Babesias, formerly called Piroplasma, which are the cause of Texas fever or red-water fever, malignant jaundice, East Coast fever, and biliary fever amongst domestic animals. We know, again, little that is certain concerning this group, except that they are unpigmented parasites of the red corpuscles, and are carried by ticks. They are the most destructive to the blood of any we know. In an ox, I have seen the red corpuscles decrease from 8,000,000—the normal—to 56,000 per cubic millimetre in two days.

Another important group, the Leishmania, is still uncertain of its exact position. In the body they occur as small bodies with a nucleus and micronucleus, but when cultivated on artificial media they become flagellated organisms of herpetotomas type. It is not quite certain what insect plays the part of carrier, but the different varieties of this group cause the diseases known as Kala Azar or tropical splenomegaly, Oriental sore, Delhi boil, Biskra boil, &c., and also infantile splenic anæmia.

The last class are the Hæmogregarines. These are parasites of the red corpuscles of reptiles principally, but they have been described in mammals and birds. We only know certain stages of the greater part of them; they are large, sausage-shaped bodies, not pigmented, and they are supposed to be carried by leeches, ticks, lice, and fleas. They generally have a capsule. In some instances the host-cell is enormously enlarged and entirely dehæmoglobinised, but in most cases the host-cell is not enlarged.

I have now taken you over some examples of all the known types of blood-parasites, but, at best, the picture in your minds must be like that of a landscape taken from a railway carriage at full speed; and the result, I fear, only a kind of clarified confusion, but it will be something if I have succeeded in making it transparent at the edges. What must have struck you most is the smallness of our exact knowledge of many of these extraordinary organisms and the gaps that there are even in this. But the incitement to future work lies in this fact, for

"Things won are done, joy's soul lies in the doing."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

At University College, Reading, Mr. S. B. McLaren, assistant lecturer in mathematics at Birmingham University, has been appointed professor of mathematics, and Mr. R. C. McLean lecturer in botany.

An article dealing with the number of students at German universities during the session 1912–13 is contributed by Prof. Rudolf Tombo, junior, of Columbia University, to the issue of *Science* for July 18. The total number of matriculated students was 58,844, and, including auditors, the total reached 64,590. Of the matriculated students 3213 were women, of whom 904 attended the University of Berlin. Of the male matriculated students 26,988 were studying philosophy in the various universities. The largest number of matriculated students, namely 9806, was enrolled at Berlin. The Universities of Munich and Leipzig had 6759 and 5351 students respectively, and Bonn 4179. There were sixteen other universities with from one to three thousand matriculated students. The largest enrolment of foreign students was found at Berlin, where there were 1605, while Leipzig, Munich, Halle, Heidelberg, and Königsberg had numbers from 784 in the first to 244 in the last-mentioned case. Altogether there were 5193 matriculated foreigners enrolled at the German universities; of these 4648 were from Europe, 338 from America, 184 from Asia, twenty-two from Africa, and one from Australia. Of the European countries, Russia had the largest number of students, 2840, Austria had 900, Switzerland 340, and Great Britain 145.

The following announcements relating to the Imperial College of Science and Technology, South Kensington, have reached us:—Mr. Otto Beit has announced his intention to found three fellowships for scientific research to be held at the college. Mr. Beit's intention in founding these fellowships is to foster only the highest research. The fellowships will be limited to Europeans, men or women, who have graduated at universities in the British Islands, Colonies, and Dominions, or are recognised by the trustees to be of the same standing. The annual value of each fellowship is not to exceed 150*l*.—Prof. S. M. Dixon, professor of civil engineering at the University of Birmingham, has been appointed to the new chair in civil engineering in the City and Guilds (Engineering) College. The department in the City and Guilds (Engineering) College which has hitherto covered the subjects of civil and mechanical engineering will next session be divided into two departments, one dealing with mechanical engineering and motive power, under Prof. Dalby, and the other with civil engineering, including theory of structures, hydraulics and hydraulic machinery, ferro-concrete construction, docks, water supply, and surveying, under Prof.

Dixon.—Prof. H. C. H. Carpenter, professor of metallurgy in the Victoria University of Manchester, has been appointed to the chair of metallurgy in the Royal School of Mines. Mr. S. J. Truscott has been appointed assistant professor of mining. These changes form part of a complete scheme of staff and curriculum reorganisation in the Royal School of Mines now being carried out. The work of the school will be transferred in October to the commodious pile of buildings now approaching completion in Prince Consort Road, South Kensington.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 21.—M. F. Guyon in the chair.—B. **Baillaud,** as president of the Bureau des Longitudes, presented the results obtained by the French committee charged with the execution of the preliminary operations relating to the measurement by wireless telegraphy of the difference of longitude between Paris and Washington, made under the direction of MM. Renaud and Bourgeois. The preliminary results include the determination of the time of transmission of the signals between the Eiffel Tower and Arlington (6175 kilometres), 0·0315 second, and the differences of longitude and colatitudes observed by the observers attached to the French Navy and Army independently. The signals emitted by Paris were received at Arlington with a sufficient intensity to be registered photographically.—J. **Boussinesq**: A new demonstration of the formula of surface potential energy in perfect liquids.—Armand **Gautier** and P. **Clausmann**: A remarkable condition of the attack of quartz by gaseous hydrofluoric acid. It had been noticed in some work on the determination of fluorine that quartz was scarcely attacked by quantities of hydrofluoric acid a hundred times greater than the amount giving a good etching on glass. It has now been found that the position of the surface of quartz under attack by the acid with respect to the axis of the crystal causes large variation in the amount of corrosion produced. Taking the attack of glass as 1000, that of fused quartz is about 100; quartz cut parallel to the axis is 11, cut perpendicular to the axis about 1.—A. **Haller**: The production of tetra-alkyl derivaties of the α or 1-methyl*cyclo*hexanone.—G. **Gouy**: The conditions of equilibrium of the solar atmosphere with respect to the repulsive force of radiation.—Magnus de **Sparre** was elected a correspondant of the academy for the section of mechanics in the place of M. Bazin, elected non-resident member.—René **Baillaud**: A new method of determining the horizontal flexure of meridian instruments.—M. **Fessenkoff**: Photometric observations on the zodiacal light.—F. S. **Zarlatti**: Some singular integral equations.—J. A. Le **Bel**: The catathermic radiation.—V. **Schaffers**: Electrical conduction in cylindrical fields under atmospheric pressure.—MM. **Massol** and **Faucon**: Absorption of the ultra-violet radiations by some organic colouring matters in aqueous solution.—H. **Gaudechon**: The relation between the thermal effect accompanying the immersion of dry powders in liquids and the aptitude of the latter to form associated molecules. Dried clay, starch, silica, and charcoal on addition to water or various organic liquids give off a certain amount of heat. This has been determined, and it is shown that with normal, non-associated liquids the temperature rise is very small; with associated liquids the heat evolution is greater.—Gabriel **Bertrand** and G. **Weisweiller**: The composition of coffee extract: the presence of pyridine. Amongst the products of coffee infusion to which the aroma is due pyridine has been found, and in a proportion greater than any other volatile constituent. The possibility of this base playing an appreciable part in the physiological action of coffee is discussed.—A. **Damiens**: Study of the action of water on the carbides of the rare earths. The carbides of cerium, lanthanum, neodymium, praseodymium, and samarium were studied, the hydrocarbons being analysed by the method recently described by Lebeau and Damiens. The primary reaction between the water and carbide is—

$$C_2M + 3H_2O = M(OH)_3 + C_2H_2 + H_2.$$

Ethylene and ethane are formed by the interaction of some of the hydrogen and acetylene, but no trace of methane is found.—J. **Clarens**: The spontaneous transformation of hypochlorites into chlorates and of hypobromites into bromates.—A. **Mailhe**: The catalytic preparation of the ketones with oxide of iron. At temperatures between 430° and 490° C. in presence of oxide of iron vapours of the fatty acids are catalytically converted into ketones, carbon dioxide and hydrogen being simultaneously evolved. Mixtures of benzoic acid with fatty acids give good yields of the mixed ketones. The worst yields were obtained with *iso*valeric and *iso*butyric acids.—H. **Giran**: Researches on sulphuric acid and sulphuric anhydride.—Paul **Lebeau** and Marius **Picon**: The action of sodammonium on phenylacetylene and styrolene. The reaction differs from that recently proved for acetylenic hydrocarbons of the fatty series, phenylacetylene giving ethylbenzene by reduction.—Jacques **Bardet**: The spectrographic study of French mineral waters. The salts from fifty-four springs have been examined using the arc spectra. Lead was found in all the samples, silver and tin in most of them. Germanium and gallium were found in a considerable number, and amongst other elements not usually mentioned as constituents of mineral waters were molybdenum, copper, antimony, cobalt, chromium, mercury, nickel, gold, thallium, vanadium, and tungsten.—M. **Gard**: The sexual elements in the vine.—Marcel **Delassus**: The influence of the partial suppression of the food reserves of the seed on the anatomy of the plant. Removal of part of the reserves of the seed results in development on a reduced scale, the differentiation of the tissues is retarded, and the number of fibro-ligneous bundles of the stem is diminished.—**Audebeau** Bey: The permeability of Egyptian soils.—J. **Winter**: The total volume of the gastric juice secreted during digestion.—G. **Bourguignon** and H. **Laugier**: The apparent differences of polar action and localisation of the stimulation on closing the circuit in Thomsen's disease.—Miromond de **Laroquette**: A new method for discovering foreign bodies in the tissues. The apparatus described is simple to use, and permits of the discovery of the exact position of the foreign body in less than one hour.—M. **Gerber**: The identity between the rennet, casease, and trypsin of one and the same latex. The existence of two types of proteolytic plant ferments.—Pierre **Thomas** and Mme. Sophie **Kolodziejska**: The proteid substances of yeast and their products of hydrolysis.—H. **Bierry** and Mlle. F. **Coupin**: *Sterigmatocystis nigra* and lactose.

NEW SOUTH WALES.

Linnean Society, May 28.—Mr. W. S. Dun, president, in the chair.—Dr. A. Jefferis **Turner**: Studies on Australian Micro-Lepidoptera. This contribution is intended to be a supplement to Mr. Meyrick's revisional paper on the Plutellidæ (Proceedings of the Linnean Society of New South Wales, 1907, p. 47). Additional localities for known species are given, and a number of species are described as new.—R. J. **Tillyard**: Some descriptions of new forms of Australian Odonata. This paper adds four new species, three new subspecies, and the hitherto unknown female of *Diphlebia hybridoïdes*, Tillyard, to the list of Australian Odonata.—H. **Maiden** and E. **Betche**: Notes from the Botanic Gardens, Sydney. No. 18. Seven new species are proposed. Notes on proposed new varieties, plants new for New South Wales, and plants with interesting new localities are given.—Mr. **Tillyard**: Study of zoo-geographical distribution by means of specific contours. In this method, instead of attempting to subdivide the recognised zoo-geographical regions into distinctly marked-off sub-regions and lower divisions, it is proposed to study the various groups of plants or animals occurring over the whole region, by constructing "specific contours" by the following rules:—(1) The group selected must be a *natural* group, *i.e.* a genus, tribe, or family which forms a homogeneous whole, and not merely a group separated off for convenience of classification. (2) The records available must be sufficiently numerous to give the *general form of the contour*, but absolute accuracy is neither attainable (without infinite labour) nor necessary. (3) Each species of the selected group is reckoned as a unit. On the map of the region under study, against each locality which has been "worked," the number of units occurring there is to be put down. Then contour lines, in the form of free curves, are to be drawn so that all localities having an equal number of units shall be between any two successive contour lines.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye"—WORDSWORTH

No. 2284, VOL. 91] THURSDAY, AUGUST 7, 1913 [PRICE SIXPENCE

Registered as a Newspaper at the General Post Office.]

THURSDAY, AUGUST 7, 1913.

MANIHOT RUBBER.

Der Manihot-Kautschuk. Seine Kultur, Gewinnung und Präparation. By Prof. A. Zimmermann. Pp. ix+342. (Jena: Gustav Fischer, 1913.) Price 9 marks.

THE subject of rubber cultivation is one which has received much attention during recent years. Hitherto the Middle East has confined its attention almost entirely to the cultivation of *Hevea brasiliensis*, rather than that of Manihot, which is the subject of Dr. Zimmermann's book. Manihot is not regarded in the Middle East as being so profitable to cultivate as *Hevea brasiliensis*, but it certainly takes a very high place among the arborescent forms of rubber-yielding plants in virtue of its rapid rate of growth, its hardy characteristics, and quality of rubber.

Four species are dealt with by the author, viz., *Manihot Glaziovii*, Müll. Arg.; *M. dichotoma*, Ule; *M. piauhyensis*, Ule; *M. heptaphylla*. The first species is that which has been most largely distributed throughout the tropics, and is the source of "Ceara" rubber of commerce. The other species have only recently come into prominence, mainly as the result of the work of Dr. Ule in tropical America.

A full description is given in chapter ii. of these species and their natural habitats. The cultivation in different countries, the variability of the plant, its anatomy, morphology, and diseases of various parts are also dealt with. An interesting diagram is shown, giving a good idea of the distribution of the bands of laticiferous tissue. A transverse section through the cortex and bark of *Manihot Glaziovii* shows the connected tangential bands of laticifers near the cambium being broken up as one passes outwards; in fact, from this transverse section one would be inclined to infer that if the tapping instrument was pressed deep enough it would, on every occasion (except where it touched a medullary ray), puncture a laticiferous vessel, and thus give rise to an exudation of latex.

An instructive chapter deals with the various methods of tapping, and a series of diagrams showing the half spiral, half herring-bone, full herring-bone, full spiral, and "V" tapping is given. Some of the tapping implements depicted are somewhat out of date, but will prove of interest to the general reader. Various systems of tapping, including pricking and vertical incisions, are very well illustrated.

The last six chapters of the book (xvi. to xxi.) deal with the general research which has been done in connection with rubber, and go somewhat deeply into the problem of tackiness, colour, and preparation of rubber. Even an account is given of the proceeds and revenue from plantations, and of the further uses of rubber trees. The book therefore covers a very wide field, and should prove of great interest to all connected with the rubber industry. Dr. Zimmermann's book will probably stand out for some time as one of the best on species of Manihot.

H. W.

COMPARATIVE ANATOMY.

Vorlesungen über vergleichende Anatomie. By Prof. Otto Bütschli. 2. Lieferung: Allgemeine Körper- und Bewegungsmuskulatur; Elektrische Organe und Nervensystem. Pp. iv+401—644. (Leipzig: W. Engelmann, 1912.) Price 9 marks.

THE first volume of these lectures was reviewed in NATURE in July, 1911, and attention was directed to the comprehensive scope of the work, the lucidity of exposition, and the excellence of the simple semi-diagrammatic illustrations. These qualities are fully maintained in the second volume, which deals with the muscular and nervous systems.

In a work covering such an extensive field of investigation it is quite impossible for one man to acquire a first-hand knowledge of all the material of which he treats, or even to do more than sample the voluminous flood of literature dealing with all the subjects discussed in such lectures as these. In such circumstances it would be easy for the specialist in any one branch of research to criticise the facts and inferences, and in many cases also the choice of interpretations borrowed from other writers. But such defects, which are, of course, inevitable, are more than compensated by the broad, well-balanced, and consistent view the general reader obtains when one competent writer surveys the whole subject.

In recent years intensive specialisation has made most of our text-books a badly-fitted patchwork of the scraps of knowledge which a host of authors has garnered, each in his own patch of cultivation; and most students and teachers have become only too familiar with the ill-jointed and distorted ideas such books convey. In studying such lectures as Bütschli's, even if one admits that the detailed information may not be as accurate as can be obtained in the patchwork type of book by several authors, the reader gets a truer perspective, and sees the facts blended into a picture which, on the whole, is a closer representation of the facts of nature than a collection of more accurate scraps of knowledge not properly assimilated one to the other can possibly be. Those biologists who find it a matter of the utmost difficulty to keep abreast of the growth of knowledge in one small corner of the vast field of comparative anatomy can alone appreciate the magnitude of the task Prof. Bütschli has accomplished in these volumes. For a man who has built up a deservedly great reputation by original investigation in the domain of protozoology to write the best comparative anatomy of the Vertebrates is surely an achievement that is not likely to be repeated.

G. E. S.

RESUSCITATION.

Resuscitation from Electric Shock, Traumatic Shock, Drowning, Asphyxiation from any cause by means of Artificial Respiration by the Prone Pressure (Schaefer) Method. By Dr. C. A. Lauffer. Pp. v+47. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1913.) Price 2s. net.

IN this little book of forty-seven pages Dr. Lauffer, the medical director of the Westinghouse Electric and Manufacturing Company, East Pittsburg, deals with the subject of artificial respiration as applied to resuscitation in electric shock. Dr. Lauffer is an enthusiastic advocate of the prone pressure (Schaefer) method of resuscitation, and his enthusiasm appears to be based upon considerable experience. He narrates several cases which have come under his immediate notice in which it has been successfully employed: one of concussion of the brain, with unconsciousness and failure both of heart and respiration, requiring an hour's application of the method: two severe cases of electric shock; one of suffocation from smoke, in which life appeared to be extinct; one of an injury to the head, in which respiration was completely arrested and the patient would have died but for the prompt assistance of artificial respiration on the part of one of the men whom he had instructed who happened to be present; and one of drowning. In addition to these cases, he states that he knows a man who has resuscitated six victims of electric shock, all of which cases would have been fatal but for his prompt and efficient efforts at artificial respiration. The author adds, "This man is an enthusiastic advocate of the prone pressure method."

Dr. Lauffer does not, it will be seen, confine himself to those cases in which he is more immediately interested, but has carried on his observations on cases of asphyxia from whatever cause. He points out the various circumstances in which artificial respiration may be necessary, including asphyxia arising from poisoning from carbon monoxide, ammonia fumes, gasoline fumes, sewer gas, suffocation by smoke, inhalation of confined air, inhalations of chloroform and ether, overdoses of laudanum, shock from a heavy blow on the abdomen, and apparent death from drowning. He explains the process of respiration, and gives a clear account of the manner in which artificial respiration should be performed. He especially emphasises the fact that by the prone pressure method resuscitation can easily be carried out by a single individual and without the aid of any extraneous apparatus; even if the operator be a mere boy and the victim an adult, the boy can utilise more than 80 per cent. of his weight by raising his knees from the ground and supporting himself entirely on his toes and the heels of his hands, the latter being properly placed over the floating ribs of the patient. He might perhaps have added that if the boy were to kneel directly upon the back of the patient, an even larger proportion of the operator's weight might be utilised.

Dr. Lauffer has never seen a case of fracture of the ribs or any damage to internal organs arise from the prone pressure method. He considers that the teaching of the subject should be made a part of every gymnastic course, especially in college and Y.M.C.A. gymnasiums and in Boy Scout organisations (which we believe is already the case in this country); he states that it is employed in the United States Army as part of the setting-up exercises.

The author further deals with the question of supplementary assistance which might be rendered if there is any second person to assist, but rightly points out that nothing must be allowed to interfere with the immediate application of artificial respiration, nor should this be desisted from nor the patient permitted to get up until his breathing has become regular. Dealing with the question of mechanical assistance, whilst not averse to the employment of any such assistance if it is immediately available, he points out that extravagant claims are made for various mechanical devices, and that, since such devices may be too remote, or when procured may be out of order, he concludes that there is nothing so dependable as the hands of a man's friends, and that no reliance can be placed on any outfit that cannot be carried with every electrical workman and which is not instantly available.

We commend Dr. Lauffer's little book to all who are interested in the subject.

MATHEMATICAL TEXT-BOOKS.

(1) *A School Algebra.* By F. O. Lane and J. A. C. Lane. Pp. viii+333. (London: Edward Arnold, n.d.) Price 3s. 6d.

(2) *A Treatise on Hydromechanics.* Part ii. Hydrodynamics. By A. S. Ramsey. Pp. xiii+360. (London: G. Bell and Sons., Ltd., 1913.)

(3) *Les Appareils d'Intégration.* By H. de Morin. Pp. 208. (Paris: Gauthier-Villars, 1913.) Price 5 francs.

(4) *Einführung in die höhere Mathematik für Naturforscher und Aerzte.* By Dr. J. Salpeter. Pp. xii+336. (Jena: Gustav Fischer, 1913.) Price 12 marks.

(5) *Elements of the Precision of Measurements and Graphical Methods.* By Prof. H. M. Goodwin. Pp. 104. (London: Hill Publishing Co., Ltd.; New York: McGraw-Hill Book Co., 1913.)

(6) *Matrices and Determinoids.* By Prof. C. E. Cullis. Vol. i. Pp. xii+430. (Cambridge University Press, 1913.) Price 21s. net.

(1) MESSRS. LANE'S "Algebra" looks as if it would prove a useful school-book. In dealing with the binomial and exponential series the authors state certain properties, with the explicit warning that they are not proving them. This is as it should be; but the chapter on exponentials and logarithms is not so clear as it might be; in particular, Arts. 135-7 would be better if arranged in the reverse order. In the earlier pages we have the old fallacious and meaningless statement: "to multiply a number a by a second number b, we do to a what is done to the unit to obtain b." It would be much better to give the rule of signs as a rule pure and simple, and then to show by cases of $(a-b)(c-d)$ that it does actually work out in practice. There are hundreds of examples—some, alas, of a highly artificial character; for instance, "If the hypotenuse of a right-angled triangle is x, and the other sides are y and z units of length, show that

$$1/\log_{x+z}y+1/\log_{x-z}y=2,"$$

or, again:

"Multiply $3\sqrt{xy^3}-xy+2\sqrt{y^5x^{-1}}$ by $\sqrt{x^3y}-2\sqrt{xy^3}$."

The most interesting chapters in the book are those on simultaneous equations, which are illustrated by appropriate graphs.

(2) Mr. Ramsey's "Hydrodynamics" is a treatise specially suited for university candidates, and as such may be highly praised for its clearness, elegance, and helpfulness. The chapter on discontinuous motion is exceptionally good, the cases discussed being worked out in unusual detail. The book includes a chapter on vibrations of strings, and one on sound waves; there is a large number of excellent examples, with their sources indicated; and sufficient references are given to original memoirs. As a text-book for capable students, Mr. Ramsey's work will be very hard to improve upon, and is certain to have a favourable reception.

(3) Mr. de Morin describes various kinds of planimeters, integrometers, integraphs, harmonic analysers, and compound integrators. We have summaries of the mathematical theories involved, diagrams of the mechanisms, and pictures of the different machines that have actually been constructed. No written account can be equivalent to inspection and use of the machines themselves; allowing for this fact, the author seems to have done all that could be expected. By the way, we wonder what the author of "Erewhon" would have said if he had been shown machines for doing sums, and predicting tides, and calculating moments of inertia.

(4) Dr. Salpeter's work is chiefly interesting as an example of a course in higher mathematics for medical men and men of science drawn up by an author acquainted more or less with modern pure mathematics. As might be expected, he appeals mainly to intuition; but he gives a whole introductory chapter to the notion of a limit, he proves $\partial^2z/\partial x\partial y=\partial^2z/\partial y\partial x$, when it can be proved, by the mean value theorem, and gives in an appendix some examples of discontinuous functions. For some reason, not apparent, there is a chapter on the second law of thermodynamics; in other respects the scope of the book is not of an unfamiliar kind; we have differential and integral calculus treated separately, then ordinary differential equations of the second order, and then some easy cases of definite integration. Naturally, many of the examples are chosen to illustrate physical or chemical formulæ.

(5) Dr. Goodwin's work is based on a course given by him for years past in the Massachusetts Institute of Technology. The sort of problem he deals with is such as: "Calculating g from π^2l/t^2, how closely should l, t be measured, so that the resulting value of g may be true within 0·1 per cent.?" He quotes, without proof, certain results of the theory of errors; in other respects the discussion is quite elementary, and includes a section on graphical methods. We can quite believe that a course of this kind has been of great value to the Massachusetts students; whether an actual course is given or not, laboratory students must become familiar with the connection between the probable values of their data and the probable value of their result. Dr. Goodwin gives a set of seventy-nine unsolved questions, which teachers of physics would find very useful exercises.

(6) Prof. Cullis associates with any rectangular

matrix an expression he calls its determinoid. This is, in fact, a sum of maximum determinants, taken from the matrix, with a rule of sign for each. There can be no doubt of the value of the theory of matrices, and that a good book on the subject is a desideratum. Whether the notion of a determinoid is likely to be anything like so valuable is a doubtful question, and we confess that we would rather have had a treatise on matrices alone. The present volume ends with a chapter on the solution of any system of linear equations, and to read this first of all is perhaps the best way to become favourably impressed by the treatise. The earlier chapters seem rather diffuse, and contain a large number of new technical terms, some of which, like "corranged," are not at all attractive. The next volume will contain applications to algebra and geometry, besides a discussion of matrix equations of the second degree. When this appears it will be easier to form a judgment on the work as a whole; meanwhile, we can see that it contains a great deal of valuable matter expressed in one consistent notation.

G. B. M.

OUR BOOKSHELF.

Brands Used by the Chief Camel-owning Tribes of Kordofan. (A Supplement to "The Tribes of Northern and Central Kordofan.") By H. A. MacMichael. Pp. viii + 40 + xvii plates. (Cambridge University Press, 1913.) Price 6*s.* net.

Nearly thirty years ago Robertson Smith lamented that no good collection of *wasm* (the tribal marks with which every Arab tribe brands its cattle) had been made, and now Mr. MacMichael has published as a pendant to his history of the Arab tribes of Kordofan a collection of the marks used by these tribes as camel brands. The utility of such a work to the members of the Sudan Civil Service is too obvious to need accentuation, but there is also a good deal of scientific interest attaching to it, although the writer's experience in the Sudan makes him regard it as improbable that the high hopes cherished by Robertson Smith will be realised, that such collections will enable us to trace the ancient history of the people.

No doubt each tribe, or each section of a nomad tribe, once had a distinctive brand, but it seems that in many cases this has been lost, or at least has fallen into disuse. The brands themselves are for the most part named after common objects, such as *bersham*, the "cross-hilt of a sword," and *bab*, "a door," while others derive their names from the part of the camel which is branded; thus, *bakkai*, derived from the word meaning "to weep," is applied to a linear vertical mark below the eye, because it is here that tears trickle down. Generally the brand is highly conventional and unlike the object it represents, but in a few cases, though simplified, it retains all the essentials of the original, as, *e.g.*, the *rigl el ghorab*, a "crow's-foot," used by some of the negroid "Arabs" of the northern hills.

Rainfall Reservoirs and Water Supply. By Sir A. R. Binnie. Pp. xi + 157. (London: Constable and Co., Ltd., 1913.) Price 8*s.* 6*d.* net.

In the application of exact meteorological observations to practical life, the utilisation of rainfall records by the waterworks engineer takes a foremost place. Rainfall is moreover among the most important of the natural resources of a country, and it is fitting that Sir Alexander Binnie should put together the results of his wide experience in a book which will impress the townsman with this fact in its more direct association with his daily life, in addition to giving to the engineer a survey of the problem with which he is faced, and of the methods of dealing with it.

The first chapter treats of the measurement of rainfall and the variation in amount from year to year and place to place; diagrams are given to show how the total fall increases as the ground rises, and emphasis is laid upon the fact that in a region with a prevailing wind direction the maximum rainfall frequently occurs on the lee side of the high ground. Another diagram illustrates the approach of the average annual rainfall to a normal value as the number of years increases; thus one year may be 50 per cent. above or 40 per cent. below the normal, but the average of ten years is not likely to differ by more than 10 per cent. in either direction from the normal value.

The next chapter deals with the flow from the ground, floods, and evaporation, about which our knowledge is very deficient owing to the scarcity of trustworthy records. Subsequent chapters are devoted to the methods of calculating the available supply, the construction of reservoirs, and the arrangements for conveying the water from the source and distributing it to the users. There is much that is technical naturally in these chapters, but the subject is treated in such a way that even the details are made interesting, and their importance for safety or economy is clearly shown.

E. G.

Planetologia. By Ingegnere Emilio Cortese. Pp. vii + 387. (Milan: Ulrico Hoepli, 1913.) Price 3 lire.

In view of the fact that nearly 300 pages are taken up with terrestrial phenomena, and only eighty pages are devoted to the remaining members of the solar system, the title "Planetologia" scarcely seems suitable for the present book. Perhaps the author could not think of a more suitable title.

The book contains an exposition of some of the main physical properties of the earth's crust, the age of the earth, its past geological history, the theories of tides, earthquakes, volcanoes, the origin of the earth's atmosphere, and the principal physical features of the planets and moon. As a geologist the author claims to have formed definite views of his own on these questions, differing in many respects from commonly accepted theories; but, as he points out, it would be impossible for a writer to substantiate these varied theories unless he had travelled all over the world, besides being, at the same time, a mathematician, a physicist, a chemist, an astronomer, and a geologist. Considerable attention is given to theories of the displacement of the earth's axis.

A collection of theories of this kind, if thus propounded in a proper spirit, is not only interesting, but it opens up useful material for future discussion. On the other hand, not the least important feature is the insight which the book affords the general reader of known physical facts and phenomena connected with the earth and planets.

A Manual of School Hygiene. By Prof. E. W. Hope, E. A. Browne, and Prof. C. S. Sherrington. New and Revised Edition. Pp. xii + 311. (Cambridge University Press, 1913.) Price 4s. 6d.

The first edition of this manual, which was reviewed in our issue for August 15, 1901 (vol. lxiv., p. 373), was reprinted on three occasions before the appearance of the book in its present form. Six chapters on physiology by Prof. Sherrington have here been added. They aim at emphasising the salient portions of the subject, and deal with the body considered as a mechanism, the blood and its circulation, respiration, food and digestion, the temperature of the body, and muscle and nerve.

Library Cataloguing. By J. Henry Quinn. Pp. viii + 256. (London: Truslove and Hanson, Ltd., 1913.)

Mr. Quinn's book should prove of real service as a guide for young librarians to the various codes of cataloguing rules. His bright, helpful chapters should certainly convince the beginner in library work that the office of librarian is no sinecure; and the arrangement of his matter, and the subjects chosen for treatment, should enable information on practical cataloguing to be obtained with a minimum expenditure of trouble.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Energy in Planetary Motions.

If a particle of mass m be brought from infinity to distance r by the action of a central attraction varying as the inverse square of the distance, the potential energy exhausted in the process is $m\mu/r$, where μ is the "intensity of the centre." If the particle has experienced no resistance to its motion the kinetic energy is given by the equation

$$\tfrac{1}{2}mv^2 = m\frac{\mu}{r}.$$

But if the particle be made to move in a circle of radius r about the centre of force, the speed v is given by

$$v^2 = \frac{\mu}{r};$$

and the kinetic energy $\frac{1}{2}mv^2$ represents only half the potential energy exhausted. The other half must have been dissipated or disposed of in some way or other.

Similarly, if the particle be brought in from motion in a circle of radius r' about the centre to motion in the circle of radius r, so that potential energy of amount $m\mu(1/r - 1/r')$ is exhausted, the kinetic energy has been increased by only $\frac{1}{2}m\mu(1/r - 1/r')$, so that again only half of the potential energy exhausted is represented by the orbital motion, and the remainder has been expended in doing work against resistance of some sort. The central force has, in fact, done exactly twice as much work as that represented in the increase of the kinetic energy.

All this, of course, is perfectly elementary and well known, but it is nevertheless a curious dynamical fact that exactly half of the work done by the attraction must be expended in overcoming resistance.

I have not seen the corresponding theorem in elliptic motion anywhere explicitly stated. It is as follows:—*The time-average of the kinetic energy, taken for one revolution in the orbit, is half of the corresponding time-average of the potential energy exhausted in the passage from infinity to the distance r.* A similar theorem holds, of course, for the differences of energy concerned when the particle is transferred from one orbit to another about the same centre.

Let $2a$ be the length of the major axis of the elliptic orbit. The speed v at distance r from the centre is then given by

$$\tfrac{1}{2}v^2 = \mu\left(\frac{1}{r} - \frac{1}{2a}\right),$$

which, multiplied by m, is the equation of energy. The potential energy exhausted from infinity to distance r is again $m\mu/r$, and it can easily be shown that the time-average of the kinetic energy in the orbit is $m\mu/2a$.

Parenthetically, it may be remarked that this result is most easily and elegantly established by the following Newtonian process. If when r is the distance of the particle from the centre of force (one focus of the ellipse) r' be the distance from the other focus, and p, p' be the lengths of the perpendiculars from the foci on the line of motion at the instant, we have $r/r' = p/p'$, and, therefore, since $pp' = b^2$, where b is the length of the semi-minor axis, we have $r'/r = p'^2/b^2$. But the equation for v^2 can be written

$$v^2 = \frac{\mu}{a}\frac{2a - r}{r} = \frac{\mu}{a}\frac{r'}{r}.$$

Hence integrating for a period of revolution T we get

$$\int_0^T v^2 dt = \int v ds = \frac{1}{b}\sqrt{\frac{\mu}{a}}\int p' ds,$$

where ds is an element of the path, and the integrals with respect to s are taken once round the ellipse. Now, clearly $\int p' ds$ is twice the area of the ellipse—that is, $2\pi ab$. Thus

$$\tfrac{1}{2}m\int_0^T v^2 dt = \pi m\sqrt{\mu a}.$$

The period T is $2\pi\sqrt{a^3/\mu}$, and so the mean kinetic energy is

$$\frac{\pi m\sqrt{\mu a}}{2\pi\sqrt{\frac{a^3}{\mu}}}=m\frac{\mu}{2a}.$$

If we take the time-integral of both sides of the energy equation once round the path we get the theorem of elliptic motion stated above.

It may be remarked that $2m\pi\sqrt{\mu a}$ is the *action* for one revolution of the particle in its orbit, and thus we have the curious result (already known) that the action (and therefore the mean kinetic energy) for one complete revolution in an elliptic orbit is independent of the eccentricity. If the centre of force be shifted along the major axis, so that for different orbits about the centre of force the length of the major axis remains unaltered, the period and the action remain also unchanged.

It may be noticed that the process used above shows very clearly that the area traced out by the radius vector from the "empty focus" is proportional to the *action*, for the time given by the corresponding area traced out by the radius vector from the centre of force. I observed this fact some years ago, but found that it had previously been put on record by Tait.

For a hyperbolic path round the centre of attraction the energy equation is

$$\tfrac{1}{2}mv^2=m\mu\left(\frac{1}{r}+\frac{1}{2a}\right),$$

where $2a$ is the distance between the vertices of the two branches of the hyperbola; and we see that in this case the kinetic energy at distance r *exceeds* the potential energy exhausted in the transference from infinity to that distance by the mean kinetic energy of the motion in an ellipse of semi-major axis a. Thus if a planet formed in the course of the condensation of a nebula is to have a hyperbolic orbit, it must, by an explosion of chemical energy, or by some other convulsion or process, have a quantity of kinetic energy given to it, in excess of that produced by the transference of the matter from infinite dispersion in space. In the evolution of planets according to the nebular hypothesis hyperbolic orbits would thus be exceptional cases.

It may be noted that in a certain sense $m\mu/2a$ is also the mean kinetic energy in the hyperbolic orbit. For, when r has become considerable, $\frac{1}{2}mv^2$ is sensibly equal to $m\mu/2a$, and the time for this sensibly constant value is infinite.

A. GRAY.

Boat of Garten, July 23.

"Phosphorescence" of Pennatulida.

PROF. NEWSTEAD and I have had two of the few British Pennatulida—*Pennatula phosphorea* and *Funiculina quadrangularis*—"phosphorescing" to-day before our eyes, so it may be worth recording the impressions while they are fresh. *Pennatula phosphorea*, as its name indicates, has long been known to emit light, and, writing from memory, I think Sir Wyville Thomson, in his "Depths of the Sea," refers to the "lilac phosphorescence of Pavonaria" (=Funiculina). Prof. Newstead and I have just seen the colour and distribution of the light very clearly in a makeshift dark-room (the lazarette of the yacht), and also on the deck at midnight. In Funiculina the distribution of the luminosity is very curious and quite different from that of Pennatula. There are many distinct sparkles over the polype-bearing part of the colony (corresponding, no doubt, to the individual polypes), but the long, bare lower part of the stem, 9 in. to a foot in length, when gently stroked in the dark glows with a continuous sheet of light of (it seems to me) a pale-green colour which flickers or pulsates like a lambent flame. The light on this bare part of the colony is certainly more intense than that of the polypes, and is the most brilliant "phosphorescence" I have seen in any marine animal. I have not seen Pyrosoma alive, but I imagine from the descriptions it may be even more brilliant than Funiculina.

In Pennatula, on the other hand, the light appears to be restricted to the polypes. I have not been able to excite any luminosity in the stem portion of the colony, but the illumination of the polypes is very general and beautiful—more general and more lasting than the sparkles that the polypes give in Funiculina.

Prof. Hickson, in a letter just received, asks me, if possible, to observe the phosphorescence of the other British Pennatulid, *Virgularia mirabilis*. I have not yet succeeded in dredging Virgularia here, but it ought to be found in these waters, and probably when examined alive in the dark will show some degree of phosphorescence like its two relations referred to above.

We have been able to get detailed colour notes of the living Funiculina, and some photographs of polypes extended to nearly an inch in length, which we hope may be useful.

W. A. HERDMAN.

S.Y. *Runa*, Loch Sunart, N.B., July 26.

A Red-water Phenomenon due to Euglena.

A VERY remarkable red-water phenomenon is at present observable in a small pond in Broad Oak Park, Worsley, near Manchester, just in front of the seventh tee on the golf course. The surface of the pond—at any rate at times—is covered in places with an almost blood-red scum, which seems to float on the surface film like fine dust. The scum sometimes assumes a greenish hue. Microscopical examination shows that it is due to the presence of immense numbers of a large species of Euglena, the green chlorophyll of which, as in the case of Hæmatococcus, is more or less replaced by red hæmatochrome.

On keeping some of the water and scum under observation in a soup-plate, it is seen that the organism occurs chiefly in two conditions—crawling on the bottom in an elongated form, and resting on the surface in a spherical form. It does not seem to swim freely about in the intermediate zone of water, so that the red colour is confined to the bottom and the surface, and not, as in the case of the active form of Hæmatococcus, dispersed through the water itself. Crawling seems to be effected by typical "Euglenoid" contractions, but a very long flagellum is sometimes visible at the anterior end, while the posterior extremity is formed by a sharp projection free from pigment.

Since writing the above I have been able to observe how the Euglenæ reach the surface of the water. They evidently secrete some sort of slime in which they become entangled. Bubbles of oxygen gas, given off by the Euglenæ in presence of sunlight, are also caught in this slime, and when these reach a certain size they rise to the surface, trailing strings of slime, with numerous entangled Euglenæ, after them.

ARTHUR DENDY.

University of London, King's College, July 30.

The Terrestrial Distribution of the Radio-elements.

IN my letter of June 19 I briefly outlined three arguments which consistently point to a concentration of the radio-active elements in the earth's crust, such concentration having been accomplished at the expense of the material of the interior. The first of these arguments (in which the limited distribution of the radio-elements is deduced from the earth's temperature-gradient) is made the basis of a revival of Arrhenius's view that radio-active disintegration may be inhibited under the conditions prevailing at great depths (NATURE, June 26, July 10, and July 17). Thus, in place of the deduction that the amounts of uranium and thorium existing in the earth's interior are negligible, even thermally negligible, is put forward the alternative deduction that these parent elements are not necessarily absent, but only temporarily impotent, their output of energy, by which alone we could be aware of them, being inhibited by the enormous pressures to which they are subjected.

The latter alternative is favoured by the philosophic conception embodied in Le Chatelier's law of reaction, viz. that the internal reactions within a material system are such as will tend to oppose any external influences by which its equilibrium may be disturbed. It would at once be deduced from this "law" that radio-active transformations, implying as they do an immense output of energy in the form of electronic and atomic bombardments, must be inhibited by the application of sufficiently high pressure and temperature. Under high pressures the internal reactions will tend to oppose the pressure and therefore an increase of volume, and similarly under high temperatures the internal reactions will tend against a further rise of temperature. The internal reaction is favoured which results in the absorption of energy from an external source. Hence, radio-active changes, involving increase of volume and rise of temperature, would presumably be opposed by the physical conditions of the earth's deep interior.

As yet, however, we are unable to assert whether this deduction may safely be made to the extent of assuming inhibition. Frankly, it is a step taken in the dark. The law of reaction is known to be a useful guide as regards the tendency of molecular activities; its extension to include the internal activities of atoms has yet to be demonstrated. The evidence from direct experiment is manifestly insufficient, but so far as it goes it betrays on the part of the radio-elements an astonishing disregard for all external influences. For the present, then, the problem stands unsolved, as indeed it must remain until we know more of the internal mechanism of the radio-active atom.

However, whether one favours radio-active inhibition or independence, the remaining arguments in support of a crustal concentration of radium stand unaffected. The highest concentration of the radio-elements is found in the acid rocks, which contain six times as much radium as the ultra-basic rocks. That is to say, the lighter rocks in their capacity as solvents are capable of carrying a higher proportion of the radio-elements than are the heavier rocks. It is for this reason that uranium, which is the heaviest element of all, has not gravitated to the earth's metallic core, as Dr. Schiller considers would be most probable. Further, there is clearly a marked antipathy between the radio-elements and native iron, for in all the terrestrial examples of the latter which have been examined, uranium and thorium are barely detectable. Correlating these facts with the earth's trizonal structure, we should expect an internal metallic core free, or nearly so, from the radio-elements, an intermediate zone originally poor in, and now almost devoid of, these elements, and an outer crust more richly endowed, its wealth of radium, like its wealth of silica (and perhaps of many of the metallic ores), having accumulated in the course of the earth's evolution at the expense of the more sparsely distributed internal stores.

On the parallel drawn by Daubrée and extended by Suess between iron meteorites and the earth's metallic core and between stony meteorites and the earth's intermediate ultra-basic zone, this conception receives still more convincing evidence. The stony meteorites are even more poverty-stricken in radium than the ultra-basic rocks, and the iron meteorites contain no radium whatever.

ARTHUR HOLMES.

Imperial College, London, S.W., July 18.

Area of Earth's Surface Visible at any Altitude.

IN these days of aviators and of record heights attained by them, perhaps the following rule to find the area of the earth's surface visible from a given height may be of interest. The rule depends upon the fact that if the height above a sphere is $\frac{1}{x}$th part of the sphere's diameter, then the area visible from this height is $\frac{1}{x+2}$th part of the sphere's total area. This admits of an easy geometrical proof.

Rule.—Express the height above the earth's surface as a fraction of the earth's diameter; multiply the numerator of this fraction by 2, and add the result to the denominator, then the resulting fraction gives the fraction of the earth's surface visible.

Examples.

Height above earth's surface	Height expressed as a fraction of earth's diameter	Fraction of earth's total surface visible
24,000 miles	$\frac{3}{1}$	$\frac{3}{7}$
8,000 ,, ...	$\frac{1}{1}$	$\frac{1}{3}$
70 ,, ...	$\frac{7}{800}$	$\frac{7}{814}$
1 mile	$\frac{1}{8000}$	$\frac{1}{8002}$
506·881 in.	$\frac{1}{999998}$	$\frac{1}{10^6}$
42·24 ft.	$\frac{1}{10^6}$	$\frac{1}{10^6+2}$
At the moon (240,000 miles)	$\frac{30}{1}$	$\frac{30}{61}$

Of course, the effects of refraction are neglected; otherwise the rule is strictly accurate.

W. MOSS.

Municipal Secondary School, Bolton.

Submerged Valleys and Barrier Reefs.

As I have never visited the Pacific Islands, I do not attempt to bring their valleys under the same category as those of the coast of the Red Sea and East Africa. Darwin's theory having been so often held to apply to all barrier reefs, it seemed to me interesting to refer to cases to which that theory does not apply, though superficially resembling that cited by Prof. Davis (NATURE, February 6 and June 26).

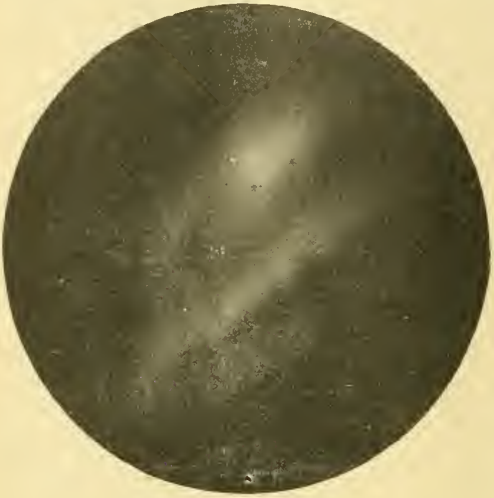
I wished also to emphasise the resemblance between fault and subaërial erosion valleys, and in spite of Prof. Davis's assertion that they can be distinguished readily I think we need definite assurance that those he cites are without doubt of the latter kind. Given that assurance, Dana's proof of Darwin's theory holds true for that case, but not universally wherever barriers (and atolls) are found. I myself took it for granted that those of Pemba and British East Africa were due to erosion by streams and tides alone, until I compared the better preserved examples of this almost rainless climate.

CYRIL CROSSLAND.

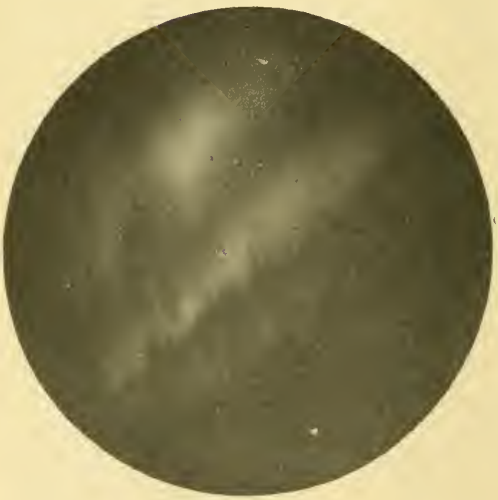
Dongonab, Red Sea, July 12.

PHOTOGRAPHS OF THE AURORA.

AN important advance in the knowledge of the aurora is the outcome of the spring expedition to Bossekop, under M. Carl Störmer. This expedition was undertaken to complete the work done in the 1910 expedition, which was so fruitful of results. The experience gained on the first occasion has been most successfully utilised, and M. Carl Störmer has recently but very briefly communicated an account of the research to the Paris Academy (*Comptes rendus*, June 16).



Bossekop.



Korsnes.

Fig. 1.—Photograph of the same aurora taken on March 3, 1913, at 10h. 36m., Central European time, from Bossekop and Korsnes.

From February 28 to April 1 of the present year the expedition secured 636 pairs of simultaneous photographs of the aurora at the two stations, namely, Bossekop and Store Korsnes, the latter station being about 27 kilometres to the north of Bossekop. Of these photographs 450 pairs are stated to be very satisfactory and furnish material sufficient to compute with a large degree of accuracy the form, position, and altitude of all the principal kinds of aurora borealis.

Further, exactly at the same time as the photographs of the aurora were taken, other photographs, with a prismatic camera, were secured. On these latter photographs can be seen not only the spectra of the stars, but several superposed impressions of the auroræ corresponding to different spectrum lines.

As in 1910, a kinematograph was employed to try to secure the changing phases of the aurora: for the most part the auroral images were too faint. On three occasions, how-

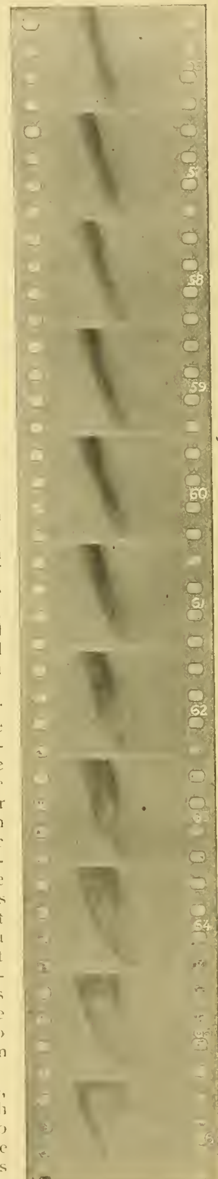


Fig. 2.—Kinematographs of Aurora.

ever, when the auroræ were very bright, consecutive exposures were given, lasting from 0·5 second to 1 second for each image.

Another series of about 100 photographs was taken on April 8 with the kinematograph, each exposure lasting about four seconds. These photographs demonstrate the great utility of this instrument not only in obtaining consecutive features of the displays, but in securing ordinary photographs at the two stations. The communication is accompanied by two most interesting plates. The first of these shows excellent reproductions of the aurora on March 3, photographed at the two stations at the same time, with clear impressions of the stars, demonstrating at a glance the parallactic effect (Fig 1). The second plate reproduces four portions of the kinematograph strip exposed on April 8 at Bossekop. These speak for themselves in indicating the valuable aid the kinematograph brings to auroral studies. A portion of these strips is here reproduced, the exposures for each portion being four seconds (Fig. 2). The gradual change in form and density of the filaments illustrated is here clearly indicated. M. Störmer states that the results of this expedition will be published in considerable detail in a subsequent memoir, and the above brief summary is sufficient to show that the memoir will be a most valuable contribution to our knowledge of the aurora.

THE INTERNATIONAL MEDICAL CONGRESS.

THE International Medical Congress, which is now meeting in London, may fairly be described as the greatest scientific congress ever held in the metropolis; for the time has gone for ever when a medical congress can be confined to the sciences commonly thought of as medical, and it is probable that the future will remember with most gratitude those contributions to the present congress which may seem to have the least relation to medicine.

No single fact marks better the advance of medical thought since last the congress met in London, thirty-two years ago, than the delivery of an address by Mr. W. Bateson on heredity. The supreme names of the past may have no living parallels, but their work bears fruit. Pasteur is gone, but the bacteriologists are all in force at the congress, and his pupil Laveran, who discovered the parasite of malaria a generation ago, is here to see, at any rate in tropical medicine, something like the realisation of his master's *dictum* that "it is in the power of man to make all parasitic diseases disappear from the earth." Lister is not here, but Prof. Cushing can scarcely fail to refer to the surgery of the pituitary body, which seemed wildly impossible only a few years ago. Jonathan Hutchinson is not here, but Prof. Ehrlich will report on the modern treatment of syphilis, though Schaudinn, who found the spirochæte, did not live to hear of salvarsan.

The congress will greatly serve science, but it may still more greatly serve public opinion, and even develop something like public wisdom in some respects. The international resolution on the value of vivisection will be an illustration of this, and also the discussion on alcohol and degeneracy; but most may be hoped from the discussion, in the Albert Hall itself, of the duty of the State in respect of syphilis. This can scarcely fail to reinforce the demand for a Royal Commission lately made by the leaders of medicine in this country, supported by the British Medical Association at Brighton, and repeated by the English-Speaking Conference on Infant Mortality in London on Tuesday, on behalf of absolute innocence, now commonly murdered by our immoral neglect of this subject.

THE RIVERS OF THE SCOTTISH LOWLANDS.[1]

THE handsome volume before us is about evenly divided between the physiographic and industrial questions of the Forth area, and in this combination of interests serves to remind us of the enormous scope of modern geography.

Mr. Cadell has qualified himself to be the historian of the Forth by a long period of service in the Geological Survey of Scotland; and for the subjects treated in the latter half of the book by an almost equally long period of public service in the Lothians.

The history of the Forth begins naturally with the origin of the solid rocks which form the floor of its valley. These foundation-stones were laid in the far-off times of the Old Red Sandstone lakes and the steamy swamps of the Carboniferous. In the first three chapters an excellent light treatment of the many points of interest in connection with the deposition of these rocks, especially the economic materials they contain, is given. After the formation of this basement there must have been a long period of peneplanation, then submergence, and finally re-emergence of the peneplane with a slight tilt *en bloc* to the east. This tilt determined the direction of the Forth and other consequent rivers.

The most original and interesting portion of the book, perhaps, is that which deals with the development of the river system. The Forth, however, cannot be treated in this respect as a separate entity. Its origin involves that of the Clyde and Tweed, and also the lochs of Dumbartonshire and Argyllshire. The Forth originally rose in the highlands of the latter counties, but its headwaters were captured by an energetic stream which flowed southward down what is now the Firth of Clyde. The well-marked narrow trench crossing the Midland Valley from Clydebank to Grangemouth is now occupied by small streams totally disproportionate to its size, and is regarded by Mr. Cadell as the course of a former large tributary of the Forth. The Clyde

[1] "The Story of the Forth." By H. M. Cadell. Pp. xvii+299+plates (Glasgow: James Maclehose and Sons, 1913.) Price 16s. net.

system has thus been formed largely at the expense of the Forth, and in its later depredations has also appropriated part of the Tweed. It has been favoured by the comparatively soft rock-material along its earlier course, by its steeper gradient, but most perhaps, by the more copious rainfall of the western mountains.

The subsequent Glacial period, although causing considerable modification in detail, has not altered the essential features of the topography developed by the rivers. Neither has the submergence which has drowned the seaward parts of the Clyde and Forth valleys, and transformed the Clyde system especially into a series of sea-lochs, availed to obscure the ancient lines of the drainage-system, of which Mr. Cadell has given such a luminous explanation.

Much scattered information on related physiographic subjects, such as the buried channels of the Forth valley and the old lochs of the Edinburgh district, is brought together for the first time in this book.

The latter half of the book deals with industrial subjects connected with the Forth valley. The famous Carron Company and the rise of the Scottish iron industry are treated in chapters ix. and x., and we are reminded how great a part the Cadell family took in the establishment of this great concern in the latter half of the eighteenth century. We also note that Mr. William Cadell, after leaving the Carron Company, interested himself in the establishment of the Clyde Ironworks at Old Monkland, near Glasgow, and thus helped to lay the foundations of the iron-smelting industry in the west of Scotland.

The final chapters deal with land reclamation in the Forth valley, and a very interesting account of an old labour colony is given. This was established by Lord Kames in 1766 for the clearing of Blairdrummond Moss, a work which turned a quaking bog into a fertile plain that now supports scores of families. These later chapters are most interesting and readable, although garnished here and there with obsolescent economics. The book is finely printed, and is a pleasure to read and handle. It is illustrated by many excellent plates and maps.

THE IMPROVEMENT OF INDIAN WHEAT.[1]

NOWADAYS, when the English miller regards Indian wheat as a valuable addition to his resources, the work of the authors of this memoir in improving it is of the utmost national importance. The progress they have made already deserves to be widely known and commended. The problem is the same as that which confronts us in this country, where, however, the farmers still refuse even to try to understand it—namely,

[1] Memoirs of the Department of Agriculture in India, vol. v., No. 2. By A. Howard, H. M. Leake, and G. L. C. Howard, Agricultural Research Institute, Pusa.

the introduction of a strain of wheat, of easy cultivation, which will combine high yield with quality and give a satisfactory straw. Usually in India, as elsewhere, the consistency of a wheat varies greatly, according to the conditions under which it is grown. Although weak wheats can be improved to some extent in milling and baking qualities by cultivation, they have not been made to behave like strong wheats. Owing to the shortness of the growth-period and the liability of the water-supply to deficiency, moderate-yielding wheats are on the average the most profitable to the grower. The Pusa experiments, which have been in progress since 1907, show that the strong wheats with good milling properties retain these properties both under canal irrigation and on the black soils, and that high yield and high quality can be combined in the same wheat.

Such adverse factors as waterlogging and late cultivation affect both the yield and quality of the wheat, and the ryot requires training to the fact that rice conditions of drainage will not do for wheat cultivation. As elsewhere, the greatest financial return for the labour is obtained by growing to perfection a wheat which combines yield with quality.

We believe that the type of wheat preferred by the natives for their home consumption is altogether different from the strong wheat so desired for the export market: the authors ignore this point, but it would appear undesirable to sacrifice the home to the export market for the sake of such an elusive quality as strength.

E. F. A.

PROF. JOHN MILNE, F.R.S.

To few men is it given to follow the growth of a new science from its infancy to maturity, and to still fewer to be prime movers in bringing about such a development. Nevertheless this is the claim we can confidently make for Dr. John Milne. He found seismology in its embryo stage, as left by the pioneer Robert Mallet—with its instruments of the most unsatisfactory type, its observational methods of the crudest description, and its inferences far from conclusive—but he lived to see well-equipped seismographical observatories scattered all over the globe, seismological societies established in every civilised State, and the science of seismology universally recognised as an important and highly suggestive branch of geophysics. And it was undoubtedly to Milne's genius and energy that the impulse leading to these results has been largely due. Yet he had not reached the age of sixty-three when he died on July 31, and his earthquake studies were comprised within a period of thirty-five years!

The two halves of this period of incessant activity had each its particular outlook—the first mainly confined to earthquake-shaken Japan; the second extending to the whole globe. At the early age of twenty-five, Milne, a student from the Royal School of Mines, with a short experience in Newfoundland, Labrador, and Arabia, was appointed Professor of Geology and Mining in the University of Tokyo. Active as the young professor was in his teaching work, writing text-books on crystallography and mining, and conducting expeditions to study the volcanic and other phenomena of Japan and neighbouring lands, it was, nevertheless, outside his official duties that he began to find the fullest scope for his superabundant energies.

It was the frequent earthshakings of his adopted country that supplied food to Milne's inquiring and speculative mind. Before he was thirty he had founded the Seismological Society of Japan, and a seismological journal; but for the first ten years at least Milne might have truthfully asserted, "I am the Seismological Society, and I *write*, as well as *edit*, the journal." He established observing stations all over Japan, eventually reaching nearly 1000 in number, each of which was supplied with a register in the form of a cheque-book, and the "cheques," filled up with answers to questions in Japanese and English, when posted to Milne, supplied him with the means of drawing "isoseismal" lines on his maps for each shock. But this laborious task, with earthquakes of almost daily occurrence, was only a small part of his work. He invented and improved various forms of recording instruments, investigated the laws of transmission of vibrations through the earth's crust by "artificial earthquakes," studied the principles on which buildings that should be "earthquake-proof" may be constructed, registered the meteorological conditions under which earthquakes occur, and perseveringly followed innumerable clues in diverse directions that continually suggested themselves to his ever-open mind.

Not the least important part of his work was the training a band of native observers, who are ably continuing and extending Milne's investigations in Japan. More than one hundred memoirs, filling more than two-thirds of the nineteen volumes of the Transactions and Journal of the Seismological Society of Japan, constitute the best evidence of Milne's devotion to the science during his seventeen years of residence in the country.

But Milne's retirement from the Japanese professorship at the age of forty-five furnished the opportunity for entering on a wider sphere of labour—one to which he was able to devote the whole of his time and effort. Just before starting for England, however, a most disastrous fire destroyed his accumulated books and instruments—the most serious loss being that of the stock of precious volumes of the Transactions and Journal of his society.

Undismayed by this misfortune, Milne, within three weeks of his arrival at home, had built a brick pillar at Shide, in the Isle of Wight, and set up on it his seismographs. The site of this now famous observing station had been selected from its proximity to a line of great earth-movements during a late geological period. Established at this centre, he entered upon the task of enlisting the aid of Government departments, public institutions, and private individuals to his great work. Before he died he had the satisfaction of having forty observing stations, all furnished with his own type of seismometer, in constant correspondence with him. The careful tabulation and discussion of the records from these observatories had occupied him during the last seventeen years, and the results have been given to the world in a series of circulars and reports by the British Association, the society which, so far as its means have allowed, has constantly subsidised and published Milne's work; in later years the Royal Society has extended its powerful support to him.

To readers of NATURE it is not necessary to enlarge on the results of Milne's labours since his return to England. His important work in tracing the cause of the fracture of submarine cables; his determination of the sites of distant earthquakes from seismographic records; his proof of the distinction between vibrations that travel *through* the earth, and those going *round* it; and many other suggestive contributions, are familiar to everyone.

No more striking proof of Milne's remarkable activity can be afforded than the fact that while the British Association has, since the year 1841, published fifty-three reports on seismology, in which 562 communications are embodied, no fewer than 463 of these are from the pen of Milne! And all are in addition to his books and numerous articles in scientific and other journals.

The eighteenth (alas! it is the last!) of the luminous reports prepared since his return to England is now in the press, and will be presented at the forthcoming meeting of the British Association. It fittingly concludes with a touching and generous obituary notice of his Japanese assistant, Shinobu Hirota (the faithful "Snow"), who returned home to die last April. But, indeed, Milne's was an ever-generous soul. Students of seismology from all lands visited Shide, and were always warmly welcomed by Milne, often partaking of his hospitality. Not only these, but idle tourists, journalists in search of "copy," teachers with their pupils, and even children, were ungrudgingly received. In spite of his exacting labours, he seemed ever ready to show his instruments and talk about his work with the most casual visitor.

Some, perhaps, may suggest that Milne was wanting in sympathy with the work of co-ordinating the results of other organisations than his own; and it may be admitted that his Pegasus did not run well in harness. But it must be remembered how, from the first, he had been accustomed to bear all the weight and responsibility of great enterprises on his own broad shoulders. John Milne's death is indeed a great calamity for science—how great will only be realised when the attempt is made to supply his place.

J. W. J.

NOTES.

THE Baly medal has been awarded by the Royal College of Physicians to Dr. J. S. Haldane, F.R.S., reader in physiology at the University of Oxford, in recognition of his distinguished contributions to physiological science.

PROF. W. C. McINTOSH, F.R.S., professor of natural history in the University of St. Andrews, and director of the Gatty Marine Laboratory, has been elected president of the Ray Society in succession to the late Lord Avebury.

THE death is announced of Mr. T. H. Russell, of Birmingham, who was a fellow of the Linnean Society and the author of a work on mosses and liverworts.

A PARAGRAPH in *The Times* of August 2 states that there are 106 clocks attached to premises in the City of London, and observable from the public way. Of these, forty-two are synchronised from Greenwich Observatory. There are, in addition, twenty-nine church clocks in the City (including St. Paul's Cathedral), none of which are synchronised or even unanimous in their irregularity.

IN a letter published in *The Scotsman* of July 24, Dr. John G. Havelock, of Montrose, describes some observations which have led him to conclude that common varieties of the single petunia are true insectivorous plants. Mr. Alex. Johnstone, of the same town, has sent us an account of observations of his own which suggest the same conclusion. Sir Herbert Maxwell, in *The Scotsman* of July 28, thinks *Rhododendron barbabum* also deserves attention as probably an insectivorous plant. Only a careful experiment can determine the accuracy of the suggestion that Petunia is insectivorous, and it may be hoped the point will receive the attention of plant physiologists.

THE exhibited collection of Mesozoic crocodiles in the Geological Department of the British Museum (Natural History) has just been rearranged to incorporate some important recent acquisitions. A new specimen of Mystriosaurus from the Upper Lias of Würtemberg, prepared by Mr. B. Hauff, is one of the finest known examples, with almost complete limbs. The stomach-contents are seen, mingled with swallowed pebbles. A specimen of Geosaurus, from the Lithographic Stone of Bavaria, shows for the first time the triangular tail-fin by which this essentially marine crocodile propelled itself. The unique example of the Wealden river-crocodile Goniopholis, discovered a few years ago by Mr. R. W. Hooley in the cliff near Atherfield, Isle of Wight, and described by him in the Geological Society's Journal, has also been mounted and exhibited.

THE sixtieth birthday of Prof. W. Ridgway was fittingly commemorated a few days ago by a dinner at Caius College, Cambridge, attended by scholars and men of science from all parts of the kingdom. Few archæologists of the present day have done more, by original work, stimulating instruction, and the application of anthropological methods in the solution of historical problems, to advance English scholarship. His treatises "The Origin of Currency and Weight Standards," "The Origin and Influence of the Thoroughbred Horse," and "The Origin of Tragedy," have advanced our knowledge of prehistoric archæology, while his separation of the northern and southern elements in early Greek history, received at first with almost generally hostile criticism, has passed into the region of orthodox commonplace in the light of the Cretan discoveries by Sir A. Evans. It is much to be desired that the completion of his admirable work, "The Early Age of Greece," will not be much longer delayed.

The death is announced, in his sixty-sixth year, of Sir Richard Powell Cooper, a distinguished agriculturist, who played a very large part indeed in developing the enormous industry in exporting pedigree live-stock, which has now become a recognised part of British agriculture. He was also a member of the firm of Cooper and Nephews, chemical manufacturers and exporters of live-stock; this firm set up laboratories at Watford and Berkhamsted, and made chemical preparations for agricultural and horticultural purposes, and also conducted a number of investigations bearing on these substances. Sir Richard farmed a large estate at Shenstone Court, Lichfield, and he also owned land and live-stock in Australia, the Argentine, South Africa, Paraguay, Russia, and elsewhere. He was an exceedingly good business man, and introduced business methods into branches of agriculture and horticulture where such methods had previously been wanting. In particular he played a great part in revivifying the Royal Agricultural Society, when a few years ago it came dangerously near to collapse.

As the white man spreads over the tropical regions of the earth, he comes continually into contact with new and unfamiliar forms of disease, often of a deadly kind. One of the most recent additions to the white man's burden is a peculiar malady known as Verruga (or Verruca) Peruana, also as Fiebre de la Oroya, or Carrion's fever, described by Darling as "an infectious disease in which a fever of irregular type, associated with more or less severe anæmia, is followed by a wart-like eruption of the skin, and sometimes of the mucous or serous membrane." Two forms of the disease are recognised, malignant and benign. It occurs in certain valleys on the western slopes of the Peruvian Andes at altitudes of from 1000 to 12,000 ft., most often between 2000 and 6000 ft. According to the researches of Mayer, Rocha-Lima, and Werner (*vide* Tropical Diseases Bulletin, No. 12, p. 727), the parasitic cause of the disease is one of the problematic class of organisms known as Chlamydozoa. In a recent letter to *The Times* (July 12) Dr. Anderson states that, according to a telegram from Mr. Billinghurst, President of the Peruvian Republic, it has been discovered by Prof. Townsend, of Lima, that verruga is transmitted by one of the small blood-sucking midges of the genus Phlebotomus. These insects are small, hairy, moth-like flies, widely distributed in tropical or subtropical regions; one species is known to transmit "Papataci fever" in Dalmatia, and by some authorities the dissemination of Oriental sore is also attributed to midges of this genus.

Mr. W. M. Newton has republished from the Journal of the British Archæological Association for last March an important paper entitled "Palæolithic Figures of Flint Found in the Old River Alluvia of England and France, and called Figure Stones." These are nodules of flint assuming the shapes of animals or of animals' heads. These objects were discussed by Boucher de Perthes in his "Antiquités Celtiques et Antédiluviennes," published in 1840, and by the late Sir John Evans in *Archaeologia*, vol. xxxviii., 1860, the latter eminent authority regarding them as "the effects of accidental concretions and the peculiar colourings and fracture of flint, rather than as designedly fashioned." Mr. Newton has, in recent years, found similar objects in a gravel-pit at Dartford, Kent. In the present paper he describes his fine collection, and suggests their analogy with specimens found in Egypt and elsewhere. The full materials and fine illustrations supplied will enable archæologists to study the facts, which are certainly striking. Meanwhile, the conclusions of Sir John Evans do not appear to be materially affected by the fresh evidence now presented.

A remarkable group of long-snouted representatives of the Lower Tertiary perissodactyle family Titanotheriidæ, from the Uinta beds of Utah, forms the subject of a paper by Mr. E. S. Riggs in the Geological Publications (vol. iv., No. 2) of the Field Museum, Chicago. Four generic types (one of which, Rhadinorhinus, is described as new) are recognised in this group, collectively forming the subfamily Dolichorhinæ.

It is well known to poultry-breeders that birds produced by crossing white Leghorns with black or dark-coloured breeds frequently exhibit a barred plumage ("cuckoo-marking"), of which there is no trace in either of the parent stocks. As the result of experiments, Dr. P. B. Hadley is enabled to demonstrate, in the July number of *The American Naturalist*, that this barring occurs in a certain proportion of such cross-bred birds of the F_2 and subsequent generations, and that the pattern is derived from the white stock. The result of the experiments has, however, no bearing on the ultimate origin of this type of marking, but merely indicates the existence in white Leghorns of factors tending to produce both black and barring.

According to an illustrated article by Prof. C. L. Edwards, in the June number of *The Popular Science Monthly*, "abalones," as the various species of Haliotis are locally called, are extensively fished in California, both as a food-supply and for the sake of their shells, which form an important source of mother-of-pearl, and, when polished, are also used as ornaments and as shades for electric lights. A considerable number of pearls are also yielded by abalones. The price of the shells ranges from 1000 to 4000 dollars per ton, and the total value of the shells and flesh taken at Long Beach alone during the year ending in July, 1912, was no less than 95,800 dollars.

To part 4 of the first volume of *Mitteilungen landwirtschaft. Lehrkanzeln k.k. Hochschule für Boden-*

kultur (Vienna, 1913), Dr. Paul Saborsky contributes an exhaustive and well-illustrated account of Welsh black cattle, in which their characteristic features, corporeal measurements, osteology, and etiology are dealt with in detail. The author fully endorses the opinion that these cattle are nearly related to the extinct black aurochs (*Bos taurus primigenius*) on one hand, and to the white British park-cattle on the other, such resemblances as they display to the Celtic shorthorn (*B. longifrons* or *brachyceros*) being, perhaps, inherited from a local race of the aurochs. It is to be regretted that as the memoir is written in German it is not likely to be widely read in this country.

According to the report for 1912 the Field Museum of Natural History, Chicago, continues to make rapid progress, both in the matter of adding to its scientific collections, and in the installation of realistic exhibits in the public galleries and halls. The report is illustrated with photographs of several of these

Sonoran grizzly bears in the Field Museum, Chicago.

striking exhibits, including a group of grizzly bears in a forest and a colony of beavers on a dam in one of the great rivers; in all of these the foreground is occupied by the animals themselves, mounted with their natural inanimate surroundings, while the background is artistically painted.

During a visit to a whaling station in the Faröes in the summer of 1911, Dr. L. Freund had the opportunity of studying portions of the anatomy of several species of whales, and has published the results of his investigations in the issue for November and December, 1912, of the *Sitzungsberichte* of the Vienna Academy of Sciences. It may be recalled that a short time ago reference was made in Nature to Mr. T. B. Goodall's opinion with regard to the homology of the whalebone plates of the whalebone whales. According to Dr. Freund, this opinion is by no means new, but was long since adopted by Eschricht, who contended, in opposition to current views, that the plates do not represent the palatal rugæ of land animals. If we understand him rightly, Dr. Freund appears inclined to support this interpretation, although he points out that there are considerable differences in the structural arrangement of the plates in different groups of whalebone whales. Other items in cetacean anatomy are also discussed in the paper, which likewise contains a section on the genitalia of the porpoise.

We have received from the Government Printing Office, Calcutta, a series of extremely useful notes on Indian timbers (Forest Bulletins Nos. 16 to 21, price 4*d.* each). The timbers dealt with are *Gmelina arborea*, *Pterocarpus marsupium*, *Terminalia tomentosa*, *Lagerstroemia lanceolata*, *Ougeinia dalbergoides*, and *Anogeissus latifolia*. Each of these bulletins gives the distribution, locality, and habit of the tree, properties and uses of the timber, minor products, if any, natural reproduction and rate of growth, and other information, and includes a specimen of the wood in the form of a thin section mounted in a stout cardboard frame. These bulletins form part of a series of notes on the lesser-known Indian timbers, compiled by officers of the Forest Research Institute, Dehra Dun, and it is announced that on application to the forest economist specimens of any timber will be supplied free, and inquirers put in communication with local forest officers.

As a result of much recent work on the effect of various metal salts on plant growth in water culture, pot culture, and in the field, the possible value of manganese salts as fertilisers is discussed in a leaflet published by the U.S. Bureau of Soils, Circular No. 75. Beneficial effects have been observed in the cultivation of numerous crops, and in many cases the increase has been very appreciable—upwards of 25 to 30 per cent. Its effect in soils is attributed partly to a direct action on the soil constituents, partly to an acceleration of enzymic changes in the plant, and also to the stimulation of micro-organisms in the soil. It has further been found that manganese increases the absorption of other ingredients by the plant, particularly lime and magnesia. For experimental work and as a complementary fertiliser to sodium nitrate, phosphates, potash, and lime, the use of soluble manganese salts in quantities not greater than 100 lb. per acre is recommended.

In connection with the movement for the conservation of natural resources in the United States, an investigation has been made into the occurrence of potash salts in such amounts as to warrant their extraction on a commercial scale (U.S. Bureau of Soils, Bulletin 94). In no case has an artificial or natural (subterranean) salt been found suitable for further extraction, but the bitterns derived from the manufacture of salt from sea-water contain potassium in such amounts as to make it probable that they could be evaporated to make valuable manure salts. In addition to this, the brine of one desiccated lake of southern California has been found to contain sufficient potash to make it a possible commercial source, but the largest and most practicable source is to be found in the giant kelps of the Pacific littoral.

We have received the first part of the *Palaeontologische Zeitschrift* (Berlin: Gebrüder Borntraeger, price 25 marks annually), the publication of the Palæontologische Gesellschaft, which was founded in Germany last autumn. The society is intended to be of an international character, and besides about 130 German palæontologists, it already counts nearly eighty members in other countries. The headquarters are in Berlin, and a meeting is to be held once a year in some locality, either in Germany or in another country, where there is an important collection of fossils or where the fossiliferous strata are of special interest. The first president is Prof. Otto Jaekel, of Greifswald, and on the council the representatives of Great Britain and the United States are respectively Dr. Smith Woodward and Prof. Charles Schuchert. The published *Zeitschrift* deals with fossils from every point of view, but especially in their biological aspect, and begins with a presidential address on the study of palæontology in general. Prof. Jaekel quotes O. Merkel's claim to have discovered that fossils were intelligently collected even so far back as the Bronze age. One or two examples of each of fifty-eight species of Tertiary shells are said to have been found, with two recent Mediterranean species for comparison, in a cinerary urn of this period. Prof. H. Rauff contributes an important illustrated paper on Pharetrone sponges, and Dr. C. Wiman discusses cases of the sudden destruction and burial of swarms or large troops of animals. Prof. Jaekel also begins an account of the remarkable discovery of numerous dinosaurs and other vertebrates in a clay-pit in the Upper Trias of Halberstadt, north Germany.

To the July number of *Symons's Meteorological Magazine* Mr. R. C. Mossman, of the Argentine Meteorological Office, makes an addition to his third article on southern hemisphere seasonal correlations (NATURE, July 17), showing that a relation can be traced between rainfall at Malden Island (South Pacific) and mean temperature at Punta Arenas (Magellan Strait) from May to August. When the rainfall at Malden Island is above the average the temperature at Punta Arenas is below the normal, and *vice versâ*. During the seventeen years 1890–1906 there are only two years, 1894 and 1904, in which the signs are the same, but in each of the four years 1907–10 a low mean temperature at Punta Arenas is associated with a deficient rainfall at Malden Island during the four months in question. Dr. Hildebrandsson has shown that an apparently well-established correlation may break down for a few years, and Mr. Mossman remarks that the case under discussion offers another instance of the snapping of the chain.

A MEMORANDUM on the meteorological conditions prevailing over various parts of the earth before the advance of the south-west monsoon in India, issued by the Director-General of Observatories on June 8, has been recently received. The distribution of pressure is most favourable when the latter is high in March, April, and May in Argentina and Chile, and low in May in the Indian Ocean; on the whole the general pressure conditions appear slightly unfavourable. The inferences to be drawn from the winds and rainfall in the Indian Ocean during the previous two months do not affect the present monsoon prospects very strongly, while the accumulations of snowfall lying on the hills are probably normal. Although no explanation is forthcoming, there is apparently a tendency for years of which the average pressure over India is high to be associated with a good monsoon in the succeeding year, and *vice versâ*; in 1912 pressure was in moderate excess, and the tendency therefore affords grounds for hope. From these indications all that can be inferred is that a large excess or defect in the total monsoon rainfall of India is unlikely.

THE electron theory makes the dielectric constant k of an electrical insulator vary so that $(k-1)/(k+2)$ is proportional to the density. Temperature, therefore, which has little effect on the density, should have little on the dielectric constant. Measurement has shown, on the other hand, that the effect of temperature on the constant is considerable, and Prof. Debye, of Zürich, recently suggested that this effect could be explained by the presence of electrical doublets in the dielectric so long as it is in the liquid state. The product of the absolute temperature into the expression above should then be a linear function of the absolute temperature. This Debye showed to be the case. In the *Verhandlungen* of the German Physical Society for June 30, Dr. Ratnowsky, of Zürich, shows that the dielectric constant should in these circumstances depend to a small extent on the electric field to which the insulator is subjected. A series of measurements by him on a solution of amyl alcohol in benzol made by the alternating-current bridge method has confirmed this deduction and gives the number of doublets per cubic centimetre and their electrical moment in fair agreement with the values found by Debye.

WE have received vol. vi. of the Journal of the Municipal School of Technology, Manchester, which consists of a reprint of the scientific and technical papers which have been communicated to societies or published in the technical Press by members of the staff or by students of the school during the year 1912. Nineteen such papers cover the 267 pages of the journal, and deal with subjects like the investigation of the best form and speed for durability of cutting tools, the forces which produce corrugation of tram rails, the properties of porcelain insulators used in high-tension electrical power transmission, the influence of alkalis in the dyeing of cotton, the action of metallic chlorides in sizing cotton yarn, the action of light on colouring matters. We know of no other technical school in this country which can show so valuable a series of researches turned out in a single year, and we wish the Manchester School every success in its avowed intention, by offering "systematic training in the principles of science and art as applied to industry," of producing "men of character, wide knowledge, and practical experience," and so fostering industry.

THE Optical Convention held at South Kensington on June 19–26 of last year was described in an article published in the issue of NATURE for June 27, 1912 (vol. lxxxix., p. 435). The Proceedings of the convention have now been published for the University of London Press, Ltd., by Messrs. Hodder and Stoughton. The handsome volume runs to 359 large pages, and contains the inaugural address of the president, Prof. S. P. Thompson—extracts from which were published in Nature of the date mentioned—and the papers read at the convention. The papers are chiefly of a technical description, largely directed to the issues of technical inquiry, and a few are devoted to the details of manufacture. Among the contents of the volume of more general interest may be mentioned the report of Prof. Turner's lecture on the great observatories of America, and Prof. Stirling's popular lecture on optical illusions. A table of constants for calculating spherical aberration forms an appendix; this comprises a selection of logarithms of use in some of the more laborious calculations which the designers of lens combinations have to make. The price of the volume is 10s. net.

The National Academy of Sciences of the United States of America was founded in 1863, and 1913 sees completed the fiftieth year of its existence. It was decided in 1909 to have prepared for publication, in connection with this semi-centenary of the academy, a volume containing as complete an historical summary as could be brought together in the time available. A committee was appointed to take charge of the matter, and in the summer of 1910 the services of Dr. F. W. True were secured as editor. The result of the labours of this committee is seen in the "History of the First Half-Century of the National Academy of Sciences, 1863–1913," a copy of which has reached us from Washington. It was hoped that a list of the scientific communications presented to the academy since its foundation, some two thousand in number, might be added to the volume, but it has been found impossible in the time available to compile the necessary data. The completion of the undertaking is deferred until a later date. The present handsome volume runs to some 400 large pages, and gives exhaustive information as to the founding of the academy, its annals, and its work as scientific adviser of the U.S. Government. Biographical sketches of the incorporators of the academy add interest to the work, while the numerous appendices provide most useful lists of members, medallists, officers, and so on.

Mr. Francis Edwards, 83 High Street, Marylebone, London, W., has published the August issue of his catalogue of second-hand books in all classes of literature. The volumes listed include a number from the library of Mr. Thomas Pennant, the antiquary and naturalist.

OUR ASTRONOMICAL COLUMN.

August Meteors.—The most interesting and important season of the year for meteoric work has now arrived. The Perseids return regularly in August, and always repay observation, though there are marked variations in their annual displays.

During the last few years this shower has scarcely justified expectation, but the conditions have not been very favourable. At the ensuing return possibly the meteors may return in their old-time abundance, but there will be a little interference from moonlight before midnight. This need not, however, materially affect the character of the display, for on the nights of August 11 and 12, when the maximum will occur, our satellite will be only just past the first quarter, and will set on August 11 at 11h. 13m., and August 12 at 12h. 9m. p.m.

It seems desirable to watch the phenomenon closely every year for several reasons. Its period is not yet exactly ascertained, and we are not sufficiently well acquainted with its annual variations. The hourly number of meteors visible should be determined, and the time of their maximum abundance. It is also important to record the apparent paths of such brilliant meteors as may be visible.

In the case of fireballs the lingering streaks give evidence of rapid currents in the upper atmosphere, and should be specially watched. It will be useful to note the position of the streaks amongst the stars and to record the rate and direction of their drift, at short intervals, during the period of their visibility. The streaks are usually from sixty-five to fifty-five miles in height.

Directly a streak is seen a telescope or field-glass should be directed towards it. A streak which remains visible to the naked eye a few seconds can sometimes be watched for five or ten minutes with a glass.

It is astonishing how many of the meteors of the August stream are destroyed every year by collision with the earth's atmosphere. Basing calculations on observed facts, it is probable that between 80 and 100 millions of these meteors are encountered every year. This great annual expenditure might be thought to have a perceptible effect in diminishing the visible numbers, but when we remember that Prof. H. A. Newton computed the number of meteors in the August system as 300,000,000,000,000, it is certain that any apparent falling off in the richness of the shower would only become sensible after many thousands of years.

Displacement of Spectrum Lines of Metals due to Impurities.—An important piece of research work, chiefly interesting to spectroscopists, is that recently communicated by M. Keivin Burns to the *Comptes rendus* for June 30 (vol. clvi., No. 26, p. 1976). M. Burns finds that the presence of a large proportion of luminous vapour in an arc of iron or mercury displaces the spectrum lines of those metals contained in a small proportion in the arc (such as barium, manganese, cadmium) in relation to the positions they would occupy if the metals which produced them were predominant. He suggests that this displacement may be the result of numerous particles in a special condition where they emit light and not of ordinary molecules or atoms; the displacement is not explained by a pressure effect. He points out that the existence of this displacement does not render it prudent to use such lines of impurities as standards in attributing the wave-lengths found from measures made under other conditions.

Circulation in the Solar Atmosphere.—Anyone who has closely studied a number of photographs of solar prominences photographed on the limb of the sun would have the idea of solar currents brought to his mind.

A systematic study of a large number of such photographs becomes therefore of extreme interest from the solar circulation point of view, and such a study has been undertaken by Prof. Slocum, of the Yerkes Observatory, from spectroheliograph photographs he has taken with the large Yerkes refractor. His second paper on the subject appears in *The Astrophysical Journal* (June, vol. xxxvii., No. 5), and the conclusions at which he arrives can be best conveyed in his own concise summary. Many prominences, by their shapes or movements, seem to indicate the existence of a horizontal current in the solar atmosphere. This current may have opposite directions at different altitudes in the same locality. It may change its direction, just as the wind changes upon the earth. In middle latitudes the average tendency for movement is towards the poles. In high latitudes the tendency is towards the equator. This tendency is more marked in the northern than southern hemisphere. From lat. 10° N. to 10° S. the average tendency is from north to south directly across the equator. The prevailing directions mentioned above apply to prominences of all heights.

THE BRIGHTON MEETING OF THE BRITISH MEDICAL ASSOCIATION.

A MEDICAL congress, especially in view of the wide development of specialism, rarely if ever helps to bring to light a new discovery or to promote a new theory, or at least to work out an application in practice of some basic theoretic facts. It has, however, the importance of grouping together men who work on widely different lines and are enabled to exchange ideas in a favourable atmosphere. In so far the Brighton meeting of the British Medical Association was undoubtedly very successful. We had, for example, a very interesting address by Prof. C. G. Barkla, F.R.S., on the secondary X-ray radiations in medicine, which, being delivered by a prominent physicist, introduced an element of exact science into empiricism of therapeutic applications. Prof. Barkla gave a detailed description of the scattered, fluorescent, and corpuscular rays. He reminded his audience that all chemical, therapeutic, and physical action attributed to X-rays was due to the secondary radiation of negative electrons. He pointed out that in order to produce a definite effect in an organ there must be a transformation of the energy of Röntgen radiation into energy of corpuscular radiation, as well as an absorption of the latter by the respective organ.

The solid basis and irrefutable arguments of physics could not be found or expected in the discussion on anaphylaxis. This was opened by Prof. W. E. Dixon, who entered into various details of the condition of experimentally produced hypersensitiveness, describing the changes occurring in the muscular and circulatory systems, and emphasising the significance of local symptoms. When he came to declare his preference for one of the three leading hypotheses as to the causation of the "anaphylactic shock," he declared himself in favour of the ferment theory, because he regarded the "classical" side-chain theory as a purely speculative hypothesis, and the more recent "colloidal theory" as still being in its infancy, whereas he found the ferment theory to be based on carefully recorded physiological facts. Prof. G. Sims Woodhead and Dr. Myers Coplans gave examples of clinical conditions which may be looked upon as similar to that of experimental anaphylaxis. Prof. Woodhead made a very interesting remark as to the possibility of explaining some of the phases of pneumonia by the sensitisation of the system by the specific bacterial protein. He also referred to the view largely held as to the possibility of organs being specifically sensitised, as instanced by the uterine muscle in eclampsia.

Drs. Embleton and Thiele related the results of their very remarkable experiments, which have shown that by sensitising laboratory animals by injection of bacterial protein of purely saprophytic bacteria like *B. mesentericus* one may make them so highly susceptible that a subsequent inoculation of live bacteria of the same species will kill the animals under symptoms of acute septicæmia. These experiments are undoubtedly of a very wide importance, as they may help in producing typical specific disease conditions in experimental animals naturally refractive to the infection produced by ordinary means.

A less debatable basis for discussion was given by Prof. George R. Murray, who dwelt on the importance of internal secretion in disease in a masterly presidential address. He explicitly limited the name of "secretion" to the useful products of glandular activity which pass into the blood stream in order to play some definite part in metabolism. Ductless glands in particular act on other tissues by means of "hormones," which excite definite forms of chemical activity in cells for which they have a special affinity. The glandular cells may form more than one specific hormone; they may also produce "inhibitory hormones," *i.e.* substances which inhibit the chemical activity of the tissue cells instead of exciting them. He passed in review the consequences of an insufficient as well as superabundant supply of glandular hormones, and insisted particularly on the relations of the thyroid and pancreatic gland which tend to inhibit each other. This, as proved by further discussion, is one of the most important facts for the practice, as it tends to explain the machinery of diabetes and all forms of glycosuria. Dr. A. E. Garrod, F.R.S., could not discover any basis for a sharp differentiation of the diabetic and non-diabetic glycosurias. In his belief the progress of research was strengthening the viewpoint that the internal secretion of pancreas was the almost only controller of carbohydrate metabolism in the system. The peculiar forms of glycosuria without a definite diseased condition he tried to explain by a disturbed correlation between the various glands of internal secretion.

A general impression gained from all the various discussions can be summarised in that the medical profession is fully alive to the importance of "control" experiments, that it errs rather in the application of a severe criticism to its scientific contributions, and keeps to the moral, "Prove all things, holding fast that which is good."

HYDROGRAPHIC AND PLANKTON OBSERVATIONS IN THE NORTH SEA.

WE have received from the Board of Agriculture and Fisheries the subjoined communication relating to observations to be made in the North Sea:—

The research vessel s.y. *Hiawatha*, chartered for fishery research in the North Sea, left the Tyne on Tuesday for the purpose of making certain practically continuous hydrographic observations, at a fixed position during the first fortnight of August. She will be taking part in a coordinated research into the movements of the great water masses in the North Sea, and for this purpose she will drop her anchor about 150 miles "E. by N. ½ N." of Shields and commence her work. Her labours will be identical in aim and in the main in methods with researches simultaneously carried out on board eight other vessels, also at anchor, at positions which collectively will permit of the study of conditions representative of the hydrographic conditions over the whole of the North Sea.

Two of these other vessels will be research vessels, acting on behalf of Sweden and Scotland, the Swedish vessel working in the Skagerak, the Scottish well to the north-east of Aberdeen. The remaining vessels are light vessels, two acting for Holland, the other four, by courtesy of the Brethren of the Trinity, for the English department.

The observations will consist of current measurements made near both surface and bottom every hour night and day, throughout the fortnight, and in fine weather at other intermediate depths. Special attention will be paid to the submarine waves which are, it is expected, to be met with at the depth at which the heavier bottom water and the lighter surface water are in contact; but information will be obtained as to all layers. Specially devised current meters are used in this work, some depending for their operation on small propellers, resembling those of an anemometer and worked by the current, others upon the deflection of a wire from which a metal cylinder depends, caused by the force exerted by the current. The temperature and salinity of the various layers of the sea will also be ascertained in the course of the work, special water-bottles being employed to secure samples of the sea from any desired depth. Samples of the minute floating organisms which, directly or indirectly, constitute the food of all our food fishes will also be taken at various depths and at the extremes of the tide.

Some idea of the scale of the operations may be gathered by the fact that it is expected that some 8000 independent current measurements will be made from the English vessels alone.

The hydrographic operations are planned by a special committee of the International Council for the Exploration of the Sea. They are undertaken because a knowledge of the constitution and movements of the sea-water is essential to the understanding of the movements and even of the abundance of the fishes upon which our fishing industry depends. As a classical instance, the herring of the Kattegat and Skagerak may be cited. Its abundance or scarcity has been found to be connected directly with the amount of water which enters the Baltic from the North Sea; and, indeed, not only the herring fishery but other fisheries of southern Sweden have been shown to change with the ebb and flow of this layer of cold salt water. It is clear, in fact, that a state of knowledge of marine currents which would permit of prognostication as to their movements and volume at a later period would in the case of many fisheries permit the fishermen to reap the utmost harvest which the year would afford or to anticipate a time of scarcity and take such precautions as were possible to mitigate its effects.

A NEW METHOD OF COOLING GAS-ENGINES.

THE summer meeting of the Institution of Mechanical Engineers was held in Cambridge last week. Among the many papers read and discussed, that by Prof. Bertram Hopkinson, of Cambridge University, takes a prominent place; the subject of the paper was a new method of cooling gas-engines. The most important peculiarity of the gas-engine, that which determines the characteristic features of its design and operation, is the heat-flow from the hot gases into the cylinder walls. About 30 per cent. of the heating value of the fuel passes into the metal of the engine in this way. The method hitherto employed in removing this heat has been by the circulation of water in jackets, except in the case of small air-cooled engines. In large engines, the piston and exhaust valve have also been kept cool by circulation of water. The appliances necessary for the carrying out of this method have been responsible largely for the great weight and cost of large gas-engines.

Water circulation has secondary effects which tend to make a large engine untrustworthy in working. The cylinder walls in places may be 3 in. thick or more. To cause the heat to flow from the inner to the outer surface of the metal requires a temperature difference of the order of 50° C. per inch, and this may become serious with thick walls. It is also difficult in large engines to secure adequate circulation about all parts of the cylinder walls and piston, and some parts may be much hotter than others. Severe stresses may be set up in consequence of the unequal expansion, and the overheating of certain parts of the inner surface is apt to cause pre-ignition of the charge. In consequence of the dangers of overheating it has been found impossible to work gas-engines, especially of large size, continuously at the maximum power which they can develop.

In Prof. Hopkinson's method of cooling, water is injected internally in thin jets directed against the walls of the combustion chamber and the end of the piston. There is thus no heat flow through the metal and no difference of temperature between the inner and outer surfaces. The water is so distributed that each part receives it in proportion to the rate at which it receives heat from the hot gases. Practically uniform temperature all over is thus maintained, and the stresses due to unequal heating are eliminated. A simple single-walled casting can be used for the cylinder, resulting in a great saving in weight and cost and in improved trustworthiness on account of the elimination of casting stresses. Piston-cooling arrangements—a frequent cause of trouble—can be dispensed with. Finally, pre-ignitions are entirely prevented.

To obtain success in this method of cooling, the water must be projected in comparatively coarse drops or jets directly against the surfaces to be cooled, so that it reaches these surfaces in the liquid form without much loss by evaporation on the way. Water which reaches the walls in the liquid form, and is there evaporated, absorbs, out of the heat given to the walls by the gas, the *whole* of its own heat of evaporation; there is no loss of thermodynamic efficiency because the heat used is waste heat, which in a jacketed engine would go to warm the cooling water. Any steam formed in this way is pure gain; and, if anything, there is an increase in the work done.

Further, if the cylinder walls are allowed to become and remain wet, they are destroyed rapidly by corrosion. This is due to the presence of sulphur dioxide in the gas, which forms sulphurous acid when dissolved in water. This difficulty has been overcome by regulating the amount of water injected in such a way that the temperature of the whole of the engine is kept well above 100° C. Under these conditions every drop of injected water is boiled when it reaches the walls, and no liquid can accumulate. It is found to be sufficient to inject water on to the surface of the combustion-chamber and the head of the piston only; the cooling of the barrel is effected by conduction into the piston. Thus no water falls on the sliding surfaces, where it would cause damage by the dissolved salts producing grinding.

Trials have been made on a Crossley engine fitted with a new cylinder embodying the principles explained above. The cylinder is 11½ in. diameter by 21 in. stroke, and is rated at 40 brake horse-power at 180 revolutions per minute. The success of this engine, as compared with the original water-jacketed cylinder, has been remarkable. After considerable preliminary trials, the engine was put to drive a dynamo in a factory engine-room, at a speed increased to 195 revolutions per minute. It developed frequently 50 brake horse-power with coal gas for several hours together. Since then the engine has been taken to Cambridge, and is now engaged in regular service with a suction-producer, driving the workshops, and producing electric current for the engineering laboratory. It is left to itself like an ordinary gas-engine, giving no trouble at all, and has been in regular work for two years, the total time of running being 5000 hours.

Judging from the success which has so far been obtained, it seems likely that Prof. Hopkinson's method of cooling the cylinder will revolutionise the design and construction of large gas-engine cylinders.

RECENT PAPERS ON VERTEBRATE PALÆONTOLOGY.

A VERY remarkable announcement is made by Mr. J. W. Gidley in vol. lx., No. 27, of the Smithsonian Miscellaneous Collections, namely that an associated series of five upper cheek-teeth of a large ruminant from a Pleistocene cave-deposit near Cumberland, Maryland, U.S.A., indicate an antelope apparently closely related to the elands of Africa. So near, indeed, is the resemblance that the author deems himself justified in referring the fossil to the existing genus, under the name of *Taurotragus americanus*; and the plate showing these teeth alongside those of the existing *T. oryx* goes a long way in confirming his conclusion. It should have been mentioned that the present writer (see Cat. Siwalik Vert. Ind. Mus., part i., p. 1885) has provisionally referred certain teeth from the Indian Siwaliks to Taurotragus (= Oreas); and if the identification be correct, it would explain how eland might have reached America from Asia by the Bering Sea route. Mr. Gidley quotes the occurrence in the Pleistocene of Nevada of remains of certain ruminants described as Ilingoceros and Sphenophalus as corroborative evidence of the former existence of tragelaphine antelopes in America; but he omits to mention that although these genera were at first assigned to that group, they have been subsequently regarded as akin to the American family Antilocapridæ (Merriam, Bull. Dept. Geol. Univ. California, vol. vi., p. 292). If this be correct, is it quite impossible that the supposed eland represents another member of the same group?

In a second communication (*op cit.*, No. 26) Mr. Gidley records the occurrence of a toe-bone of a camel in a superficial deposit at the mouth of Old Crow River, in the Yukon Territory, in association with remains of mammoth, horse, and bison. The occurrence of the camel-bone confirms "the theory of the existence of a wide Asiatic-Alaskan land connection of comparatively recent date, which for a very considerable length of time served as a great highway for the free transmission of mammals between America and the Old World."

As being only in part palæontological, brief notice must suffice for a paper, by Mr. K. S. Bardenfleth, on the form of the carnassial tooth in Carnivora, published in *Vidensk. Meddel. Dansk. naturh. Foren*, vol. lxv., pp. 67–111. After reviewing the various theories of the homology of tooth-cusps, the author proceeds to observe that in order to demonstrate that the simple reptilian tooth-cone is represented by the middle one of the three longitudinally arranged cusps of the Purbeck Triconodon, and that the tritubercular crown has been formed by rotation of the other two, indisputable evidence has yet to be furnished, "first, of the Triconodon-like forms being the ancestors of Dryolestes, &c.; second, of the supposed protocone and protoconid of these being really homologous with the median cusp of Triconodon. One can scarcely imagine how such a rotation could take place, and if Gidley is right in his interpretation of the molar cusps of Dryolestes, the rotation has not taken place, but the so-called protocone is a secondary acquirement; the true protocone is still to be sought in the central one of the three outer cusps. If this holds good the whole nomenclature and theory of Osborn falls to the ground; neither protocone nor protoconid are then identical with the reptilian cone."

Three papers, by Dr. R. Broom, form part 6 of vol. vii. of the Annals of the South African Museum, and relate to the extinct reptiles of the same country. In the first of the triad the author shows that while in Pariasaurus the digital formula is 2.3.3.4.3, in the allied Propappus it is probably 2.3.4.5.3. In the second he describes, as *Noteosaurus africanus*, a new genus allied to Mesosaurus, of which three of the known species are South African, while the fourth is Brazilian. The last paper comprises a classified list of the early Mesozoic reptiles of South Africa, which, apart from dinosaurs, crocodiles, rhynchocephalians, &c., are arranged in no fewer than nine ordinal groups, brigaded in three "superorders." R. L.

AN ALGEBRA FOR PHYSICISTS.[1]

THE principal novelties in Dr. Macfarlane's calculus are that a distinction is made between linear and cyclic successions of vectors, and that the commutative law of addition, as well as that of multiplication, is abandoned. To express what most vectorists write $\beta+\alpha=\alpha+\beta$, Dr. Macfarlane writes $\Sigma(\beta+\alpha)=\Sigma(\alpha+\beta)$. Thus $\alpha+\beta-\alpha$ is not the same as β, but either three sides of a parallelogram, or three coinitial vectors, according as we take linear or cyclical succession. By introducing some subsidiary and rather artificial rules, the author is able to get formulæ that are, in appearance, analogous to the binomial and exponential theorems, and so on.

The actual divergence from quaternion results is not very great, as may be easily shown by an example. Let x be a scalar, α a unit vector, and let $\exp(x\alpha)$ be defined to mean $\Sigma(x\alpha)^n/n!$. Then $\exp(x\alpha)=\cos x+\alpha\sin x$, and if y is another scalar, $\exp(x\alpha).\exp(y\alpha)=\exp(y\alpha)\exp(x\alpha)=\exp\{(x+y)\alpha\}=\cos(x+y)+\alpha\sin(x+y)$.

But, if β is another unit vector,

$$\exp(x\alpha)\exp(y\beta)=\cos x\cos y+\alpha\sin x\cos y+\beta\cos x\sin y+\alpha\beta\sin x\sin y,$$

which differs from $\exp(y\beta).\exp(x\alpha)$, while both, in general, differ from $\exp(x\alpha+y\beta)$: the latter, observe, being by definition the same as $\exp(y\beta+x\alpha)$. Dr. Macfarlane, after writing down his exponential formula, breaks it up into four parts, practically the same as the four given by the quaternion formula above, when written in the form—

$$\exp(x\alpha)\exp(y\beta)=(\cos x\cos y+\sin x\sin y\,S\alpha\beta)+\alpha\sin x\cos y+\beta\cos x\sin y+V\alpha\beta.\sin x\sin y.$$

It must be left to physicists themselves to decide whether Dr. Macfarlane's new algebra is superior to those already available; the need of a sign to express a resultant is a rather severe handicap. To the pure analyst it presents the appearance of a conglomerate, though possibly, with a change of notation, it could be fitted into a place in the family of linear associative algebras. One thing ought to be said: it is not, properly speaking, an "extension" of quaternions. Analytically, the calculus of quaternions is a linear algebra of a perfectly definite type,

[1] (1) "Account of Researches in the Algebra of Physics," I.–III. (Reprint from Journ. Wash Ac. of Sc., 1912)
(2) "On Vector-analysis as Generalised Algebra" (Intern. Congress of Mathematicians, 1912.) By Dr. A. Macfarlane.

just as an oak is a perfectly definite type of a tree. Taking $q=x+yi+zj+wk$ as the type of a quaternion, we may generalise the "scalars" x, y, z, w, by making them ordinary complex numbers, or elements of some other algebra, commutative with i, j, k, and combining according to laws of their own. We thus embed the quaternion algebra, so to speak, in a larger composite algebra; but it is most undesirable to call this an extension, still less a completion, of quaternions.

The reader should be warned that the author often says "must" when there is no logical necessity at all. For instance, we are told that, β having one dimension in length, β^2 "must" have two; yet on the next page we are told that $\alpha\beta\gamma\delta$ means a solid angle, thus apparently having no dimensions in length, at any rate not four. This kind of fogginess is very common, even among quaternionists. Thus $ij=k$, so the product of two vectors can be a vector, and the law of dimensions is violated, or rather does not apply. Of course, in physics, it is convenient to represent areas, moments, &c., by vectors, and then the quaternion formulæ become more significant. We might, if we liked, put $ij=k_2$, $jk=i_2$, $ki=j_2$, regarding i_2, j_2, k_2 as areal units, and then have what Grassmann would call a regressive multiplication, $i_2j_2=k$, $j_2k_2=i$, $k_2i_2=j$, bringing us back to one dimension again. But anyone can see that this is unnecessary complication; in all physical applications of quaternions it is easy to see whether a vector is to be interpreted literally, or as the representative of some areal quantity.

Whatever may be the ultimate fate of this particular algebra, Dr. Macfarlane's researches deserve recognition. He has the spirit and the courage of a heretic, and every honest heretic helps to advance the truth.

UNITED STATES METEOROLOGICAL PUBLICATIONS.[1]

(1) THE first thirty pages of the report of the Chief of the Weather Bureau for the year 1911–12 contain a summary of the work accomplished by that department during the year. This is followed by a general statement of the weather conditions prevailing in the individual months, while the last and by far the longest part of the report is devoted to tabulated statistics of the different meteorological elements with summaries of sunshine, excessive rainfall, &c.

An account of the work done at the upper-air station on Mount Weather is given first place in the volume, and from this we learn that it is proposed to modify the plan hitherto followed of attempting to obtain a kite or balloon flight on each day, regardless of the weather conditions, and to substitute a series of special ascents made to investigate particular problems. It is interesting to learn that a special department is being inaugurated at this observatory for the training of observers for duty at the 200 out-stations of the weather service. At the central office a synoptic weather chart is prepared each day for the whole of the northern hemisphere, and on this map are based general forecasts of the weather and temperature conditions over the United States for a week in advance. It is intended shortly to institute a service of wireless reports from ships in the Atlantic, and to transmit information as to the location and movements of dangerous storms to vessels from one of the high-power stations on the coast. Extensive observations are now being made on the snowfall of the western mountain ranges, and it is hoped to be able in the future to give useful forecasts of the flow of those rivers which are fed in the spring and summer by the thawing snow. A feature of the report is the list of new books added to the library during the year. Many of the more important of these works are referred to individually, and a short account is given of the scope covered by each book. This should prove useful for purposes of reference. It is evident from a perusal of the volume that the operations of the bureau are conducted on a very large scale, as befits an institution dealing with meteorological information from an area like that of the United States.

(2) The impending opening of the Panama Canal renders the subject of the second paper of especial importance at the present time. In addition to dealing with the West Indian hurricanes, the author sets out comparative data for the typhoons of the Pacific and the cyclones of the Bay of Bengal. All these disturbances are of the same type, characterised by a moderate decrease of atmospheric pressure to within forty or fifty miles of the centre, and then the rapid fall associated with the destructive winds which cause such havoc in the belt passed over by the central region of the disturbance. Nearly all the West Indian hurricanes have their origin in a well-marked area bounded by the parallels of 12° and 26° N. latitude, and lying between 56° and 90° W. longitude. The typical track is parabolic in shape, the storm moving W.N.W. at first, then curving round to the N., and finally passing in a north-easterly direction to the North Atlantic. The average rate of travel of these storms is only 300 miles per day, so that the forecaster is often enabled to give a fairly long warning of their approach. Much useful information is contained in the paper, and Dr. Fassig is to be congratulated on the completion of a trustworthy piece of work.

REFLECTION AS A CONCEALING AND REVEALING FACTOR IN AQUATIC AND SUBAQUATIC LIFE.[1]

AS a result of observations and experiments carried out on ponds built for the purpose, and by the use of apparatus for observing organisms in their natural environments, I have arrived at certain conclusions as to the value of reflection as a concealing factor in various forms of aquatic and subaquatic life. The general principle upon which these ponds are built is as follows:—In one bank of the pond is a glass window, and beyond this window an underground observation chamber. No light enters this chamber except through the surface of the water. By this means everything in the pond is seen by *entirely* natural illumination, the observer cannot be detected, and as there is no reflection from the glass the making of photographic records is greatly simplified. In the first pond, built for the observation of objects in the water, the glass is perpendicular. In the second, for observing objects on the surface, the glass is at an angle of 45° to the surface.

Of apparatus I use a tube 18 in. square and 5 ft. long. On one side at the lower end is a window; into this tube slides a reflex camera, so that the lens is opposite the glass. When in use, a heavy weight carrying a hook is lowered into the water, with the end of the tube attached to the hook. The whole apparatus can be tilted at any angle, and by this means the incident rays from any object in any position—except overhead—are made to strike the glass at right angles, and thus distortion, due to refraction through the glass, is rendered negligible.

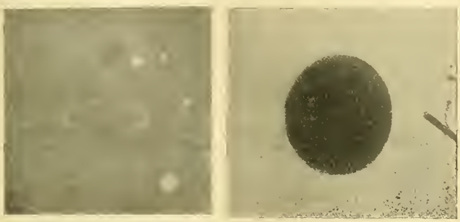
[1] Discourse delivered at the Royal Institution on Friday, June 6, by Dr. Francis Ward.

The apparatus has been mainly used as a check upon observations in the ponds.

For observing and photographing life on the bottom, I use a tube 3 ft. long, with a glass partition inside, a foot from the end. This apparatus acts as a boat-like sea telescope, and is fitted with a camera. Lastly, through the kindness of Prof. Herdman, I have established at Port Erin a large wooden tank above ground. Three sides of the tank incline at an angle of 45°; the fourth is perpendicular. In the perpendicular side is a glass window, and attached to it an observation box, 6 ft. by 4 ft. The tank and observation box revolve together on a platform; by this means an object in the tank can be seen by reflected and transmitted light at will.

It is usual to consider pigmentation as the main factor in the concealment of subaquatic life. Among organisms that live in more or less the same character of surroundings, pigmentation is undoubtedly most important; but in the forms of life that are constantly changing their environments, the best concealed are those that most effectively reflect their surroundings.

When, however, an organism depends mainly upon reflection for its concealment, the reflection of light from above has to be modified, or else the organism is revealed. In some forms of life, particularly fishes, pigmentation upon the back is the method of modifying this reflection from above. In other forms this top light is cut off by position, *e.g.* in light-coloured



White saucer on the surface in the area of total reflection. White saucer on the surface in the circle of light.

Fig. 1.

anemones, which are only to be found attached to the under-surface of shelving rocks.

Before proceeding further, I would like to illustrate the appearance of a white object, as seen from under the water. I show a sheet of white cardboard pinned on a red stick, which in turn was stuck in the centre of an *empty* pond. The sides and bottom of the pond were covered with green confervæ. In this position the card appeared white, and incidentally the stick red.

The pond was then filled up with water, and now the white card so exactly reflected the colour around that it became practically invisible, yet its position was revealed by a streak of light along the upper edge of the card.

In nature all white subaquatic organisms reflect in a similar manner, and white is never seen under the water, except when there is no provision made for modifying the reflection of light from above, or when the organism turns on its side.

As an illustration of this point, let us consider the white anemone (*Actinoloba dianthus*). I show a colour-plate of this anemone attached to the top of a rock and, of course, it appears white, but as soon as it moved only a distance of 2 in. under the shelving edge of the rock, the top light was cut off, and you will see the white anemone appears green as it reflected the prevailing colour below.

It will be noticed that the white serpula on the rock reflects in the same manner; and as the light parts of rock also appear of a greenish colour the anemone and the serpula are practically invisible. Advisedly I say practically invisible, for the greenish anemone when closed makes a uniformly shaded green mass against a patterned rock.

It will have been noticed that the red stick holding the white card, when seen from under the water in green surroundings, appeared a dull black.

When *Tealia crassicornis* (a red and white anemone) is attached to the under-surface of a rock with a green coloration below, the whites of this anemone appear green and the red markings appear dark, so that now the anemone shows a general green coloration with dark markings upon it, which fit in with the dark markings on the stone. Many forms of light-coloured marine life are found under shelving rocks. I consider they escape destruction in this position owing to the fact that they reflect their surroundings.

Next let us consider the modification of reflection by pigmentation. This is best illustrated in fishes. Until one has observed fish by *entirely* natural illumination, it is difficult to realise how important a

Fig. 2.—Lesser black-backed gull on surface in area of total reflection. (From life.)

part reflection plays in rendering both silvery and highly pigmented fishes inconspicuous.

The silvery fish does not appear silvery, but red, brown, or green, according to the general colour around, and in addition it will reflect upon its body stem for stem the reeds into which it has rushed in order to hide itself.

As an illustration to show how a highly pigmented fish reflects light, I show a tench, only 6 in. under the water, and it will be seen the dark back appears quite silvery.

Pigmentation on the back conceals a fish against the bottom, but undoubtedly the important function is to conceal it, for protective and aggressive purposes, from other fish on the same level as itself. I would point out that the same light which is reflected from the sides of the fish, through the eye of the fish, controls the amount of contraction of the pigment cells on the back: thus the reflection from above is correctly modified, and the fish is rendered a uniform shade. But this uniform shade only conceals against a uniform background.

Thayer has shown in the animal world how th counter-shaded bird, or beast, without markings, when seen against a patterned background, becomes conspicuous, because it interrupts the pattern. The same is seen in the fish world, and in illustration I would direct your attention to the appearance of a perch (*Perca fluviatilis*) swimming past a reed bed.

In the autochrome of a brown trout lying under a stepping-stone, I show the value of reflection; here, the back green, and the belly red, as they reflect the stones above and below, are undoubtedly the main factors in concealing this fish, and the markings simply prevent the body from appearing patternless.

I would next direct your attention to the possible influence of reflection of light, from some forms of marine vegetation, upon the pigmentation of various marine organisms. Several red and brown seaweeds seen by transmitted light appear red and brown, but when seen against a dark background they reflect at various points a brilliant bluish-purple colour. Chondrus shows this well. In certain positions the whole side of a dark rock, covered with red and brown seaweed, shows blotches and streaks of bluish-purple. This is well marked upon the concrete blocks on the old breakwater at Port Erin.

FIG. 3.—Cormorant on surface dipping head under water. (From life.)

Lobsters, crabs, and many other forms of marine life, usually found in crevices among dark rocks covered with red and brown seaweeds, show a pigmentation exactly similar in appearance to the colour reflected from the seaweed. This is particularly well marked in the swimming crab, *Portunus puber*.

I would now refer to the appearance of life on the surface, as seen from below. This appearance entirely depends upon the position that the particular organism occupies on the surface, relatively to the point of observation from below the water.

On looking up to the surface, an observer sees above him a circle of light, through which he can see the sky and clouds. Beyond this circle there is total reflection, and the surface of the water reflects the general colour below. Transparent organisms are practically invisible, both in the circle of light and beyond. Now it is generally understood that forms of life that occasionally or habitually float on the surface are white underneath, so as to conceal them against the clouds and wave foam.

In dealing with this subject it is necessary to make a difference between white organisms that are opaque and those that are translucent. Commencing with the opaque, I will illustrate the point with the appearance of a thick white saucer. This was floated from some distance over my head. Outside the circle of light the surface of the water was reflecting the green bottom of the pond, the white saucer did the same, and, therefore, was invisible against the surface of the water. When, however, it came into the circle of light it still reflected the dark colour below and was revealed as a well-defined dark object against the sky and clouds.

A white-breasted gull swimming on the surface is concealed and revealed in an exactly similar manner. Therefore, an opaque white organism in the circle of light is not concealed, and when seen against the clouds the whiter the object the more conspicuous it becomes, because it reflects the dark water below. A white object is, however, concealed by reflection in the area of total reflection.

How does this explanation affect the concealment of an opaque white object on the sea from a fish? The size of the circle of light on the surface depends entirely upon how far the fish is under the water, for lines drawn from the two ends of the diameter of the circle make an angle of 97° at the eye of the fish.

When the fish is some depth under the water there may be several white seagulls on the surface within

Shell of argonauta on the surface in circle of light. Shell of argonauta on the surface in area of total reflection.

FIG. 4.

the circle of light, but as the fish comes up to feed his circle of light is narrowed down, and the gulls slip into the area of total reflection and by reflection become invisible to the fish.

For my experiments with translucent organisms I used the shell of an argonauta. In the circle of light you will see the shell is still very obvious, but as it transmitted a considerable amount of light it did not appear black like the white saucer. In the area of total reflection, however, the shell appears white, for in consequence of not being an opaque object it is no longer a reflector.

Argonauta seems to slip between two stools; it is too opaque to be concealed in the circle of light, and too translucent to be concealed in the area of total reflection. In the latter situation it certainly may be protected by simulating the appearance of wave foam, for wave foam in the area of total reflection appears as a flickering light.

So far we have only considered that portion of an object that is actually immersed. If, however, the organism under consideration is not too far distant, that portion of it above the water is visible on the edge of the circle of light, and the parts respectively above and below appear to be separated by a considerable interval of water surface. When the portion above the water is white, as in a gull, it is difficult to detect against the sky. The above remarks only refer to open water, and I will illustrate how a wading bird is concealed against the image of a reed-bed many yards behind him. Looked at from below the markings on a heron are in bold upright lines, for the plumage is greyish-white with black patches on each side of the head, and the black patches on the shoulders appear continuous with the black primaries of the wings. Seen against an open sky, the white parts of the wading heron blend with the sky, but the black parts stand up in bold relief. The head and shoulders of the bird are seen on the edge of the circle of light, but so also is the reed-bed many yards behind. The reeds, seen as perpendicular images, and the perpendicular markings on the heron blend, and thus make the bird inconspicuous.

2 4

1. Stuffed heron with neck straight out prepared to strike a fish.
2. Appearance of heron under the water. (From life.)
3. The same bird as he appears on the edge of the circle of light against the sky. Notice how the tree 160 ft. away and the body of the bird appear to be one.
4. Reeds were then placed 5 ft. behind the bird, and now his head and neck are not easy to detect.

When the above photographs were taken the lens of the camera was a foot below the water-level, and the heron was 4 ft. distant.

FIG. 5.

I have referred to white as a concealing agency. Black objects, when they retain air-bubbles on their surface, also become reflectors under the water. The black water-spider under a leaf appears green and is lost to sight. A waterhen swimming on the surface in the area of total reflection reflects the green weeds below, and becomes difficult to discern against the surface which is reflecting the same colour.

In conclusion, I will refer to reflection as a revealing factor. I have already illustrated this point with the anemone. I now show a slide of a shoal of young rudd wheeling round, and as they turn each fish is revealed as a flash of light as he catches the light from above.

Among diving birds the cormorant does not retain air bubbles in his feathers to the same extent as the loose-plumaged waterhen, yet by reflection he appears light or dark, according to the nature of the bottom over which he is swimming. When, however, the cormorant dives his track is marked by a series of brilliant flashes of light.

Now this bird when swimming on the surface has the habit of dropping his head under water at regular intervals—shags do the same. Seen from below, every time he does this, there is a flash of light not unlike the flash from a silvery fish turning. It is quite possible that fish, such as pollock and codling, are attracted by this flash, and thus swim towards their destroyer. These flashes of light are still better shown in the case of the penguin, and this I illustrate with individual pictures cut out of a kinematograph film.

I have had to leave the subject of refraction of light on the present occasion; first, because time does not permit of my dealing with it, and, secondly, because during the last fortnight I have tested all my experiments at Port Erin, and some of the results have made me reconsider the conclusions at which I had arrived with regard to the refraction of light in its relation to marine organisms.

TECHNICAL EDUCATION FOR INDIAN STUDENTS.

THE report of a Committee appointed by the Secretary of State for India to inquire into the system of State technical scholarships established by the Government of India in 1904, has been published as a Blue-book (Cd. 6867). On March 27, 1912, the Secretary of State appointed a Committee "to inquire and report as to the facilities available for Indian students for industrial and technological training in this country, with special reference to the system of State technical scholarships established by the Government of India in 1904." The Committee was constituted as follows:—Sir Theodore Morison, K.C.I.E. (chairman), Sir K. G. Gupta, K.C.S.I., Mr. J. H. Reynolds, Prof. W. E. Dalby, Mr. P. H. Dumbell (secretary), Mr. R. E. Field (assistant secretary). The Committee held its first meeting at the India Office on May 9, 1912, for the purpose of discussing the itinerary, and considering questions of procedure. On various occasions the Committee visited Glasgow, Leeds, Manchester, and Birmingham, where they received evidence from the higher education authorities, and visited the various laboratories, and so on, devoted to technical education. Altogether during the provincial meetings the Committee took evidence from seventy-five witnesses, of whom twenty-nine were professors and other representatives of the universities and technical colleges, twenty-eight gentlemen intimately connected with various industries as owners and managers of works, &c., and eighteen Indian technical students.

The information laid before the Committee at the four centres visited has been sufficient to enable it to prepare a report which will indicate the main lines of the policy which should be followed, but the inquiry as to the facilities available for Indian students for industrial and technological training is by no means exhausted, and it will, the Committee thinks, be necessary—if possible, early next session—for some representative of the Secretary of State to visit such centres as Sheffield, Liverpool, Bradford, and Newcastle, where it appears probable that special facilities exist for the study of particular subjects.

Among recommendations made by the Committee the following may be mentioned:—Students sent to this country should ordinarily have read in India up to the standard of the B.Sc. or B.A. with science, or have obtained an equivalent diploma. Exceptions may, however, be made in favour of students who have an hereditary connection with the industry which they propose to study, provided that they know enough English to follow lectures in this country.

Wherever possible, students should be familiar in India with the industry which they are sent here to study. In mining, this condition must in the future be enforced strictly, and no student be sent to the United Kingdom to study mining unless he has had at least a year's experience down an Indian mine.

The Local Governments should, in making selections, consult the business men and directors of industry in the province to a greater extent than appears to have been the practice hitherto. Business men are often likely to know of a promising lad who would make excellent use of a technical scholarship; they could also advise the Local Government as to the type of man whom the industries of the province need, and to whom they would readily offer employment.

Practical training in a business firm should be considered an integral part of the technical scholar's education, and consequently the period for which the scholarship is tenable should be extended so as to cover the time spent in undergoing such training.

A technical scholarship should not, except in rare cases, be tenable for more than five years, and in very few cases should it be granted for less than three; whatever duration is assigned to the scholarship it should be long enough to include a spell of continuous practical training. Wherever possible this training should be given in the United Kingdom.

The general effect of the recommendations will be to increase the cost to Government of the system of State technical scholarships. This additional expenditure will, however, be amply justified if in consequence of the changes the Committee proposes the men are better selected and better equipped for the work they have to do. Indeed, the expense of technical scholarships cannot be defended at all, says the report, unless they give the best preparation possible for the highest kind of industrial work. The ideal training for an industrial career is both lengthy and costly, and for this reason it should only be given, at public expense, to men of quite exceptional capacity. The average man, who can never be expected to do more than carry on well-known industries by well-known methods, can be trained in India; if he is trained in England it should be at private expense. But when the best men, so far as human foresight can discriminate, have been selected, it is false economy to give them any but the very best training.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The General Board of Studies will in the ensuing Michaelmas term proceed to appoint a University lecturer in surveying and cartography to hold office until September 30, 1916. Particulars of the stipend and duties of the lecturer can be obtained on application to the Vice-Chancellor. Candidates are requested to send their applications, with such testimonials as they think fit, to the Vice-Chancellor on or before October 11.

Mr. J. H. Burn, of Emmanuel College, has been elected into the Michael Foster research studentship.

The Royal Commissioners for the Exhibition of 1851 have, on the recommendation of the Vice-Chancellor, appointed Mr. I. Abrahamson, of Clare College, to an industrial bursary.

The Raymond Horton-Smith prize for 1913 is awarded to F. A. Roper and F. S. Scales, who are adjudged equal for theses for the degree of Doctor of Medicine. Subjects: "Creatinine and Creatin Metabolism, especially in Reference to Diabetes," and "The Electrocardiogram as an Aid to Diabetes." The M.D. degree committee expresses appreciation of the high standard attained by most of the theses submitted for the degree of Doctor of Medicine. Many of these theses, either records of clinical investigations on obscure diseases or of original laboratory research, ought, in the opinion of the committee, to be published. The theses submitted by Dr. A. Abrahams, on the analysis of nystagmus, Dr. H. T. Ashby, on the anæmias of infancy and childhood with special reference to the connection of iron with anæmia, Dr. A. F. MacCallan, on trachoma and Egyptian ophthalmias, and Dr. L. B. C. Trotter, on embolism and thrombosis of the mesenteric vessels, are adjudged worthy of special distinction. Amongst the theses not eligible to compete for the Raymond Horton-Smith prize that submitted by Dr. W. E. Hume, on a clinical and pathological study of the heart in diphtheria, attained a very high standard of merit.

London.—Since the appointment of a full-time secretary, the work of the Appointments Board, constituted by the Senate to assist graduates and students of the University in obtaining appointments, and to coordinate and supplement the work done by the schools and institutions of the University in this direction, has increased to a very considerable extent. The secretary, Dr. A. D. Denning, will be pleased to give further information as to the Board, and to see graduates, at the central offices of the University, South Kensington, on Wednesday afternoons, 2 to 5, or Thursdays, 12 to 1.30, or at other times by arrangement. Approximately 1000 posts have been notified to suitably qualified graduates registered with the Board within the last three months and many appointments secured.

By the will of the Right Hon. Stuart, Baron Rendel, of Hatchlands, Guildford, who died on June 4, the sum of 5000*l*. is bequeathed to the University College of Wales, Aberystwith, of which he was president.

We learn from *Science* that the General Education Board of the United States recently promised Washington and Jefferson College a grant of 20,000*l*. on condition that the college raised 80,000*l*. by June 30 last. On the date mentioned the college was able to announce that 88,000*l*. had been collected. Except for 10,000*l*., which is to be expended on a physics department, the entire sum now at the disposal of the college is to be added to the general endowment fund.

The organisation created by Lord Morley in 1909 for the benefit of Indian students included an Advisory Committee, and was mainly composed of influential Indian residents; fresh regulations have now been promulgated, we learn from *The Times*, giving the committee a definite constitution and specifying its functions. At least half of the committee are always to be Indian gentlemen resident in this country. The appointments are to be made by the Secretary of State for a term of three years. The functions of the committee are to keep itself informed as to the views of parents in India; to advise the Secretary of State; and to bring to his notice matters respecting the needs of the students. The committee has arranged to meet regularly on the first Monday in each month, and has appointed Sir M. M. Bhownaggree vice-chairman.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, July 28.—M. F. Guyon in the chair.—Maurice **Hamy**: Study of the nitrogen radiations. The explanation of the width of the lines of the spectrum of rarefied gases, based on the Doppler-Fizeau principle, has been recently verified experimentally by Buisson and Fabry working with Geissler tubes containing the rare gases of the atmosphere. Similar work on nitrogen, a gas furnishing a band spectrum, is now described by the author, and he concludes that the band spectrum of nitrogen obeys the same laws as line spectra, as regards the difference of path required to make interference bands disappear. —E. **Jungfleisch** and L. **Brunel**: The sulphur set at liberty in the action between sulphurous acid and water. A study of the condition in which the sulphur is deposited in this reaction. Five photographs accompany the paper.—Lucas **Championnière**: Operation for club foot by ablation of all the bones of the tarsus. Osseous regeneration in young subjects. The operation consists in the removal of all the tarsal bones with the exception of the posterior portion of the calcaneum. A description of the results in forty-two cases is given. In young children there is distinct regeneration of a portion of the bone removed.—Couyat **Barthoux** and H. **Douvillé**: The Jurassic in the desert to the east of the Isthmus of Suez.—P. **Duhem**: The formula for the velocity of sound. A correction of a formula recently published by M. Ariès.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the second quarter of 1913. Observations were possible on seventy-seven days, and the results are grouped in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—Rodolphe **Soreau**: An approximate formula for the arc of an ellipse.—E. **Stiemke**: Numbered moduli.—Kr. **Birkeland**: The conservation and the origin of terrestrial magnetism.—Georges **Claude**: The maintenance without difficulty of a temperature of $-211°$ C. by the use of liquid nitrogen. A rapid stream of hydrogen, 20 to 25 litres per minute, previously cooled by flowing through a copper spiral immersed in liquid nitrogen, is passed through about 0·75 litre of liquid nitrogen contained in a capacious Dewar vessel. The temperature rapidly falls, and after about twenty minutes remains steady at $-211°$ C., the melting point of nitrogen. At this point about two-thirds of the original liquid remains in the tube.—R. **Ladenburg** and F. **Reiche**: The absorption of coloured flames. It was shown more than thirty years ago by M. Gouy that the absorption of a coloured flame for the narrow lines of the spectrum which it emits is far from being complete, and that it was possible to calculate from his measurements the brightness of the lines as a function of the product of the thickness of the layer by the density of the metallic vapour. In the present paper these experimental results are compared with relations furnished by the electronic theory of dispersion. The two are shown to be in good agreement. If, on the other hand, the intensity of the lines is governed, not by the theory of dispersion, but by Rayleigh's theory according to the Doppler effect, then there is no agreement between the theory and Gouy's experiments.—E. **Briner**: The dissociation of the molecules into atoms considered as one of the factors of reaction velocity.—Victor **Henri** and René **Wurmser**: The negative photocatalysis of hydrogen peroxide. The stimulating or poisoning effect produced by certain substances on ferment actions has been hitherto ascribed to the action of the stimulant or poison on the ferment; the authors hold that this view must be modified in so far as this action may take place not on the ferment but on the body under transformation. In support of this view they adduce experiments on the photocatalysis of solutions of hydrogen peroxide in presence of traces of various substances, including sulphuric acid, caustic soda, iodine, potassium cyanide, &c. The addition of traces of these substances caused an increase of stability of the hydrogen peroxide towards ultraviolet rays.—F. **Bourion** and A. **Deshayes**: The quantitative separation of chromium and aluminium. The analysis of chromite. The method proposed is based on the use of a mixture of chlorine and sulphur chloride.—C. J. **Pitard**: Statistics and affinities of the flora of Chaouïa.—O. **Mengel**: The evolution of mildew according to the conditions of the medium.—Ch. **Julin** and A. **Robert**: *Ascidia fumigata*. Contribution to the study of the classification of the Phallusiideæ.—M. **Ruot**: *Bacillus lactis fermentens*, a spore forming butyleneglycol ferment of milk sugar. This organism produces an active fermentation of milk, 2:3-butyleneglycol accumulating in the culture, other products being carbon dioxide, hydrogen, acetylmethylcarbinol, acetic and formic acids.—Maurice **Renaud**: The irradiation of bacteria and the irradiated vaccines. For all the organisms studied irradiation with a quartz mercury-vapour lamp rendered the media sterile, leaving intact the histochemical properties. Irradiation prolonged beyond the period necessary for sterilisation does not diminish the activity of the soluble products of bacterial origin, such as toxins. The therapeutic application of irradiated cultures is discussed.—F. X. **Lesbre** and R. **Pécherot**: A calf born without the upper jawbone; a new Cyclocephalian type.—Eric **Gérard** and Hermann **Chauvin**: The waters of Spa. Radioactivity, electrical resistance, and cryoscopy.—J. **Ventre**: The influence of the yeasts on the variations of dry extract and of glycerol in wines.—L. **Lindet**: The soluble albuminoid matters of milk.—Ch. **Dhéré**: The diversity of hæmocyanines according to their zoological origin.

New South Wales.

Linnean Society, June 25.—Mr. W. S. Dun, president, in the chair.—C. **Hedley**: Studies on Australian Mollusca. Part xi. During 1912 the writer spent a furlough in Europe and America. Opportunities occurred for prosecuting conchological studies. Many types were examined, and much information was gathered from the Cumingian collection at the British Museum, the Lamarckian collection at Geneva, the collection of A. Angas at Newcastle, and that of Gould at Washington. Ten weeks were spent in constant study at the British Museum, during which almost the whole series of Australian marine gastropods and bivalves was examined. From these sources critical notes on 160 species, mostly from East Australia, are presented, to which are added illustrations of thirty hitherto unfigured species. Numerous corrections of nomenclature are offered, both in restoring prior names, and in re-erecting species wrongly sunk in synonymy.—E. W. **Ferguson**: Revision of the Amycterides. Part ii., Talaurinus continued. In continuation of last year's paper, the species comprised in Sections B and C and groups vii.–xx., inclusive, are now dealt with. The types of all the species described by Macleay have been examined, as well as specimens compared with most of Pascoe's types.—T. G. **Sloane**: Descriptions of two new species of Cicindela from Western Australia. One of the two new species proposed is allied to *C. saetigera*, Horn, and is represented by specimens from Lake Austin, near Cue. The types of the other, which is allied to *C. tetragramma*, Chaud., were collected 100 miles north of Kalgoorlie.

MATHEMATICS IN CHINA AND JAPAN.

The Development of Mathematics in China and Japan. By Yoshio Mikami. Pp. x+348. Leipzig: B. G. Teubner; London: Williams and Norgate, 1913.) Price 18 marks.

THE time has not yet come for anything like a complete or final history of mathematics in the Far East; meanwhile Mr. Mikami's work will be welcomed as being practically the first book on the subject accessible to Europeans. Its contents are unavoidably miscellaneous, but there are two or three topics on which some remarks can be made.

First of all we find, as usual, that in the earliest periods there is a special calculating apparatus, which dominates not only methods of computation, but forms of mathematical thought, for many generations. In the case of China this consisted of a board ruled in columns, and a set of calculating sticks or counters. So far we have the equivalent of the abacus; but there is a very important modification, apparently familiar at least as early as 50 B.C. Red counters were used for additive, and black for subtractive numbers, so there was a visible distinction between $+a$ and $-a$ of a most convenient kind.

An abacus does not lend itself to calculation with vulgar fractions, and strangely enough it failed to suggest decimals. However, the Chinese appear to have been in possession of all the rules for working with vulgar fractions as early as the middle or later half of the sixth century, although it was confessed a difficult subject even by learned men. In this respect they were 1000 years or so ahead of Europe. Unfortunately Mr. Mikami does not give any account of the notation (if any) used for fractions at this date.

Approximations to π occupied the attention of many mathematicians both in China and in Japan. Perhaps the most remarkable fact in this connection is that Tsu Ch'ung-chih (A.D. 430–501) calculated π in an Archimedean manner, arriving at upper and lower limits 3·1415927 and 3·1415926. In some unknown way he hit upon the values 22/7 and 355/113, which he called the inaccurate and accurate values respectively. The appearance of this celebrated value 355/113 at so early a date is very remarkable. It may be added that $\pi=\sqrt{10}$ occurs before A.D. 139, and that many Chinese and Japanese have calculated π to a large number of places of decimals.

Another striking thing is that the Chinese seem to have practised Horner's method of solving numerical equations in the thirteenth century (see pp. 74–8). In fact, both Chinese and Japanese constantly use the principles of reversion of series and successive approximation. We can venture to smile at Mr. Mikami's hint that it is "not impossible" that Europeans may have known of the Chinese method; but while doing so we must be careful not to accuse our Eastern kinsmen of borrowing without acknowledgment, unless due evidence is at hand.

There is, in fact, an extraordinary instance of independent discovery, upon which Mr. Mikami makes no remark, but which appears to be absolutely certain, unless somebody has committed an ingenious and elaborate fraud. Early in the nineteenth century Steiner published some extremely elegant results about rings of touching circles (or spheres) touching two given circles (or spheres). His proofs depend partly upon using the method of inversion, so as to change one of the fixed circles (spheres) into a line (plane). Under certain conditions we have a poristic ring of variable touching circles. Now on pp. 238–46 of the present work Mr. Mikami gives a summary of work by the Japanese Ajima Chokuyen, dated 1784, where Steiner's problem for circles is discussed without inversion, and the algebraic conditions are given (in their simplest form) for poristic rings of n circles when $n=3, 4, 5, \ldots 10$: and the method is general enough for the condition to be calculated in any case.

Various problems are given from time to time. Some of these are of a familiar type, and may be of Indian or even Egyptian origin (*e.g.* we have a variation of the sloping reed question). Others, especially of the Japanese, are evidently of native origin—suggested by toys, jugglers' tricks, and so on.

Matters of more general interest are a rule for finding out whether an expected child is to be a boy or a girl, the author's interview with one of the last great Japanese mathematicians of the older school, and lastly the title-page, which is a very significant document. Written in English by a Japanese, the book has been revised by an American professor and published by a German who has probably done more than any of his craft for the spread of scientific literature. The language is that of the lazy lion; the rest belongs to the lands of the two eagles and the rising sun. Let the lion beware lest reflection show him that he has an ass's head.

The reviser, Prof. G. B. Halsted, has shown admirable taste in not converting Mr. Mikami's idiom into standard English. In some cases it is rather difficult to understand the author's explanation of obscure rules and processes; but, on the whole, the impression produced is that the greatest of modern tongues is branching off into a new and picturesque variety, destined to flower in due course as it passes from science to poetry.

G. B. M.

TECHNOLOGICAL CHEMISTRY.

A Dictionary of Applied Chemistry. By Sir Edward Thorpe, C.B., F.R.S. Assisted by Eminent Contributors. Revised and enlarged edition. Vol. iv. Pp. viii + 727. (London: Longmans, Green and Co., 1913.) Price 45*s.* net.

THE fourth volume of Sir Edward Thorpe's well-known "Dictionary of Applied Chemistry" covers subjects ranging from oilstone to soda nitre. Among the longer articles are those dealing with some important oils, paints, opium, oxygen and ozone, paper, paraffin, petroleum, photography, platinum, polarimetry, potassium, pottery, quinones, radio-activity, rubber, saponification, sewage, silicon, silk, silver, smoke, soap, &c.

The first edition of this work has won for itself a well-deserved place in the library of the consulting chemist. A book of this description cannot be reviewed adequately by one writer, even after making due allowance for the omniscience of reviewers generally. Each important subject appears to have been written by a specialist, and accordingly none but a specialist in a particular subject is competent to express an opinion on the merits or demerits of each of the articles. I must say, however, that after reading those subjects in which I myself am more particularly interested, I have formed the opinion that the new edition of the dictionary will supplant the old one, not merely because it brings the subject-matter up-to-date, but also because it is a higher-class production. There seem to be very few misprints, and, without taking up the rôle of a schoolmaster correcting exercises, I must confess that I did not like the phrase "monoatomic chemical reaction" in the article on radio-activity (p. 535)—it is my opinion that "monomolecular," or better, "unimolecular," should have been written.

This dictionary—as perforce all dictionaries—is not likely to be consulted by a specialist in his own particular subject, since the articles are too brief for that; but it will prove exceedingly useful when it is necessary to look up outside subjects, because the main facts and principles are not here befogged with detail, as would be the case if reference were to be made to a comprehensive monograph. The book will also prove very useful for the university or college student of general technological chemistry. It is not easy to name a text-book which covers this ground adequately. Such a text-book could certainly not be properly written by any one man, or indeed, by any half-dozen men. A writer of a general treatise is almost certain to err when he attempts to describe unfamiliar processes by paraphrasing the writings of those who know. Pottery as described in treatises on general chemistry might be cited in illustration. One excellent text-book on chemistry has some eight lines on the subject, and in those eight lines there are five mistakes of fact! A student of technological chemistry working through the special articles in this dictionary has some assurance that the articles are written by men who have first-hand knowledge, and his confidence is accordingly well founded.

J. W. Mellor.

CLIMATOLOGY.

(1) *Das Klima.* By Dr. Eugen Alt. Bücher der Naturwissenschaft herausgegeben von Prof. Siegmund Günther. 12 Band. Pp. 136. (Leipzig: Philipp Reclam, jun.) Price 1.50 marks.

(2) *Aus dem Luftmeer.* Meteorologische Betrachtungen für mittlere und reife Schüler. Von Max Sassenfeld. Pp. iv + 183. (Leipzig und Berlin: B. G. Teubner, 1912.) Price 3 marks.

(3) Contribution a l'Etude des Relations existant entre les Circulations Atmosphériques, l'Electricité Atmosphérique et le Magnétisme Terrestre. By Alfred Vialay. Pp. viii + 203. (Paris: H. Dunod et G. Pinat, 1911.)

(4) *Meteorology: A Text-book on the Weather, the Causes of its Changes, and Weather Forecasting.* For the Student and the General Reader. By Prof. W. I. Milham. Pp. xvi + 549 + 50 charts. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1912.) Price 19*s.* net.

(1) IN this little book Dr. Alt seeks to give an account of the fundamental principles and facts of climate, and its importance in the development of civilisation. The first four sections deal with the methods of climatological research, and with the climatic elements, temperature, wind, rainfall, and humidity in their relations with each other, and their distribution in time and space. In the next two sections the author considers climatic zones, viz., polar, cool temperate, warm temperate, tropical with small rainfall, and tropical with one wet season or two wet seasons. The seventh section is devoted to types of climate, land and sea climate, mountain climate, and after

brief notes on variations of climate, and on climate culture, he concludes with an account of the climate of each of the five continents. The book is well written and arranged, and the author has made discriminating use of recent investigations.

(2) It is a commonplace that men seize upon the exceptional and regard it with especial interest while they let pass unobserved the beautiful and wonderful processes which are taking place every day. Herr Sassenfeld has written his book with the object of stimulating and guiding the youth of Germany in the observation of the recurring phenomena of meteorology, which may be for all, as they are already for some, a source of interest and pure delight.

In fewer than 200 pages the author covers the whole ground of meteorological observation and investigation: he devotes a chapter to the temperature of the upper atmosphere, giving Wagner's results for the temperature at heights of 1, 2, . . 10 km. for January and July, and for the whole year. In a small table he indicates the characteristic lag in annual variation of temperature by showing how the difference between the autumn and spring temperatures increases with altitude. Special attention is given to clouds, and three excellent illustrations of different types are reproduced from photographs lent by Dr. Süring, of Potsdam. Pressure is introduced in the middle of the book, after temperature, water vapour, dew, hoar frost, clouds, and rainfall have been considered. Although pressure is of fundamental importance in the study of meteorological processes, it introduces an idea which is strange to the mind and difficult of apprehension; and it is probably wise to impart some knowledge of the meteorological phenomena which affect human life most directly before seeking to teach the bases of dynamical meteorology. Wind, types of weather, and electrical and optical phenomena are next discussed in turn, and an appendix contains a valuable set of monthly rainfall normals for about forty places. The book is printed in Gothic type.

(3) This is a discursive book which shows that the author has read very widely: he deals with the atmospheric circulation in winter and summer in the northern and summer hemispheres, and shows that he is acquainted with most of the literature on the subject. In the second and third sections he deals with atmospheric electricity and terrestrial magnetism, in which he is equally widely read and up-to-date: he includes, for example, a page on Simpson's results regarding the electricity of rain, and proposes his own interpretation of them. The author disagrees with or disparages a large part of the work in meteorology of men like Ferrel and Helmholtz, but there is no evidence of his ability to succeed in solving the problems in which he concludes their work failed. His book may, however, be very useful for the references which it contains. Many of these are not found in current works, *e.g.* the reference on p. 118 to Beale's observations of the diurnal variation of the barometer in 1666.

(4) Prof. Milham has made an excellent plan for his text-book of meteorology. To each chapter is prefixed a table of headings and subheadings, which indicate the scope of the text: each chapter is followed by sets of questions, of topics for investigation, of practical exercises, and of references to the more recent and directly important works and researches on the special subject of the chapter. The book extends to more than 500 pages of text, in addition to a number of plates reproducing beautiful photographs of clouds, snow-crystals, and other phenomena. It is generally well written and trustworthy, but the author lapses occasionally as when, in describing what the world will be like after the atmosphere has gone and the temperature has fallen below the boiling point of hydrogen, he says: "The constant bombardment by meteors will make life in the open more dangerous than on a modern battlefield." The practical way, in which the United States weather service is regarded, is indicated by the appearance early in the book of "the financial saving caused by the Weather Bureau" as a suitable subject for investigation.

The first part of the book deals with meteorology proper, the atmosphere, its constitution, temperature, and circulation, and with weather offices and their work. In the second part the author treats of climate, of atmospheric optics, acoustics, and electricity, and, what is more novel, but of considerable importance, of floods and river stages, their measurement, characteristics, and prediction, the latter forming, in the United States, a part of the regular work of the weather bureau.

E. G.

THE HABITABILITY OF THE PLANETS.

Are the Planets Inhabited? By E. Walter Maunder. Pp. iv + 166. (London and New York: Harper and Brothers, 1913.) Price 2*s*. 6*d*. net.

THE question discussed in this little book used formerly to be considered in every popular book on astronomy, and it was generally supposed that all the planets were very probably inhabited by some sort of intelligent beings. The progress of astrophysics has thrown a great deal of light on the physical constitution of the planets, and this excellent summary of modern telescope-work, and of the consequences of the heat and light received by the planets and the force of gravity at their surfaces, is therefore most useful. Mercury and the outer planets are easily disposed of, and Mr. Maunder even considers what would be the condition of Jupiter and Saturn if cooled sufficiently to become solid at the surface. The results are not encouraging.

Special interest attaches to Mars, which is therefore discussed in considerable detail. The atmosphere is thinner than that at the top of the Himalayas, and though the maximum temperature is well above the freezing point, water must be normally in the state of ice and cannot be liquid to a depth of more than one or two inches, and that only in the torrid zone and during a few hours each day. Mars is therefore essentially a frozen planet, and the extremes of cold experienced there, not only every year, but every day, far transcend those of our polar regions. If there is any vegetation it must be confined to some hardy forms of a low type, stretches of which may account for the so-called "seas." The polar spots cannot be caused by snow, but only by hoar frost.

In a chapter on the illusions of Mars it is shown that recent observations tend to resolve the canals into disconnected knots of diffused shadings. They are therefore caused by an immense number of minute markings which, when fairly near each other and separately below the limit of distinct vision, appear like lines. Several other illusions of Mars not alluded to by the author were exposed by Johnstone Stoney in his papers on telescopic vision in the *Philosophical Magazine* in 1908.

Venus is thus the only planet left which may be inhabited; but the question hinges altogether on whether the rotation-period is something like that of the earth, or equal to the period of revolution round the sun, which is still uncertain. In the latter case one half of the planet will be scorched and the other half frozen.

OUR BOOKSHELF.

Life in Ancient India in the Age of the Mantras. By P. T. Srinivas Iyengar. Pp. x + 140. (Madras: Srinivasa Varadachari and Co., 1912.)

This little book is a good example of the kind of work which native Indian scholars are competent to undertake. The author wisely leaves to European scholars the comparative study of ancient Hindu beliefs and custom. He has undertaken the more useful, if less ambitious, task of analysing the Vedic Mantras, that is to say, the older collection of hymns, as contrasted with the Brahmanas or ritualistic treatises which supplement them. He brings together in a systematic, readable form the scattered references illustrating belief and custom. On the religious side he quotes the original texts describing the priest and his duties, magic, sacrifice, the fire cult, and the state of the soul after death. In the social department he deals with the king and his nobles, agriculture and other occupations, medicine and surgery, household life, war, sea voyages, amusements, the status of women, and so on. In each case he gives literal translations of the original texts, either made by himself or collected from authoritative versions, with detailed references to the originals. The value of such a collection is obvious, and the work, so far as it goes, has been carefully and judiciously carried out. In a new edition he would do well to replace the extracts in Sanskrit, which is unintelligible to most European anthropologists, by a Latin version in those cases where it is impossible to give an English rendering.

Mr. Srinivas Iyengar proposes, with the help of other scholars, to extend this series through the later periods of Indian history. If these monographs are prepared as carefully as that now before us the series will be welcomed by European students of Hindu beliefs and sociology.

Probleme der physiologischen und pathologischen Chemie. By Dr. Otto von Fürth. 2 Band. Stoffwechsellehre. Pp. xiv + 717. (Leipzig: F. C. W. Vogel, 1913.) Price 23 marks.

The appearance of the second volume of Prof. v. Fürth's important book will be welcomed by all who have profited by reading the first volume. The total work is divided into fifty lectures, twenty-five in each volume. They might just as well have been called chapters, for no teacher could ever give lectures of such portentous length. Those before us treat of the large subject of metabolism, both in health and disease. We therefore not only find a description of the chemistry of nutrition, secretion, gaseous exchanges, and so forth, but large sections are devoted to the consideration of such subjects as diabetes and fever.

The book is fully worthy of its author's eminence in this branch of knowledge, and abundant references to literature occur on every page. The information is admirably up-to-date, and the book can be confidently recommended to advanced students as authoritative and interesting. The interest might have been increased by the insertion of illustrations; even the advanced student will find it difficult, for instance, to grasp the meaning of dissociation curves of hæmoglobin unless these are graphically represented.

Prof. v. Fürth is to be congratulated on the completion of his ambitious task, and his readers will wish it every success. W. D. H.

Practical Management of Pure Yeast. The Application and Examination of Brewery, Distillery, and Wine Yeasts. By Alfred Jörgensen. Translated by R. Grey. Second edition. Pp. 128. (London: *The Brewing Trade Review*, 1913.) Price 5*s*. net.

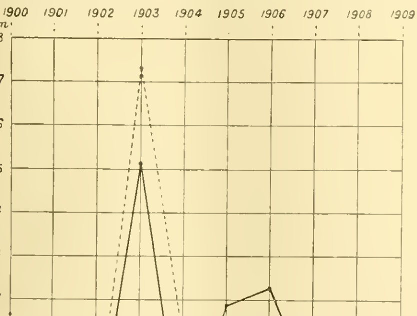
The first edition of this book was reviewed in Nature of November 5, 1903 (vol. lxiv., p. 4). The present issue has been revised and greatly extended by the author, who is director of the Laboratory of Physiology and Technology of Fermentations at Copenhagen. The new work is a remodelling of the first edition, and due regard has been paid throughout to the advancement of this branch of applied science during the last decade. The absence of an index is scarcely compensated for by the somewhat full table of contents.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Variation of Mean Sea-Level.

The many papers which have been written in recent years upon the above subject have dealt chiefly with the now well-known annual fluctuation (first noticed by Lord Kelvin nearly fifty years ago), by which the mean intertidal level of the sea stands on our North Sea and Baltic coasts something like 20 cm. higher in autumn than in spring. But while we still know too little about the details and the causes of this phenomenon, we know much less about the fluctuations of longer period, or even of the elementary facts of correspondence between different coasts in regard to the mean level in successive years.



Mean annual heights of mean sea-level, 1900–9, compared with the mean for the whole period. ------ At Dundee. ——— Mean of fourteen Danish and German ports, after Dr. Brehmer.

A paper published a couple of months ago by Dr. Brehmer, of Hamburg, in the *Annalen der Hydrographie*, gives a valuable set of data for the years 1900 to 1909, drawn from fourteen German and Danish ports, from Bremerhaven to Memel. The results at all these ports are very concordant, and all show a remarkable elevation of mean sea-level in 1903. I had lately been analysing the tide records at Dundee (for the years 1897–1912), and the correspondence of the mean annual values at Dundee with Dr. Brehmer's observations, as the accompanying diagram shows, is so remarkably close as to deserve particular attention. Only between the years 1905–7, and especially in 1906, is there any noteworthy discrepancy.

D'Arcy W. Thompson.

August 1.

On the Transmission of X-Rays through Metals.

When a beam of X-rays is allowed to pass normally through thin rolled metal sheets and fall upon a photographic plate placed behind and parallel to the sheet, some curious patterns are obtained.

These patterns fall into two classes: (*a*), in which the central spot produced by the direct beam is surrounded by an irregular halo of smaller spots, and (*b*), in which the central spot is surrounded by faint extended patches forming a *perfectly symmetrical pattern*. The design varies with the metal.

Class (*a*) markings are given by metal sheets which are either well aged or recently annealed, while the symmetrical patterns of class (*b*) are only obtained with newly rolled sheets. The spots of the former are due to reflections from the microcrystals within the metal, while the symmetrical patterns of the latter are produced by the structure imparted to the metal in passing through the rolls. These star-like patterns are evidently analogous to those obtained when a beam of light passes through a crystal which appears streaky to the naked eye. By annealing a newly rolled sheet the pattern changes from class (*b*) to class (*a*) and *vice versâ*.

It will be of interest to study the nature of the structure which gives rise to the symmetrical patterns.

University of Birmingham, August 7.

A Red-water Phenomenon due to Euglena.

A phenomenon of dichromatism in Euglena precisely similar to that described by Prof. Arthur Dendy in Nature of August 7 was recorded by me in *The Essex Naturalist* in 1890 as occurring at Donyland Heath, near Colchester. During July and August the surface of the largest pond on the heath was almost completely covered with a film which was red in the morning and turned to green in the afternoon. I watched the change take place on August 3 at noon, the transformation taking about half an hour. The omen of blood was viewed with some alarm by the superstitious in the village, and was held to betoken some ill for the community. After the heavy rains of August the pond was quite clear of the film, and no earthquake occurred.

Dr. D. D. Cunningham mentions, in *Science Gossip*, 1886, a similar phenomenon in tanks around Calcutta.

Colchester, August 8. Charles E. Benham.

The Ribbon-Fish.

A specimen of the rare, deep-sea ribbon-fish, *Trachypterus arcticus*, which was landed at the Grimsby market recently, has been sent to me. The following details of the specimen are perhaps worth reporting:—Length, 5 ft. $8\frac{1}{2}$ in.; greatest width, $10\frac{3}{4}$ in. No anal or pelvic fins. Caudal fin not axial, and the ventral portion without fin rays. Base of pectoral fin horizontal. Dorsal fin with 154 smooth rays. Teeth small but sharp. Skin silvery, and spinous on the ventral edge of body and along lateral line. Eye 3 in. in diameter. Lower line of body straight.

F. J. Cole.

University College, Reading, August 2.

THE INTERNATIONAL MEDICAL CONGRESS.

After an interval of thirty-two years, the International Medical Congress returned to London, and was opened at the Albert Hall on August 6 by Prince Arthur of Connaught on behalf of the King. The number of members ran far into the eighth thousand, as compared with 3182 a generation ago. Before this unprecedented assemblage the foreign delegates, whose names are given below, were presented to Prince Arthur, and each said a few words, the fewest and most appreciated, apparently, coming from Dr. Wu, representing the Chinese Republic. After Sir Edward Grey had welcomed the foreign members, Sir Thomas Barlow, the president of the congress, gave his address, which took the form of a retrospect of the progress attained since 1881. The president recalled the supreme names of Pasteur, Lister, Virchow, Huxley, and Koch, remarking that there were giants in those days; but he showed how their pioneer work has been, and is being, followed up by the many devoted workers of our own time. He took occasion, also, to defend vivisectors, especially in this country, from the charges of cruelty and futility commonly brought against them by malice and ignorance.

The general addresses to the congress were delivered on succeeding days by Prof. Chauffard, of Paris, on prognosis in medicine; by Prof. Harvey Cushing, of Harvard, whose discussion of the relation between surgery and medicine was found to contain, as its main feature, the finest defence of experiments on animals that has been heard for many years—a defence supported by the resolution in favour of vivisection which was later passed by the various sections of the congress; by Prof. Ehrlich, of Frankfurt, on pathology nominally, but actually on the most remarkable and beneficent of single achievements in scientific therapeutics that the history of medicine can record; by Prof. W. Bateson, on heredity, a subject which, in his lecture, and in other pathological aspects, received, as was long overdue, much attention at the congress; and by Mr. John Burns, President of the Local Government Board, upon public health. An address on this subject from a determined opponent of vaccination was, perhaps, the most startling novelty of the congress, though the address was well worth hearing, and this aspect of it would fortunately be unknown to most of our foreign guests at the time.

Amid the multitudinous features of the congress, with its hundred or so set discussions and its more than six hundred papers, one subject stands out in clear relief, as would be expected by every reader of Prof. Ehrlich's great address on chemio-therapy, a slightly abbreviated form of which is to be found on p. 620. Those who heard that address were well prepared for the discussion on the duty of the State in regard to syphilis, which was held in the Albert Hall on Saturday at a combined meeting of the sections of dermatology and syphilography, and of forensic medicine, under the presidency of Sir Malcolm Morris, whose initial part in the public advance we have made in the last two or three weeks must be duly honoured by future historians of public health. The result of Saturday's discussion was the unanimous passage of a resolution calling upon the Governments of all countries represented at the congress to make systematic provision for the diagnosis and treatment of all cases of syphilis not otherwise cared for.

Monday's debate on the treatment of syphilis by salvarsan made clear the real significance of the resolution already passed. The reception accorded to Prof. Ehrlich will never be forgotten by those who were privileged to be present. He introduced the discussion, and was followed by Prof. Wassermann, to whom we owe the invaluable blood reaction for the recognition of syphilis, and by Prof. Hata, of Japan, who helped Ehrlich in the great constructive search which led to salvarsan as the six hundred and sixth synthetic compound tested, and now acknowledged to be, as Prof. Wassermann said, "the mightiest weapon in the whole of medicine." Lieutenant Gibbard, R.A.M.C., reported on the revolution wrought by salvarsan in the treatment of syphilis in the British Army, and other speakers, from all parts of the world, whose total experience must run now into scores of thousands of cases, testified to the power of this remedy. Fate has been cruel, indeed, that young Schaudinn, who found the spirochæte only some seven years ago, thus providing Ehrlich with the living object of his chemical genius, should have been struck down in his early thirties, even before the first molecule of salvarsan came into existence upon a planet which the spirochæte has so long ravaged. It need only here be added that, thanks to Schaudinn, Wassermann, and Ehrlich, the whole problem of syphilis is now utterly revolutionised. The medical profession to-day asks only to be allowed to cure the victims of this infection, thereby preventing it as nothing but cure can ever do. The Royal Commission now demanded will be concerned with that central question, "the provision of diagnosis and treatment"; the horrible and useless measures taken in the past can never again be contemplated, and only unteachable ignorance and prejudice against knowledge can excuse the suggestions already made by two members of the House of Commons in this respect.

Another racial poison, alcohol, was the subject of an important discussion on alcohol and degeneracy, in the section of forensic medicine, introduced by Dr. Laquer, of Wiesbaden. The discussion was valuable, but as one-sided as that on the same subject which was held at the International Eugenics Congress last year, for at neither did the distinguished English author of a familiar report on parental alcoholism appear to defend his unique results on this subject.

The debates on various surgical problems, notably the operative treatment of cerebral tumours, excited great interest, and were doubtless profitable. Sir Victor Horsley had a notable reception as a pioneer in this field. But when all credit is accorded to the skill and success of surgeons, we must acknowledge that it will be better to use salvarsan early, which means having ever fewer patients in need of it, than to operate, however skilfully, upon cerebral syphilis; and it will be a great day, certainly, though too slowly approaching, when the principles of "chemiotherapy" can be brought to bear upon the cells of malignant tumours, in the brain and anywhere else. The debate on cancer at the congress was undoubtedly disappointing. Devoted, laborious, and valuable work has been done, very notably by Dr. E. F. Bashford, who was the first reporter upon the subject, and his associates of the Imperial Cancer Research Fund, but the goal is not yet reached. The work of Dr. Freund, of Vienna, who followed him, and who has found substances in malignant cells which are toxic to normal cells, and *vice versâ*, is very promising, and it may be surmised that the views as to specific ferments respectively favouring and disfavouring the chemical processes of the malignant cell, which were advanced by Dr. John Beard, of Edinburgh, some years ago, on the basis of Pasteur's fundamental stereo-chemical discovery, are nearer the line of effective advance than was at the time supposed. Prof. Ehrlich, who worked at cancer in past years, may perhaps return to the subject now and surpass himself. Meanwhile, the results of surgery, and very notably of radium, that astonishing agent, which certainly produces cancer under some conditions, and certainly cures it under others, are very welcome, and improve rapidly every year.

Prof. Simon Flexner could not come, and so we did not hear from his own lips about his work on the ultra-microscopic organism of infantile paralysis. But there was an important debate on "filter-passers," and the time is coming when biology and our views of protoplasm and living matter in general will have to face the strange results of recent research into this subject.

On Wednesday, with a lofty appeal for peace in the name of medical science, from the lips of the president, the congress was brought to a close. Its record, its numbers, its knowledge, have never been equalled, and will most surely and soon be utterly surpassed; but mankind will have ceased to care at all about health and disease, sanity and madness, life and death, before the visit of Prof. Ehrlich, the merciful records and the illimitable promise of his creative genius, at the International Medical Congress of London, 1913, are forgotten, or without homage, wonder, and gratitude remembered. C. W. Saleeby.

The following is the official list of delegates from foreign Governments to the congress:—United States of America, Dr. William Thayer; Austria, Prof. Ritter von Haberler; Argentina, Dr. Eliseo Segura; Belgium, Prof. Heger; Brazil, Prof. Marcos Cavalcanti; China, Dr. Wu; Cuba, Dr. Aristides Agramonte; Denmark, Dr. Madsen; France, M. Landouzy; Germany, His Excellency Prof. v. Schjerning; Guatemala, Dr. Azurdia; Holland, Dr. Rijnberk; Hungary, Prof. Emil de Grosz; Italy, Prof. Bianchi; Japan, Dr. Takamina; Mexico, Dr. Jose Larumbé; Monaco, Dr. Caillaud; Nicaragua, Dr. Alejandro Cesar; Norway, Prof. Dr. Uchermann; Portugal, Dr. Luiz de Freitas Viegas; Russia, General Dr. Rapschewsky; Servia, Dr. Subbotitch; Spain, Dr. Recasius; Switzerland, Prof. Sahli; Sweden, Prof. Essen Möller.

On August 6, in connection with the congress, the Royal College of Surgeons conferred its honorary fellowship upon Prof. R. Bastianelli, Rome; Prof. A. Bier, Berlin; Mr. F. D. Bird, Melbourne; Dr. G. W. Crile, Cleveland, U.S.A.; Dr. Harvey Cushing, Harvard; Dr. von Eiselsberg, Vienna; Dr. E. Fuchs, Vienna; Dr. H. Hartmann, Paris; Prof. W. Korte, Berlin; Dr. W. J. Mayo, Rochester, U.S.A.; Dr. A. Monprofit, Paris; Dr. J. B. Murphy, Chicago; Dr. J. Nicolaysen, Christiania; Dr. F. J. Shepherd, Montreal; and Prof. T. Tuffier, Paris.

At the closing meeting it was announced that the Permanent Commission of the International Congress had unanimously decided to accept the invitation of the Bavarian Government and of the town and University of Munich to hold the next Congress of Medicine in that town in 1917.

The commission further accepted the recommendations of the committees appointed to award the congress prizes as follows:—

(*a*) The Moscow prize, awarded to Prof. Charles Richet, of Paris, for his work on anaphylaxis.

(*b*) The Paris prize, awarded to Prof. A. von Wassermann, of Berlin, for his work on experimental therapy and on immunity.

(*c*) The Hungary prize, awarded to Prof. A. E. Wright, of London, for his work on anaphylaxis.

The committee of the Permanent Commission has been elected as follows:—

President.—Prof. Dr. Friedrich von Müller, of Munich (president-elect for the eighteenth congress).

Vice-Presidents.—M. Calman Müller, of Budapest (president of the sixteenth congress); Sir Thomas Barlow, of London (president of the seventeenth congress).

Secretary-General.—M. H. Burger, of Amsterdam.

Assistant Secretary.—D. Ph. van der Haer, of The Hague.

Member.—M. L. Dejace, of Liège (president of the International Association of the Medical Press).

The following resolutions sent up by the sections of congress will be considered by the commission:—

(A) That, sensible of the ravages wrought by syphilis in the health of the community, and deploring the inadequacy of existing facilities for checking its dissemination, the International Medical Congress calls upon the Governments of all the countries here represented—

(1) To institute a system of confidential notification of the disease to a sanitary authority, wherever such notification does not already obtain.

(2) To make systematic provision for the diagnosis and treatment of all cases of syphilis not otherwise provided for. (Submitted by the combined sections of dermatology and syphilography and of forensic medicine.)

(B) (*a*) That the section is of opinion that beri-beri among natives who live principally on rice is brought about by the continuous and too exclusive use of rice submitted to a too complete milling, which removes the cortical and subcortical layers of the grain.

(*b*) The section urges all authorities charged with the health of native communities to restrain by every means in their power the use of this rice in the dietary of coolies.

(*c*) In view of the proved non-infectiousness of beri-beri the section suggests that all port and sanitary authorities should abolish foreign quarantine and other restrictive measures against this disease.

(*d*) The section resolves that the malady known hitherto under the name of Malta fever shall in future be named "undulant fever." (Submitted by the section of tropical medicine and hygiene.)

(C) That this congress records its conviction that experiments on living animals have proved of the utmost service to medicine in the past, and are indispensable to its future progress. That, accordingly, while strongly deprecating the infliction of unnecessary pain, it is of opinion alike in the interests of man and of animals that it is not desirable to restrict competent persons in the performance of such experiments. (Submitted by various sections.)

THE CONTINUATION OF MILNE'S WORK IN SEISMOLOGY.

A WELL-INFORMED writer in *The Times* of August 7 has insisted on the importance of securing the continuity of the late Prof. Milne's great scheme of seismological observation and research. Milne himself always fought strenuously against his own undertaking being absorbed and lost in any international scheme. It is true that in connection with the international system there are some admirably equipped laboratories, furnished with a variety of instruments of extreme delicacy and sensitiveness; but the establishment of one of these is so costly an undertaking that such laboratories can never become numerous. Milne's aim was to secure a great number of seismological stations, scattered as widely as possible over the globe, each furnished with instruments of the same pattern, the records of which would be strictly comparable. The practical results which have been secured by Milne's scheme have shown that the comparatively simple type of apparatus which he advocated has furnished just such an observational basis for research as is necessary. Milne, at the outset, saw in the British colonies and dependencies the means for a wide extension of his scheme—though he by no means limited his efforts within the Empire. It would, indeed, be a disgrace, as well as a misfortune, to British science if the great undertaking originated by Milne were to suffer dislocation, or to be lost by absorption in any other scheme; and, at the same time, no more worthy monument to Milne's enterprise could be imagined than the maintenance and development of the system of observations to which he devoted his genius and energy, and for which he received little practical encouragement during his lifetime.

It is a very fortunate circumstance that the British Association is holding a meeting so shortly after Milne's lamented death, for no time must be lost if his invaluable organisation is to be rescued from the ruin which is threatened by the loss of its master-spirit. From the year 1841 onward, the association has been the nursing mother of seismological science in this country, and has helped Mallet, and afterwards Milne, by contributions from its funds, and especially by publication of their results. Milne was always ready gratefully to acknowledge the great aid afforded to him by the association, and devoted much of his time during the last year of his life to drawing up a valuable index to the numerous contributions to seismology scattered through seventy-two volumes of the association's reports. This index is now in type, and will be presented at the forthcoming Birmingham meeting. It may be hoped that on this occasion a means may be found for consummating the great aid which the association has always furnished to seismological science, by inaugurating an effort to place Milne's system of observation and research on a sound and permanent basis. It may be suggested that as a national system of meteorological observation has been evolved from the meteorological committees of the British Association, a national seismological scheme may, in like manner, be developed from the association's committees on the subject.

On August 8 a second letter appeared in *The Times* from the president of the Royal Society, strongly urging the importance of continuing Milne's organisation, and making it a national undertaking. Sir Archibald Geikie, besides bearing eloquent testimony to Milne's genius and enthusiasm as a scientific worker and his loveableness as a man, is able to quote from a letter just received from Prince Galitzin, the president of the International Seismological Association, in which it is asserted that Milne "through his most important investigations set seismology on a firm scientific basis, founded upon instrumental observation," that "he can duly be considered as the real founder and promoter of this new and important branch of geophysics," and that the continuation and development of his great work "would be the best monument to his memory." J. W. J.

THE ULTIMA THULE OF POLYNESIA.[1]

EASTER ISLAND, so called because of its discovery by the Dutchman Roggeween on Easter Day, 1722, presents several as yet unanswered problems in ethnology and linguistics. One of these is the provenance of the gigantic stone statues found in the island, another the decipherment of the singular incised tablets which appear to show a form of writing or hieroglyph, though written characters are found nowhere else east of Java. A third problem, the origin and settlement of the present population, or rather of the generation which is now so rapidly passing is less difficult, and is that which Mr. Churchill has set himself the task of investigating in the present volume.

In his former book on the Polynesian wanderings (see NATURE, September 21, 1911, p. 381), the author discussed the entry into the Pacific of the primitive Polynesians, whom he called the proto-Samoans, and their settlement in the region he defined as Nuclear Polynesia, comprising the island-groups surrounding Samoa, and including

[1] "Easter Island. The Rapanui Speech and the Peopling of South-east Polynesia." By William Churchill. Pp. iv+340. (Washington: Carnegie Institution of Washington, 1912.)

the Tonga and Viti clusters, with Rotuma, Uvea, and Fakaafo. He maintains that there was a later migration of the same race, the course of which into Polynesia cannot now be traced. These second comers he calls the Tongafiti, and regards them as having been so long separated from the proto-Samoan that their language had independently and divergently developed. But during the dominance of the Tongafiti in Nuclear Polynesia their speech had become mixed to some extent with the proto-Samoan.

After the expulsion of the Tongafiti from Samoa about the eleventh century of our era, they took refuge in the islands eastward, the Cook and Austral Islands, which became the centre of the migrations which ultimately reached Hawaii and New Zealand. This central region is not dealt with in Mr. Churchill's present work, and he defines the region discussed as "south-east Polynesia," comprising the Paumotu group with Mangareva, the Marquesan and Tahitian groups, and Rapanui or Easter Island.

Mr. Churchill's material for the examination of the languages consists mainly of the vocabularies collected by the French missionaries in Rapanui, the Marquesas, and Tahiti, with Tregear's vocabularies of Paumotu and Mangareva, also derived from French sources. All these lack, as Mr. Churchill notes, the fullness and detail of the Samoan, Tongan, and Maori dictionaries of Pratt, Baker, and Williams, for they start with an original list in French, for which their compilers have sought to ascertain the Polynesian equivalents.

Mr. Churchill's method in the present work is similar to that followed in the "Polynesian Wanderings." After a valuable discussion of the Polynesian alphabet, and of metathesis in Polynesian words, he deals with the sources and variety of Rapanui speech, deducing from its treatment of modern loan-words (European) its principles of deviation from the Polynesian standard. Then, by an examination of the Rapanui vocabulary, he proceeds to distinguish the words which occur (1) in both proto-Samoan and Tongafiti; (2) in proto-Samoan alone; and (3) in Tongafiti only. The first are called general Polynesian. In a table of 957 Rapanui words he refers 436 to general Polynesian, 110 to proto-Samoan (*i.e.* with cognates in Samoan), and 119 to Tongafiti (*i.e.* with cognates in Maori). But 292 words are restricted to south Polynesia alone, that is, have cognates only in Paumotu, Mangareva, the Marquesas, and Tahiti. He states that "the proto-Samoan element represents an older and more primitive type than is shown in the modern languages of Nuclear Polynesia," pointing to the migration from Samoa as having taken place whilst two aspirates were in use, and before the formative elements had been acquired which have enabled the language in Nuclear Polynesia to maintain the final consonant of a closed stem, as in Mr. Churchill's proto-Samoan stem *ikof*, which became *i'ofi* in Samoan and *iko* in Rapanui.

Paumotu is regarded as the "second station of the Tongafiti migration after its expulsion from Samoa, and its centre of distribution to the seats of the present great settlements of this swarm." Mangareva is also dealt with as a centre of distribution, and the Marquesas as affording indications of their being in the fairway of the migration to Hawaii. All these are numerically dealt with, and their words classified as general Polynesian, proto-Samoan, and Tongafiti. A very important result appears in the statement that in the Paumotu vocabulary, whilst 52 per cent. of its words are cognate with the other Polynesian languages, 48 per cent. are found peculiar to Paumotu. Mr. Churchill regards these words as true Polynesian which have gone out of use, as Polynesian words are prone to do, or have been invented to express a new environment, and quotes Dr. Friederici on word-tabu and the theoretical formation of new words. Here two important facts seem to have been lost sight of. In other languages the words used as substitutes for tabu-words are *not* usually new inventions, else they would not be understood by the hearers, but are words really belonging to the languages, though not in general use. Similarly, unless a foreign word is introduced, a new object or action is named by a word already known. In the opinion of the present writer, the fact that the peculiar Paumotu words are totally unlike any others in the island region (except a few in the allied Tahitian) appears to show that they are not Polynesian at all, but rather a remnant of some pre-Polynesian speech.[2]

Mr. Churchill finds in the four languages discussed a wide speech-group of broad diffusion and of considerable complexity. He subdivides this into: (1) a Polynesian speech which has passed from the use and memory of other Polynesians; (2) a later proto-Samoan colony taking refuge from Tongafiti tyranny; (3) a Tongafiti settlement; (4) a migration of associated proto-Samoan and Tongafiti from the west which was caught in the Paumotu chain, only a few stragglers reaching the other groups; (5) from the Paumotus, part of a subsequent migration reached Rapanui, the last home of the Polynesians.

Apart from its theory, with all the interesting issues involved, Mr. Churchill's book has the very practical advantage of presenting in a convenient form Rapanui, Paumotu, Mangarevan, Tahitian, and Marquesan vocabularies, with an extremely useful finding-list in English and Rapanui. The student, whether in accord with Mr. Churchill's theory or not, will find it of much value as a record of the languages.

Sidney H. Ray.

THE SOUTH AFRICAN NATIONAL BOTANIC GARDEN.

THE work of the last session of the Union Parliament included the establishment of a National Botanic Garden at the Cape. This was the natural outcome of the cordial reception given in the House of Assembly to the resolution moved by Sir Lionel Phillips on May 6.

2 Cf. Reports of Cambridge Anthropological Expedition to Torres Straits, vol. iii., p. 519 *et seq.*

Kirstenbosch, the site selected, is peculiarly favourable for the purpose, and affords scope for the development of a singularly beautiful South African garden. It is a farm on the Rhodes estates, to the south of Groote Schur, on the eastern slopes of Table Mountain. It contains the ruins of at least three old homesteads, and was probably occupied very early in the history of the settlement of this portion of the Cape Peninsula. The country seat of Van Riebeek, the first Dutch Governor (1652–1662), adjoins Kirstenbosch on its eastern boundary, and, according to tradition, Van Riebeek obtained from the latter a large supply of native woods for building purposes.

The survey of the Kirstenbosch estate is not yet completed; its area is probably about 400 acres. Of this, the eastern half consists of flat or slightly undulating land, about 200 ft. above sea-level. Above this the western half rises to about 1000 or 1500 ft. The latter includes the lower ends of three richly wooded gorges, in which the native vegetation during recent years has been little interfered with except by occasional fires. The lower-lying parts have been heavily planted with pines (*P. pinaster* and *P. pinea*), oaks, and poplars. Here the native bush has been mostly exterminated. The poplars have completely taken possesion of considerable areas. The oaks, most of which were pollarded many years ago, have been altogether neglected, and now, with few exceptions, are in an advanced state of decay.

The underlying rock, except perhaps in the most elevated parts of the estate, is granite. The slopes, however, are for the most part strewn with blocks of Table Mountain sandstone, fallen from above. Along one edge of the area there is believed to be an outcrop of Malmesbury slates. Many acres are overlain by a rich deposit of humus derived mainly from the oaks and the poplars. The water supply is exceptionally good. Two of the streams from the adjacent gorges, traversing the whole breadth of the estate, are permanent, and a spring, issuing about 200 ft. above the eastern boundary, is perennial. It will therefore be a matter of no great difficulty to irrigate as much of the cultivated land as may be necessary. In the cultivation of South African vegetation the importance of aspect is very considerable. Kirstenbosch offers a choice which is unlimited, save towards the west (where it is shut in by the lower slopes of Table Mountain), and also, of course, there is no direct exposure to the sea. Another factor which calls for careful consideration is that of wind. The well-known Cape South-Easter, which is of frequent occurrence during the season of most active growth and of flowering, has a most injurious effect upon very many species. Owing to the curvature of the Table Mountain range between Mowbray and Muizenberg, and the situation of Kirstenbosch in the curve, the south-east wind rarely reaches it.

Kirstenbosch, therefore, possesses a combination of natural features which make it eminently suitable for the cultivation and study of a very large proportion of the varied floras of South Africa. It already bears several hundreds of species more or less representative of the Cape region itself. Experience already obtained of the cultivation in the Cape Peninsula of dry-climate species from Namaqualand and the central plateau, and of sub-tropical forms from the south-eastern coast belt, affords no room for doubt that many of these also will find a suitable home side by side with the flora of Table Mountain and the adjacent Cape Flats.

The control of the garden is vested in a board of five trustees, to which the following have been nominated by the Government:—Lord de Villiers, Sir David Graaff, Sir Lionel Phillips. Two further nominations are yet to be made, one by the Corporation of Cape Town, and another by the Botanical Society of South Africa, constituted for the purpose of giving general and financial support to the project.

The trustees have made the following appointments:—Hon. director, Prof. H. H. W. Pearson; secretary, Miss H. J. Davison. Plans for a director's residence and a laboratory have been approved. A gardening staff will be appointed immediately.

WIRELESS TIME SIGNALS.

IN the *Annuaire* for 1913 of the Paris Bureau des Longitudes will be found a full account by Commandant Ferrié of the development of wireless time-signalling.

For a long period in the past local time was the only requirement of this kind, until the discovery of America rendered the determination of longitude at sea a matter of great practical importance, thus making the knowledge of the time on a fixed meridian as necessary as that of local time. The growth of railway enterprise in the nineteenth century made the adoption of standard time over large districts an obvious convenience, with the result that different countries adopted their own standard time, and Paris time, for instance, was made legal time throughout France in March, 1891. The subsequent gradual adoption of Greenwich time, or time differing from Greenwich by an exact number of hours or half-hours, has continued until the present time, France, only so recently as March, 1911, substituting Greenwich time for Paris time throughout France and Algeria.

The accurate determination of local time (or Greenwich time altered by a constant) comes into the domain of practical astronomy, and is responsible for a considerable amount of routine work, especially at Government observatories. The difference of longitude between two stations, including, for instance, the "constant" mentioned above, has provided a problem the solution of which has steadily progressed towards accuracy since the invention of the electric telegraph; but for any place not in telegraphic communication with a fixed observatory the greatest stride in advance since the invention of the chronometer has been the application of wireless telegraphy, of which the possibilities began to be considered in this connection very soon after Marconi's first success.

Few unexplored districts of the habitable globe would be beyond the reach of a powerful wireless installation if distributing stations were an ordinary adjunct of every national observatory, and it is likely that the network of stations will be able to distribute Greenwich time over the whole of the oceans.

For general purposes time-determination within a quarter of a second is sufficiently exact, but this accuracy at a fixed observatory was by no means always attainable under old conditions, since a week of cloudy skies, especially if accompanied by considerable changes of temperature, would leave the fixed observatory almost as dependent on the rate of a chronometer as a ship at sea. Here, however, the new development steps in and suggests that, since it is not likely to be cloudy everywhere, the time can be checked by that of an observatory perhaps thousands of miles away; so that no error approaching a second of time need be feared.

This state of things, needless to say, is not yet universal; but there is no doubt about the beginning that has been made. The distributing stations, requiring great electrical power and much more costly and elaborate fittings, will always be comparatively few, but the receiving stations can also take part in the scheme. The Eiffel Tower station sends out the Paris Observatory determination of Greenwich mean midnight, for instance, and this is received, say, at Greenwich with a modest equipment and compared with the Greenwich determination. The difference can be sent without much delay to Paris by post or telegram. When it is remembered that at night, under favourable conditions, signals from the Eiffel Tower have been received at a distance well above 3000 miles (5200 kilometres), it will at once be seen how this device will prevent any accumulation of error due to a spell of bad weather.

But a quarter of a second cannot be regarded as indicating the possible limit of accuracy attainable. By employing clocks with a small difference of rate, coincidences of beat can be noted with great accuracy, the arrangement forming what might be called an acoustic vernier. For example, if two sidereal clocks supposed to be synchronised differ by a small fraction of a second owing to a difference of lag in taking up the current from the control clock, this difference can be readily obtained by comparing each with the same mean solar clock, as the coincidences will occur at a definite interval. An accuracy of one-hundredth of a second (to use a loose, convenient phrase) is not by any means impossible in this way, and Commandant Ferrié suggests one-thousandth of a second as practicable. In this way may be measured not only the lag between the clock beat and the closing of the transmitting circuit, the additional lag before the Hertzian waves actually leave the Eiffel Tower, and the lag at the receiving station, but also the velocity of the waves themselves, which can be measured, he says, with an error of less than 3 per cent., though this velocity nearly reaches 200,000 miles per second.

It is part of the routine of the station to transmit time-signals by night and by day, the latter being followed by a meteorological report giving barometric pressure, direction and force of the wind, and the state of the sea for six stations in and around the Atlantic. Similar work, at times arranged not to interfere with that of the Eiffel Tower, is done at the German station at Norddeich, and other extensions will doubtless follow. Japan, at any rate, has already started an independent system.

Commandant Ferrié's account gives very full mechanical details of each step of the process, and should be of great interest to the growing number of people possessing private wireless installations, some of whom compare their time almost daily with both Eiffel Tower and Norddeich. There is no indication at present of any intention to erect a distributing station at Greenwich, and, as stated above, it may be considered unnecessary, the fortuitous presence of the Eiffel Tower giving Paris a great advantage, as its range goes far beyond the British Isles.

W. W. B.

NOTES.

The exhibition of specimens illustrating the modification of the structure of animals in relation to flight which has been in preparation for many months at the Natural History Museum will be open to the public on Friday, August 15. It occupies the fourth bay on the right of the central hall, and comprises 166 mounted objects and twelve microscopic specimens for the purpose of elucidating the subject in a popular manner. The adaptation of each kind of flying animal for aërial locomotion is explained, and the changes that must have taken place in the structure of the body before the animal could really fly are indicated, and attention is directed to the remarkable fact that the power of flight has been evolved independently in different groups of animals—*e.g.* bats, birds, Pterodactyles, and insects.

The death is announced, in his fifty-first year, of Prof. Edwin Goldmann, honorary professor of surgery in the University of Freiburg i/B. since 1892. Prof. Goldmann's scientific career and work are referred to in an appreciative notice contributed by Prof. Ehrlich to *The Times* of August 13, and here summarised:—As a pupil and friend of the famous pathologist Weigert, he mastered the technique of microscopy completely. In early days he busied himself principally with researches into biochemistry. Here he turned his attention especially to the study of minute vascular changes. And then an inner impulse compelled him to devote himself to the important field of cancer research, and by ingenious experiments to advance our knowledge of this difficult problem. His great work with a large number of instructive illustrations set in a right light the significance of cell division for biology and the spread of cancer; and afforded far-reaching insight into the complicated means of curing tumours. He reached the summit of his work in the last few years, during which he prosecuted his studies, which must be regarded as classical, in the staining of living tissues. Goldmann recognised clearly that if we desire to know and study the functions of the living cell the staining of living tissues offers the most profitable means. There were previously only a few works dating from an older generation, such as those on methylene blue, but they, corresponding to their own time, followed an incomplete technique. Here came in Goldmann's work. He succeeded in discovering a method of carrying out an exact pursuit of *intra vitam* staining in microscopic sections. The staining material, pyrrol blue, possesses the peculiarity of colouring a very special kind of cells which are found in the connective tissue and of making them visible to the eye, while the dye allows certain round granules contained in these cells to show up distinctly and in an intensive blue. Now Goldmann was able with the help of his method completely to clear up the great significance of the function of these cells, and to show that both in normal functions, as, for example, in digestion, and also in the majority of disease derangements, as in the case of tuberculosis and carcinoma, they play a very important part. His last important work also, "Ueber die Vitalfarbung am Centralnervensystem," dealt with that method and arrived at important conclusions concerning the nutrition of the central nervous system and the circulation of the cerebro-spinal fluid.

Prof. H. C. Jones, professor of physical chemistry at the Johns Hopkins University, has been awarded the Edward Longstreth medal of the Franklin Institute of Philadelphia for his work on the nature of solutions.

The inaugural address at the re-opening of the School of Pharmacy in October will, by invitation of the Pharmaceutical Society, be delivered by Dr. F. B. Power, director of the Wellcome Research Laboratories. On the same occasion Dr. Power will be presented with the Hanbury medal.

The Paris correspondent of *The Times* announces that the expedition to Franz Josef Land, under the command of M. Jules de Payer, left Havre on August 10. The object of the expedition is to explore the little-known north-eastern corner of Franz Josef Land, and a programme of scientific work has been prepared. The base will be established in Zichy Land.

Prof. Charles F. Marvin, professor of meteorology to the U.S. Weather Bureau, has been appointed to succeed Mr. Willis L. Moore as chief of that bureau. The new head of the office has been in the Government service since 1884, and is widely known for his important meteorological investigations. It is announced that under the new administration the Weather Bureau will pay greater attention to such weather reports and forecasts as are likely to affect agriculture.

The fifth annual conference of the National Association for the Prevention of Consumption was opened by the Prime Minister at the Central Hall, Westminster, on August 4, Lord Balfour of Burleigh presiding. A considerable portion of the session was occupied with a discussion on tuberculin treatment, in which Dr. H. W. G. Mackenzie, Prof. Sims Woodhead, Prof. Sali, and Dr. Lydia Rabinowitsch took part. On August 5 Sir R. W. Philip delivered an address on the need for coordination of anti-tuberculosis measures, which evoked an interesting discussion.

Official tests of a system of wireless telephony invented by a Japanese electrician, Mr. Torikata, have led to the adoption of the system by the Japanese Government, which has ordered all the shipping companies subsidised by it to install the apparatus on their principal vessels. The instructions have already been followed by the three largest Japanese mail steamship lines, we learn from *The Japan Chronicle* (July 17), with eminently satisfactory results. Patent rights for the invention have been secured in Japan, England, and France, and others are pending in Germany and the United States. It is stated that the present range of audibility of the Japanese system is sixty miles. The advantage claimed for the apparatus over competing systems is its simplicity, it being no more difficult to use than an ordinary telephone.

Asama-yama, the well-known Japanese volcano, has again been displaying great activity. On June 17, reports the Tokyo *Asahi*, an eruption occurred which is believed to be the most violent on record. Dense black clouds rose to a great height above the crater, and two streams of lava poured forth, one flowing towards Rogome Station, on the south, and the other invading the forest in Kita Saku district, on the west. Further eruptions occurred on June 20 and 26. A heavy fall of volcanic ash, lasting three hours, took place on the former date at Takazaki, thirty miles east of the volcano. On June 26 Dr. Omori, the distinguished Japanese seismologist, with a party of assistants, ascended the volcano with the view of investigating the conditions, but found advance beyond the ninth stage impossible. The party retired to the observatory at the base, intending to await a favourable opportunity of reaching the summit. Several cracks appeared in the upper half of the volcano, from which issued volumes of dust and vapour, and there were indications that a new crater is forming.

We announce with regret the death, as the result of an aëroplane accident, of Mr. S. F. Cody, the well-known airman, while flying with a passenger near Aldershot on August 7. The machine the collapse of which caused the accident was the new large biplane which Mr. Cody had built for the purpose of competing in the coming waterplane race round Great Britain. It was as a kite-flyer that Cody first came into prominence. In 1903, after two failures, he all but succeeded in crossing from Calais to Dover in a collapsible 14-ft. boat drawn by a kite. In 1906 the War Office appointed Cody chief instructor in kite-flying. In 1907 he was largely responsible for the engineering work of the Army airship, *Nulli Secundus*. In 1909 he achieved a cross-country flight of forty miles in sixty-three minutes—a record at the time. Cody was born in 1862, and was in his forty-seventh year when he began his experiments with flying machines. At the time of his death he was building a triplane on which he proposed to try to cross the Atlantic.

To the large collection of the contents of "short stone cists" found in the north-east of Scotland, and displayed in the anatomy museum of the University of Aberdeen, there have been added recently the contents of two others. One was found at Ellon, Aberdeenshire, and the other at Burgie, Morayshire. Both cists lay in elevated gravelly situations, with no external marks or monuments to indicate their positions, and had their long axes directed from east to west. Their roofs and walls were composed of large flat stones indigenous to the parts of the country in which they were found, and their floors of a layer of sand in which pebbles were embedded. The Ellon cist measured (inside) 3 ft. 4 in. by 2 ft. 1 in. by 17 in. deep, the Burgie cist 3 ft. by 1 ft. 10 in. by 2 ft. deep. The former cist contained a fully formed male human skeleton, showing characters ordinarily met with in skeletons found in short cists, viz., stature about 5 ft. 5 in., round skull, short broad face, narrow orbits, and rather wide nose. To its right lay the much-decayed remains of the skeleton of a person from fifteen to twenty years of age. In the cist at Burgie were found remains of a fully formed human skeleton, much decomposed, the skull of which had been so injured after the cist had been found that no observations could be made from it. In both cists the skeletons had been buried in a crouching position. An urn of the "drinking-cup" variety and a flint scraper were found in the Ellon cist, but nothing beyond skeletal remains in the Burgie one.

THE special feature of the present summer is the general dullness of the weather, with which is also necessarily associated a persistent low day temperature. Greenwich this year has the least sunny July on record since the registration of sunshine has been established, and although since August opened the weather has been somewhat brighter, still, many days have been very dull. Only one day at Greenwich has had the mean daily temperature in excess of the average from July 1 to August 11, a period of six weeks, and the highest maximum temperature observed is 76°, on July 12. Notwithstanding the cloudy character of the summer, there has been remarkably little rain, and prior to August 9 a drought had occurred in many parts of the British Isles. At Greenwich no rain fell from July 22 to August 6, a period of sixteen days; at Bath there was no rain for seventeen days, and at Nottingham for eighteen days. For the first sixty-eight days of summer from June 1 to August 7 the aggregate rainfall at Kew is 47 per cent. of the average, and at Greenwich 61 per cent. For the corresponding period in other parts of England Bath had only 20 per cent. of the average, Jersey 27 per cent., Nottingham 33 per cent., Liverpool 65 per cent., and Dover 68 per cent. In Scotland Leith had only 32 per cent. of the average rain and Wick 59 per cent., whilst in Ireland Valencia had 57 per cent., and Birr Castle 68 per cent. Rain has now fallen in many parts of the British Isles, but in places the conditions continue dry.

MR. C. ROBINSON, writing from Lancaster, says that while walking along a grassy path near some trees on a dark night he saw, "gleaming out of the darkness at my feet, what might have been a piece of frosted silver reflecting moonlight." Upon picking up the object he found it was a piece of decayed wood, which he took away with him, but was disappointed to find afterwards that the wood had lost its luminosity. The phosphorescence of decaying wood is not an unusual phenomenon, and is frequently due to the mycelium of a fungus which permeates the wood of old tree-trunks, and has the property of emitting light under the same conditions as those of respiration. When the wood is taken away from its natural surroundings, the luminosity disappears because the relations and conditions of life of the fungus are not the same as before.

IN his lecture on the pygmies of New Guinea recently delivered at the Royal Institution, Capt. C. G. Rawling gave a full account of the expedition organised by the Ornithologists' Union, assisted by the Royal Geographical Society, which left England in 1909 to explore the south-west coast of Dutch New Guinea. He sums up the results as follows:—Large and valuable collections of birds, mammals, reptiles, butterflies, and moths, with botanical and ethnographical specimens, have been made; a new and hitherto unknown race of pygmies was discovered, studied, measured, and photographed; a range of mountains, containing the greatest precipice in the world, together with 3000 miles of country, have been surveyed and mapped; new snow mountains and great rivers were found and explored; a long stretch of coast-line was surveyed. This, the longest cross-country journey ever undertaken in Dutch New Guinea, has proved the impossibility of the Mimika River as a line of advance to the snows, and, on the other hand, the value of the great rivers to the east, if an expedition in the same direction is again contemplated.

CERTAIN human bones discovered in 1911 by Mr. Hiram Bingham in gravel near Cuzco, Peru, have been considered to indicate the existence of man in that country between 20,000 and 40,000 years ago. In an article in the July number of *The American Journal of Science*, Mr. G. F. Eaton, who has visited the spot, states that the associated remains are essentially of a modern type, including, as they do, bones of domesticated cattle. He therefore concludes that the bones were buried some time "during the three centuries and a half that have elapsed since the Spaniards brought domestic cattle to Peru." In a second article in the same issue, Mr. H. E. Gregory states that although his investigations on the spot do not definitely disprove the theory of the great age of the bones, yet "the geologic data do not require more than a few hundreds of years as the age of the human remains found in the Cuzco gravels."

IF we may judge from a report on their breeding in that State, published in the Bulletin of the Illinois

State Laboratory of Natural History, vol. ix., art. 7, carp seem much more highly esteemed as food-fishes in those parts of the United States where they have been introduced than in this country. Their greatest enemies are garpike, which attack the young, and a fungus which infests the spawn, and against the ravages of these two foes remedial measures are suggested by Dr. S. A. Forbes in the article cited.

The King has presented to the British Museum (Natural History) a tiger shot by himself in the Nepal tarai during his Majesty's tour in India in the winter of 1911–12. The specimen, which was mounted by Rowland Ward, Ltd., has been placed on exhibition in a special case on the second floor of the building, between the Banks statue and the upper mammal gallery, opposite a portion of the Hume collection of Indian big-game heads. The animal is set up in a partially crouching attitude on artificial groundwork amid real Indian jungle-grass.

According to the sixth annual report (for 1912) of the American Bison Society, the number of pure-blooded bison in the United States and Canada increased during the season 1911–12 from 2760 to 2907 head. At the instigation of the society the U.S. Government has allocated a tract of 15,000 acres in South Dakota and the adjacent States to form an additional bison-preserve. As it includes part of the winter feeding-grounds of the great herds of bison that formerly ranged to the north and north-east, it ought to be admirably suited for the purpose.

In spite of several more or less well-attested instances of such an occurrence, there is a very general tendency to refuse to believe that female mules may occasionally be fertile. A case recorded in *The Field* of August 2, by Mr. G. J. Harvey, Government Veterinary Surgeon at Nicosia, Cyprus, seems, however, to be beyond reasonable doubt. In this instance the mule, which is stated to have given birth to another foal a year previously, was seen by Mr. Harvey in the act of suckling her foal, then two months old. The parent, which stood 13·2 hands, is stated to be the offspring of a she-ass by an unknown sire, and certified to be an undoubted mule.

The brown discoloration and unpleasant flavour acquired by peaches shipped for long distances has been attributed to so-called "ice-scald." That this injury is not a temperature effect is shown by recent experiments by Mr. G. R. Hill (Cornell University Agricultural Experimental Station, Bulletin 330), and evidence is adduced indicating the harmful effect to be due to an accumulation of carbon dioxide within the paper wrapper round the fruit during transit. During the investigations it was found that growing tissues, such as green peaches and germinating wheat, respire more than twice as rapidly aërobically as anaërobically, whilst ripe fruits respire as actively anaërobically as aërobically. Ripe apples lose their colour, texture, and flavour, and assume the qualities of half-baked apples by being kept for a sufficient length of time in oxygen-free gases. The softening of peaches (hydrolysis of pectose) appears to be decreased greatly by carbon dioxide and to a considerable extent by hydrogen and nitrogen; under similar conditions the fruit becomes brownish, and acquires a very bad flavour. Good ventilation and refrigeration, therefore, would appear to be the essential conditions under which this fruit should be stored.

A further report on the Isle of Wight bee disease has been issued as Supplement No. 10 to the Journal of the Board of Agriculture. Of the various sections of the report the first is contributed by Drs. Fantham and Porter, and deals with the life-history of the parasite (*Nosema apis*), with parasite carriers, examination of pollen, honey, and wax, and of certain insects found in hives; the second section, by Dr. Graham-Smith and Mr. Bullamore, describes results of infection experiments with the parasite, the mode of spread, and the means of treatment and prevention. The bacteriology of the disease is reviewed by Dr. Malden, and a summary of the investigations forms the last section. Up to the present no curative measures have been found, but certain preventive measures have yielded satisfactory results. No species of bacteria constantly associated with the disease has been found, and *B. pestiformis apis*, which is frequently in diseased stock, and was at one time thought to be the causal agent, is not pathogenic in pure culture. Bacteria, however, may play an important secondary part in producing the symptoms when the resisting powers have been lowered by the action of Nosema.

Mr. G. Ricchieri has contributed a lengthy summary of recent work on the nature of the earth's interior to the "Miscellanea di Studi" (R. Accad. Scien. Letter. di Milano). The conclusions of mathematicians and hypotheses of mathematicians, seismologists, and geologists are generally given in detail; but an account can scarcely be held complete which refers for the Rev. O. Fisher's views to the article on geology in the ninth edition of the "Encyclopædia Britannica," and omits all reference to the work of Dr. Milne and the deductions of Mr. R. D. Oldham.

In a paper communicated to the R. Accademia dei Lincei, Dr. G. Agamennone describes an interesting spurious earthquake caused by the sudden fall in Rome of a wall 60 metres long, 20 metres high, and 1·25 metres in mean thickness. The resulting shock was sensible to man at a distance of 350 metres, and it was recorded by a seismograph at the Collegio Romano, about 700 metres from the fallen wall. The maximum amplitude of the movement was only 0·005 mm., and this was attained two or three seconds after the beginning; the period of the vibrations was about one-third of a second, whereas in earthquakes of near origin the period is rarely less than one second.

The meteorological charts of the North Atlantic and North Pacific Oceans, issued by the U.S. Weather Bureau, for August, contain instructive articles by Mr. W. E. Hurd on the formation and movements of tropical cyclones. Several physical causes play a prominent part in their formation, but heat and moisture are necessary conditions. Mr. Hurd refers in detail to the works of various investigators, including such well-known names as Viñes, Meldrum, Algué, and others; to the variation of the storms with time and place; to their tracks and rates of progression of the vortices; the whole of which will repay careful perusal. Actual reference is not made to the article on the same subject in the valuable "Barometer Manual" issued by the London Meteorological Office, which epitomises the results of observations and experience extending over many years. A glance at this work, in conjunction with Mr. Hurd's compilation, explains how in either hemisphere the wind travels round the cyclonic centre in a direction contrary to the apparent diurnal course of the sun, the westerly wind being therefore always found in the portion of the whirl nearest to the equator. The average rate of progression (irrespective of the wind-force in the whirl) varies from about 300 miles a day in the West Indies to from fifty to 200 miles in the southern Indian Ocean. Fassig found that in the West Indies the average daily rate further increased after the recurve of the storm.

THE *Ergebnisse der magnetischen Beobachtungen* of the Royal Observatory of Wilhelmshaven for the year 1911, in addition to valuable information about magnetic diurnal and secular variation at Wilhelmshaven, contains an elaborate discussion by Prof. Bidlingmaier of what he calls "die erdmagnetische Aktivität." By "activity" he means a more exact numerical measure of the energy of magnetic forces than is afforded by the present international scale, which assigns 0 to a quiet, 1 to a moderately disturbed, and 2 to a highly disturbed day. Prof. Bidlingmaier's introductory remarks on the theoretical side are of extreme generality, but practically he assumes the "activity" for a given interval of time in a magnetic element to be proportional to the mean square of the differences of its values taken at a large, theoretically infinite, number of equidistant times throughout the interval from the mean value during the interval. By summing the "activities" for three rectangular components one would have a measure of the total "activity." The interval of time may be the hour, the day, or the year. In the first case, in practice, Prof. Bidlingmaier seems to approve of values at six-minute intervals. The labour involved in arriving at hourly "activities" throughout the whole year being very great, an attempt was made to see whether the "activity" in this case could be expressed as a definite function of the range. Hours having the same range were collected in groups, and the corresponding mean measured "activities" were plotted as ordinates of a curve of which the abscissæ were the ranges. A regular curve was thence derived, somewhat resembling part of an hyperbola. The work merits the attention of all interested in magnetic disturbance.

Engineering for August 8 contains an illustrated account of experiments on the distribution of wind velocity in the space surrounding a circular rod in a uniform current of air. These experiments were conducted at East London College by Prof. J. T. Morris. The wind velocity was measured by electrical apparatus. Electrically heated wires were attached to the circular rod, and the cooling of these wires by the air current was used as a measure of the wind velocity. The method has been described already by Prof. Morris at the Dundee meeting of the British Association, and at the recent soirée of the Royal Society. The present article gives complete sets of curves showing the wind velocity at different distances from the rod for various speeds of main air current, together with velocity-contour lines for currents of fifteen and five miles per hour. The "shadow" of the rod is brought out clearly by these graphs, and extends much further at low than at high velocity. Judging from the results, the electrical method of measuring air velocities seems to possess considerable advantages in the field of experimental aërodynamics.

THE foreign commerce and navigation of the United States for the year ending June 30, 1912, is dealt with in a volume prepared by Mr. O. P. Austin, and published at Washington by the Department of Commerce and Labour in the United States. The bulky volume of 1342 pages is concerned almost wholly with statistics, and provides detailed information of every department of the trade of the United States. In the fiscal year 1912 the exports of manufactures from the States were larger than in any earlier year in the record of American commerce, and imports of manufacturers' materials also showed larger totals than in any earlier year except 1910. This increasing share which manufactures form in American exports, and manufacturers' materials form in the imports, is chiefly a development of recent years. Manufactures are supplanting foodstuffs as a leading factor in the export trade of the United States. While the value of foodstuffs exported increased from 1885 to 1900, it has actually declined since that date. The percentage which foodstuffs formed of the total exports has declined steadily since 1880; on the other hand, the percentage of manufactures has as steadily increased.

OUR ASTRONOMICAL COLUMN.

RADIAL VELOCITY OF 915 STARS.—Prof. Campbell publishes in Lick Observatory Bulletin, No. 229, a further valuable contribution to the radial velocities of stars secured with the Mills spectrographs attached to the 36-in. refractor at Mount Hamilton, and with the instruments of the D. O. Mills Expedition at Santiago, Chile. Prof. Campbell states that the results for those brighter stars of classes F, G, K, and M, of which the radial velocities appear to be substantially constant, or the approximate systemic velocities may be estimated, including proper-motion and other auxiliary data, relating to nearly 900 stars, have existed in manuscript form ready for the printer for more than a year. It was proposed to issue them in the form as previously published for the stars classes B and A, but want of funds made such a scheme impossible. Even now the necessary means are not forthcoming, so, to avoid further delay, he publishes them in the briefest form in the present bulletin.

All available results for stars of these spectral classes have been included, whether the observations of the same stars have been published or not in former lists; there are also included velocities for a few stars of classes B and A. Results for a few stars obtained at other observatories are also inserted in the tables. Thus this and all preceding publications make available all the radial velocity results obtained at Mount Hamilton and Santiago up to date, excepting suspected variables and stars the spectra of which contain lines not sufficiently serviceable for measurement. The published lists include, therefore, all stars as bright as the 5·00 visual magnitude in the Revised Harvard Photometry, Annals 50, and, in addition, many hundreds of stars fainter than magnitude 5·00.

STELLAR PARALLAXES.—Prof. Frederick Slocum, in conjunction with Prof. S. A. Mitchell, of Columbia University, publishes in the July number of *The Astrophysical Journal* (vol. xxxviii., No. 1) the results of some stellar parallax determinations from photographs made with the 40-in. refractor of the Yerkes Observatory. The apparatus and methods used were similar in general to those previously described by Prof. Schlesinger, so the communication, to which reference is here made, is limited to the actual results of the investigation. The following table sums up in brief the values determined :—

Star	R.A. (1900) h. m.	Dec. (1900) ° ′	Mag. and spectrum	Relative parallax ″	Probable error ″

THE BIRMINGHAM MEETING OF THE BRITISH ASSOCIATION.

WE understand that the argument of the presidential address to be delivered by Sir Oliver Lodge at the Birmingham meeting is as follows :—A marked feature of the present scientific era is the discovery of, and interest in, various kinds of atomism, so that continuity seems in danger of being lost sight of. Another tendency is toward comprehensive negative generalisations from a limited point of view. Another is to take refuge in rather vague forms of statement, and to shrink from closer examination of the puzzling and the obscure. Another is to deny the existence of anything which makes no appeal to organs of sense, and no ready response to laboratory experiment.

In his address the president will contend against these tendencies. He will urge a belief in ultimate continuity as essential to science; he regards scientific concentration as an inadequate basis for philosophic generalisation; he believes that obscure phenomena may be expressed simply if properly faced; and he will point out that the non-appearance of anything perfectly uniform and omnipresent is only what should be expected, and is no argument against its real substantial existence.

Since we gave, in NATURE of July 17, summaries of the provisional programmes of most of the sections of the British Association, for the meeting to be held in Birmingham on September 10–17, notes on the forthcoming proceedings of the Engineering Section have reached us. A varied programme of engineering activity will be presented at the meetings of this section, under the presidency of Prof. Kapp, who will deal with electric traction in his opening address. A group of connected papers on the various influences which affect the propagation of electromagnetic waves will be read by Profs. Howe and Marchant and Dr. Eccles. Heat tests of electrical machines will be discussed by Mr. W. R. Cooper, and a practical demonstration of the varied uses of electric cooking appliances will no doubt prove of interest to the members of all sections.

Mechanical engineering claims a large share of the attention of the members, and will include an important paper by Mr. Lanchester, on the application of the internal-combustion engine to railway locomotion, in which he will describe his very successful work in this branch of engineering. Prof. Burstall will discuss the much-debated subject of solid, liquid, and gaseous fuels, and the committee on gaseous explosions will probably present a report on the temperature distribution in the cylinders of internal-combustion engines. A novel hydraulic weighing machine will also be described by Dr. Hele-Shaw, and a new process of bank-note engraving by Mr. Bawtree.

Considerable interest attaches to the report of the new committee for investigating the stress distribution in engineering materials, which will be discussed with the Mathematical and Physical Sections, and connected with this subject Prof. Coker will describe some optical determinations of stress in chain links and in thick cylinders under fluid pressure, Mr. Reid will discuss the flow of plastic solids, Prof. Dixon will deal with impact tests, and Mr. Robertson with the strength of free-ended columns.

Civil engineering is represented by a group of interesting papers, including one by Dr. Cornish on land-slides, accompanied by upheaval in the Culebra cutting of the Panama Canal, while Dr. J. S. Owens and Mr. E. R. Matthews will discuss the movements of sand and shingle in connection with marine engineering work.

A paper of great local interest, by Messrs. Gleadow and Shackle, will describe the fine new station of the Great Western Railway at Snow Hill, while the subject of metals for structures will be discussed by Mr. Walmisley.

The programme of the meeting of Section G is therefore not only of unusual interest, but many of the papers to be read are of considerable importance in relation to industries for which Birmingham is famous.

BONAPARTE RESEARCH FUND GRANTS.

THE committee of the Paris Academy of Sciences appointed to consider the distribution of the Bonaparte Research Fund has made the following recommendations for the year 1913 :—H. Caillol, 3000 francs, for the completion of his work entitled "Catalogue des coléoptères de Provence"; A. Colson, 2000 francs, to enable him to continue his experimental work in physical chemistry; E. Coquidé, 2000 francs, to assist him in carrying out his study of the turf lands of the north of France from the agricultural point of view; C. Schlegel, 2000 francs, to enable him to continue his researches on Crustacean development; Jules Welsch, 2000 francs to assist him in his geological exploration of the coast lines of France and Great Britain, and to extend them to Belgium and Scandinavia; MM. Pitard and Pallary, 6000 francs, equally divided, for their scientific expedition in Morocco, organised by the Société de Géographie; Louis Roule, 2000 francs, for the continuation and extension of his researches on the morphology and biology of the salmon in France; M. Pougnet, 2000 francs, to enable him to continue his researches on the chemical and biological effects of the ultra-violet rays, and for the construction of a quartz apparatus to be used for studying the action of ultra-violet light upon gaseous bodies; M. Dauzère, 2000 francs, for his work on the cellular vortices of Bénard; M. Gard, 2000 francs, for the publication of a work and atlas dealing with the material left by the late M. Bornet; M. Chevalier, 4000 francs, to meet the expenses necessitated by the classification of the botanical material collected in the course of his travels in western and equatorial Africa, and the publication of memoirs on the flora of these regions; Paul Becquerel, 2000 francs, for the continuation of his physiological researches relating to the influence of radio-active substances on the nutrition, reproduction, and variation of some plant species; Le Morvan, 4000 francs, for the completion of his photographic atlas of the moon; M. Pellegrin, 2000 francs, to aid him in the pursuit of his researches, and to publish his work on African fishes, more particularly those of the French colonies; M. Rengade, 3000 francs, for his proposed systematic examination of mineral waters for the presence and distribution of the rare alkaline metals; M. Alluaud, 3000 francs, for facilitating the study and publication of documents collected by M. Jeannel and himself on the alpine flora and fauna of the high mountainous regions of eastern Africa; M. Lormand, 2000 francs, for the purchase of a sufficient quantity of radium bromide to undertake methodical researches on the action of radio-activity on the development of plants; A. Labbé, 2000 francs, for the study of the modifications presented by various animals passing from fresh to salt water or the reverse; de Gironcourt, 3000 francs, for the publication of the results of his scientific expeditions in Morocco and western Africa: M. Legendre, 3000 francs, to assist him in the publication of the maps and documents dealing with his travels in China; H. Abraham, 2000 francs, for the determination, with Commandant Ferrie and M. A. Dufour, of the velocity of propagation of the Hertzian waves between Paris and Toulon.

THE EDUCATION OF EUROPEANS AND EURASIANS IN INDIA.[1]

THE reality of the problem dealt with in the report before us calls for no demonstration. The Hon. Mr. Madge, himself a member of the community, as also of the conference which, at the invitation of the Government of India, met at Simla in July, 1912, was stating a sober fact when he said on that occasion that to his community education was a matter of life and death.

The problem has been said to have two phases, of which one is concerned with the future of the lower stratum of the Eurasian community—the crux of the half-caste question at its worst. The problem in its other phase does not necessarily involve the difficulties inseparable from mixed descent. Undoubtedly every European resident in India is anxious to send his children "home" for at least a part of their education, but there is a substantial and increasing body of Europeans in India who must educate their children there. It is in this body that this phase of the problem centres. Dr. Graham, of Kalimpong, once wrote that one of the saddest experiences was to trace the gradual downcome, generation by generation, of the descendants of men who had helped to build up the British Empire in India.

The more specifically Eurasian problem is clearly not yet solved, for Sir Harcourt Butler, the President, told the conference that according to the best calculation available there were some 7,000 children who were receiving no education, and a Roman Catholic priest stated that there had been recently 134 applications for four vacancies in a Roman Catholic Orphanage. Compulsion was discussed, and, though the President made it quite clear that Government had no present intention of legislating to make attendance at school obligatory—the administrative difficulties involved would be very great—the conference passed a resolution pressing upon Government its opinion that the introduction of compulsory education was necessary to secure that certain classes of the community attended school, adding that it was recognised that this would involve the introduction of free education for all who could not pay fees.

The report shows that the conference realised that the solution of the second of the two phases of the problem lies primarily in the provision of efficient secondary schools, as such institutions are defined in the regulations of the English Board of Education, and now generally understood in this country, but the somewhat nebulous discussion which took place on the grading of schools suggests that those who in India are tackling the problem would be well advised to define more exactly the terms, such as "elementary," "secondary," and "collegiate," which are now becoming current there.

The European schools in India are provided and maintained by the denominations, the local governments assisting with grants and generally supervising the working of the system. This system will, and should, remain, for Government could not possibly undertake the task, and it is a mere waste of time to make vague proposals for Government schools. If, however, there is a danger to which the present system is prone, it is to be found in the tendency to attempt in a considerable number of schools work which could be done more efficiently in a few. The difficulties resulting from this quite natural tendency would decrease if there was less confusion as to the respective functions in the community of the elementary and the secondary school. It may be, as was suggested at the conference, that there is no place in the domiciled community for merely elementary education, though with 7000 children without any education at all this sentiment would seem to savour somewhat of aspiration.

In England we are beginning to appreciate the futility of teaching a child certain rudiments and then at the age of fourteen setting him adrift to find for himself. It is one thing to admit this; it is quite another thing to proceed as if it were within the scope of practical politics that every child should go through a secondary-school course, and to belittle in consequence the function of the school of the higher elementary type. The value to the community of a particular type of school does not depend upon the name by which that type is designated, and as one member of the conference pointed out, no one type of school is really higher than another. If one of the results of the recent Simla conference is the elimination from the minds of managers of the sway of "motives of fictitious prestige," a real advance will have been made.

[1] Report of the Conference on the Education of the Domiciled Community in India, Simla, July, 1912. Pp. iv+202. (Calcutta: Superintendent Government Printing, India.) Price Re. 1 or 1*s.* 6*d.*

THE MOUNT WILSON SOLAR OBSERVATORY.

THE Mount Wilson Observatory received from the Carnegie Institution of Washington the grant of 254,075 dollars, or 50,815*l.*, for the year 1912, for construction investigations and maintenance, and the report of the director shows the magnificent way in which this great sum is being utilised. It is impossible in a short note to give an adequate account of the very admirable report of the director, which covers forty-one pages of very condensed matter. On the first page Mr. Hale modestly states, "among the results of the year's work the following may be mentioned," and then he follows this with brief paragraphs, *thirty-five* in number, each of which is a piece of valuable research work far-reaching in its aim and an important thread in the web which comprises the complete knowledge of stellar distribution and development. Some of the results of these researches have been published in *The Astrophysical Journal*, and received notice in our astronomical column.

The past year has marked the completion of the 150-ft. tower telescope, and great things are expected of it in the future. The work so far done with it has proved that it is perfectly stable and on no occasion has trembling of the image been recorded. It may be mentioned here, and it is not generally understood, that the girder work forming the visible tower is really in duplicate, each girder containing another one inside completely independent of it, and not touching it, and thus forming a complete second but invisible tower. The outside girder work is thus designed to protect the inner one from vibration caused by the wind. The cœlostat and secondary mirror placed at the top of the tower are fixed to a

Fig. 1.—The tower telescope as seen from immediately below, showing the platform and dome at the top.

platform resting on the inner tower. The definition of the solar image is stated to be better than that of the Snow telescope after the early morning hours in consequence of the protection of the beam. In our astronomical column for March 20 a statement was quoted from *The Observatory* for March that the 100-in. mirror, when tested, was found to be probably useless. Mr. Hale, in his report, states that the tests indicate that it may become necessary to discard the disc, but in a footnote adds that "since the above was written. . . . There is now every reason to believe that the present mirror will prove suitable for use in the telescope." It may be that the information in *The Observatory* refers to a further examination subsequent to the footnote. The 60-in. reflector has a very large programme of work allotted

Fig. 2.—The observing house is directly below the tower and above the spectroscopes, which are situated in a deep vertical pit in the mountain.

to it, and mention is made that Prof. Barnard would prefer it for visual work on the planets to any of the large refracting telescopes with which he is familiar. This report will be a revelation to those who work at astrophysics or solar physics this side of the Atlantic, and will probably make some workers very downhearted when they compare their own means of research with those available at Mount Wilson.

CHEMIO-THERAPY.[1]

It must be a great pleasure and a special honour for all of us to meet here personally on British soil for a scientific purpose, in order to take part in the great work which will be of benefit to the whole world. Are we not here in a country that has produced two men who must be considered among the greatest men of all times, Jenner and Lord Lister? Like a star in the darkness of his age, Jenner's great achievement, which broke the power of such an awful public plague as smallpox, still shines with peerless splendour. And on the occasion of the last congress which was held here we gathered with wondering admiration round Lord Lister, who through his introduction of antiseptics brought about a revolution in surgery which stands alone in the history of medicine. Here in England the first example of a modern Institute for Tropical Diseases, which is a model for

[1] From an address delivered before the seventeenth International Congress of Medicine at London on Friday, August 8, by Prof. Paul Ehrlich.

all other institutes of this kind, was created under the direction of Sir Patrick Manson. Through Ross's excellent work, Laveran's discovery of the causes of malaria was so far advanced that entirely new lines were opened up for the hygienic struggle against tropical and subtropical diseases.

The proof by Castellani that a trypanosome is the cause of sleeping sickness, the classical work by Bruce on illnesses caused through trypanosomes, the specific cause of kala-azar (Dum-dum sickness) as proved by Leishman, are all well known to us. The therapeutic influence of atoxyl in the cases of trypanosome diseases was first established in the Liverpool Tropical Institute by Thomas and Breinl, and quite recently Plimmer has brought forward the use of tartar emetic as an effective weapon against protozoal diseases.

The life-work of Almroth Wright is also known to all of us, *i.e.* his work on opsonins and on the prophylactic treatment of typhoid fever, which has been carried out in a practical and most excellent manner. Even these few names, to which I might add many others, show what a high and leading position England has taken and still holds in the fight against infectious diseases. To prevent the spread of and to heal infectious diseases was at all times the highest aim of medical aspirations; however, a systematic pursuit of this purpose has only been possible in recent times, as through the labours of all civilised nations we have got an insight into the nature of infections, the cause of diseases, and the means by which they are transmitted. Through these methods it has been possible to infect animals artificially and so obtain material on which to test the drugs in a systematic and rational manner. From the very first beginnings of therapeutics, chemio-therapy has indeed been in existence, as all the remedies which we employ are chemicals; on the other hand, experimental chemio-therapy could only develop in modern times in a fruitful manner as a result of all this pioneer work. But here also it has been proved that the four most important factors are: patience, skill, luck, and, last but not least, money.

Now, gentlemen, I may perhaps take the liberty of giving you an insight into the workshop of the chemio-therapeutic work. The whole area is governed by a simple, I might even say natural, principle. If the law is true in chemistry that "Corpora non agunt nisi liquida," then for chemio-therapy the principle is true that "Corpora non agunt nisi fixata." When applied to the special case in point this means that parasites are only killed by those materials to which they have a certain relationship, by means of which they are fixed by them. I call such substances "parasitotropic." But I should like immediately to add that there are evident exceptions to this law. So, for instance, we are acquainted with a small series of cases in which the apparent therapeutic results are obtained, although the allied substances in question do not possess parasite-destroying qualities. That is the case in the infiltration of the subcutaneous tissues which is caused by a kind of yeast (sporotrichosis). Here Block proved that the clinically highly therapeutic iodide of potassium first of all dissolves the cells of the infiltration, whilst the parasites, as such, are not in the first instance attacked.

But, in any case, it is safest and best for the development of chemio-therapy not to build on the basis of exceptional work, but it is better to start with such substances as produce the destruction of the parasites by fixation.

Now it has been assumed in different quarters that some of the more modern remedies are incorrectly regarded as parasiticides, but in reality they are not such. Thus, for example, salvarsan or mercury salts are not intended to act directly on the parasites but indirectly, owing to the fact that they excite the organism to the formation of specific anti-substances. This view is based mainly upon the fact that if one mixes the substances in question, such as, for instance, neosalvarsan, with certain pathogenic agents, *e.g.* spirochætes, in test-tubes, one cannot perceive any reduction in their mobility after observing them for hours together. From this fact, which was first discovered by Prof. Hata, the conclusion has been drawn that salvarsan or neosalvarsan, as such, did not in any way directly influence the spirochætes. Now it can very easily be shown that this conclusion is quite incorrect. If, for instance, following Castelli, one suspends the spirochætes of relapsing fever in indifferent mixtures of serum which do not injure their vitality, and if one fills two small tubes therewith and adds to one of the tubes a very small quantity of salvarsan or neosalvarsan, and if one then centrifugalises and then draws off the liquid; if one washes the remaining spirochætes again in a mixture of serum and again centrifugalises it; then one obtains in both tubes a deposit of spirochætes which on microscopic examination shows the same properties, *i.e.* equally good mobility of the spirochætes. If, however, the spirochætes obtained in this manner are injected into test mice, then one can very soon convince oneself that the spirilla treated with salvarsan do not give any infection to the animal, whilst the mice vaccinated with the contents of the control tube promptly shows signs of infection. This proves that salvarsan or neosalvarsan, as the case may be, is absorbed by the spirochætes, and must have damaged them, and that this trace of salvarsan, which is so exceedingly minute that it can scarcely be weighed, was sufficient to prevent the increase of the parasites in the animal body. Therefore, by this very simple and easily intelligible experiment, the direct effect of salvarsan and neosalvarsan on the spirochætes, and thereby the principle of fixation, is absolutely proved; the objection of the indirect effect based upon anti-substances therefore falls to the ground.

It was necessary, however, to penetrate more deeply into the mechanism of this fixation of remedies, and it is only after long-continued efforts that success has been attained in obtaining a clear conception. In order to make practical progress it appeared to be necessary not to be satisfied with the primordial idea, but to see in what manner the drugs are fixed by the parasites, or, as the case may be, by the cells. Only by taking a very roundabout way has it been possible to obtain clearness with respect to these complicated relations, and in this connection it was especially the studies on trypanosomes and especially the investigations of "drug-fast" strains of germs, which led to quite definite representations with regard to the process of fixation. There was no difficulty by continued treatment of the experimental mice with certain definite remedies, *e.g.* fuchsin, in finally obtaining a race of trypanosomes which had become immune against these remedies, *i.e.* "drug-fast," in the case mentioned above immune to fuchsin. There were especially three classes of different remedies which were very suited to this purpose:—

(1) The class of the arsenic compounds, in the following historical order: arsenious acid, arsenilic acid (atoxyl), arsenophenylglycine (salvarsan and neosalvarsan).

(2) The class of the so-called azo-dyes (the trypan red, manufactured by Weinberg, with which Shiga and I made experiments, and the trypan blue of Mesnil).

(3) Certain basic triphenylmethane dyes (fuchsin, methyl violet, &c.).

When a race of trypanosomes has been rendered immune against fuchsin, then this race is immune against all the allies of fuchsin and methyl violet, &c., but it is not immune against the two other classes.

Also a race immune against arsenic compounds is only immune against such, but not against the two other classes. We see, therefore, that the immunity is of a specific nature inasmuch as it is limited to a definite class of chemical substances.

It was just this specific character which indicated that it must be a question of purely chemical processes. Earlier studies relating to another subject, *i.e.* those relating to toxins and antitoxins, pointed to the nature of the said processes. In connection with these it had been shown that the destructive toxins developed their injurious action on the cell by the fact that they are absorbed by certain specific component parts of the cell—side chains—which I have characterised as "receptors," and that the anti-substances represent nothing else than the cell receptors produced in excess under the influence of the toxin and thrown off.

For many reasons I had hesitated about transferring these views relating to receptors to chemical bodies at all, and in this connection it was especially the brilliant investigations by Langley relating to the effects of alkaloids which caused my doubts to disappear and made the existence of chemo-receptors seem probable to me.

From this point of view, the phenomena observed in connection with the "drug-fast" strain of germs can be readily explained experimentally, owing to the fact that the chemo-receptors under the influence of drug-fastness suffer a reduction of their affinity for certain groupings connected with the remedy, which can only be regarded as purely chemical. This reduction in affinity explains in the simplest possible manner why continually increasing quantities of the arsenic compound become necessary for the destruction, *e.g.* of a race of arsenic-fast trypanosomes, for the smaller avidity can only be overcome by a corresponding surplus of the arsenic compound, if the quantity necessary for the destruction of the parasites is to be finally fixed.

We, therefore, come to the conclusion that in the parasites there are present *different specific chemo-receptors*, for instance, the *arseno-receptor*, which fixes the trivalent group of arsenic as such; and the *acetico-receptor*, which fastens to itself the acetic acid group, an *iodine-receptor*, an *orthoamidophenol-receptor*, which conditions the fixation of the salvarsan, and many others in addition. A complete exhaustive knowledge of all the different chemo-receptors of a certain definite parasite is what I should like to characterise as the *therapeutic physiology of the parasite cell*, and this is a *sine quâ non* of any successful chemio-therapeutic treatment. I should like to emphasise the fact that many observations indicate that certain chemo-receptors are due to several different kinds of parasites, not to a single one. The knowledge of these is of special practical importance, because remedies which are adjusted to these have a healing influence on a very large series of the most various pathogenic agents. *The larger the number of different chemo-receptors, therefore, which can be demonstrated the greater is the possibility of a successful chemio-therapy.*

Now if we seek for specific remedies, then the first condition is that they must possess a certain definite grouping, which is chemically allied to one of the chemo-receptors of the parasite. This is only a necessary prior condition of the toxic effect, but in general it is not a sufficient one in itself. Hundreds of substances may fix themselves on a parasite and only a few are capable of bringing about its destruction.

In the therapeutically suitable substance there must, therefore, in addition to the fixing group, which brings about the fixation of the *haptophorae*, be another, which as such brings about the destruction, and therefore is to be characterised as the "poisoning" or *toxophoric*. This representation exactly corresponds to the views which we have already long since obtained with respect to toxins, in which we distinguish the presence of a haptophoric group which conditions the cell fixation and also the formation of the antitoxins, and a toxophoric group which brings about the injurious action on the cell. In the case of the highly complicated synthetic drugs the assumption will have to be made that the haptophoric group and the toxophoric group are not *directly* connected with one another, but as separate groups are linked with a chemical molecule in the character of side-chains. In this way we arrive in a natural manner to this, that chemio-therapeutic agents, built up in a complicated manner, may be compared to a poisoned arrow; the fixing group of the drug which anchors itself to the chemo-receptor of the parasite corresponds to the point of the arrow, the binding member is the shaft, and the poison group is the arrow poison fixed to the shaft of the arrow. Corresponding to this scheme in the case of salvarsan (dioxydiamidoarsenobenzol) the benzol group would correspond to the shaft, the orthoamidophenol group to the point, and the trivalent arsenic group would correspond to the toxophoric group.

If we continue this comparison, then the substances which are used for poisoning the arrows are alkaloids and similar substances, which act injuriously on certain definite vital organs of the body; and so we shall also have to assume that the toxophoric grouping of the synthetic drugs poisons the protoplasm of the bacterial cell, and this only appears to be possible when a chemical affinity exists between the toxophoric grouping and the constituents of the cell. The circumstance that all the derivatives of arsenic which contain arsenic in the pentavalent form, *i.e.* in the fully saturated form, do not bring about any therapeutic action, but that this only commences when the arsenic group exists in the unsaturated condition corresponding to the trivalent radical, certainly points in the same direction. This difference between the saturated and unsaturated arsenic radical was discovered by the master mind of Bunsen, for in the year 1843, in his comparative studies relating to the non-poisonous cacodylic acid with the pentavalent arsenic and its poisonous reduction product, the cacodyl with the trivalent arsenic, he came to the conclusion that "the cacodylic acid had lost the power to form an attacking point, and at the same time it had lost its effect on the organism." In the subsequent period a very large series of analogous cases have become known corresponding to this truth, which point to the increased effectivity of the unsaturated radical. The best-known example is doubtless the high degree of toxic power of carbon monoxide as compared with the almost indifferent carbon dioxide.

Dyes act as bactericides only as such, but not in the form of their colourless products which correspond to the saturated type. *The fact is that all these unsaturated combinations contain unsatisfied avidities which render them capable of reacting additionally with other combinations.*

If, therefore, we poison a spirochæta with salvarsan, then there occur at least two different chemical fixations: first of all the fixation of the orthoamidophenol group, which primarily fixes the salvarsan to the parasite. It is only in consequence of this fixation that secondarily the trivalent arsenic group is given the opportunity of entering into chemical combination with the arseno-receptor of the cell, and so to exert its toxic effect. The avidity of the arseno-receptor can in itself be such that it can only react if favouring factors, which chemically must be regarded as a stereo-chemical facilitation, come into action.

Examples of such stereo-chemical facilitations are frequently found in chemistry, *e.g.* in the chemistry of the ortho-condensations. And so the haptophoric group of the arsenic molecule primarily brings the arsenic along to the cell, and secondarily brings about its possibility of action.

Now, it is a frequent practice of many uncivilised peoples, in order to be certain of killing their enemies, that they not only rub over their arrow with one kind of poison but with two or three totally different kinds of poison. And so it also appeared advisable to imitate this procedure against the parasites, which is otherwise not very praiseworthy, and to poison our synthetically poisoned arrows not singly but doubly. In association with Dr. Karrer I succeeded in depositing the reduced arsenic compound, *e.g.* salvarsan, even on metals, and so in arriving at remedies which, used experimentally on animals, show an increased effect.

In the previous remarks I have described the conditions which are necessary in order that a certain substance may exert a parasiticidal effect, and indeed must effect such, if it operates directly on certain definite parasites in an aqueous solution, such as, for instance, is the case with the ordinary disinfectants. In the manner described above it is easily possible to arrive at a very large number of substances which will destroy bacteria and allied substances in aqueous solutions. But, of course, the problem is much more difficult when it is a question of internal disinfection or of the destruction of living parasites within the infected organism. If the problem is set before us of sterilising a room, then indeed it is an easy matter to do so, owing to the present advancement of science; but the task becomes more difficult when the room is filled up with materials; and when these materials are of such a delicate sensitiveness as living cells, then the difficulty of the problem will be manifest without any further explanation. As a matter of fact, it has proved that substances which bring about a colossal bactericidal effect in aqueous solutions even when they are highly diluted, are totally ineffective in therapeutics properly so called. For it has turned out that, generally speaking, these disinfectants are more or less powerful cell poisons, and seriously injure the organism; they are, therefore, not only parasitotropic but also *organotropic*.

Now, it depends exclusively on the relationship between parasitotropic and organotropic as to whether a certain disinfectant can be used as a remedy. In Robert Koch's celebrated experiment, in which even the largest doses of sublimate did not produce even a trace of therapeutic effect on anthrax infection, it is evident that the parasitotropic effect was reduced to nil by the organotropic effect. If the relationship of organotropic to parasitotropic is somewhat more favourable, then one may observe a peculiar phenomenon, consisting in the course of the infection being rendered worse to an extraordinary degree by the remedy, owing to the effect that the parasites increase to a much greater extent than is generally the case.

This phenomenon, discovered by Hata, is explained by the fact that the ratio of organotropic effect to parasitotropic effect is of such a nature that almost the whole of the poison is absorbed by the organism, but only in infinitesimal quantities by the parasites. According to a biogenetic foundation principle it is quite a common thing for substances which act destructively in *large* quantities to bring about an *increase in the vital functions* in smaller doses. Only such substances, therefore, can be used as therapeutic agents in which the ratio between organotropic effect and parasitotropic effect is a favourable one, and that can be easily ascertained by experiment by a comparison between *dosis toxica* and *dosis tolerata*. *Only such substances can be considered therapeutic agents of which a fraction of the dosis tolerata is sufficient to bring about therapeutic effects.*

The organotropic effect of drugs is, of course, to be attributed, according to the views of Langley and myself, to this, that there are, in the most various cells of the body and its organs, quite different chemoreceptors, exactly in the same manner as we have postulated for the parasites. Apart from the pharmacological effect of the various remedies, this chemical difference of the organs appears clearly in the vital colouring.

I will mention here—in order only to indicate a few examples—the methyl blue colouring of the nerve trunks, the neutral red colouring of the cell granules, and the distribution of the isamine blue in the so-called pyrrol cells, so carefully and excellently investigated by Edwin Goldmann. The pathologico-anatomical findings point also to a chemical divergence on principle. When we see that after the introduction of paraphenylenediamine only the summit of the diaphragm assumes a black colouring; when we see that vinylamine in the case of all kinds of animals isolates and injures the renal papillæ and causes them to die; when after the introduction of cyanosin, as Hata and Goldmann have found, certain definite regions in the hair of mice become coloured, and the colouring matter becomes stored to the greatest degree in the milk glands; when a colouring material of the pyronine series in the case of mice brings about a general dropsy amounting to 50–60 per cent. of the body without injuring the kidney, which doubtless is only to be referred to an alteration of the vessels of the subcutaneous connective tissue, then all these phenomena can only be explained by the fact that at these particular spots definite chemical connections of a specific nature must take place, which must be referred to the presence of certain definite chemoreceptors.

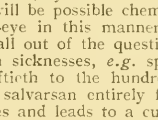
Now, according to the above representations, all these fixations are dependent on the haptophoric grouping of the drugs, and, therefore, it was a matter of great interest to observe how phenylarsenic acid, the mother-substance of the modern arsenic compounds, behaves when various different groups are attached thereto. In this connection it has turned out that when we introduce different constituent fixation groups, *e.g.* chlorine, the oxygen group, the hydrocyanic acid group, the sulphuric acid group, the ammonia radical, we can manufacture, starting out from one substance, a series of combinations, the toxic effect of which may vary fifteen hundredfold. The combinations which are to the greatest extent free from poison—these are derivatives of sulphuric acid, especially the sulpho-phenylarsine acid and its salts—are less toxic than sodium chloride, and, on the other hand, there are substances the very smallest quantity of which brings about death. And in this connection we can see that, according to the nature of the substances, very different organs of the animal's body are injured. Sometimes it is the intestinal tract, and the animals die of profuse diarrhœa; sometimes it is the liver, and the mice—a rare occurrence—become jaundiced and die of serious alterations in the liver; sometimes the red blood corpuscles become dissolved, and the animals die of severe anæmia. Frequently also the central nervous system becomes injured, and in the case of mice this usually relates to the vestibular nerve of the inner ear. The interference with the equilibrium, produced in this way, causes the mice constantly to turn in circles just like the Japanese dancing mice. In the case of human beings the optic nerve is the point of attack for numerous derivatives of phenylarsine acid. The cases of blindness which have been observed after the use of very large doses of atoxyl, arsazetin, and other drugs are due to this injury.

From this it is evident that according to the selection of the group annexed to the phenylarsine acid quite different organs will be affected. This is only explained according to the above views by the fact that there are, as already previously stated, in the various organs specific chemo-receptors which energetically attract certain fixation groups somewhat as the magnet attracts iron. And this view also provides us with the principle *according to which we have to construct our poisoned arrows.* We must attach to the phenylarsine acid group, or, as the case may be, to the phenylarsenobenzol group, such grouping as is only related in a small degree to the organs of the sick body, but, on the other hand, is very closely allied to the receptors of the parasites.

I have explained above that the parasites possess a whole series of chemo-receptors which are specifically different from one another. Now if we can succeed in discovering among them a grouping which has no analogue in the organs of the body, then we should have the possibility of constructing an ideal remedy if we select a haptophoric group which is especially adjusted to the functions of the parasites.

A remedy provided with such a haptophoric group would be entirely innocuous in itself, as it is not fixed by the organs; it would, however, strike the parasites with full intensity, and in this sense it would correspond to the immune productions, the anti-substances discovered by Behring, which, after the manner of the bewitched balls, fly in search of the enemy. Let us hope that it will be possible chemio-therapeutically to hit the bull's-eye in this manner also. I do not consider this at all out of the question, as it may be proved in certain sicknesses, *e.g.* spirillosis in hens, that from the fiftieth to the hundredth part of the *dosis tolerata* of salvarsan entirely frees the animals from the parasites and leads to a cure. Such a dose truly represents a nil dose, as the hen cannot be damaged thereby in the slightest degree. But such favourable conditions have only very rarely been discovered up to the present; we shall have to be satisfied if we can succeed in obtaining good therapeutic results with the tenth or even the fifth or sixth portion of the *dosis tolerata.*

In the main the above are the principles which guided us in the construction of the new remedies. Among the numerous combinations which have been tested in experiments on animals in the case of trypanosomes and spirillar infection, and in the preparation of which I have been supported by the untiring co-operation of Dr. Benda, Dr. Bertheim, Dr. Kahn, and Dr. Karrer, and which have been biologically tested, especially by my respected friend Prof. Hata, and later by Dr. Castelli and Dr. Gonder and Frl. Leupold, salvarsan has proved to be the most efficient, the dioxydiamidoarsenobenzol of the formula.



Here the orthoamidophenol group acts as the conducting and the arsenic group as the toxophoric group.

But now, gentlemen, the step from the laboratory to practice, *i.e.* to the bedside, is an extraordinarily difficult and dangerous one—a step which can only be taken with the greatest care. Its difficulty and danger are in the main based upon two factors:—(1) On the fact that in the case of men there exist so-called idiosyncrasies, forms of supersensitiveness which do not occur in the case of animals; (2) it has been shown that certain illnesses of a constitutional nature can cause a supersensibility.

The treatment of patients is an exceedingly difficult and responsible task, and the clinical pioneers, such as Schreiber, Wechselmann, Iversen, &c., deserve our warmest thanks. They have thrown the first light upon the most important questions (dosology, indications, and counter-indications). From a series of observations, which is now so vast that it can scarcely be surveyed, there has, however, resulted what I might call the "therapeutic tactics," which I should here like briefly to explain.

The *therapia sterilisans magna,* which consists in this, that by means of one or at most two injections the body is freed from the parasites. In experiments on animals, and also in the case of a series of important maladies, this principle can be carried through in a clear and pure manner. Here, therefore, the old therapeutic remedy is applicable: "Frapper fort et frapper vite."

We have to ask ourselves the question, What are the causes which make it possible for a favourable result to be obtained, a result which may be taken as *therapia magna sterilisans,* radical cure of the body by means of a single injection? Typical antibodies can be shown to be produced fairly rapidly by the destruction of parasites, and especially of protozoa. Hence, it is quite evident that this assisting action of the organism ought to be eminently efficacious. For if the medicine has destroyed not the whole of the parasites, but only 95 per cent., and 5 per cent. have resisted its action, then these remaining 5 per cent. are sure to succumb to the influence of the antibodies which are rapidly formed. If this is the case, the *therapia sterilisans magna* is attained. Unfortunately, it has been shown that this salutary process may frequently be minimised considerably owing to the biological properties of the parasites. For it may happen that a part of the parasites which survive the first injection escape destruction by the serum either wholly or in part, and subsequently change into new varieties which have become serum-proof, and are known as a relapsing crop. It is clear that parasites of this kind which are able to form a large number of relapsing crops offer very great difficulties in their treatment, as in this case the auxiliary forces of the body fail to act, so that it is necessary to do one's utmost to destroy the whole of the parasites all at once by means of drugs, as owing to their great power of adaptation a single germ surviving may perhaps be the cause of the infection breaking out afresh.

If we compare the fight against parasitic diseases with a state of warfare, we find that, on one hand, great battles are fought which may lead to victory in the course of one or a few days. In combating bacteria such a victory would compare with *therapia magna sterilisata.* If, on the other hand, a fortress has to be taken, the goal cannot be reached with one single stroke, but it may take months and even years.

The measures employed in connection with a bacteriological siege aim on the whole at rendering the places which are not easily accessible more accessible for the therapeutic agent than is the case under ordinary conditions. On the other hand, however, the greater power of resistance of certain parasites has to be taken into account, and this is a purely chemical question which can only be solved by chemical means. The road leading to its solution which promises the best results is that of combined therapy.

From what has been said it will be seen that combined therapy is best carried out with therapeutic agents which attack entirely different chemo-receptors in the parasites. For instance, it is useless to combine euchsin with its nearest relative, methylviolet; and it is useless to combine therapeutically trypane blue and trypane red, for both attack the same spots in the parasites, but it is necessary to select from each group the most effective substance and then to combine the most suitable representatives of the various types. It is clear that in this manner a simultaneous and varied attack is directed on the parasites, in accordance with the military maxim, "March apart but fight combined."

Combined therapy will in the future conquer an ever-increasing field of action. Thus, for instance, Broden, in the Congo, succeeded in connection with sleeping sickness in the human subject—it is true only in the early stage of this infection, which is so difficult to fight against—in obtaining good results by the combination of salvarsan and two basic colouring matters (trypaflavin and tryparosan) by treatment lasting about a week.

It is precisely in the manifold character of the possibilities of combination that I see a special advantage, and peculiar possibilities of development. When once we are acquainted with the majority of the chemoreceptors of a particular kind of parasite, which will be a long piece of work, occupying many hands and heads, we shall have the most far-reaching possibilities of simultaneous attack by various agencies. And on this account combination therapeutics are also absolutely pluralistic in contrast to antitoxins, which may be said to act rather in one single direction.

And now, gentlemen, may I be permitted to refer to a few practical results? You are all aware that with a number of spirillar diseases the principle of *therapia sterilisans magna* has proved most successful. You are aware that it is possible by one single injection of salvarsan to cure frambœsia (yaws), which is also caused by spirochætes, and is a scourge of the tropics, curing it completely except in rare cases where unimportant relapses occur; this has been shown by the work of Strong, Koch, and Castellani. Thus, in Surinam, a hospital in which more than 300 patients with frambœsia were constantly under treatment was closed and turned to other uses after the introduction of the salvarsan treatment, as one single injection sufficed to cure the disease, and the patients could all be discharged but two. It is to be hoped that in this way it will be possible altogether to extirpate frambœsia.

Exactly the same favourable results have been attained with recurring fever in the human subject, the fever immediately subsidising after the injection of salvarsan, and the patients being cured by one injection. The very rare cases of relapse occasionally occurring are also readily curable.

To continue dealing with salvarsan, in syphilis, which is so closely related to frambœsia, a fair percentage of cures has been obtained in the very first stage of the disease by a single injection of a large dose, but, of course, the abortive cure by intensive treatment is far more certain.

With Vincent's angina and the diseases of the mucous membrane of the mouth, which are caused by spirochætes of the mouth, *therapia sterilisans magna* is possible; in fact, in many cases a mere local application of salvarsan suffices. I may here further mention tertian malaria, in which form, but in this form alone, salvarsan has proved successful, and blastomycosis (Petersen) and the Aleppo boil. As regards diseases of animals which can be cured by one single injection of salvarsan, I might specially mention breast disease of horses, which is of such enormous importance to the military authorities, and lymphangitis epizootica, the African glanders in horses.

Most important are the recent observations of Rogers, who found emetin to be a specific against the very serious amœbic dysentery. And if here it is indeed advisable and necessary to repeat the injections, yet the triumph of therapeutics remains unassailed; it is all one to the patient as to whether *therapia sterilisans* or *sterilisans fractionata* is employed, provided only he is relieved of his sufferings in a harmless manner.

Piroplasmosis also, which exerts a disastrous action, causing serious diseases in cattle and dogs, may, according to the observations of Nuttall, be favourably influenced by a pigment belonging to the class of trypane colouring matters, viz. by trypane blue, which was first composed by Mesnil. As I am informed, the fight against this disease has been taken up in a general manner at Pretoria under the auspices of Theiler. The injections are there performed, not by veterinary surgeons, but by the farmers themselves, and they are glad to save their valuable animals scot-free from this serious disease.

It is indeed easy to understand that the schizomycetes, which in themselves are so much hardier than the tender protozoa and spirochætes, will offer an increased resistance to the attack of drugs. Naturally here, too, there are fine differences, and it is perhaps no accident that the pneumococcus, the protoplasm of which is, of course, most sensitive, should in the course of treatment also have shown itself to be particularly sensitive. (I refer here to the fine researches of Morgenroth in the treatment of laboratory animals infected with the pneumococcus by means of derivatives of quinine, especially ethylhydrocuprin.) But in the case of hardier bacteria, too, such as the *Bacillus typhosus*, the possibility of sterilisation is not beyond hope. The first successful experiments in this sphere were carried out by Conrad on rabbits, and later confirmed and extended by Uhlenhuth and his fellow-workers on this species of animal.

If I briefly allude to the very hopeful experiments of Gräfin Linden, who has endeavoured to influence tuberculous infections favourably by means of combinations of copper and lecithin, and if I add that salvarsan also has been shown to have a beneficial action upon the malignant anthrax-bacillus, and upon that of glanders, and, possibly, upon that of erysipelas, both in animal experiments and occasionally, too, in human cases, then all that we know about the chemiotherapeutics of the specific bacterial diseases has been told, so that it is just in this direction that there lies a wide field still to be worked. This field, important as it is, is still in the very first stages of experimentation.

And if after what has been said we cast a glance over the development of medicine and especially of the fight against infectious diseases, we must recognise that in the last fifty years the most important advances have been made in every direction, advances connected above all with the names of Pasteur, Robert Koch, and von Behring.

On one hand we have the isolation of the pathogenic bacteria, which was made possible really by the Koch method of the solid culture medium, and in which Robert Koch's pupils and fellow-workers, Löffler, Gafftey, Pfeiffer, in the first order, participated; the study of protozoa, which started from Laveran's discovery of the germ of malaria; the discovery by Löffler and Frosch, Roux and Nocard, of the viruses which pass through filters; and the recognition of insects as intermediate hosts and transmitters of infectious diseases, which is connected with the name of Theobald Smith, and has led to the most important consequences.

On the other hand we have the study of the immunity theory which was first inaugurated so brilliantly by Metchnikoff, and received a new impetus from the wonderful discovery of antitoxin by von Behring, through which a wide new field, that of the science of immunity and the investigation of serums, was opened up, on which Pfeiffer, Bordet, Widal, Wassermann, and many others, including myself, have worked with successful result. Some of the most valuable fruits of these labours from a practical point of view have been the diagnosis of diseases first in the form of the Widal-Grüber reaction, and later the Wassermann syphilis-reaction, the importance of which for diagnosis and therapeutics cannot be estimated.

All these discoveries, especially in regard to the ways of spreading diseases on the part of the infecting agencies, have, in accordance with the principle that "Prevention is better than cure," been made good use of in the fight against epidemics and for prophylactic measures, and have brought about an improvement surpassing expectation. In the second place the struggle with diseases which have already broken out has been able to derive advantages from these discoveries, the most wonderful example being the diphtheria serum.

Now that the liability to, and danger of, disease are to a great extent circumscribed, so far as epidemics and many other diseases are concerned, the efforts of chemio-therapeutics are directed so far as possible to fill up the gaps left in this ring, more especially to bring healing to diseases in which the natural powers of the organism are insufficient. And I believe that now when definite and sure foundations have been laid for the scientific principles and the method of chemio-therapeutics, the way is visible before us; not always an easy but yet a practicable way. In the diseases involving protozoa and spirilla extraordinarily favourable results, as I have shown, have already been gained, which can also satisfy far-reaching tests. There are many valuable indications that in a series of other diseases—smallpox, scarlatina, typhus exanthematicus, perhaps also yellow fever, and, above all, infectious diseases caused by invisible germs—the prospects of success are brightening. But in contradistinction to these super-parasites the ordinary or common bacterial diseases (diseases due to the streptococcus and the staphylococcus, coli, typhoid, and dysentery, but, above all, tuberculosis) will still require a hard struggle. Nevertheless, I look forward with full confidence to this development also, and might, without being set down as an optimist, put forward the view that in the next five years we shall have advances of the highest importance to record in this field of research. There are indeed problems which often prove too great for the powers of individuals, and can only be solved by a many-sided effort. Considering the enormous number of chemical combinations which are taken into consideration in a struggle with diseases, it will always be a caprice of chance or fortune or of intuition that decides which investigator gets into his hands the substances which turn out to be the very best materials for fighting the diseases, or the basal substances for the discovery of such. But the chances in favour of finding a real cure, and so of winning the big prize, will naturally rise with the number of those who occupy themselves with the definite problem. It is just at this point, above all, that necessity arises to gather and unite all powers, and here special force attaches to that motto, *Viribus unitis*, which gives guidance in so many other fields; which in so exemplary and fine a way is the foundation of this great International Congress, to which thousands have been drawn from all lands, to give their testimony that in the world of science all national barriers have disappeared.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LEEDS.—The council of the University has accepted with deep regret the resignation of Mr. Roberts Beaumont, professor of textile industries. To mark its sense of the value to the University of his work, extending over a period of thirty-four years, the council has placed on record its high appreciation of the services which, during his long tenure of the professorship, Prof. Beaumont has rendered to the clothworkers' departments of the University, and to technical instruction in the textile industries.

LONDON.—Dr. W. C. McC. Lewis, having been appointed to the chair of physical chemistry in the University of Liverpool, has resigned his office in connection with the department of chemistry at University College. Dr. R. E. Slade has been elected to succeed him as assistant. Dr. Slade was educated in the University of Manchester. In 1909, he was appointed assistant-lecturer in physical and electrochemistry at the University of Liverpool, and was subsequently appointed lecturer-in-charge of the department of physical chemistry.

Dr. A. J. Clark, assistant in the department of pharmacology at University College, has been appointed lecturer in pharmacology at Guy's Hospital Medical School. His successor at University College will be appointed at the beginning of next session.

THE short Education Bill recently introduced into the House of Commons by the President of the Board of Education, which dealt with grants in aid of building, has been dropped for this session, owing to the great pressure of Parliamentary business.

BY the will of the Rev. L. C. Chamberlain, we learn from *Science*, 5000l. is bequeathed to the Smithsonian Institution for its mineralogical collections, and 2000*l*. for its collection of molluscs. There was also bequeathed 1000*l*. to the Academy of Natural Sciences in Philadelphia for increasing and maintaining the Isaac Lea collection of Eocene fossils. These bequests were made for the benefit of the scientific work in which the late Mr. Isaac Lea was interested, Mrs. Chamberlain, his daughter, having inherited the money from him. Mr. Chamberlain also bequeathed 20,000*l*. and his residual estate to the Thessalonica Agricultural and Industrial Institute, Turkey.

THE programme for the session 1913–14 of the department of technology of the City and Guilds of London Institute has now been published by Mr. John Murray. It contains the regulations for the registration, conduct, and inspection of classes, for the examination of candidates in technological subjects, and for the award of teachers' certificates in manual training and domestic subjects. The regulations are in the main the same as those of last year, but the rules respecting the award of full technological certificates have been revised. The passing of examinations in science, and in some cases in art, held by approved schools will be accepted as a qualification for the full certificate. Under certain conditions, candidates from approved schools may be exempted from the examination in the first grade in some subjects in which the examinations are held in more than two grades. In a number of technological subjects the syllabuses have been rearranged and redrafted.

THE Illuminating Engineering Society has issued a preliminary report of the joint committee appointed in 1911 to consider the questions in connection with the artificial lighting of schools. The report appears in *The Illuminating Engineer* for July. The committee was chiefly concerned with the needs of the children. The intensity of illumination necessary in schoolrooms depends on the nature of the work carried out. It is suggested that for ordinary clerical work the minimum illumination measured at any desk where the light is required should not fall below 2 foot-candles—four members of the committee say $2\frac{1}{2}$ foot-candles. For special work, such as stitching with dark materials or that in art classes, a minimum of 4 foot-candles is desirable; and for general illumination in assembly-rooms one foot-candle. As regards blackboard lighting, the committee recommends an illumination on the blackboard about 60 per cent. in excess of that prevailing in the rest of the room. To avoid glare it is recommended that no lamps should come within the solid angle subtended at the eye by the blackboard, and a space 2 ft. above it, unless they are completely screened from the eye by a shade impervious to light. With the same object it is suggested that for text-books intended for the use of young children matt paper, sensibly free from prejudicial reflection, should be employed. The use of light-tinted surroundings which serve to diffuse the light is recommended to avoid inconvenient shadows.

SOCIETIES AND ACADEMIES.

MANCHESTER.

Literary and Philosophical Society, July 22.—Dr. H. **Wilde**: Some new multiple relations of the atomic weights of elementary substances, and the classification and transformations of neon and helium. In several of the author's papers on the origin of elementary substances, published by the society (1878–1906), special attention was directed to the seventh series of his classification, on account of the magnitude and importance of its primary members in the economy of nature, viz. nitrogen, silicon, iron, and gold. Silicon in combination with oxygen constitutes more than half the weight of the earth's crust, and is the principal constituent of glass for all the purposes of civilised life. The policy of several writers in doubling the atomic weights of four of the gaseous members of this series, viz. neon, argon, krypton, and xenon, induced the author to review the multiple relations of the seventh series with the important result (1) that six triads are formed out of the eight principal members of the series, in which the sum of the atomic weights of the extreme members is double the atomic weight of the means, and are all multiples of seven. Triads of atomic weights have been fully recognised by Dumas, Faraday, and other philosophical chemists, as indubitable evidence of community of origin, of transmutation, and important factors in the classification of elementary substances. Radium (as was indicated in Dr. Wilde's tables of elements some years previous to its discovery) is one of the synthetic transformations of helium, and is the next higher member of the series to barium, as was since confirmed by Mme. Curie. Helium is also shown in the author's table of 1878 as the analytic transformation ultimate of radium and other members of the second series of elements. The positions of helium and neon, as the transformation ultimates of the second and seventh series respectively, are further interesting in connection with the recent announcements that these elements have been found in glass vessels and tubes in which they had no previous existence. Assuming the reality of these observations, the phenomena not only admit of explication from Dr. Wilde's classifications, but also account for the discordant results obtained by the experimenters engaged in the research. One of the investigators could only find neon, while others, working independently, found helium alone, and in other cases a mixture of both gases. These results were of sufficient interest to induce the author to ascertain the composition of various glasses used in the arts. The principal and most important constituent of the glasses tabulated by Dr. Wilde is silicon, the transformation ultimate of which is neon. The next important constituents of the glasses are barium, calcium, and lead, all members of the second series of elements, the transformation ultimate of which is helium. The alkali methods, sodium and potassium, are constituents of nearly all glasses, and their transformation ultimates (with others of the first series) will be hydrogen and neon, but without helium. All the silicates of the first and second, and some of other series, are easily vitrified in small quantities in laboratory crucibles. Their spectra can then be examined during electrification in tubes (under suitable conditions of temperature and pressure) for the discovery of new elements and the identification of those already known.

PARIS.

Academy of Sciences, August 4.—M. F. Guyon in the chair.—J. **Boussinesq**: The complete determination, by its partial differential equations, of the problem of slow regularised movement of a heavy liquid mass, in the midst of another fluid mass, indefinite and at rest, and equally incompressible.—G. **Charpy** and A. **Cornu**: The displacement of the critical points of iron by the addition of silicon. Contradictory results on this subject have recently been published by Vigouroux and Baker. Seven alloys have been prepared by the authors from Swedish iron to which increasing quantities of ferro-silicon were added. Complete analyses are given of the seven alloys, the silicon ranging from 0·11 to 6·10 per cent. The critical points were determined by the velocity of cooling method, the curves being recorded automatically with the double Saladin-Le Chatelier galvanometer. The point a_3 vanishes when the silicon reaches 1·5 per cent. The point a_2 remains clear throughout, but each increase of 1 per cent. of silicon lowers the temperature by about 11° C. The temperature of a_1 is slightly raised as the proportion of silicon increases, and tends to disappear when the silicon is more than 5 per cent.—Paul **Vuillemin**: The greening of the wood of the pear-tree. The wood is rendered green by *Helotium aeruginosum* and *H. aeruginascens*, the two species differing in the size of the spores. The name of Chlorosplenium is without systematic value, since several genera have been described under this name which are not closely allied. The colour of the wood is retained indefinitely and has been utilised in the arts.—R. **Gateaux**: Continued and analytical functionals.—Jules **Andrade**: The law of similitude of circular springs.—J **Rey**: A method of testing optical reflectors. The proposed method, which is applicable to all optical systems giving a real or virtual image of a luminous point placed at its focus, is based on a photograph of the image of square mesh wire gauze. The photograph shows not only that there is an imperfection of the surface, but gives the points of the surface the curvature of which is incorrect. Two reproductions of such photographs accompany the paper.—MM. **Massol** and **Faucon**: The absorption of the ultra-violet radiations by some mineral colouring matters in aqueous solution. The various colouring matters studied (potassium ferrocyanide, gold chloride, sulphate of copper, potassium chromate, uranium nitrate, nickel sulphate, chromium sulphate) absorb the ultra-violet radiations unequally. From a quantitative point of view, the absorbing power of synthetic organic colouring matters is much greater than that of the mineral colours.—Daniel **Berthelot** and Henry **Gaudechon**: The rôle of uranium salts as photochemical catalysts.

With the exception of uranium salts, none of the fluorescent and radio-active bodies used had any accelerating effect on photochemical reactions. The accelerating effect of uranium salts is limited to a special class of reactions, those which are produced spontaneously in ultra-violet light. The photocatalyst enables the reaction to proceed in ordinary light.—A. **Damiens**: The products of incomplete reduction of cerium oxide. By the action of a limited quantity of carbon on ceric oxide Sterba obtained a substance described by him as cerium oxycarbide. The reduction of ceric oxide is now shown to give a mixture of Ce_2O_3, CeC, and CeC_2; there is no confirmation of the existence of a definite oxycarbide.—F. **Jadin** and A. **Astruc**: Manganese in drinking water and mineral water. The results of a series of determinations of manganese in the drinking water of eight towns and nine mineral springs. All the latter showed appreciable amounts of manganese varying from 0·09 to 0·20 milligram per litre.—Charles **Nicolle** and E. **Conseil**: An attempt at the experimental reproduction of mumps in the ape.—H. **Pottevin** and H. **Violle**: Experimental cholera in the lower apes.—Jacques **Mawas**: The structure and morphological signification of the comb (*peigne*) of the eye of birds.—M. **Arabu**: The Neogene of the north of the Sea of Marmora.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical series), parts 1 and 2 for 1913, contain the following memoirs communicated to the society:—

December 21, 1912.—F. **Bernstein**: Contributions to mathematical statistics. I., The method of treating incomplete material.—G. **Tamman**: The phase-diagram of water.

January 11, 1913.—A. **Peter**: The diatomaceous flora of southern Hanover, including the Harz, and its distribution in the waters of the region.

January 25.—R. **Wedekind**: Further contributions to the zonal partition of the Upper Devonian.—E. **Perna**: The relations of the Upper Devonian of the Eastern Ural and that of Westphalia and Silesia.

February 8.—G. **Tamman**: The relation of the volume-surface to the polymorphism of water.—B. **Dürken**: The transplantation of young osteoblasts into the orbit of the larval frog.—O. **Wallach**: Researches from the Göttingen University Chemical Laboratory. XXVI., The behaviour of carvoxime and of eucarvoxime towards free hydrogen in the presence of colloidal palladium.

February 22.—M. **Planck**, P. **Debye**, W. **Nernst**, M. von **Smolukowski**, A. **Sommerfeld**, and H. A. **Lorentz**: Preliminary report on the course of lectures on the kinetic theory of matter instituted by the committee of the Wolfkehl foundation.—P. **Hertz**: The statistical mechanics of the spatial "aggregate," and the probability of a given "complexion" (kinetic theory of gases).—H. **Bolza**, M. **Born**, and Th. von **Kármán**: Molecular streams and discontinuity of temperature.—P. **Koebe**: Boundary adaptation in conformal representation.

March 8.—W. **Voigt**: Electric and magnetic double-refraction.—R. **Trümpler**: Determination of fundamental star-places from altitude-transit observations.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2286, Vol. 91] THURSDAY, AUGUST 21, 1913 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

THURSDAY, AUGUST 21, 1913.

ETHNOGRAPHY OF NORTHERN NIGERIA.

Hausa Superstitions and Customs: an Introduction to the Folklore and the Folk. By Major A. J. N. Tremearne. Pp. xv – 548 + plates + map. (London: John Bale, Sons, and Danielsson, Ltd., 1913.) Price 21s. net.

IN this book Major Tremearne has provided students of folklore with a feast of tales from Northern Nigeria, and it may be said at once that the material is arranged in such a way as to enable the reader to deduce from the tales themselves a very fair picture of the ethnography of the people amongst whom they were collected. The main portion of the book consists of one hundred stories, each of which is accompanied when necessary by a note on the local variants and on parallel tales in other parts of the world. The stories are preceded by a chapter in which they are analysed, and which contains all that can be deduced from them relative to the manners and customs, the mode of thought, and the beliefs of the Hausa, together with many explanatory passages drawn from the author's own experience and reading. They are followed by notes which explain separate words or incidents in each tale, the existence of each note in a particular story being indicated by a number inserted in the text. The book concludes with two short chapters, on tribal marks and on the Bori dance respectively.

The first, or analytical, section has been carefully prepared, and contains much material which will be of value to anthropologists at large. It can scarcely be studied apart from the tales themselves, and the serious student will find it necessary to read this section carefully both before and after studying the text of the legends. The great majority of the stories were obtained at Jemaan Daroro, in the Nassarawa Province, from five informants, two soldiers, two personal servants, and the head of the leather-workers, and the table of contents indicates the individual responsible for each.

A great feature of this collection is constituted by the number of stories in which animals figure as the chief characters, and, as might be expected, one is continually reminded of "Uncle Remus." The favourite character, however, is not "Brer Rabbit," but the spider (which plays also a very large part in Jamaican folklore). He is invariably shown as the epitome of greed and cunning, and though he sometimes comes to grief, he is generally successful in outwitting the other animals. A less frequent character, though more consistently successful in his trickery, is the jerboa, while the hyæna is the buffoon whose unintelligent greed nearly always lands him (or her) in difficulties. Here we have typified the general morality of the native as expressed in his folklore; cunning and wit are the passports to success, and the man who possesses them to a sufficient degree may be excused dishonesty, cruelty, and greed. The one unpardonable sin is stupidity, though disobedience to the wishes of parents is also usually visited with punishment. It is not, however, low cunning only that is held up for admiration; mental acuteness of a high order is also highly esteemed, and a certain number of stories occur which celebrate judgments of a Solomon-like order. The point lies rather in the fact that there seems little, if any, distinction in the native mind between the two varieties of cleverness.

Many of the stories have their counterparts in other regions of the world; we have our old friend the tar-baby, and a story of the equally familiar "open sesame" type; a cumulative tale, similar to that about the old woman and the pig, is also found, and a whole host of characters, such as many-headed giants, witches (who must be utterly destroyed even to the last drop of blood to prevent their resurrection), half-men (like the Japanese *Ippi*), and so forth.

Etiological tales are disappointingly few; but one interesting example explains the relative positions of the eye and eyebrow. In this is related a contest between a man called "You-are-wiser-than-the-king" and the ruler; the latter chases the former, both assuming a variety of shapes, until finally the king's adversary falls into the eye of an old woman and becomes the pupil, while the king transforms himself into the eyebrow to watch for the other to come out, and thus they remain.

One story, apparently told in all seriousness, is interesting as showing singular deficiency in mental arithmetic. A man dies leaving a fortune of 20,001 cowries. It falls to the lot of the king to divide this among three children, and he is at his wits' end to know how to divide the one cowrie. Finally, the aid of a wise man is called in, and he divides the inheritance piecemeal, finally leaving six cowries, of which he gives two to each and thus solves the extraordinarily difficult problem.

Especially worthy of remark is a very full account of the sign-language current among the Hausa, which is found in the first section of the book, and also the short account of the Bori dance, in which the performer becomes possessed by a definite spirit with a definite name and attributes. This dance is now forbidden.

The book contains a large number of illustrations in half-tone and line. The photographs are of very unequal value, and it would have been better if the author had given some indication in cases where they had been retouched. The line-drawings are better, except those of the tribal marks, the value of which is impaired by over-reduction. The principal criticism, however, that may be brought against the illustrations as a whole is that they have very little organic connection with the text.

PHYSIOLOGICAL PATHOLOGY.

A Text-book of Pathology for Students of Medicine. By Dr. J. George Adami and Dr. John Macrae. Pp. x+759+plates. (London: Macmillan and Co., Ltd., 1912.) Price 25*s.* net.

THE appearance of a text-book of pathology which is intended for the use of medical students, and comprises so many of the admirable features of Prof. Adami's larger work, is a very welcome event. "The Principles of Pathology" has taken its place as the standard work on pathology in the English language, but a system of pathology occupying two large volumes is inevitably beyond the powers of the average student, who is obliged, within a limited space of time, to acquire a reasonable knowledge of the numerous subjects of the final examination. The full and detailed treatment which is accorded to the subject in the larger work is, moreover, unsuited to the student at the outset of his studies in pathology. In spite of the authors' claim that the new book is no mere epitome, we are glad to recognise in an abbreviated form many of the best features of the larger work. The articles on inflammation and on the general pathology of tumours are instances in point.

To the student who has received a sound training in the general principles of the biological sciences this book will make a direct appeal. To the medical student the study of pathology should form the natural sequence to the study of chemistry, of physics, of physiology, and anatomy. A work in pathology should be no mere catalogue of the morbid changes in various organs. The student who has been taught to base his views on conclusions to be drawn from experimental facts will find this method of teaching continued and exemplified in this text-book of pathology. The sections which deal with general pathology are written in a most attractive manner, and afford a delightful introduction to the subject. The portion of the work devoted to special pathology is of necessity somewhat brief. Such omissions as occur will, however, be readily filled by the knowledge derived from a practical experience of the subject.

The essential object of this work is, we imagine, to afford an introduction to the subject. This object has been successfully attained. To those who merely seek a compressed epitome of morbid anatomy this book is entirely unsuitable.

H. R. DEAN.

VEGETABLE ALKALOIDS.

The Plant Alkaloids. By Dr. T. A. Henry. Pp. vii+466. (London: J. and A. Churchill, 1913.) Price 18*s.* net.

THE alkaloids of plants have long offered a most interesting and attractive, if always difficult, field of research to both chemists and physiologists. The subtle chemistry of the vegetable cell evolves no objects more fascinating to study than these "vegetable alkalis," as Sertürner first termed them; bodies usually of highly complex chemical structure, and often of appalling potency in their physiological effects. Of the problems which they offer, one in particular—that of their chemical constitution—has received a large amount of attention during the last two or three decades, and much progress has been made with it. *How* much is perhaps scarcely realised until the results are collected and collated, as in the book under notice, in such fashion that a bird's-eye view of the whole field can be readily obtained. Then the reader notes that "alkaloids of unknown constitution" form only one group out of nine, and that group not a remarkably large one; whilst in the case of several members even of this group—for example, the aconites, colchicum, and ergot—knowledge of their structure is beginning to accumulate.

When, however, the chemical structure of an alkaloid has been elucidated, there yet remains a problem of great general importance, namely, how its chemical constitution is correlated with its action on the animal system. What is the deft arrangement of atoms which confers upon strychnine its tetanising action, convulsing all the muscles of the body; and what, on the other hand, is the arrangement in curare, a drug which paralyses the motor nerve endings without affecting the excitability of muscle? Many useful observations have been made on this question, but the difficulties are great, and progress slow. A comparatively simple case is quoted where two investigators, after studying the relation between the mydriatic action and the chemical constitution of the tropeïnes, were forced to the conclusion that no generalisation could be made which would explain all the results they obtained.

Another question which has been much debated is the mode of formation of the alkaloids in the plants. The view mostly favoured is that they, or at least some of them, are decomposition-products of proteins, chlorophyll, and other complex substances. As regards their function in the plants, they have been variously considered as nutrient materials, protective substances, or end-products of metabolism, rendered harmless to the plant, and stored chiefly in special cells whence they are not readily re-absorbed into the active plant tissues.

On these and other general questions Dr. Henry touches, though but lightly, in the introduction to the work under review. It is rather a pity that more space was not given to this aspect of the subject: the one criticism which the book invites is that it is too much like a collection of extracts from the Journal of the Chemical Society. But it is a good collection, and includes the chief historical, chemical, physical, and physiological data relating to the numerous alkaloids dealt with; whilst in the case of those which have been successfully studied, a concise summary is given of the experimental evidence, and of the arguments founded on this evidence, which elucidate their structure and establish their accepted chemical formulæ. In particular, readers whose business or pleasure it is to study the less-known alkaloids will often be moved to call down a benediction on the head of the author.

C. Simmonds.

(4) *Dispersion und Absorption des Lichtes in ruhenden isotropen Körpern.* Theorie und ihre Folgerungen. By Dr. D. A. Goldhammer. Pp. vi+144. (Leipzig and Berlin: B. G. Teubner, 1913.) Price 3.60 marks.

(5) *Cours de Physique Générale.* Leçons professées à la Faculté des Sciences de l'Université de Lille. By H. Ollivier. Tome Second. Thermodynamique et Etude de l'Energie Rayonnante. Pp. 295. (Paris: A. Hermann et Fils, 1913.) Price 10 francs.

(1) THIS book is intended for beginners, but covers the syllabus of the lower certificate examination of the Board of Education. The order of treatment adopted is:—magnetism, electrostatics, current electricity. Each branch is introduced by a simple qualitative account before the more advanced quantitative aspects are considered.

The treatment of the electrostatics is most lucid, and the author makes, and rightly, a special plea for more experimental work, performed by the student himself, in this part of the subject. A number of qualitative experiments are suggested, several of which could be made roughly quantitative, even without the spherical condenser, charged to a known potential, which Mr. Hansel desires installed in every laboratory.

There is very little fault to be found: too much stress is laid on the experimental verification of the inverse square law with very long magnets; an elementary account of the Cavendish proof of the same law should be given in electrostatics, and an account of the kathode rays and allied phenomena would increase the utility of the book for many students.

Each chapter contains a number of questions, the numerical answers being given at the end. The diagrams, if in some cases rather crude, are clear, and have not been stinted. Anyone seeking a class-book in elementary electricity will scarcely better this.

(2) A complete account of the subject to the standard of the pass degree is given in this, the latest issue from the University Tutorial Press; but the descriptive portions are necessarily reduced to the mere outline required to make the mathematics intelligible. Selected portions will be found helpful by all preparing for examinations in electricity, whether of intermediate or honours standard.

The author's aim is to equip the man already familiar with the elements, so that he may read the advanced treatises with understanding, and at the same time to give him that precision of thought which can only be obtained by working numerical examples. The mathematics involved is of a very simple character, a very slight knowledge of the calculus being required for the chapters on condensers and induced currents.

The last chapter contains a summary of the corpuscular theory, marred by one unfortunate statement. On p. 296 we find: "Practically the whole inertia of the atom is supposed to belong to its negative corpuscles. Of these there are roughly 1800 in the case of a hydrogen atom." Later: "These ideas must not be regarded as facts." True, but they should at least represent the current notions of the subject.

(3) Prof. Houllevigue has collected under this title a set of twelve essays dealing, in a semi-popular fashion, with some modern aspects of

physics and chemistry. In the course of his introduction M. Ed. Bouty pays high tribute to the author's skill as an exponent of popular science, and it must be admitted that the anticipations so raised are not disappointed, for the explanations are clear, the analogies happily chosen, and the whole is written in a bright and interesting fashion.

Among the subjects dealt with are "L'ultramicroscopie" and "Le Mouvement Browien," "L'état colloïdal et la vie," "Le cycle de l'azote," and "Les Terres Rares." This last includes an interesting account of the applications of the so-called rare elements, and justifies to a considerable extent the dictum that "the only really rare bodies are those for which no practical applications are known."

(4) Prof. Goldhammer chooses as the basis of his treatment of dispersion that particular form of the theory first advanced in 1902 by M. Planck. In this book the theory is generalised and extended to conducting media with more than one absorption band. An investigation, in vectorial notation, of the vibration of Planck's resonator—the "Electrische Dipole" is followed by the development of the theory in terms of this body. The theoretical results are then compared with the experimental data: gases and vapours, solutions, metals and various compounds all being considered. This portion of the book is especially commendable, being fully illustrated with tables of data and curves.

In the last chapter dispersion is considered from the point of view of the electron theory, the author, following J. J. Thomson, making no distinction between the bound and free electrons. It is concluded finally that, so far, this generalisation of Planck's theory is nowhere in antagonism with the results obtained by experiment. An excellent little treatise, being a notable addition to the literature of the subject.

(5) This is the second volume of a complete course of physics based on the notes of lectures delivered at the University of Lille. The work is to be completed in three volumes, of which the first and third are still in the press.

The thermodynamics is treated mathematically on the usual lines, a knowledge of partial differential coefficients being assumed. The ground covered is extensive, and the treatment rather uneven. For example, thermodynamic potential is dismissed in a single page, and the study of the solid state in a chapter of three pages, while, on the other hand, the section on univariant systems is particularly good. Interspersed in the text are a number of worked numerical examples.

Radiation is treated descriptively on modern lines, mathematical formulæ only being given. Nearly a third of this part of the book is devoted to the astrophysical aspects of the subject: an interesting section, but only inserted at the expense of the rest of the subject.

OUR BOOKSHELF.

Les Pyrénées Méditerranéennes, Etude de géographie biologique. By Prof. M. Sorre. Pp. 508 + xi plates, 41 figures and a map. (Paris: Armand Colin. 1913.) Price 12 francs.

THIS book is not the outcome of a wholly new method of inquiry, but it is a more complete examination of local influences, past and present, acting in a defined area, than most works of a similar nature. The subject is treated historically, especially in relation to man's activity, from the earliest times, in altering or modifying the aspects and composition of the vegetation and in the development of animal life, in relation to advancing civilisation. It is a consolidation of knowledge obtained by workers in the various branches of research connected with life, animal and vegetable, and physical conditions.

The area under consideration comprises the eastern part of the Pyrenees from Andorra in the west and the whole of the low mountains, hills and plains falling therefrom to the east and to the south, to the sea. There are altitudes of nearly 10,000 feet, and the essentially alpine vegetation begins at about 8000 feet. Phytogeography plays an important part in the history of the human race and naturally occupies a large place in this book, where the results of Prof. Ch. Flahaut's investigations are largely drawn upon. The map shows the distribution of the characteristic trees of the successive zones, beginning with the purely littoral vegetation and followed by the evergreen oak and olive, the stone pine, the cork oak, hairy oak, beech, silver fir, Scotch pine, mountain pine, and the alpine zone.

The plates mostly illustrate *paysages* or scenery, and the figures physical conditions and phenomena. An idea of the arrangement of the matter may be obtained from the headings of the chapters:—I. Les Paysages. II. Le sol et les formes du Relief. III. Climat. IV. Les Eaux. V. Les formes de la Végétation Spontanée; and VI. to VII. Les Genres de Vie of the different regions, with a final chapter on La Vie de relations, son influence sur la Vie locale. W. B. H.

Travers' Golf Book. By Jerome D. Travers. Pp. xi + 242 + xlvi plates. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1913.) Price 8*s.* 6*d.* net.

THIS book will prove interesting reading to all golfers, and especially to those who aim at being champions. Mr. Travers tells how he attained his expertness—simply by thoughtful, deliberate practice. He gives many valuable hints on stance and grip, and elucidates these by means of photographs of himself in all sorts of positions, and with all kinds of clubs. He has the good sense to abstain from either superficial or profound discussion of the dynamics of the golf ball in air. He has no particular interest in the value of underspin, except in the extreme form for short approaches with mashie or niblick.

The Development of the Human Body. A Manual of Human Embryology. By Prof. J. Playfair McMurrich. Fourth edition. Pp. x+495. (London: Henry Kimpton, 1913.) Price 12*s.* 6*d.* net.

In this edition, Prof. McMurrich, who is professor of anatomy in the University of Toronto, has incorporated the results of all important recent contributions to the subject of human embryology. To avoid increasing the size of the volume unduly, several chapters have been recast and the rest of the volume revised thoroughly.

LETTERS TO THE EDITOR.

The Post-Embryonic Development of the Spiny Lobster.

JE reçois actuellement au Laboratoire de Plymouth l'hospitalité scientifique la plus large, comme premier titulaire de la fondation annuelle récemment créée par l'Association britannique de biologie maritime en l'honneur de votre éminent compatriote M. le Professeur E. Ray Lankester. Les recherches que je poursuis en cette qualité me paraissent de nature à intéresser les zoologistes, et comme elles viennent de conduire à un résultat notable, je me permets de vous les signaler en sollicitant pour celui-ci l'hospitalité de votre important journal.

Ces recherches sont relatives au développement post-embryonnaire de la Langouste commune, *spiny lobster* des Anglais, *Palinurus vulgaris* des zoologistes, espèce peu répandue sur les marchés de la Grande-Bretagne, mais fort estimée en France où, d'ailleurs, elle devient rare et atteint des prix élevés. La famille des Langoustes compte à peu près vingt espèces, toutes de grande taille et comestibles, et toutes localisées dans les mers chaudes à l'exception d'un petit nombre qui s'avancent quelque peu dans la zone tempérée. La Langouste commune se range parmi ces dernières; c'est la seule Langouste des mers d'Europe; on la trouve en Méditerranée et, dans l'Atlantique, jusqu'à l'entrée de la Manche où elle atteint Plymouth grâce à la douce température des eaux du Gulf-Stream; on la pêche assez fréquemment autour du phare d'Eddystone.

Le développement post-embryonnaire des Langoustes est des plus remarquables, mais obscur en bien des points encore. On sait, depuis Couch (1857) et Gerbe (1863), que les Langoustes sortent de l'œuf sous la forme de larves pélagiques aplaties et transparentes que Leach (1816) avait prises pour un genre spécial et désignées sous le nom de Phyllosoma; on admet également, depuis les recherches de M. Boas (1881), mises en lumière par M. Calman (1909), qu'elles acquièrent ensuite une apparence macrourienne et deviennent nageuses sous une forme que M. Ortmann considérait comme autonome et désigna sous le nom de Puerulus; mais on n'a jamais suivi, depuis l'œuf jusqu'à l'adulte, le développement d'une espèce de Langoustes, l'on ne sait rien sur le genre de vie des puerulus qui sont d'une rareté extrême (vingt exemplaires environ dans tous les musées du monde), et ce dernier stade, pour notre Langouste commune, est resté jusqu'ici complètement inconnu.

C'est pour jeter quelque lumière sur ces points obscurs que je suis venu au Laboratoire de Plymouth; il se trouve à proximité du phare d'Eddystone, autour duquel notre Langouste commune n'est pas rare et se tient forcément localisée, ce qui le rend, plus que tout autre, favorable aux recherches de cette sorte. Je savais d'ailleurs que M. Cunningham avait recueilli près d'Eddystone, dans la première quinzaine de Juillet, des phyllosomes aux premiers stades, si bien qu'on pouvait s'attendre à capturer au même endroit, un peu plus tard, des phyllosomes plus âgés et peut-être, avec beaucoup de chance, le stade puerulus jusqu'alors inconnu. La réalité, comme on va le voir, a dépassé mon espérance.

Depuis le 20 Juillet jusqu'à ce jour, l'*Oithona*, bateau du Laboratoire, a capturé autour du phare d'Eddystone *tous les stades phyllosomes de la Langouste commune*; il y en a huit pour le moins. Au stade le plus jeune, décrit et figuré par M. Cunningham, la petite larve foliacée mesure environ 3 mm. de longueur; au stade le plus âgé, sa longueur atteint 20 à 21 mm. A l'heure actuelle, la plupart des phyllosomes sont âgés et, sans aucun doute, bien près de leur transformation. Le moment est donc des plus favorables pour obtenir le stade natant ou puerulus.

Puerulus de la Langouste commune; grandeur naturelle (photographie prise par M. F. Martin Duncan, du Laboratoire de Plymouth).

En fait, au cours d'une heureuse pêche effectuée le 31 Juillet sous la direction de M. Clark, on a recueilli des phyllosomes assez nombreux et un magnifique puerulus, *le premier puerulus connu de la Langouste commune.* Il fut pris avec le filet Petersen, entre deux eaux ("mid-water"), dans l'intervalle Looe-Eddystone, au-dessus d'un fond de 27–29 brasses.

Le petit animal est de même longueur que les grands phyllosomes (voir la figure, qui est de grandeur naturelle), comme eux incolore et translucide, mais avec la forme macrourienne normale. Ses grandes antennes ressemblent déjà beaucoup à celles de la Langouste commune, mais les antennes internes sont bien plus courtes et l'arceau qui les porte est bien plus large. Le rostre est réduit à une petite pointe médiane comme dans notre Langouste, mais les cornes rostrales ne présentent pas encore d'armature épineuse sur leur bord inférieur. Le bouclier céphalothoracique a dû se dilater anormalement sous l'action du formol, car ses parois latérales sont toujours abruptes et à angle droit avec la face dorsale dans les autres puerulus; d'ailleurs, il porte déjà quelques-unes des épines propres à l'adulte: deux paires de fortes épines post-rostrales, trois ou quatre paires de spinules gastriques, deux ou trois paires de spinules cardiaques et, sur chaque région branchiale, une série longitudinale de quatre ou cinq autres spinules; on trouve sur les régions hépatiques, dans le prolongement des grandes antennes, trois fortes épines plus développées encore chez l'adulte, et, à quelque distance en arrière, trois épines branchiales antérieures qui semblent faire défaut à ce dernier. Les grandes pointes marginales des épimères abdominaux ressemblent beaucoup à celles de l'adulte, mais les petites n'existent pas encore, les épines de la nageoire caudale sont moins nombreuses; toutes les autres, si abondantes chez l'adulte, font complètement défaut. D'ailleurs, les téguments sont coriaces et sans calcification aucune, l'abdomen est dépourvu des sillons transverses qu'on observe chez l'adulte, les pléopodes natatoires s'accouplent au moyen de crochets rétinaculaires, et les sternites thoraciques se prolongent en une pointe à la base des pattes, surtout à la base des pattes postérieures.

Ainsi, le petit animal ressemble déjà quelque peu à une Langouste, mais il s'en distingue par de nombreux caractères. On peut être assuré d'ailleurs qu'il passe directement à la forme définitive, car les très jeunes Langoustes sont à peu près de même taille.

On sait que la Langouste commune se range parmi les Palinuridés brévicornes (antennes internes à fouets courts); il en est de même de notre puerulus qui, par là même, ressemble aux puerulus de la Langouste du Cap (*Jasus lalandei*), de la Langouste néo-zélandaise (*Jasus verreauxi*) et d'une espèce caraïbe, le *Palinurus longimanus*. Il se rapproche surtout du puerulus de cette dernière espèce, car il présente comme lui des pointes sternales et, comme lui également, un exopodite flagellé sur les maxillipèdes externes. Les pointes sternales et le fouet des maxillipèdes font totalement défaut dans les autres puerulus brévicornes.

Nous voici donc, pour la première fois, *complètement renseignés sur le développement post-embryonnaire d'une espèce de Langouste*, et précisément sur celui qui nous intéresse le plus, le développement de notre Langouste commune: j'en possède tous les stades, depuis l'œuf jusqu'à l'adulte, et notamment le puerulus resté jusqu'ici inconnu. Que devient ce puerulus? Il est, on le sait maintenant, d'abord pélagique à la manière des phyllosomes, mais il doit gagner très vite le fond où il se cache et où une mue lui fait acquérir la forme des Langoustes.

Les résultats précédents semblent avoir quelque importance, car ils donnent la solution définitive d'un problème qui occupait les zoologistes depuis près d'un siècle. Je dois en rendre grâces au personnel si aimablement dévoué du Laboratoire de Plymouth, surtout au Directeur, M. Allen, qui fit multiplier pour moi les pêches pélagiques, et à M. Clark, Assistant, qui s'est employé à rendre les occupations fructueuses et, aidé de M. Gossen, a recueilli le premier exemplaire de puerulus. J'adresse à tous mes vifs remercîments, et à vous aussi, Monsieur le Directeur, si, comme je me plais à le croire, vous voulez bien donner l'hospitalité de votre journal anglais à un travail effectué par un Français dans les eaux anglaises.

The Origin of Actinium.

THE question of the origin of actinium is one of very great interest at the present time. The law governing the position of the radio-elements in the periodic table led A. S. Russell, K. Fajans, and myself independently to predict the existence of a new member of the uranium series, the direct product of uranium-X, occupying the vacant place in the periodic table in the VA family, the heaviest known representative of which is tantalum. I suggested that if this "eka-tantalum" disintegrated dually, as in the case of the C-members occupying the place in the VB family, one mode with the expulsion of a β and the other with the expulsion of an α ray, the product of the first mode would be uranium-II., and of the second actinium. This could only have remained undetected if eka-tantalum had a very long period. The suggestion was disproved almost at once by the discovery of the missing element by Fajans and Beer, which has since been confirmed by Hahn and Meitner, and also by Fleck in this laboratory. It turns out to be a very short-lived member with a period of average life of about 1·7 minutes, and gives β rays only, the hard β rays before ascribed to uranium-X, which itself gives only soft β rays.

The obvious alternative was that actinium must be produced from radium in a β-ray change, that is that the first change of radium must be dual, the well-known α-ray change into emanation taking place simultaneously with a β-ray change into actinium. This suggestion receives some support from the fact that radium, as found by Hahn and Meitner, does give, in addition to α rays, a very soft β radiation.

But some experiments, of which I now wish to give a preliminary account, seem also to disprove this alternative. A specimen of Giesel's original radium bromide, now ten years old, containing 13·2 mgs. of radium (element) on the international standard, has been examined for actinium, and not the least trace could be detected. During the whole time since it was purchased, it had not previously been removed from its original ebonite capsule or subjected to any treatment. It was found to consist for the most part of insoluble sulphate, due to its action, no doubt, upon the sulphur in the ebonite capsule. It was brought into complete solution as chloride, radium-D, -E, and -F removed with a trace of bismuth by hydrogen sulphide, and a trace of aluminium chloride added and removed with ammonia. The aluminium hydroxide was repeatedly dissolved in acid and reprecipitated with ammonia until free from radium. The actinium and radio-actinium would remain with the aluminium, the actinium-X being completely removed with the radium from which it is non-separable. Tests for the active deposit were carried out in a stream of air, designed to replace the air in the box containing the preparation once every 5·6 seconds, the period of the actinium emanation. This was in order to suppress the effect of any radium relatively to that of the actinium, but it was not necessary, as neither radium nor actinium were present. On the other hand, a minute amount of the pure thorium active deposit was detected.

The α-ray effect obtained in the air stream mentioned with three hours' exposure, four days after preparation, when one-half of the equilibrium amount of thorium-X would be present, equalled that of about 0·15 mg. of uranium oxide, and was amply sufficient to characterise beyond all doubt. At first sight this result is surprising, but it is exactly what is to be expected if the chemical operations had been successful in their purpose. For there is thorium in Joachimsthal pitchblende, withal a very minute amount, and the corresponding mesothorium would be quantitatively removed with the radium, in the course of time to grow radiothorium. The detection of this infinitesimal trace of radiothorium by the active deposit test is a guarantee that if actinium had been formed it would have been detected, for radio-actinium and radiothorium are non-separable. An actinium active deposit, equivalent to less than 0·1 mg. of uranium in activity, could have been detected, and, taking into account the various corrections, it is reasonable to conclude that the full equilibrium amount cannot certainly be greater than that equivalent in α activity to 2 mg. of uranium. At present the preparation has reached about one-fourth of its equilibrium value as regards actinium-X.

In ten years, of the 13·2 mg. of radium in the preparation, 0·053 mg. would have disintegrated. On the assumption that uranium is the primary parent of actinium, Rutherford has calculated that 8 per cent. of the atoms disintegrating must choose the actinium route ("Radioactive Substances," p. 523). So that, if it were formed from radium, the amount of actinium present in the preparation would be 0·0042 mg. But the active deposit from this quantity has an α activity not greater than 2 mg. of uranium. Hence the period of average life of actinium must be at least fifteen million years, the quantity in minerals must be at least 170 grams per ton of uranium, and the α activity of pure actinium in equilibrium could not be greater than 1650 times that of uranium. But a specimen of actinium, prepared and presented to me by Dr. Giesel, must have, judging from a cursory examination, a far greater activity than this, and Mme. Curie ("Radioactivité," I., p. 189) speaks of some actinium preparations as of the order of 100,000 times as active as uranium. All the researches go to show that its actual quantity in minerals is very small, and, if there were anything like 500 times as much actinium as radium in minerals, one would have expected it long ago to have been isolated and its spectrum and chemical reactions characterised. So that the experiments appear to disprove the possibility that actinium can be formed directly from radium. Similar arguments to those above may be used to show that it cannot be a primary radio-element, and its origin remains still a mystery. In the current number of the *Physikalische Zeitschrift* (p. 752) Hahn and Meitner modify my original suggestion and suppose that the branching of the uranium series takes place at uranium-X, two simultaneous β-ray changes occurring, which produce two eka-tantalums, one the known short-lived β-ray-giving product, and the other a still unknown long-lived α-ray-giving parent of actinium, also in group VA. There seems nothing improbable about this. It is almost the only other alternative remaining to be tested, and it should not be difficult to settle by experiment.

Radium and the Evolution of the Earth's Crust.

Having been away from home, I did not see Mr. Holmes's letter on radium and the evolution of the earth's crust, contained in Nature of June 19, until some weeks after its publication, and thought that the interest in the subject would have so far passed as to make it not worth while referring to, what I believe to be, a considerable misapprehension of the structure of the earth as revealed by earthquakes. Later correspondence has shown that interest in the subject has not waned, and as a correct appreciation of what has been established regarding the constitution of the interior of the earth seems likely to remove some of the difficulties which have arisen out of the study of radio-activity, it may be useful to review the results obtained from the study of the transmission of earthquake waves to long distances.

To begin with, it must be distinctly understood that this line of research can tell us nothing, directly, regarding the chemical composition of the earth, nor can we distinguish between stony and metallic material; all that can be established is the rate at which two distinct forms of wave motion are transmitted, and if, at any particular depth, we find a marked change in these rates of transmission, we may say that it is caused by a change, either in chemical composition or physical state, of the material through which the waves have travelled. With this premised; the first great change takes place at, probably, about ten miles or so from the surface, and seems to correspond with the passage from the heterogeneous and fractured rocks of the outermost skin to more homogeneous material. Below this, and to a depth of about 100 miles, it is difficult to say whether any further change takes place; there are indications of change at about fifty and about one hundred miles, but it is not such as has a great effect on the rate of transmission of the simpler forms of elastic waves, and, as the differences in the time intervals concerned are not of a greater order of magnitude than the inevitable uncertainties of observation, it is difficult to be certain of the reality of the supposed alteration.

Below a depth of about 100 miles there is no evidence of any change until a depth of about 2400 miles is reached; throughout this layer there is a progressive increase of elasticity, but it is gradual and seems to be directly connected with the increase of pressure, with the result that the material, whatever it may be, develops a high degree not only of resistance to compression but also of rigidity as against stresses of short duration. At the depth mentioned, or at somewhere between 0·6 and 0·5 of the radius, measured from the surface, a very marked and remarkable change in the nature of the material, of which the earth is composed, takes place. The change is rapid, and is characterised by a small decrease in resistance to compression, accompanied by a great reduction, if not the complete disappearance, of rigidity. It is impossible to determine how this change is brought about, but it is very much what would be produced either by passage from the stony shell to the metallic core, of one hypothesis, or from the fluid or solid-fluid to the gaseous state, of another.

Whatever may be the final interpretation of the distant records of great earthquakes, the important point to be noticed is that the two great changes which they indicate in the constitution of the interior of the earth are, first, at a depth of only a few, probably not more than ten, miles, and, secondly, at about 2000 to 2400 miles from the surface. Between these depths there are suggestions of variations in composition down to a depth of 100 miles or thereabouts, but they seem to be of only minor importance, and apart from this no change in physical character, or, presumably, in chemical composition, can be detected.

Poroscopy: the Scrutiny of Sweat-pores for Identification.

At the recent meeting of the British Medical Association some attention was directed to a method of criminal identification which has been used at Lyons and elsewhere. A fully illustrated account of it occurs in *Les Archives d'Anthropologie criminelle* for July, from which, after careful perusal, I cannot find that there is anything in the method that does not come under the scope and practical working of dactylography. Dr. Locard has shown good reason why we should give more attention than has been usual to small patches of finger-prints, and to seek among the pores for what the ridges are too meagre to supply. Dr. James Scott, at Brighton, rightly describes "poroscopy" as founded on a study of the "impressions or orifices of the sweat ducts of the finger pulp, instead of the ridges." But pores, the openings of sweat ducts, as printed impressions, cannot be studied quite apart from the ridges, or ridge substance, any more than the holes of which Pat's classic stockings consisted can be considered without reference to the slender remains of the fabric in which they occur.

Dr. Edmond Locard, the writer of the article, "La Poroscopie," alluding to certain landmarks in finger-print patterns (*puntos caracteristicos* they have been called), adduces in one of his illustrations some *îlots* of a single dot, each containing the opening of a single sweat-pore. The effect when printed is that of a more or less regularly shaped O or ring. Of course, if the smoked-glass method were used, what I have called the negative effect would be produced, and the pore would show up as a black dot on a white ground. In such a case as that illustrated the value of such a coincidence would be seen at once, but the value belongs much more to the system of ridges than to that of the pores. A dozen such pores might easily be found to coincide in two patterns having no real relation to each other by way of personality. I should not expect, however, after considerable experience of finger-print patterns, to find three volcanic or coral islets such as are depicted in Fig. 3 coinciding in any but two prints from the same person. But these volcanic islands are not mere pore openings. It is the sharp definition of the ridge element in them that gives character for identification.

It is difficult to conceive of many cases in actual practice where simple coincidence of pores could be made convincing to a jury. Such cases are presented with a magnification of forty-five diameters. But Dr. Locard says:—"Un jury, que trente ou quarante points caractéristiques homologues auront laissé indifférent, sera frappé par la concordance de forme, de position, et de nombre de quelques centaines de pores trouvés identiques sur les deux empreintes comparées." If the illustrations are from the exhibits in the criminal cases quoted, as one would be led to infer, the jury would seem to have been aided very greatly with outlines filled in by official pens, by which the rough places have been made smooth, and coincidences which would not strike any but police officials seeking a conviction, have been made vivid, if not always quite convincing. All this is, I trust, now quite foreign to English criminal procedure.

It is in cases where fewer than some twelve of what an English detective would in the witness-box call "characteristics" are to be found that the additional scrutiny of the pores might be useful. I agree with Dr. Locard that they remain locally fixed in position, but I have mentioned in "Dactylography" (Twentieth Century Science Series), which Dr. Locard does not seem to have read, that, their physiological activity being very variable, their shapes are constantly altering. They may be nearly closed one moment, and quite patent the next, a useful fact which makes it hopeless to forge finger-print signatures effectively with rubber stamps. This variability is most vividly shown in the illustrations to the very article now referred to, and where a finger-print pattern is doubled the pores always agree in position but rarely in shape or size. Henry Faulds.

36 Lichfield Street, Hanley, Stoke-on-Trent.
August 13.

Calanus—a Further Record.

On getting back to Tobermory on Saturday, we found the plankton to be in marked contrast to its condition four weeks ago (see Nature, p. 504). The vast swarm of Calanids has gone, and there are now no signs of mackerel feeding in the bay. In fact, the change has been noticeable for some days in the seas outside, and we have not been getting lately the large plankton catches that were usual in the latter half of July. On July 14 a haul of the large surface tow-net, in the open sea off Ardnamurchan, gave such a huge catch of Calanus (about 1000 c.c.) that we promptly took a second similar haul, and had it cooked as a sort of potted "shrimp" confection for tea (sampled by ten persons, including the crew, who were much interested to try this new edible "fish"); while on August 11 a haul of the same net, taken at the same spot, gave only a small catch of some 15 c.c., containing very few Calanids, along with the usual scanty summer zoo-plankton. I have not yet seen any statistics of the mackerel fishery, but should not be surprised if this proves to be an exceptionally good year in this neighbourhood, especially in July.

I have only just received Nature for the last few weeks, and am glad to read Mr. G. E. Bullen's further remarks (p. 531) upon swarms of Calanids and the fisheries. His excellent work—along with that of Dr. Allen—on the connection between mackerel and Calanus and sunshine in the English Channel, some years ago, is valued as the type of observational and statistical work that is required for the investigation of many fishery problems. W. A. Herdman.

S.Y. *Runa*, off Island of Eigg, August 12.

The Structure of X-Radiation.

In a letter which appeared in Nature of June 19 we described some effects obtained with various metals used as obstacles to X-radiation, which showed that the bands and haloes produced on X-ray plates up to distances of 450 cm. were neither dependent on crystalline structure (other than metallic) nor should probably be termed "diffraction" effects in the strict sense.

Further investigation, in which crystals have been entirely discarded, has led us to believe that some part of these effects at least must be referred to the structure of the primary beam.

In one of our early trials arranged to study the disposition of the spots from a thin lamina of mica, normal to the beam and covering a quarter of an inch aperture, we were surprised to find that spots were not present, but instead the photo plate, exposed at a distance of 50 cm., was entirely covered by dark parallel bands about half a centimetre in breadth and normal to a sharply defined bright cross. In later experiments without mica, and using cast-iron and other screens, both with and without apertures, a system of crossed similar bands has appeared, and a great number of trials have confirmed the result that particular metals (brass, lead, cast- and wrought-iron, &c., of various thicknesses up to 1 cm.) cannot be held responsible for these phenomena, which have even appeared when no other obstacle than a thick sheet of plate-glass has been interposed. A platinised-nickel antikathode has generally been used and 0·5 to 1 milliampere was kept constant through the bulb.

At it appears from Mr. Keene's letter in Nature of August 14 he has used only thin sheets of metal *with apertures*, we can understand that he has obtained somewhat dissimilar effects from ours obtained without any aperture in the screen. Also with super-cooled glass plates there can scarcely be any question of crystalline structure. We have substituted special rapid plates of various makers and changed all the non-essential conditions many times. When photo plates are placed one behind the other at distances of 15 cm. (up to 100 cm.) from the source, these bands have invariably shown most clearly on the plates farthest from it. This certainly would seem to suggest masking, by secondary radiation, of an effect which properly belongs to the primary or "hardest" portion of the rays. W. F. D. Chambers.

90 Gordon Road, Ealing.

SCIENTIFIC MOUNTAINEERING IN INDIA.[1]

H.R.H. the Duke of the Abruzzi undertook this expedition chiefly in the hope of contributing to the solution of the vexed problem as to the greatest height which can be reached by mountaineers. But, as usual, he supplied himself with such a staff as would be able to make good use of every opportunity which his journey might afford for scientific research. The basin of the Baltoro glacier was chosen for the attempt, owing to the number of high peaks at its head. K^2 itself proved to be unclimbable, in spite of several strenuous attacks and much close reconnoitring, and on July 1 the Duke turned his attention to Bride Peak, 25,110 ft. Such were the unexpected difficulties encountered that it was not until July 10 that camp was pitched on Chogo Lisa Saddle, 20,784 ft. On July 12 a height of 23,458 ft. was attained, but bad weather forced them to retreat. On July 17 another start was made, and that evening they pitched their two diminutive Mummery tents at 22,483 ft., the highest strictly authenticated camp to date, though Rubenson and Monrad-Aas probably camped as high on Kabru.

FIG. 1.—Jhula bridge at Karmang. From "Karakoram and Western Himalaya."

Next morning at 5.30 the Duke, with the guides Petigax, Henri and Emil Brocherel, started on what they realised was the final assault. At first all went well. But as they climbed mists settled on the mountain, and the snow got so soft that they sank in 2 ft. or more at every step. Yet "their fatigue was not very great" until at 24,278 ft. they reached a steep outcrop of rock. "Directly they had to climb with hands as well as feet, great difficulty in breathing became apparent," and it cost two hours to reach the highest rocks at 24,600 ft. A steep corniced snow-ridge stretched vaguely up into the mist.

FIG. 2.—Southern view of K^2. From "Karakoram and Western Himalaya."

The recurring tragedies on the Lyskamm are

[1] "Karakoram and Western Himalaya, 1909: An Account of the Expedition of H.R.H. Prince Luigi Amedeo of Savoy." By Filippo de Filippi. With a preface by H.R.H. the Duke of the Abruzzi. Vol. i., pp. xvii+469+plates; vol. ii., plates and maps. (London: Constable and Co., Ltd., 1912.) Price 63s. net.

an eloquent warning to all climbers against persistence in face of such dangers. The Duke waited vainly for two hours in the hope that the mist would lift, but at 3.30 p.m. was forced to retreat. Fortune was against the attainment of the highest peak—and in high mountain and polar regions weather is fortune—but the "man-level" was raised by 700 ft.

It is almost impossible for the uninitiated to realise the courage and fortitude called for by such a feat. For seventeen days they were never below 18,000 ft., and of these nine were spent at or

FIG. 3.—Empty basin of glacial lake. From "Karakoram and Western Himalaya."

above 21,000 ft. None of the party suffered from mountain sickness, and it is obvious that the limit of man's endurance has not yet been reached. The barometer stood at 12·35 in.: a further drop of only about 1·6 in. would be registered on the top of Mount Everest. But the successful aspirants will be very exceptional individuals—and of a consummate resolution

Dr. de Filippi has produced much more than an interesting and readable account of a memorable mountaineering expedition. Almost every chapter gives him occasion for the discussion of some branch of physical science. He appears to be familiar with the whole of the literature of his region, and gives so many references to the writings of his predecessors and other authorities that his book has the further merit of being, in the best sense, a work of reference.

The author's suggestive discussion of the past history of the Indus valley is of particular interest, but cannot be dealt with in this brief notice. Naturally glacial phenomena occupy most of his attention, and he throws new light on several vexed questions. The puzzling fact that the greatest glaciers of this region lack terminal moraines is ascribed to the immobility of their lower reaches. In a very long glacier lying in a narrow trough any increment shows itself by a rapid advance of the snout. The glacier overshoots itself, and if the increment is only temporary and the excess of pressure abates, this overshot portion becomes, in effect, merely a mass of stagnant, dead ice. Rickmers has reached, quite independently, a similar conclusion in regard to some of the glaciers of Russian Turkestan. Probably the few large boulders which do reach the snout of these great glaciers quickly sink below the surface of the water-soaked plain of glacial débris which is such a typical feature at the snouts of most of these glaciers.

The fact that the most careful barometric readings consistently gave lower values than trigonometrical observations suggests a reference to variations in gravity. It is by research on the lines adopted by Burrard that we may eventually look for an answer, and this problem is one of the many which the author has placed on the programme of his expedition to Baltistan and Ladak for 1913–14.

The author agrees with Ujfalvy in ascribing to the Baltis an Aryan rather than a Mongol ancestry. It is pleasant to read of the excellent relations existing between the Italians and their Balti coolies, for whom the author has nothing but praise and admiration, and to whom he frankly acknowledges much of the success of the expedition was due. The geological results are specially dealt with in an appendix. The most striking discovery was that the main axis of the Gasherbrum range consisted of sedimentary rocks, notably conglomerates and marbles. These are continued into the Teram Kangri range north of the Siachen glacier, and quite probably still further to the eastward.

The narrative is enriched with numerous illustrations by Vittorio Sella, that prince of mountain photographers; it is impossible to praise them too highly. In a separate case, uniform with the narrative volume, are placed a very remarkable series of large panoramas. These with the maps combine with the letterpress to give an extraordinarily vivid description of the region dealt with, especially of the Baltoro glacier. A useful innovation is that the indices are placed in a loose fascicle along with the panoramas and maps, which obviates the difficulty of reference so distracting with a heavy volume.

A CRITICISM OF MODERN METHODS OF MEDICAL EDUCATION.[1]

THE report drawn up by Mr. Flexner for the Carnegie Foundation is a sequel to the report on medical education in the United States and Canada issued in 1910. Primarily intended for the guidance of medical education in the United States, the report deals so fully with conditions in Germany, Austria, France, England, and Scotland, and adopts so critical an attitude towards them, that it must compel the attention not only of those directly concerned, but of educational authorities everywhere.

The report opens with an historical sketch of the rise of modern medicine, and is followed by a chapter on the number and distribution of physicians in the countries under review. We learn that the medical profession is overcrowded both in countries like Austria and Germany, where the practitioner is educated entirely on a high university basis, and in countries like our own, where medical qualifications of varying standards, some undeniably low, are obtained partly in universities and partly in proprietary schools under the control of the medical and surgical corporations. A later chapter in the report shows how quackery flourishes in Great Britain and Germany, a phenomenon Mr. Flexner attributes solely to the laws which permit it. Incidentally he remarks upon the inconsistency of British law which throws all manner of restrictions upon properly qualified men of science in experimentation upon the lower animals, but allows medical and surgical practice upon human beings without evidence as to training, competency, or skill, provided only the practitioner does not assume an unearned title.

From a purely educational point of view the most interesting part of the report is that which deals with the nature and standard of the medical preliminary examinations, and with the position of the preliminary sciences, physics, chemistry, and biology. The conditions in Germany, France, and Great Britain are closely reviewed, and much valuable information is collected. The German system of secondary-school leaving certificates, and the somewhat similar French system, are favourably considered; the want of method, multiplicity, and low standard of some of the British medical preliminaries receive severe condemnation. The work of the General Medical Council in raising the standard of the preliminary is acknowledged, but the condition of secondary-school education in England, though improving, is still lamentably poor, proprietary interests in the medical schools, and even in the universities, constitute a formidable barrier to progress, and the General Medical Council is not vested with sufficient legal authority to enforce everything it deems desirable.

The existence in Great Britain of proprietary interests in the teaching of medicine meets with severe criticism throughout the report; again and again vested interests are held responsible for inefficient teaching, low standards, and other evil influences. While we can agree with the author in many of his strictures, it must be remembered that the proprietary conditions have often been the only ones possible in a country which prides itself upon the voluntary character of its institutions. It must be remembered, too, that this report is drawn up for an educational body in the United States, where the proprietary medical school is a source of much scandal. The president of the foundation, in an introduction to the report, states that if the lowest terms upon which a medical school can exist abroad were applied to America, three-fourths of the existing American schools would be closed at once.

Mr. Flexner advocates the omission of physics, chemistry, and biology from the overcrowded medical curriculum, and would have them taught in the secondary schools. Much of this part of the report is a plea for the development of efficient secondary schools in which higher mathematics, the sciences, and German must replace the time-honoured classics.

Laboratory development is found to be very uneven in Great Britain as compared with Germany. Anatomy is too much drilled into the students by repeated lectures and demonstrations; more practical work is necessary, but is largely restricted by insufficiency of material. British physiology receives a high tribute, but is hampered by the student's lack of preliminary training in physics and chemistry, and by the anti-vivisection laws. Pharmacology barely exists but for a few notable exceptions. Pathology suffers by the separation of its laboratories from the post-mortem departments of the hospitals, by lack of funds for research, and by sentimental objections to pathological experimentation which carry great weight in hospitals chiefly supported by voluntary contributions.

Clinical instruction, the medical curriculum, and the position and standard of the professional examinations are each considered separately in the case of Germany, Great Britain, and France. Clinical education in England is essentially practical, and at graduation the English product is more dexterous than the German, but the latter is held to have received the more stimulating scientific training, and one which will eventually carry him further. The English graduate lacks ideas, the German lacks practice.

Criticism is abundant and frankly bestowed. The clinical school in Great Britain is accused of being unproductive of research, and wanting in scientific ideals. The German clinician and the British physiologist seek advancement by scientific achievement. The English medical man is able and practical, makes a good physician and surgeon, but is empiric, and only occasionally a contributor to scientific knowledge.

The report is bound to excite adverse criticism, for it is often detailed and very frank. It is the

[1] "Medical Education in Europe." A Report to the Carnegie Foundation for the Advancement of Teaching. By Abraham Flexner. With an Introduction by Henry S. Pritchett. Pp. xx+357. (New York City: 576 Fifth Avenue, 1912.)

work of an educational expert who has certain ideals, and does not hesitate to show how far existing conditions differ from them. Strong opinions are given on the vexed question of the London hospital medical schools, and on the constitution of London University. How far the recommendations are practical is a question that must be left for the authorities concerned to decide. It is certainly desirable that London as a teaching centre of medicine should not occupy a position inferior to the great schools of Berlin, Vienna, and Paris.

Whatever we may think of some of the author's criticisms, one cannot but admire the ability and thoroughness with which he has collected information and drawn up his report. Educationists generally, and medical teaching authorities in particular, owe a debt of gratitude to the Carnegie Foundation for the Advancement of Teaching.

LIQUID CRYSTALS AND THE X-RAY WORK.

IN two memoirs contributed to the current volume of the *Verhandlungen des Naturwissenschaftlichen Vereins*, Karlsruhe, Prof. O. Lehmann gives a valuable summary of his well-known researches on the so-called liquid crystals, and reviews the proofs now available of molecular structure and of the operation of molecular forces, and especially the tangible proofs of the actual existence of molecules. Naturally, the most interesting part of such a communication from Prof. Lehmann is the expression of his views concerning the most recent of such proofs, afforded by the experimental work of Laue, Friedrich, and Knipping with X-rays and crystals at Munich and Zurich. The events leading up to this remarkable development are clearly indicated, and their individual significance emphasised. From the initial stages of the kinetic theory of gases in the days of Count Rumford and Robert Mayer—the former of whom was connected with Munich, and is there represented by a fine statue—to the reflection of X-ray electromagnetic waves from the invisible parallel planes of atoms in the interior of a crystal, and the impression of the systematic symmetry of the crystal on a photographic plate by the reflected rays, is a long step.

It will be with universal consent that Prof. Lehmann hails this new work as of richest consequence not only to crystallography, but to general physics. He considers it the first practical proof of the existence of those molecular forces which he has so long contended for as causing the deposition, layer upon layer in regular order, of the chemical molecules in their erection of the edifice of a crystal—that is, in the production of a three-dimensional grating or "space-lattice."

One of the surest signs of the magnitude of the discovery made at Munich is the fact that the experiments, as on the occasion of the discovery of radium, are being repeated and extended by numerous workers all over the world, as the columns of NATURE, in which many of the results have been described, have lately abundantly testified.

It is a generally accepted maxim amongst men of science that the pioneer of a new discovery should be permitted to work out undisturbedly its further development, and it is sincerely to be hoped that Prof. Laue and Drs. Friedrich and Knipping will be able to carry their work to its logical conclusion. The bearing of the discovery on Prof. Bragg's theory of X-rays has, however, fully justified its further independent investigation by him and by his son, Mr. W. L. Bragg, who has crystallographic knowledge, and has added very considerably to the subject, both by further experiments and by an explanation which agrees with the crystallographic facts in a most remarkable manner. There are indications that the near future will see a surprising further development in the direction of arriving at the absolute dimensions of the cells of the space-lattice—that is, of the actual distances separating the chemical atoms, thus converting the topic axial ratios, which have been so useful a conception for affording us the relative dimensions of the cells in related compounds, into absolute spacial values. Moreover, the dimensions of the material parts of the atoms themselves appear likely to be also determinable within definite narrow limits, for the reflector, the atom, must be larger than the wave reflected, and it is now clearly proved that an ordinary reflection, and not a diffraction effect, is in question.

Another secondary result is that the intensity of the reflection is proving a direct function of the density with which the atoms are strewn in the reflecting plane, thus affording us an experimental means of carrying out Prof. von Fedorow's quest for the primary facial planes, so as to arrive at a proper descriptive setting for the crystal; for these primary planes, sometimes obscured by fortuitous better development of other planes on the exterior of the crystal, are invariably those most densely strewn with the atomic points.

For a discussion of the physics of the whole subject, especially as regards the position immediately before the Munich discovery, the two memoirs of Prof. Lehmann forming the subject of this notice may with advantage be consulted. A brief abstract of some of the most recent work of Mr. W. L. Bragg will be found in the report of the proceedings of the Mineralogical Society of June 17 (see NATURE of June 26, p. 441).

A. E. H. TUTTON.

THE PILTDOWN SKULL.

AMONG the questions discussed by the anatomical section of the International Congress of Medicine was the date and reconstruction of the famous Piltdown skull. At South Kensington the fossil portions of the skull have been put together by Dr. Smith Woodward so as to represent a being partly ape, partly human, and named *Eoanthropus dawsonii*. From this model the brain gives a capacity of 1076 c.c.—an amount intermediate between the highest anthropoid and the highest form of man.

Dr. Smith Woodward fixes its date in the very early Pleistocene period, contemporary with the well-known Heidelberg jaw. Prof. Rutot, of Brussels, assigns the Piltdown stratum of gravel in which the remains were found to the latter part of the Pliocene period. If these views be accepted, it is of much earlier date than the remains of Neanderthal man recently discovered in France; and while Prof. Rutot estimates the duration of the Pleistocene period at 150,000 years, Prof. Penck, one of our greatest authorities on the Glacial period, estimates its duration from half a million to a million and a half of years.

On the other hand, Prof. Keith, of the Royal College of Surgeons, has articulated the portion of the skull to represent a large and well-modelled human head with a brain capacity of 1500 c.c—an amount slightly above the average of modern human brains.

The difficulty of accepting Dr. Smith Woodward's reconstruction is in believing that Eoanthropus could be transformed into modern man in the short period represented by the first half of the Pleistocene period. On the other hand, to quote the admirable summary of the question in *The Times* of August 11, "if Prof. Keith is right, then it is quite possible that mankind may have reached the stage represented by the Galley Hill remains before the middle of the Pleistocene period. If Dr. Smith Woodward is right, we have to seek the beginnings of our modern culture and civilisation at the middle of the Pleistocene period; if his opponent's reconstruction is well founded, we have to go a whole geological period further back—perhaps a million of years—to find the dawn of modern man and his culture."

In the discussion which took place, reported in *The Times* of August 12, the weight of scientific opinion seems to have been decidedly in favour of the views of Prof. Keith. But the importance of the question is so vital to the science of anthropology that we may be well advised to await further developments of the controversy.

HELMINTHS AND CANCER.

In a memoir recently published,[1] Dr. Johannes Fibiger brings forward strong evidence in support of the view, by no means novel, that the lesions of the tissues produced by parasitic worms may act as the starting-point for the development of cancerous growths and tumours. The author found in wild rats a disease of the œsophagus and stomach characterised by an epithelial proliferation and inflammation leading, in pronounced cases, to a papillomatous growth which was the precursor of a malignant epithelioma. Examination of the primary lesions revealed the presence of a nematode worm, an undescribed species of Spiroptera.

From a series of experiments it was concluded that cockroaches (*Periplaneta americana* and *P. orientalis*) serve as intermediate hosts for the Spiroptera. The cockroach becomes infected by ingesting eggs of the worm which are passed out in the excrement of the rat; the eggs develop in the cockroach and the embryos of the worm become localised in the striated muscles of the prothorax and the legs. The rats become infected by eating cockroaches, and the embryos of the worm, set free from their cysts, attack the epithelium of the stomach, sometimes also that of the œsophagus or buccal cavity, and develop into the adult nematode, the cause of the lesions already mentioned. From his investigations the author concludes that all the anatomical alterations are due to toxic products of the nematode.

From the primary lesions caused by the nematode secondary metastases may be produced in other organs. The metastases contain neither the parasites nor their eggs. The development of the metastases is ascribed to the faculty of the epithelial cells to multiply in other organs independently of the parasite. The author thus confirms the view put forward by Borrel and others that nematodes may produce malignant tumours in rats and mice, and considers it not improbable that in human pathology also cancerous tumours may owe their origin in some cases to the presence of helminths.

NOTES.

A circular from the Institut International de Physique Solvay informs us that a sum of 20,000 francs is available for the encouragement of experimental work in physics and physical chemistry, particularly for investigations on radiation phenomena (Röntgen rays and those of radio-active bodies) and for studies of the theory of energy quanta and of molecular theories. Grants from the fund will be awarded, without distinction of nationality, by the administrative commission of the institute on the recommendation of the international scientific committee. The administrative commission is composed of Profs. P. Heger, E. Tassel, and J. E. Verschaffelt, Brussels, and the scientific committee of M. H. A. Lorentz, president, Haarlem; Mme. M. Curie, Paris; M. Brillouin, Paris; R. B. Goldschmidt, Brussels; H. Kamerlingh-Onnes, Leyden; W. Nernst, Berlin; E. Rutherford, Manchester; E. Warburg, Berlin; and M. Knudsen, secretary, Copenhagen. Applications for grants should be made before September 15 to Prof. H. A. Lorentz, Zijlweg 76, Haarlem, Holland. They should state precisely what problems are to be investigated, the proposed means of inquiry, and the amount required, in order that the committee may have before it all details necessary in considering the awards to be made.

An exhibit illustrating the damage caused to biscuits sent out in soldered tins for the use of the troops in South Africa—especially during the Boer war—Gibraltar, Malta, Ceylon, &c., has just been placed in the central hall of the British Museum (Natural History), where it will be kept open about a month. The larvæ of certain minute moths and beetles were the active agents; and it appears that since these cannot, in all probability, withstand the high temperature to which the biscuits are subjected in baking, the eggs must be laid by the moths during the period when the biscuits are being cooled before tinning. Two species of moths, *Ephestia kuehniella* and *Corcyra cephalonica*, both imported into this country, are the chief causes of the damage; and as a consequence of the ravages of the larvæ, the contents of many of the tins are reduced to uneatable rubbish.

The death is announced, as the result of an accident, of Prof. C. Bourlet, professor of mechanics at the Conservatoire des Arts et Métiers in Paris.

The Permanent International Eugenics Committee has accepted the invitation of Dr. C. B. Davenport, of Cold Spring Harbour, Long Island, to hold the International Eugenics Congress in the United States next year, probably in the month of September.

Mr. C. Carus-Wilson has recently presented to the Royal Albert Memorial, Exeter, the large specimen of a granite geode exhibited by him at more than one Royal Society soirée, and awarded the bronze medal of the Franco-British Exhibition. The specimen is a fine mass of granite in which the mineral constituents have crystallised out around the walls of a large cavity.

It speaks well for a general appreciation of the scientific value attaching to Arctic and Antarctic research that the actual conquest of both poles has not been followed by any diminution of exploring activity. News is to hand of the success of Captain Koch's Danish expedition for the crossing of Greenland. Captain Koch, who accompanied Mylius Erichsen on the journey which ended with that brilliant explorer's death, started in June, 1912, with the object of visiting Queen Louise Land. The party failed to carry this out owing to an accident which kept Captain Koch a prisoner for three months, after which winter was passed on the inland ice of Greenland. The expedition, starting on April 20 of this year from near the east coast, reached Proeven, near Upernivik, in the middle of July, after a march of 750 miles towards the close of which the party was within a few hours of starvation. A more prolonged journey is planned by Captain Amundsen, the first explorer to reach the south pole, who is shortly to board the *Fram* at Colon, when that famous vessel will sustain the honour of the first passage through the Panama Canal. She will then convey Amundsen to the Arctic, where he hopes to carry out a drift (such as Nansen attempted) across the polar area, being prepared to spend six years over the task, a period which should afford him almost unprecedented opportunity for scientific investigations.

In the issue of *Man* for August Mr. T. A. Joyce describes the representation of the clan ancestor in animal form on ancient pottery from the Peruvian coast. The result of the investigation is to emphasise the importance of the clan ancestor in Peruvian cults, to illustrate the custom of dancing in dresses simulating animals, these dresses being almost the only kind of personal property under the communistic system of the Incas, and to show the wide distribution of the centipede as a *huaca* or totem in the Nasca Valley.

Perhaps the most important paper in the excellent issue of the Journal of the Royal Anthropological Institute for January–June is the report by Mr. A. R. Brown, Wilkin student in ethnology, Cambridge, on three tribes in Western Australia—the Kariera, Ngaluma, and Mardudhunera. The paper describes in detail the complicated tribal organisation, totemism, rites of initiation, sociology, and religious beliefs of a people now rapidly disappearing. A good series of outline maps and a bibliography of the scanty published literature add to the value of this paper.

In the issue of *L'Anthropologie* for January-February, 1913, Prof. H. Breuil and H. Obermaier publish a review of the work done in examining the cave paintings in Spain during 1912. A number of curious illustrations of men and animals is provided. The visit of M. Breuil and Prof. Sollas to Bacon Hole, near Swansea, is described. It is possible that the red bands observed on the cave walls may be the work of Palæolithic man, or they may belong to some later period; but there is no reason for trusting the local gossip which ascribes them to quite modern times.

In 1906 Mr. R. F. Cummings supplied the Field Museum at Chicago with funds for an ethnological expedition to the Philippine Islands. The first part of the results of the investigations by Mr. F. C. Cole has now been issued in vol. i., No. 1, of the Museum's Anthropological Series. It is devoted to a study, historical and ethnographical, of the introduction of Chinese pottery into the islands. This pottery was chiefly intended for use by some of the Filipinos as burial jars. These in time acquired a high value, and were believed to possess supernatural properties. Among some tribes the bride-price is paid wholly or partly in jars. Porcelain plates are used by female mediums in summoning spirits, and such plates are so highly valued that they are never sold during the lifetime of the medium, and after her death only to her successors in office. The medium falls into an ecstatical state, chants songs invoking the spirits, and holding the plate on the finger-tips of her left hand, she strikes it with a string of seashells or a piece of lead, in order that the bell-like sound may attract the attention of the spirits. Suddenly a spirit possesses her, and she announces its wishes to the audience. This elaborate and well-illustrated monograph will interest anthropologists and collectors of Oriental porcelain.

A profusely illustrated article by Mr. George Shiras on automatic flashlight photography of wild animals by night forms the leading feature of the July number of *The National Geographic Magazine*. In fixing self-acting cameras in the haunts of nocturnal mammals, the author states that he has frequently used the same baits and scents as those employed by the trapper, and he adds that in many instances animals, after a brief experience, take little or no notice of the flashlight, which they perhaps regard as a form of lightning.

Mr. M. C. Tanquary has published, as article 9 of vol. ix. of the Bulletin of the Illinois State Laboratory of Natural history, an account of recent biological and embryological studies on Formicidæ, based on investigations into the habits and life-history of the American cornfield ant (*Lasius niger americanus*). Although this is believed to be the most abundant insect in the United States, such an investigation had never previously been undertaken, so that a number of new facts in its ecology have been brought to light.

ALTHOUGH the majority of the birds represented by fossil bones in the Pleistocene of the Oregon desert belong to species still existing, it is not a little remarkable that they include two extinct species of swan, one of which—*Olor matthewi*—is described for the first time in a paper on the fauna of the tract by Dr. R. W. Shufeldt, in the Bulletin of the American Museum of Natural History, vol. xxxii., art. vi. Noteworthy, too, as indicative of climatic changes, is the occurrence of remains of the snow-goose. In connection with the determination of fossil bird-bones, Dr. Shufeldt points out that in many cases allowance must be made for great differences in length due to differences in age and sex of the birds to which they belonged, and other conditions. Neglect of this may lead to very erroneous determinations.

AT the conclusion of an article on the food of insects in *Naturwissenschaftliche Wochenschrift* of July 13 and 20, Dr. Hans Petersen points out that the chlorophyll found in the intestine of caterpillars becomes modified into a red substance—"vanessa red"—which is used in the epithelium, and, after pupation, as a pigment in the wings and other parts. Part of the red matter remaining unabsorbed in the intestine is finally voided. He also comments on the remarkable fact that the larvæ of clothes-moths subsist on absolutely dry keratin—the main constituent of wool—which all other animals seem completely unable to digest and assimilate. In regard to the consumption of wax by the larvæ of the wax-moth, it is considered that although this substance is essential to their existence, it is largely supplemented by remnants of pollen, honey, &c.

APPARENTLY more or less harmless in its reputed native country, the Argentine ant (*Iridomyrmex humilis*) is a serious enemy to vegetation and crops in the numerous lands—including the warmer parts of the United States, Madeira, and Portugal—into which it has been introduced. So injurious indeed is this insect in Louisiana and some of the neighbouring States that its ravages, according to a special report by Messrs. W. Newell and T. C. Barber, published as Bulletin No. 122 of the U.S. Bureau of Entomology, are fully as bad as those of the caterpillars of the gipsy-moth, the boll-weevil, and the San José scale-insect. With the view of checking this mischievous ant, full details of its life-history have been worked out and recorded in the bulletin, together with suggestions as to remedial measures. In the orange orchards, where these ants have done incredible damage, the most successful plan has been to induce the colonies to congregate during winter in boxes filled with decaying vegetable matter, where they are subsequently destroyed by means of carbon bisulphide.

DR. P. VAN HARREVELD, who some years ago (*Rec. d. Trav. bot. Néerlandais*, vol. iii.) pointed out various imperfections in the forms of klinostat hitherto used in experiments on geotropism, heliotropism, and other phenomena of movement in plants, has now published in the same journal (vol. ix.) an account of a new form of this instrument devised by him. This "Universal Klinostat" is of somewhat complicated construction, which is illustrated by eighteen figures showing the various parts in detail, and the author claims that his form of this important instrument successfully eliminates all the sources of error arising from the use of the forms of klinostat that have been in use up to the present time; for details reference must be made to the author's paper.

WE have received a copy of Prof. Guignard's memorial notice on the life and scientific work of the late Dr. Edouard Bornet, who died on December 18, 1911, at the age of seventy-three years. The list of Bornet's publications extends to nearly sixty titles, but he will be best remembered for his work on the algæ, and particularly for the two well-known volumes "Etudes phycologiques" and "Notes algologiques," which he produced in collaboration with Thuret between 1876 and 1880. The magnificent plates which illustrate these two works have never been surpassed for beauty and fidelity to nature in the entire range of botanical literature. In Prof. Guignard's admirably written and sympathetic sketch of Bornet's labours, we are taken back to what now appear extremely remote times and shown what an important part Bornet played as a pioneer in establishing the sexuality of the cryptogams and the dual nature of the lichens.

IN a paper of considerable interest to geologists as well as to botanists, Dr. J. B. Scholz (*Engler's Bot. Jahrb.*, vol. xlvi.) discusses the "steppe problem" of the north German plain. There is at the present day a strong contrast between the mild equable climate of north-west Europe and the dry continental climate of the steppes of south Russia and west Siberia, but that the steppes had formerly a greater westward extension during at least one drier climatic phase in late Glacial times was shown by Nehring from the distribution of the loess with its characteristic steppe fauna, implying a corresponding steppe flora and climate. Scholz now brings forward various botanical evidences against the probability of a long steppe period in west Prussia, with interesting notes on the distribution of the characteristic steppe grass, *Stipa pennata*, and accompanying plants, pointing to the conclusion that these plants have entered north Germany along the valleys of the Vistula, Oder, and Elbe, all of which have the general direction south-east to north-west.

IN a paper published by the Survey Department of the Egyptian Ministry of Finance, Dr. John Ball discusses the occurrence of the phosphate deposits found in the localities bordering on the Red Sea coast and in the Nile districts. In the Satâga district alone these phosphate beds are believed to exist over about fourteen square kilometres, and have been found to contain 20 to 70 per cent. of tricalcic phosphate. During the five years 1908–12 the output of phosphate has risen from 700 to 70,000 tons, and, now that the mines are connected by rail with the seaboard, Egypt bids fair to contribute a not insignificant portion of the world's production.

THE first part of vol. viii. of the quarterly *Agricultural Journal of India* contains a number of interesting and important papers, including the following. Mr. H. Maxwell-Lefroy reports at length upon the Psylla disease of indigo, which apparently causes part only of the unhealthy conditions observed in the plants. The author considers that the insect is the direct cause only of curling of the shoot tips and leaves, with a checking of growth, leading to decreased weight of cut plant and a small decrease in the seed yield; while the more extensive and serious disease symptoms exhibited by indigo plants are attributed to some at present unknown organism or physiological cause quite independent of Psylla. The issue includes papers on the improvement of Indian wheat, by Albert and Gabrielle Howard, and that of the indigenous cottons of the United Provinces, by H. Martin Leake and A. E. Parr; while G. S. Henderson contributes an interesting paper on dry farming, based on his visit to dry-farm stations in Texas and New Mexico, and C. M. Hutchinson describes experiments on the relation between drainage and the growth of rice.

IN a paper by Prof. A. J. Ewart and Mr. Norman Thomson, published in the Proceedings of the Royal Society of Victoria (vol. xxv., p. 193), the question of the possibility of cross-inoculation of the root-tubercle bacteria upon native and cultivated leguminosæ is discussed. It was found impossible to cause the growth of root nodules on a number of commoner leguminosæ by inoculation with infusions of the tubercles of certain native legumes, such as *Acacia mollissima*, and different species of Papilionaceæ. This is apparently due to the fact that the bacteria of such nodules are incapable of directly adapting themselves to a new host plant. On the other hand, when the bacteria from one plant are grown on nutrient gelatin media, they appear to develop more generalised infective power, and it was found possible readily to infect peas and broad beans, grown both in water cultures and in sterilised soils, with bacteria from acacia nodules, isolated and cultivated on nutrient gelatin. Root-tubercle bacteria taken directly from the living tubercle are, however, apt to die out in sterilised soil or in water cultures before they have become sufficiently generalised to be capable of infecting a foreign host plant.

THE earthquake of November 8, 1912, in the south-east of Luzon presented several features of interest (Bulletin of the U.S. Weather Bureau). It was preceded by a number of slight shocks, beginning on November 5. Though strong enough to cause considerable damage, the meizoseismal area was small, being only twenty-two miles long and six miles wide. As the Rev. M. Saderra Masó points out, this implies that the focus was close to the surface. The earthquake was nevertheless registered at Hamburg and San Fernando, more than 6000 miles from the Philippine Islands. No lives were lost, owing to the lowness of the houses, the lightness of their materials, and the ample time that elapsed before destructive intensity was attained.

PROF. OMORI has recently described the extraordinary volcanic eruption of the Usu-san in July and August, 1910 (Bull. Imp. Earthq. Investigation Com., vol. v., 1911, pp. 1–38). The eruption was accompanied and followed by the formation of a new mountain on the northern flank of the volcano. By November the height of this mountain had increased by 510 ft., though by April, 1911, this amount was lessened by 120 ft. In a later paper in the same volume of the bulletin (pp. 101–7), Prof. Omori shows that the elevation-phenomena were not confined to the northern side. At his request the heights of the first order bench marks were re-determined to the west and north-west of the volcano in the summer of 1911, and along the same lines and also on the south side of the mountain in the summer of 1912. The first measurements indicated an elevation of the ground surrounding the mountain to a distance of three to five kilometres to the west, the maximum rise being about $2\frac{1}{2}$ metres. At a greater distance to the west there was a slight subsidence. The measurements made in 1912 showed a reversal of the movement, the area surrounding the mountain being slightly lowered, while that beyond to the west was slightly raised.

THE meteorological charts of the North Atlantic for August, issued by the Meteorological Office and the Deutsche Seewarte, contain interesting details relating to the ice in that ocean. On the east and north coast of Newfoundland, and on the northern half of Newfoundland Bank and eastwards, many icebergs are still met with. The latest reports received from the scout-ship *Scotia* relate to ice between 48° N. 50° W., and 47° N. 45° W., July 11 to 15. During June icebergs were met with, east of 45° W., as far south as the steamship routes. Small charts are published by the Meteorological Office giving the extreme limits of icebergs in the north-western Atlantic for each of the months March to June during twelve years ended 1912, and also during the year 1913. This year the bergs have been confined to higher latitudes, as a general rule, than in previous years. This is thought to be probably due to a northerly extension of the Gulf Stream, a northerly set having been reported by several steamers. The bergs seen have been comparatively few in number and of small dimensions.

THE *Mitteilungen aus den deutschen Schutzgebieten*, vol. xxvi., part 1, contain valuable tables of monthly and yearly means of meteorological observations for 1911, made under the auspices of the Imperial Colonial Office, and discussed at the Deutsche Seewarte under the able superintendence of Dr. P. Heidke. Among several useful articles we may mention an investigation of the nature of the obscurity of the air during the prevalence of the Harmattan wind at Togo, West Africa, with reports (1) by Captain v. Seefried, who conducted the experiments with glass filtering tubes packed with wadding, and (2) by the Geological Central Section for German Protectorates. The cloudiness has been supposed by some authorities to be due to ashes from grass fires, and by others to dust particles from desert regions. The geological report is to the effect that the principal cause is essentially due to the remains of diatoms, and that the presence of particles of ashes is only to be considered as a secondary and local phenomenon. It is pointed out that this result agrees with opinions as to the nature of the dust observed in the vicinity of Cape Verde Islands, and it is suggested that some botanist skilled in the examination of diatoms might determine from their forms the place of origin of the dust particles obtained in Togo.

The Survey Department of Egypt has recently published an important volume containing daily readings (August, 1872–December, 1911) of the Nile gauge at Roda (Cairo), together with summaries and diagrams. In a preface by Mr. J. I. Craig (director, Meteorological Service) it is pointed out that projects are in hand, or proposed, that will tax the supplies of the river to the utmost, and that it is more than ever desirable that existing records should be made accessible. With the exception of the nilometer at Aswan, the gauge at Roda is the oldest in the country; its readings have been recorded (with several gaps) for about thirteen centuries, but it is only from 1872 that complete daily readings exist, and up to the end of 1899 these were recorded according to the Coptic calendar and in old measures, so that the figures were of little value to European investigators. The formidable work of conversion to Gregorian dates and to modern measures, together with computations for the whole period in question, has been carried out with scrupulous care by Mohammad Effendi Kâsim (inspector, Meteorological Service), who has also contributed the introductory text. This period of daily records includes five cases of high floods (exceeding 20 metres) and five cases of low floods (not exceeding 18 metres), also years of abnormally early and late floods, such as that of 1880 (forty-nine days early) and that of 1894 (twenty-four days late).

In a paper presented to the Astronomical and Astrophysical Society of America in January, and reprinted in abstract in the July Journal of the Washington Academy of Sciences, Mr. W. J. Humphrys, of the United States Weather Bureau, examines the question whether the presence of volcanic dust in the upper atmosphere is sufficient to account for the periods of abnormal cold which have at times been experienced simultaneously over the whole earth. He finds that the meteorological records from 1750 onwards show that cold periods were in every case preceded by volcanic eruptions, and that the greater the eruption the longer the period of unusual cold. In the case of the eruption at Krakatoa in 1883 the years 1884–5–6 were all 1° or 2° F. below the normal temperature. Measurements made at the U.S. Weather Bureau since 1883 show that dust in the upper atmosphere produced by an eruption may decrease by 20 per cent. the intensity of solar radiation received at the earth's surface.

OUR ASTRONOMICAL COLUMN.

A Star with Large Proper Motion.—In *Astronomische Nachrichten*, No. 4674, Miss E. F. Bellamy directs attention to the large proper motion of Helsingfors 914, which was found when assisting the Vatican Observatory in the reductions of its portion of the Astrographic Catalogue (zones +65° to +55°). The star is close to Hels. 913, and since the seconds of R.A. in the Helsingfors Catalogue for 914 and 913 are 44·8s. and 44·2s., whereas in BD they differ by 5s., and the Vatican residuals also differed by nearly 5s., it was at first thought that there was a mistake in Helsingfors. Subsequent investigation showed that Hels. 914 had a considerable proper motion, the motions being +0·236s. and +0·36″ annually. Miss Bellamy points out that the centennial proper motion in arc of a great circle is +157·0″, the largest proper motion hitherto found in either the Oxford or Rome work, the next largest being 141·9″.

"Giant" and "Dwarf" Stars.—In an address given at the meeting of the Royal Astronomical Society in June last, and reported in the current number of *The Observatory*, Prof. H. N. Russell presented a short account of the studies which have led him to adopt a theory of stellar evolution through stages of increasing and decreasing temperatures, as Ritter deduced from thermodynamical considerations and similar to the idea of a "temperature curve" which spectroscopic work led Sir Norman Lockyer to suggest represented the course of development of a stellar body from a sparse meteoritic swarm to a dense, feebly radiating, and dying sun. Briefly, by considering absolute magnitude (a function of mass, density, and surface brightness) and spectral type, Russell finds that there are no faint white stars; all the very faint stars are red, and among the reddest stars, K and M classes, there is a distinct separation into two groups, one much brighter, the other much fainter, than the sun. To explain the existence of the two kinds of stars, the "giant" and "dwarf" stars first noticed by Dr. Hertzsprung, recourse is made to the evidence afforded by double stars and eclipsing variables; from the former differences due to mass are eliminated, and from the latter the effects of variation of density are deduced. It appears that the series of dwarf stars is one of slowly increasing density from B to M, while among the giant stars density decreases very rapidly from B to M, and it is suggested that the giant stars of class M represent a very early stage of evolution, class B a stage near the middle, and the dwarf stars later stages according to increasing faintness and ruddiness. As a confirmation of the theory it is pointed out that the actual densities of the stars of class A and B are of the order of magnitude (one-tenth that of water) at which Lord Kelvin predicted temperature should be a maximum.

The Stationary Radiation of Meteors.—The present position of this puzzling question in the field of meteoritic astronomy is discussed by Mr. W. F. Denning in the August number of *The Observatory*. The observational difficulties and possible accuracy of determinations of radiants are indicated. The reality of the phenomenon is insisted upon, and some of the unsatisfying explanations which have been offered by Greg, Ranyard, Proctor, Herschel, and Turner, among others, are briefly mentioned.

THE LANCASHIRE SEA FISHERIES LABORATORY.

THE twenty-first annual report of this laboratory contains an interesting record of the routine work and investigations carried on during 1912. The usual four classes for fishermen were held at Piel during the spring; fifty-two fishermen received instruction in marine biology, with special reference to the life-history and habits of fishes and the more common invertebrates captured in the trawl-net, and thirty-nine of the men attended also the course in navigation.

Mr. Johnstone continues his records of diseased conditions of fishes. He describes and figures a fibromatous tumour from a halibut, melanotic sarcomata in skate, and tubercular lesions in a cod. Piscine tubercle has been known hitherto only in freshwater fishes, and it is therefore of interest to find the present typical lesions in a fish living in the open and not likely to have become infected by land-drainage. Dr. Alexander contributes a review of piscine tubercle, and gives a description of an acid-fast bacillus found in the cod above-mentioned. The lesions were skin infections, resembling lupus, and containing typical tubercles. The organism was found to be non-pathogenic for the guinea-pig.

Mr. Johnstone gives a detailed report on the more important mussel-beds in Lancashire and North Wales in regard to their liability to sewage contamination. His investigations show that the mussels from certain areas, *e.g.* parts of the Conway and Lune estuaries, are objectionable as articles of food, and he urges the necessity for supervision of natural shellfish beds, in the interests not only of public health, but of the shellfish industry.

In his account of the measurements and variations in the condition of plaice, Mr. Johnstone suggests that the main cause of the periodic migrations made by plaice is change of temperature. The migration is of the nature of an adaptation to a change in the environment, the plaice responding by so moving that the temperature-change becomes minimal.

Mr. Riddell gives an account of the plankton collections obtained during 1912 in the Irish Sea. Prof. Bassett, in reporting on the water samples taken at the same time, points out that very high salinities prevailed throughout the year 1912, especially at certain stations on the line from Holyhead to the Calf of Man, due to the flooding of the English Channel and Irish Sea by water of Mediterranean origin. He briefly discusses the types of oceanic circulation in the North Atlantic, and concludes that there are corresponding meteorological conditions, and that the latter, in so far as they affect the succeeding summer, can be foreseen from the value and time of occurrence of the maximum salinities in the Irish Sea.

The intensive study of the plankton around the south end of the Isle of Man has been continued. The maxima of the diatoms and most other plankton groups were earlier in 1912 than 1911. Examination of the various forms of the diatom Biddulphia leads Prof. Herdman and his collaborators to regard *B. sinensis* and *B. regia* as two forms of the original species *B. mobiliensis*. Mr. Scott reports on the pelagic fish-eggs of this area, and Mr Jackson on the decapod larvæ.

Prof. Herdman and Mr. Riddell, in their report on the plankton of the west coast of Scotland, state that the phytoplankton, which was so widespread in July, 1909 and 1911, especially round Mull, seems in the last two summers, and particularly in August, 1912, to have become pushed back or restricted to the more land-locked waters by an unusual influx of characteristically oceanic organisms from the Atlantic, *e.g.* the copepods *Metridia lucens* and *Candacia armata*. It is suggested that in the Hebrides there is a definite connection between the presence of oceanic water containing the copepod Calanus in quantity and shoals of herrings, for large hauls of Calanus were, on several occasions, obtained at places where, either the night before or the night after, good catches of herrings were reported.

BRITISH FORESTRY.[1]

THE useful publication before us (though foresters have to mourn the death of its long-time editor) retains its high standard of excellence. At the annual general meeting of the society, instead of a formal address there was a discussion on the relation of forestry to agriculture, &c. It is sufficient to follow this discussion to see what a strong body of opinion exists amongst practical men—forest owners and foresters—in favour of a comprehensive scheme of national forestry. The conclusions arrived at in this discussion vary little from those expressed in the Coast Erosion report of 1908, and in the similar Committee reports that preceded it.

The average rental of hill grazing ground suitable for forest planting in the north-east of Scotland is not more than 1*s.* per acre. This fact opens up a great national question of the more profitable use of the land in these islands, which are themselves one of the most fertile and productive countries of the world. Then there is the question of small holdings. These are linked with forestry in the sense that they cannot generally exist under present conditions without the help afforded from winter labour in the forest. Looked at from a national point of view, the labour question means, in the case of grazing and shooting, two or three men employed per 1000 acres, against about 10*s.* per acre per year wages in forestry. The careful Prussian statistics give 11*s.* 4*d.* per acre per year as the average forest wages bill. About one man to fifteen is the grazing-*versus*-forest ratio given in the Coast Erosion Committee's report.

This rural labour, priceless from a national well-being point of view, is being lost to the country, and some 30,000,000*l.* is being sent out of the country yearly for timber and forest products which might be produced in these islands.

Says Mr. Munro Ferguson, commenting on the last forest Blue-book (Rept. of Advisory Com. on Forestry, Cd. 6713):—"While the Administration gropes its way in the dark, and while the paramount national interest of silviculture (as affording the widest scope for additional skilled labour on the land) is neglected, 3000 emigrants leave the Clyde weekly." Mr. Munro Ferguson was the first large forest owner in Scotland to bring his own woodlands under scientific management, and he has since then represented forestry in almost every capacity.

The full text is given of the address of Sir John Sterling Maxwell (the retiring president of the Royal Scottish Arboricultural Society) to the Aberdeen branch. This was summarised in the April number of the Quarterly Journal of the English Arboricultural Society. It may be looked on as the most important pronouncement, in favour of a comprehensive scheme of State forestry, that has yet been made by an influential owner of forests in these islands: It is well termed, "The Place of Forestry in the Economic Development of Scotland." No lover of trees, no one

[1] Transactions of the Royal Scottish Arboricultural Society, vol. xxvii. part ii., July, 1913. (Edinburgh: Douglas and Foulis.)

who wishes to see the scientific methods in vogue on the Continent brought to bear on the waste lands of these islands, should be without a copy of this illuminating address. It concludes with the statement that "the Belgian Government obtains on the capital it has invested in forestry a return varying from 4·9 to 5·5 per cent." In his retiring address as president (Proc., p. 10) he adds:—"Scotch forestry is in the toils of the serpent of red tape. In spite of our efforts to keep it free and independent, forestry is now entangled with a number of different departments, some of which in the nature of things can know very little, and perhaps do not care very much, about the subject."

Mr. B. Ribbontrop, who, for many years, was head of the Indian Forest Department, gives a summary of Dr. R. Albert's researches on the peat soils of north-west Germany.

The true character of the seedlings of Japanese larch raised from Scotch seed was discussed at last summer's meeting of the English Arboricultural Society. On one hand, the time (one generation) seemed too short for the environment to have altered so considerably the character of the seedlings. On the other hand, the alteration seemed to be too uniform for hybrids between *Larix europaea* and *Larix leptolepis*. Mr. A. Murray, writing from Murthly, where these seedlings have been closely watched from the first, now gives the opinion that they are not hybrids. It may be noted that a similar alteration has been remarked in the case of an Australian Eucalypt that had been one generation in southern France.

For extracting tree-stumps with gelignite, Dr. Lauder gives the following working formula:—For pine stumps, $\frac{\text{square of girth in feet}}{20}$ = cost in shillings of explosive; and for broad-leaved trees—oak, ash, elm, &c.—about double the cost of pines and firs.

THE MANUFACTURE OF ARTIFICIAL TEETH.

In the *Bulletin de la Société d'Encouragement* for April last is an interesting and well-illustrated article on "La fabrication des Dents Artificielles Minérales," by M. Maurice Picard, of the firm of MM. Henri Picard and Co., read at the opening ceremony of the first factory established in France, at Versailles, in the presence of M. Lechevalier, the representative of the Minister of Commerce and Industry.

The making of artificial teeth has for more than fifty years been a small but important industry in England and America, where millions of teeth of many shades and shapes are annually manufactured.

This industry owes its origin and early development to illustrious Frenchmen. Pierre Fauchard, in his work, "Le Chirurgien-dentiste," 1728, first suggested the use of enamel. Duchateau in 1744 substituted porcelain for ivory, with the aid of the porcelain manufacturer M. Gerrard, of Paris. Later Duchateau, with Dubois de Chaumant, a dentist in Paris, who suggested the addition of pipe-clay, made great improvements in manufacture. The latter carried the invention to England, and obtained a patent in 1791 for fourteen years. In 1808 Fonzi, a dentist in Paris, fixed platinum pins into the body of the tooth, as a means of attaching the tooth to the artificial plate which holds it in position. M. Plantou manufactured artificial teeth in America in 1817.

Felspar and silica ground to an impalpable powder, to which is added a certain amount of kaolin, form the basis of all porcelain teeth. These are made into a thick paste, and tinted in a variety of colours with oxide of titanium. The paste is pressed into moulds in which are inserted platinum pins. These teeth are then fused in a furnace at a very high temperature. The factory in Versailles already manufactures 225,000 teeth each month.

Incidentally, one may inquire why such an invention should not have found, sooner, an industrial home in the land of its origin? The answer may be suggested, not in lack of enterprise, but in the facts that French people do not readily part with their natural teeth, and they have an innate objection to artificial teeth on plates.

We have no doubt that the refined foods of an advancing civilisation are leading to an increased destruction of teeth by dental caries. We have no evidence to prove that our neighbours' teeth, however, are better than our own, but they submit more readily to the conservative treatment which dentists are trained to give in the preservation of teeth, rather than permit the ravages of the *arracheur de dents*.

R. D. Pedley.

THE MUTATIONS OF OENOTHERA.

The last decade has witnessed many remarkable advances in our knowledge of heredity and variation. The beginning of the present century may be said to mark the turning-point between the observational method of Darwin and the more intensively experimental method now pursued in the study of evolution. This change from observation to experiment in evolutionary study was participated in by many investigators. Among those whose work will ever occupy a prominent place in the renaissance of activity in scientific plant- and animal-breeding may be mentioned de Vries, whose theory of mutation, or the sudden origin of new species, has been a fruitful subject of investigation and discussion.

The views of de Vries, published in 1901, were based to a considerable extent upon his prolonged investigations with the evening primrose, *Œnothera Lamarckiana*. These now classic experiments showed that when this species is cultivated in large numbers, individuals appear sporadically but repeatedly year after year which differ from the type in nearly all their characters. These new types, or mutants, in many cases breed true, giving rise to new races, and the main facts of de Vries's observations have since been repeatedly confirmed.

It is safe to say that these remarkable and at that time unique observations have subsequently led to a more thorough and complete study of the evening primroses than has been accomplished in any other group of plants, not even excepting the garden pea of Mendelian fame. Numerous investigators have attacked the problem thus presented from many points of view, and much light has been thrown upon the general subject of mutations. This is particularly true of the cytological investigations, which have really furnished the key to the explanation of the mutation phenomena.

Since a fortunate discovery in 1906 indicated that various mutants differed in the constitution of their nuclei, the origin of these differences has been an absorbing subject of investigation. Two years later it was possible to show that a basis for changes in the nuclear constitution of different mutants exists in the germ cells, and that the process of mutation is probably in part a result of irregularities in chromosome distribution during meiosis or germ-cell formation. The chromosomes are the constituent parts of the nucleus, and their number is constant for each species, so this furnished the desired proof that, in some of the mutants at least, a fundamental change in the structure of the nuclei had taken place, and that the external changes of characters in mutation had their origin in internal structural changes of the cells and their nuclei.

The premutation hypothesis, formulated by de Vries to account for the origin of the mutations before the facts regarding their cell-structure were known, assumes that new units gradually accumulated in the germ plasm of the species previous to the beginning of the mutation process, and that these afterwards passed from a latent to an active condition, thus producing the mutations. But since the structure of the nuclei in these forms is now known, and the manner in which changes in that structure originate, this hypothesis has been superseded, and the conception of a mutation period is no longer needed.

Various writers have also suggested that the mutations of Œnothera were merely re-combinations of characters, such as occur in Mendelian hybrids. This hypothesis is also contrary to our present knowledge of the nuclear structure and behaviour in Œnothera, and furnishes another instance, like that of the sex-chromosomes, where nuclear studies throw light upon the nature of the processes of heredity and variation. By combining the study of nuclear and cell structure with that of external characters, it is evident that much further insight into the nature of mutation and heredity may be gained.

A specific case of the type of germinal change here referred to is that of *Œnothera lata*. It has recently been found that when combined with characters derived by inheritance from various other forms (*e.g. O. biennis, grandiflora and rubricalyx*), the characteristic foliage and habit of *lata* is always accompanied by the presence of an extra chromosome in the nuclei of the plant, making the number of chromosomes fifteen instead of fourteen. In other words, this type of foliage is constantly associated with the presence of an extra chromosome.

Mutations are by no means confined to the evening primroses, but are now known, through experimental studies, to occur in bacteria, fungi, mosses, and many flowering plants. And among animals, instances of sudden and inherited departure from the parent form occur in various groups from Protozoa to man himself.

The new characters thus appearing form a varied and motley array, differing often in most unexpected ways from their parent types. Many of these mutations appear "spontaneously," that is, from unknown causes. These are probably often an indirect result of previous crossing, change of climate, &c. Others have been directly produced by a variety of experimental conditions. The study of the causes of these germinal aberrations and the manner of their production is evidently destined to play an important rôle in future experimental evolution. The results already achieved point to a wide and important field of research in the application of these methods to horticulture, agriculture, and experimental breeding.

R. RUGGLES GATES.

OBSERVATIONS IN THE SOUTH MAGNETIC POLE AREA.

I BEG herewith to enclose what I trust will prove for the scientific world in general an important preliminary report by Mr. E. N. Webb, magnetician to Dr. Mawson's Australasian Antarctic Expedition, on the magnetic work, and particularly the absolute readings taken by Mr. Webb himself on a very fine journey made by him and Mr. J. F. Hurley, under the leadership of Lieut. Bage, in the direction of the south magnetic pole for the distance of 300 miles to the south-east of Dr. Mawson's base at Commonwealth Bay in Adélie Land.

You will see that a large number of very valuable observations have been obtained on the north-west side of the south magnetic pole area, and these, when considered with the observations—fewer in number but accurate—taken by Dr. Mawson himself on the occasion of the Shackleton expedition on our approach on the south-east to the south magnetic pole area, should now enable the position of the south magnetic pole in 1912 to be calculated with a degree of accuracy considerably in advance of anything previously attained.

I have ventured to add some notes in reference to the observations made by Dr. Mawson in the party—consisting of Dr. Mawson, Dr. A. T. McKay, and myself—of which I was leader in a journey to the south magnetic pole area in 1908–9. I send with it a plan on tracing cloth showing the route followed by the Australasian Antarctic Expedition, with the positions of the stations where Webb made his observations.

T. W. EDGEWORTH DAVID.

University of Sydney, May 26.

MAWSON'S AUSTRALASIAN ANTARCTIC EXPEDITION.

Preliminary Report on Magnetic Work, by E. N. Webb, Magnetician.

Early in December of 1911 the Australasian Antarctic Expedition, under the leadership of Dr. Mawson, left Australia to carry out a programme of scientific investigation on the Antarctic continent.

It was intended to conduct a magnetic observatory at one base station, and to make a magnetic survey of the coast between Cape Adare and Gaussberg. A large portion of this plan was successfully carried out. Through the kindness of Dr. Bauer, director of the department of terrestrial magnetism of the Carnegie Institution of Washington, D.C., the writer was trained during five months' field survey work in Australia, under Mr. E. Kidson, one of the department's observers.

Absolute instruments were lent by the Carnegie Institution, consisting of two unifilar magnetometers, one Kew pattern and one Lloyd-Creak dip circle, by Dover, Charlton, Kent, both fitted with 6 in. declinometer needles, and total intensity attachments.

Intercomparisons of all instruments with a set used by Mr. Kidson were made at Hobart before going south; also, the Eschenhagen magnetographs, comprising declination, horizontal and vertical intensity variometers, were set up under the direction of Dr. J. M. Baldwin, first assistant at Melbourne Observatory. Both the observatory and the field work at the main base were in charge of the writer. Field survey work was commenced at Macquarie Island, where determinations of the magnetic elements were made at two stations, one at the extreme north of the island, and the other at Caroline Cove. The average of determinations at the north end gave declination 18° 25′ E.; horizontal intensity, 0·13990; dip, 77° 47·8′ S. Leaving Macquarie Island, the expedition proceeded to Adélie Land, and at Commonwealth Bay in latitude 67° 0·0′ S., longitude 142° 39′ E., landed the main party. Here two magnetic huts were erected. In the larger, which was carefully constructed to resist wind and change of temperature, the magnetographs were set up with the frames on solid rock, and put in working order on March 21, 1912. Temperature-compensating systems were fitted to the H. and Z. variometers, and temperature effects have been almost entirely eliminated. Deflections were made once a fortnight for scale values.

In order to record the large declination changes (as high as 12°), a scale value of 2·25′ per mm. had to be employed, while the force ranges required a scale value of 8 to 10 γ per mm. The largest change in force occurred during an auroral storm, when a reduction of more than 1000 γ took place in horizontal intensity.

During the time of occupation a complete and accurate log of aurora was compiled. Between March and October, numerous displays were observed, varying from a dull nebulous glow low in the north to splendid designs of arches, curtains, and streamers vividly coloured in green, red, and heliotrope, far surpassing anything seen by Dr. Mawson in McMurdo Sound in 1908. The exact times of prominent phases were noted. A cursory comparison with the magnetograph records showed a remarkable coincidence of magnetic and auroral storms. The nebulous type of aurora seemed to have little accompanying magnetic disturbance, but when moving and coloured luminous bands scintillated across the sky, the phases of the accompanying magnetic storm would almost invariably be found to correspond to variations in form or colouring of the aurora. Three splendid displays in the evenings of July 4, 5, and 6 perhaps constituted the most brilliant series. There seemed to be some indication of a recurrence of aurora at definite intervals.

As previously arranged in a scheme of international cooperation, twenty-four special terms of two hours each were "quick run" on the magnetograph. These unfortunately proved wanting in incident, the most disturbed being that of April 16, 1912, when a fairly large movement was recorded.

From the end of March, 1912, to February 8, 1913, the magnetograph record is almost unbroken.

In the smaller hut absolute determinations of declination, horizontal force, dip, and total force were made once a week. The average values at the station were:—Declination, 6° 30′ W.; horizontal force, 0·0311 C.G.S.; dip, 87° 21·5′ S.

Observations often had to be carried out in winds of eighty to ninety miles an hour, and in a pitchy darkness, since the night hours were the only approximately calm ones magnetically.

As a check on the absolute hut station, an ice station was occupied during the winter in a cavern dug out of the glacier, half a mile distant. The difference between the two stations was trifling in all the elements. In the early spring Mr. Hannam was instructed in the conduct of the observatory, and later carried on all work there during the magnetician's absence on sledging journeys.

In early September, 1912, three reconnaissance parties were sent out. One full magnetic station was occupied 11½ miles south of winter quarters.

On account of the persistently furious gales, no start could be made on the long summer sledge journeys until the second week in November. Three main parties then got away, while a fourth was to move off in early December. Of these, one was to make a long journey east, and was provided with a theodolite trough needle for determining magnetic declination; a second was to explore the more adjacent eastern coast-line, and besides a three-inch theodolite with compass needle, carried a dip circle with two dip needles; a third party was to make a journey south along either a geographical or a magnetic meridian towards the magnetic pole; while the fourth, carrying a sextant and an improvised declinometer, was to make as far west as possible. All parties were to return not later than January 15, 1913.

The eastern coastal party, under Mr. C. T. Madigan, secured magnetic results at eight stations fairly distributed over 270 miles. Declinations were obtained with the 2-in. compass needle attached to the theodolite, and dips were determined with either one or two needles.

The third party, consisting of Lieut. R. Bage, (leader), J. F. Hurley (photographer), and E. N. Webb (magnetician), left winter quarters, Commonwealth Bay, on November 10, 1912, and was assisted by a supporting party. A 3-in. Cary theodolite was taken for astronomical observations, and for magnetic observations the dip circle with declinometer and total intensity attachment and four dip needles. Strong head-winds and heavy drift were met with throughout the following week, and, with heavy loads, the travelling, over *sastrugi* country, was very slow. On November 21, 67½ miles S. by E. from winter quarters, the supporting party left.

Magnetic observations indicated considerable local disturbance, so to get the advantage of a direct dip gradient to the magnetic pole, the magnetic meridian was followed as nearly as possible. In the course of the outward journey seven full magnetic stations were occupied at intervals of thirty to fifty miles, while, in addition, rough determinations of declination and dip were made at almost every camp.

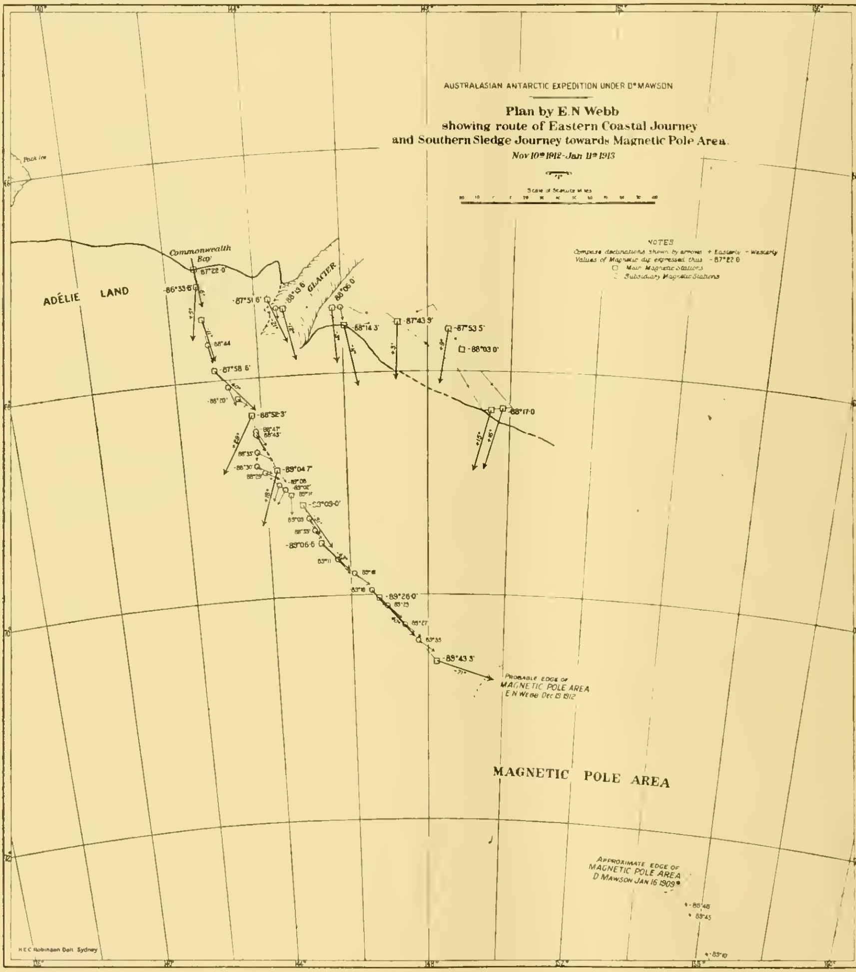
The observations at each full magnetic station comprised complete astronomical observations, observations of dip with four needles, double determinations with total force needles, and sixteen settings of the declinometer needle for declination. The declinometer trough needle proved an excellent instrument, even at the position of highest dip. Nearly all astronomical and magnetic observations were computed on the march as obtained.

For steering purposes on the journey a sun-dial or "shadow compass," computed for the sun's mean declination and equation of time, and the approximate mean latitude, was used. Granted clear weather, this is a very useful instrument. Steering south-east from the depôt, heavy head-winds were met with, the surface rising steadily and becoming rougher, with *sastrugi* increasing in size. At 100 miles and 174 miles out from winter quarters the party was held up by severe weather, but occupied itself with magnetic observations. Besides a full magnetic set at the 100 miles, a snow shaft 8 ft. deep was excavated, and a temperature gradient obtained, +9° F. at surface to −13° F. at 8 ft. At 174 miles a continuous observation of declination over twenty-five hours was made with the dip circle trough needle, the party living in a hole dug out of the snow.

On December 12 a depôt of food, oil, &c., was made at 200 miles. With the lighter sledge it was found that runs of from twelve to fifteen miles per day could be made. On December 21 the extreme station, 301 miles, was reached, at a height of 5900 ft. above sea-level, in latitude 70° 36′ S. and longitude 148° 12′ E. At most stations the magnetic meridian for dip observations was obtained by declinometer, but at this station dip was determined with four needles in two directions at right angles, and the meridian and true dip were thence computed; resulting dip, 89° 43·3′ S.; declination, 70° 49′ W.; total force, 0·6692 C.G.S. Between 200 and 300 miles out the surface was exceedingly rough, *sastrugi* 5 ft. high from trough to crest being met with.

Turning back on December 21, the first stages of the return journey were made more rapidly than had been expected, as much of the fresh snow had hardened. A depôt which had been laid at 200 miles on the out journey was picked up on December 27, and a full set of magnetic observations taken. During the remaining 200 miles almost continuous overcast weather obtained, making it extremely difficult to pick up snow-mounds built at almost every camp on the way out. The 109-mile mound was picked up, but the only other one seen was the ninety-mile. On reaching the locality of the sixty-seven-mile depôt, there were only two and a half days' rations on hand, and the ration was immediately reduced. Short marches were made in various directions, but the depôt could not have been seen 100 yards away, as light snow fell almost continuously. On the evening of the second day a fair latitude and longitude were obtained from altitudes of the sun. The party moved on to the computed position of the depôt, but could see nothing. Next day, after a long wait, a noon latitude was obtained, and a movement was made towards the supposed position of the depôt, but without success. Under these conditions, with but one day's ration in hand, it was decided to depôt all gear not essential to safety, and make a dash for the coast. The dip circle had to be left behind, but the needles were brought on.

The next two days continued heavily overcast, while a strong blizzard wind with thick drift was experienced. The third day was much brighter, and, with infinite relief, the party reached the depôt five miles from winter quarters just after midnight.



During the whole journey complete meteorological observations were made every two hours, and minimum temperatures were obtained at night. Altitudes were obtained by aneroids, standardised by a hypsometer.

The only life seen consisted of two snow petrels at eighty miles, and a skua gull at 125 miles, while no sign of rock was seen.

Longitude observations at three stations on the outward march were repeated on the return, so that the chronometer rate over three sections could be determined, giving good final longitudes.

Between 100 and 200 miles strong magnetic disturbance was evident. Declination chopped round by 90° in as short a distance as ten miles, while reversion of dip gradient was very commonly experienced. From 200 to 300 miles the declination was much more constant, and a steady dip gradient was observed. Continuing this last fair gradient, the 300-mile station was probably about forty miles from a position of maximum dip.

At the extreme western base 200 miles east of Gaussberg, and 1100 odd miles distant from the main base, magnetic conditions were better, but weather conditions were harassing. No magnetographs were provided, but periodic absolute observations were to be taken by the magnetic observer, Mr. A. L. Kennedy. Observations with magnetometer and dip circle were taken when possible. The station was situated on a floating glacier or barrier, and during the year determinations of the azimuth of the mark showed a progressive movement. During the sledge journeys—as far as Gaussberg in the west, and for 150 miles to the east—declinations were obtained at intervals with a prismatic compass, or with a declinometer attachment to a Lloyd-Creak dip circle. Two sets of dip were obtained on the eastern journey.

Term days were kept at the western base when possible by continuous eye readings of declination, while auroræ were observed and several observations of declination taken during active auroral disturbance. The accompanying plan shows most of the declinations and dips obtained. The possibilities of highly disturbed areas are illustrated by the anomalous declinations and dips about 100 to 174 miles. At 132 miles heavy crevasses were found, which seemed to indicate some unconformity beneath the ice-sheet.

Notes by Prof. Edgeworth David.

I have only just received by wireless some of the actual dips obtained by Dr. Mawson with a Lloyd-Creak dip circle other than those already published in Shackleton's work, "The Heart of the Antarctic."

First, at the Nordenskjöld ice-barrier, lat. 76° 14′ S., long. 163° 9′ E., the dip was found to be 88·1° S.; at the Drygalski Ice Barrier Tongue, in lat. 75° 28′ S., long. 163° 15′ E., the dip was 87·5°. On the Reeves Glacier, in lat. 74° 48′ S., long. 161° 30′ E., it was 87·9°. All these three sets of observations were very carefully taken. Again at lat. 73° S., long. 156° 10′ E., a careful set of observations showed the dip to be 89° 10′. The next observation, which may not be looked upon as quite so accurate as the others, gave the dip as 89° 45′, in lat. 72° 42′ S., long. 155° 40′ E., and the last observations, also of approximate accuracy only, indicated a dip of 89° 48′, at a spot thirteen miles to S. 30° E. of our furthest point to N.W., the latter being in lat. 72° 25′ S., long. 155° 16′ E.

When we reached the spot where we recorded a dip of 89° 45′, on January 15, 1909, Mawson concluded that as the rate of change of dip had considerably increased in the last twenty-five miles we were close to the edge of the area of the vertical needle. The evening of the same day, when seven miles nearer the south magnetic pole area, Mawson's measurements gave the dip as 89° 48′. On striking a curve, he estimated that the actual edge of the region of verticity was only about thirteen miles distant from where our dip of 89° 48′ was recorded. We had already travelled twenty-seven miles beyond the spot where the results of the *Discovery* observations had placed the south magnetic pole during 1902–3. Accordingly we determined to march on thirteen miles and put up the flag there, as being the edge of the area of the vertical needle. Our proceedings have already been described in vol. ii., "The Heart of the Antarctic," pp. 180–2. During these last thirteen miles we took no observations with the dip circle, the tripod of which we utilised as a mark to guide us back on our return march.

Mawson estimated that the position of our furthest point to the north-west was in lat. 72° 25′ S., long. 155° 16′ E. A short distance on our return from the spot considered to be the edge of the area of vertical needle, Mawson experimented with the horizontal needles of an ordinary prismatic compass and a Brunton transit instrument. While he considered both needles worked "dead"—that is to say if the compass boxes were twisted the needles followed them around—it was found that on tapping the boxes and making the needles spin, the more sensitive of the two showed a slight tendency for its south-seeking end to come to rest within the western hemisphere of the compass. Mawson felt satisfied at the time that even if we might not have been within the area of vertical needle, at the particular moment—about 3.30 p.m., on January 16, 1909—when the end of our journey was reached, we were still well within the region of the diurnal swing of that area. In view, however, of the recent remarkable observations by Mr. E. N. Webb, it seems doubtful whether there may not have been some local disturbing influences affecting Mawson's observations on the Shackleton expedition, such as Webb's map shows affected the magnetic observations of Mawson's present Antarctic expedition. Reference to the map will show that at several spots along their route declination varies to the amount of from 40° up to 69° within a distance of only a few miles, and the dip, in some places, lessened considerably, instead of increasing, as the magnetic polar area was approached. This suggests that it is possible that at our furthest point north-west we may have been on the edge of either a local pole, an "outlier" of the main south magnetic polar area, or on a local lobe of the magnetic pole area, or may even have been just outside an area of absolute verticity altogether. By how much, if at all, we may have been outside, can, of course, only be determined when all the magnetic results are reduced, and compared.

MEROË: FOUR YEARS' EXCAVATIONS OF THE ANCIENT ETHIOPIAN CAPITAL.[1]

On behalf of the University of Liverpool, and aided by the support of private benefactors, the lecturer has been at work for four years in scientifically uncovering the ruins of the once-famous Ethiopian capital. When his first expedition arrived upon the scene, there was little to suggest the great extent and interest of the city which has now come to light; in fact, only one wall and a few objects of sculpture were visible above the soil. Now, however, a number of temples, palaces, and public buildings have been laid bare; the walls of the royal city have been traced; and during the past season's work, from which the lecturer has just returned, a considerable portion of this enclosure has been excavated so that a visitor may enter by the city gate and walk along the ancient

[1] Summary of a discourse delivered at the Royal Institution on Friday, April 25, by Prof. John Garstang.

streets, turning right or left at will into the different buildings.

First amongst the greater buildings of the site is the Sun Temple, which is designed in a series of ascending ambulatories with stone-built cloisters, the sanctuary being found on the highest platform, in the middle. A contemporary representation of the building upon its own walls has enabled Mr. W. S. George, the able architect of the expedition, by comparison with actual measurements, to attempt a reconstruction. In character and situation this temple corresponded to the "Table of the Sun" mentioned by Herodotus. An even larger building is the Temple of Ammon, the main axis of which is 430 ft. in length; the high altar and the special enclosure for sacrificing animals, and other interesting features of the temple, are well preserved. Other monuments excavated include an extensive palace presumed to be of Roman period, two small temples, one of which was dedicated to a lion-deity, an ancient temple of Isis, later reconstructed, pottery kilns of Meroitic times, and several hundred tombs of the necropolis. All these features appear to have been outside the chief, or royal enclosure, and it appears that there is still untouched by the excavators' spades a much larger area than has yet been attacked, including the ancient township itself which abutted against the walls of the royal city. The explorer is of the opinion that without a substantial increase in the annual sum available for this work, which up to the present has been almost entirely privately contributed by a few generous benefactors, it will scarcely be possible to complete the undertaking even in ten or fifteen years.

For the last two seasons the excavation has been almost entirely concentrated upon the royal enclosure, in which remarkable discoveries have been made. In one of the royal palaces a hoard of gold treasure and ornaments was found; and the royal baths adjacent, which are on an extensive scale, illustrate in their details the character of the Meroitic arts better than any other features of the city.

Under the threshold of another public building, carefully buried in sand, amid the débris of a building, there was found a beautiful bronze head of Augustus, which is now permanently deposited in the British Museum. A short distance from the spot are the remains of a small temple of Roman style; and the lecturer believes that this bronze head of the divine emperor had once formed the cult object in this temple. Two passages from Pliny seem to have been overlooked by those who have discussed the possibility of a Roman occupation at Meroë. From these it would appear that the imperial soldiers under Petronius had not only reached Meroë, but had passed up the Nile a further 100 miles. During the past winter a bronze coin of Augustus and an increasing number of small objects were discovered, all of which tend to indicate that, for a brief time at any rate, Roman troops actually occupied the city. In this way the fact and circumstances of the discovery of the bronze head would be satisfactorily explained. When Augustus commanded the Roman troops to withdraw, the head was removed from the temple and carefully buried out of danger of violation.

Two main culture periods are traceable in the history of Meroë previous to the Roman occupation. The first was that of its foundation under King Aspelut and his contemporaries, about the seventh century B.C. In this period Egyptian influence in art is freely apparent. The second phase began with an influx of Greek ideas, which may be roughly dated to the third century B.C., corresponding to a record by the historian Diodorus of great reformations instituted by Ergamenes, who had himself been educated in Greek thought in the schools of Alexandria. It is the second phase which is the most striking in the history of Meroe, and most of the visible buildings and monuments of the site belong to this period. The Roman occupation left little permanent impress upon the civilisation of the locality, but previous and subsequent to the expedition of Petronius there must have been already some influence of Roman contact, which manifests itself in various ways.

Thereafter the history of Meroë became that of a local and somewhat barbarous civilisation, reflecting only faintly the Greek and Roman culture with which it had been earlier infused. A record of the fourth century A.D. tells us how it was sacked by a king of Axum; but as late as the seventh century it would appear that invaders from the same district (Eritrea) overran the city and threw the statues and pictures of the gods into the river.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—An important announcement was published on August 13, to the effect that the President of the Board of Education has appointed a Departmental Committee to inquire and report, after consultations with the bodies and persons concerned, as to the steps by which effect shall be given to the scheme of the report of the Royal Commission on University Education in London, and to recommend the specific arrangements and provisions which may be immediately adopted for that purpose, and as the basis for the necessary legislation. Sir George H. Murray, K.C.B., who was formerly at the Treasury, and later Secretary to the Post Office, has been appointed chairman of the Committee. The other members are Sir Amherst Selby-Bigge, Secretary to the Board of Education, Sir John Rose Bradford, Sec.R.S., Sir William MacCormick, Dr. George Franklin, Dr. Arthur Keith, Mr. John Kemp (one of the secretaries to the Royal Commission), and Mrs. Henry Sidgwick. Dr. Frank Heath, the other secretary to the Royal Commission, is appointed secretary to the Committee.

MANCHESTER.—The council of the University has appointed Dr. A. D. Imms to the newly created post of reader in agricultural entomology. Dr. Imms was formerly professor of biology in the University of Allahabad, and afterwards forest entomologist to the Government of India at the Imperial Research Institute, Dehra Dun. He will be in charge of the researches in agricultural entomology conducted under the scheme approved by the Board of Agriculture and Fisheries. The council, [illegible] assistance of a grant in aid from the Deve[illegible] Fund Commissioners, has provided special laboratory accommodation for these investigations, and will undertake the necessary provision for the work of the department.

A REUTER message from Melbourne reports that a pioneer colonist named Mr. W. Robbie has died at Ballarat, aged ninety-one years, and has bequeathed 30,000*l.* to Aberdeen University to establish scholarships.

THE vacancy in the directorship of the Agricultural College at Cornell University, caused by the resignation of Prof. L. H. Bailey, has been filled for the time by the appointment of Prof. W. A. Stocking, jun., as acting-director for a term of one year. Prof. Stocking is forty-one years of age, and has been a member of the faculty of the college since 1899.

THE Governor of Pennsylvania has, we learn from *Science*, approved the following State grants made at the last session of the legislature:—The Pennsylvania

State College, 248,000*l.*; University of Pennsylvania, 164,000*l.*; University of Pittsburgh, 80,000*l.*; and Temple University, 20,000*l.*, making the total State grant for higher education 512,000*l.* From the same source we learn that Franklin College, Indiana, has secured pledges amounting to 50,000*l.* for additional endowment. Three-sixteenths of this amount is from the General Education Board in the United States.

The Edinburgh Mathematical Colloquium was held during the first week of August in the mathematical department of the University. It was organised by the office-bearers of the Edinburgh Mathematical Society in response to a widely expressed desire on the part of mathematical teachers in England for a vacation course in the mathematical laboratory which Prof. Whittaker was instituting. In addition to five lectures by Prof. Whittaker on the periodogram and harmonic analysis, two other courses were provided. Prof. Conway, of University College, Dublin, lectured on the theory of relativity and the new ideas of space and time, and Dr. Sommerville, of St. Andrews, lectured on non-Euclidean geometry and the foundations of geometry. Nearly eighty members of the colloquium assembled from all parts of the United Kingdom, and two or three from Canada and the United States. The colloquium was in every way a great success, the novel features being the method by which Prof. Whittaker proposed to carry on the practical instruction in numerical evaluation of functions and the treatment of definite data. Each "student" sat at a specially designed desk for facilitating numerical work.

The calendar of the Edinburgh and East of Scotland College of Agriculture for the session 1913–14 has now been issued. It contains full details of the various courses of instruction which are now available in the departments of agriculture, horticulture, and forestry. The aim of the college is to supply such training in agriculture and the sciences underlying it as is indispensable to all who intend to gain their living from the land as owners, or tenants, or agents. The calendar gives full guidance as to the curricula for the B.Sc. degree in agriculture and in forestry, the college diploma in agriculture, and the college certificate in horticulture. Special note may be made of the new course in horticultural science, which will appeal to young gardeners who have served their apprenticeship in the ordinary way, but desire to make themselves acquainted with the scientific as well as the practical aspects of horticulture. Under arrangement between Ed[illegible]burgh University and the [illegible]ollege there is now [illegible]d at Edinburgh a course of training in forestr[illegible] preliminary course is intended specially for those who desire to get a knowledge of forestry for general purposes, and mainly from the practical point of v[illegible]w.

SOCIETIES AND ACADEMIES.

London.

Geological Society, June 25.—Dr. Aubrey Strahan, F.R.S., president, in the chair.—Dr. F. **Oswald**: The Miocene beds of the Victoria Nyanza and the geology of the country between the lake and the Kisii highlands; with appendices on the vertebrate remains, by Dr. C. W. **Andrews**; on the non-marine Mollusca, by R. B. **Newton**; and on the plant-remains, by Miss N. **Bancroft**. The Miocene beds of the eastern coast of the Victoria Nyanza, south-east of Karungu, form a narrow zone (covered with black earth) at the foot of cliffs of overlying nepheline-basalt, and are only exposed in a few gullies. The whole series is conformable, dipping 8° north by west. 1 (Beds 1–12). An upper group (about 70 ft. thick) of grey and brown clays and shales, with occasional current-bedded sandstones containing terrestrial shells (Tropidophora, Cerastus), as also calcified tree-stems in the uppermost bed. 2 (Beds 13–25). A middle group (about 30 ft. thick) of red and grey clays, with white sandstones in the lower half. No bone-bed, but fragmentary Chelonian and crocodilian remains occur sparsely throughout the series. Persistent horizons are a travertinous marlstone (No. 14) containing Ampullaria and Lanistes; a thin sandstone (No. 16) yielding Hyracoid jawbones; and a gravel (No. 24) yielding teeth of Dinotherium, Protopterus, crocodile, &c. 3 (Beds 26–37). A lower group (about 35 ft. thick) of current-bedded sandstones and gravels passing down into clays and marlstones. A conglomerate of calcareous nodules overlies gravelly sandstones (No. 31) containing isolated bones of Dinotherium, Anthracotheroids, rhinoceros, giant tortoises, &c., indicating a Lower Miocene (Burdigalian) age, with Ampullaria, Cleopatra, and terrestrial shells (Cerastus). The vertebrate remains described by Dr. C. W. Andrews include Proboscidea, Hyracoida, Artiodactyla, Rodentia, and Reptilia, and fully support the suggested occurrence of Lower Miocene deposits on the shores of the Victoria Nyanza. A deposit of probably Pliocene age yielded a new (?) species of Elephas, also bones of antelopes and baboons. The non-marine Mollusca associated with the Miocene vertebrates are freshwater and terrestrial shells which all belong to existing species.

Paris.

Academy of Sciences, August 11.—M. J. Boussinesq in the chair.—M. **Baillaud** gave an account of the recent meeting of the fifth congress of the International Union of Solar Research, held at Bonn.—L. E. **Bertin**: Concerning the origin of the double oscillograph for the simultaneous registration of pitching and rolling of ships.—A. **Lacroix**: The cipolin marbles of Madagascar and the associated silicate rocks.—A. **Romieux**: An attempt at gehypsographical exploration.—A. **Guillet** and M. **Aubert**: The direct expression of electrospherical functions; formation of differential equations verified by these functions.—E. **Rothé** and M. **Guéritot**: A method permitting the use of apparatus on a reduced scale in wireless telegraphy.—Jean **Bielecki** and Victor **Henri**: The quantitative study of the absorption of the ultra-violet rays by some acids of the ethylene series. In the acids studied the double bond produces an increase in the absorption of ultra-violet rays, and this increase is the more marked as the position of the double bond approaches the carboxyl group. Geometrical stereoisomers present different absorptions.—H. **Giran**: The molecular weight of sulphur trioxide. By the application of Trouton's formula, as modified by M. de Forcrand, the molecular weight of sulphur trioxide has been found to be 80, that is the simple formula SO_3 of the gaseous anhydride.—J. **Bougault**: Phenyl-γ-oxycrotonic acid.—A. **Wahl** and P. **Bagard**: The microscopical examination of coals. The chief difficulty has been the choice of a suitable etching material for the coal sections; pyridine was used with success for bringing out details of structure.—L. **Lindet**: The influence of calcium chloride on the curdling of milk.

Cape Town.

Royal Society of South Africa, July 16.—The president in the chair.—R. **Broom**: Some fossil fishes from the diamond-bearing pipes of Kimberley. This paper describes three new types of Palæoniscid fishes now preserved in the McGregor Museum, Kimberley, for which the author erects two new genera—Disichthys and Peleichthys—and three new species—*Acrolepis addamisi, Disichthys kimberleyensis,* and *Peleichthys kimberleyensis.* The fossils occur on slabs of sandstone which were taken from the Wesselton and De Beers Mines, and from the absence of conspicuous sandstones in the Ecca beds of the vicinity, and the occurrence in another slab of *Chelyoposaurus williamsi,* they are in all probability of Beaufort age. Denudation has removed all trace of the parent rocks from the locality.—W. A. D. **Rudge**: The daily range of atmospheric potential gradient at Bloemfontein and the influence of dust storms. An account is given of observations at Bloemfontein between July and December, 1912, with a Bendorff recording electrometer. The values of the potential gradient at hourly intervals are given for the whole period, and curves showing the daily range of the potential gradient are given for selected cases. These curves show (1) the normal range on clear calm days; (2) that on days when some dust was observed; (3) that on very dusty days; and (4) some special cases. The normal curves are similar to those taken in other parts of the world, but those for dusty days show great differences. In class (2) the dust is present in quantity sufficient to keep the potential almost at zero whilst in (3) for a considerable part of the day there is a very strong negative potential gradient amounting to thousands of volts per metre. This negative result is caused by the clouds of fine siliceous dust raised by the wind, as has been shown by the author in previous communications. A negative potential gradient was never recorded unless dust was blowing or rain falling. Wind alone had practically no influence. The rain which fell during the period under observation was invariably negatively charged.—J. C. **Beattie**: Further magnetic observations in South Africa. Results of observations in various parts of South Africa during 1910–13. The greater number of the observations was carried out in the western Transvaal, British Bechuanaland, and Bushmanland. In addition a number of repeat stations were re-occupied.—J. C. **Beattie**: Magnetic maps of the western and northern parts of the Union of South Africa and of Great Namaqualand for the epoch July 1, 1908. Maps are given showing the true isogonics, the true isoclinals, and the true lines of equal horizontal intensity for the above region.—T. **Muir**: Note on Clebsch's theorem.

PRACTICAL HYDRAULICS.

The Control of Water as Applied to Irrigation, Power and Town Water Supply Purposes. By P. A. M. Parker. Pp. vii+1055. (London: G. Routledge & Sons, Ltd., 1913.) Price 21s. net.

THIS comprehensive and authoritative work contains a wealth of matter relating to practical hydraulics which one might seek in vain for in any other published book on the subject. In the preface the author tells us that the book is the product of actual engineering experience, and is mainly based on a collection of notes and formulæ accumulated in some eighteen years of professional work, during the major portion of which he was engaged in independent practice, and that therefore it must be regarded not as a text-book, but rather as a manual for engineers in active work. He also remarks that, "although the initial knowledge assumed in the reader may be considered to be somewhat unusual, many portions of the book have stood the test of everyday office requirements in the hands of draughtsmen and assistants." And it is only fair to say that an examination of the work is entirely favourable to the author on these points, although, of course, in a work covering such a wide field, here and there are matters of a controversial character, which might be dealt with if the exigencies of space permitted.

The book contains the following chapters, namely: i., preliminary data; ii., general theory of hydraulics; iii., gauging of streams and rivers; iv., gauging by weirs; v., discharge of orifices; vi., collection of water and flood discharge; vii., dams and reservoirs; viii., pipes; ix., open channels; x., filtration and purification of water; xi., problems connected with town water supply; xii., irrigation; xiii., movable dams; xiv., hydraulic machinery other than turbines; xv., turbines and centrifugal pumps; xvi., concrete, ironwork, and allied hydraulic construction; (*a*) tables; (*b*) graphic diagrams. But these headings scarcely give an adequate idea of the scope of the book, as some of the chapters are divided into important sections. For instance, in chapter xiv. we have: section A, enlargements and contractions in pipes; section B, water hammer; section C, ejectors and syphons; section D, air lift and hydraulic compressor; section E, hydraulic ram; section F, resistance to motion of solid bodies in water; section G, impact of water on moving bodies. All of these are important subdivisions, and they appear to be handled in an entirely satisfactory and convincing way; but having regard to the title of the chapter, one looks in vain for any discussions on the piston-pump and Humphrey's pumps, the most important of all hydraulic machines. However, the hydraulic engineer has other books available in which these machines are fully dealt with, and the author was wise in confining himself to matters that do not so completely come within the province of the mechanical engineer.

Chapter vii., dams and reservoirs, is one of the best in the book; the 130 pages devoted to this important section will be appreciated by both designers and engineering students. A valuable feature of the work is that each chapter is prefaced by a list of its own symbols and a sequential table of an extremely useful character, and many of the chapters have also a summary of the equations and formulæ. The mathematics used in this lucid and most readable work are fairly easy, certainly to those accustomed to read works on hydraulics.

Another exceedingly valuable feature is the bibliography, as the book teems with references to original authorities; indeed, it is a standing testimonial to the author's patient and untiring labours. He is to be congratulated upon producing a work that will in all probability rank as high in connection with applied hydralics as Bellasis's work on hydraulics does in connection with theoretical questions; in fact, Mr. Parker's encyclopædic work is the most notable book of the kind that has appeared for many years, and it will probably become a classic. H. J. S.

SPHERICAL ASTRONOMY.

Lehrbuch der sphärischen Astronomie. By Dr. L. de Ball. Pp. xv+387. (Leipzig: W. Engelmann, 1912.) Price 20 marks.

DR. L. DE BALL'S excellent treatise shows abundant evidence of a long and careful preparation. From the nature of the subject striking innovations are not to be expected; it is rather in the minute details of the exposition that the merit of the present work is found. In some places the mathematical treatment has been simplified, in others the discussion has been made more rigorous and thorough. The author's long experience as a practical astronomer has led to improvements in all parts of the subject, little in themselves, but when taken together making a notable advance. According to the introduction, the book is intended to be both a text-book for students and a work of reference; it is in the latter respect that we commend it. Spherical astronomy is a rather heterogeneous collection of but distantly related problems, and a minute treatment of isolated questions, many of which are only required in special researches and have no general interest, makes a very unsuitable course of reading for the student. But for those who are seeking specially full information on any of the subjects dealt with, this work will prove a very useful aid.

The introductory chapters deal very concisely with interpolation formulæ, the chief developments in series, and the method of least squares (without any account of the error-function). A long chapter deals with the theory of the earth's rotation. This part is rather hard reading, owing to the great number of symbols introduced. It would, we think, have been worth while to set out the definition of each symbol on a separate line, in order that it might be more readily referred to; for the reader can scarcely carry in his head the meaning of all the symbols, and their definitions are scattered through a great many pages of the text. Another long chapter deals with refraction, and includes a discussion of the effect of water-vapour on the constant of refraction. The treatment of the great problems of fundamental astronomy, the determination of the equinox, the obliquity of the ecliptic, and the construction of a fundamental catalogue is most thorough and satisfactory. In the chapter on parallax it may be noted that the correction to the ellipticity of the earth is included as an unknown in the determination of the moon's parallax; this small illustration shows the author's practical acquaintance with his subject, for the two quantities are so closely related that it is not improbable that the best determination of the figure of the earth may ultimately be obtained from lunar observations.

We would strongly criticise the absence of all reference to the theory of photographic observations. Thus, whilst the effect of precession, parallax, aberration, and refraction on micrometer measures is fully discussed, the formulæ relating to their effect on photographic measures are ignored. The theory of the projection of the celestial sphere on a photographic plate is eminently a branch of spherical astronomy, and at the present day it is most constantly required by practical astronomers, yet the text-books persist in devoting their whole attention to the obsolescent position angle and distance, instead of to rectangular coordinates. Such an omission is misleading to the student, and it is a defect in a work of reference for the observatory. Much of geometrical astronomy consists in a perfunctory application of three formulæ of spherical trigonometry; but the theory of rectangular coordinates is a more difficult subject, and the observer could not generally work out for himself the necessary formulæ without guidance.

(6) *Das botanische Praktikum.* Fünfte Auflage. By the late Dr. E. Strasburger and Dr. M. Koernicke. Pp. xxvi + 860 + 246 figures. (Jena: Gustav Fischer, 1913.) Price 24 marks.

(7) *Paläobotanisches Praktikum.* By Prof. H. Potonié and Dr. W. Gothan. Pp. viii + 152 + 14 figures. (Berlin: Gebrüder Borntraeger, 1913.) Price 4 marks.

(8) *Die palaeobotanische Literatur.* By W. J. Jongmans. Dritter Band: Die Erscheinungen der Jahre 1910 und 1911 und Nachträge für 1909. Pp. 569. (Jena: Gustav Fischer, 1913.) Price 26 marks.

(9) *Icones of the Plants of Formosa, and Materials for a Flora of the Island, based on a Study of the Collections of the Botanical Survey of the Government of Formosa.* By B. Hayata. Fasc. ii. Pp. 156 + 40 plates. (Taihoku: Bureau of Productive Industries, 1912.)

(1) THE compiler of this introduction to plant geography appears to be somewhat out of touch with the modern development of the subject from the ecological point of view. The work is apparently intended for school use, but one would have thought that the best method of approach would be to deal at some length with the conditions of plant life in general, instead of devoting to this subject only twenty pages towards the end of the book as the author has done, and to lay stress on the idea of plant communities rather than to plunge, after a brief glance at a few types of British vegetation, into the descriptions of the "main vegetations of the globe," which form the greater part of the book. However, these descriptions, though extremely condensed, are thoroughly readable and vivid, but it is very doubtful whether the author's method of

treatment is calculated to give the subject of plant geography much educational value in a school curriculum. Many of the illustrations are extremely poor. However, we may perhaps hope for a more adequate and better illustrated treatment of the subject in the more advanced book promised in the preface.

(2) Prof. Ganong has already laid students and teachers of botany under a debt of gratitude for his valuable and helpful manuals, and in the present work he has produced an attractive and stimulating volume which every botanical teacher would do well to obtain. It presents the clearest and most complete picture of plant life that has appeared for many years, and should do much to popularise the study of plants among that increasing class of readers whose needs are met neither by the standard text-books intended primarily for college students, nor by the unfortunately too common type of "popular" botany book the appeal of which is made by means of coloured plates with incidental letterpress, concerning the character of which the less said the better. Prof. Ganong combines in a particularly happy manner scientific accuracy, clearness of exposition, and literary style, such as make this book delightful reading, whether he is dealing with the deeper problems of physiology or with the most familiar aspects of plant life. The work is marked throughout by freshness and originality of treatment, and the diagrams and generalised drawings which he gives so freely will be of the greatest value to teachers of botany, apart from their primary object of enabling the "general reader" to understand the descriptions which they illustrate.

(3) Mr. Bastin has produced a thoroughly attractive and interesting work, well designed to serve as a first introduction to the study of the flowerless plants, with the aid of the more detailed books on the various groups. Unlike some other writers of popular nature-study books, the author aims solely at arousing the reader's interest by means of excellent photographic illustrations and simple but, so far as they go, accurate descriptions, and takes care to point out that the reader of books of this scope will find in the text-books of the specialist "the best possible friends, incomplete in themselves, but priceless as guides to those things which alone can be truly studied in the open air." Nothing could be more different from the explicit or implicit claims of various other "popular" botanical writers to have presented a full and sufficient treatment of the subject in their books. Mr. Bastin's work is admirably calculated to stimulate interest in the hitherto somewhat neglected groups—from the nature-study point of view—with which he deals, and the reader who wishes to proceed to a more detailed study will, at any rate, have nothing to unlearn, though one rather wishes that the author had included in his excellent work a list of suitable books for the further study to which this forms such an admirable introduction.

(4) Mr. Meier's book, though written primarily for American use, contains scarcely anything that will not be found of interest and value to teachers of school-gardening in this country, as well as to amateur gardeners in general, and this despite the fact that the author does not deal with generalities or with experiments. He has succeeded admirably in his attempt to give definite instructions for the arrangement, planting, and care of a fairly wide range of plants commonly grown in the house and garden, the difficulties met in cultivating each individual plant being considered one at a time, and definite directions given for overcoming them.

(5) The second half of Mr. Clute's book covers much the same ground as the work just noticed, but its scope is somewhat wider, and the first portion constitutes an excellent general introduction to botany. Many of the illustrations of familiar objects have a fresh appearance, owing to the author's very sparing use of figures copied from other works. Nothing could be more suitable as a general introduction to botany and horticulture than the lessons on soil with which the book opens, though this portion might perhaps with advantage have been expanded. The teacher will find much that is useful in the work, despite the fact that American examples and illustrations are largely used.

(6) The late Prof. Strasburger's well-known "Botanische Praktikum" needs no special recommendation to teachers and students of botany, to whom it is well-nigh indispensable, no other single book covering so much ground. In successive editions the book has grown in size until in the present one, the fifth, it has become perhaps unduly large for convenience in laboratory use.

The present edition differs from its predecessors mainly in the addition of a considerable amount of new letterpress and illustrations dealing with micro-technique, the general plan of the work remaining unaltered. It is an open question whether there is not rather too much general descriptive matter that would be more in place in a book intended for the study instead of the laboratory; but still, the tacking-on of more or less theoretical passages to the directions for practical work has decided advantages. The chief drawback to the plan is that it is somewhat difficult to know where the line should be drawn, and that a book of this kind tends to indefinite expansion in successive editions; this objection is to some extent met by the author's smaller book, the "Kleine botanische Praktikum," but since the student can obtain the necessary theoretical matter in the ordinary descriptive text-books, it would appear better to limit the scope of a practical manual to directions for actual laboratory work. The use of the copious index relating to technique is facilitated by its being printed on coloured paper in this edition, which will be welcomed by teachers and students of botanical microscopy as the best and most comprehensive treatise on the subject in existence.

(7) This little book opens up what is to a large extent a new field, and will be of the utmost value to students of geology and plant ecology, as well as palæobotany. Despite its small size it contains an immense amount of skilfully condensed information, and is mainly occupied by concise and clear directions for the examination of fossil and subfossil plant remains in coal, peat, clay, &c. The names of Prof. Potonié and Dr. Gothan are sufficient guarantee of the excellence of the major part of the work, which is concerned with the preparation and examination of fossil and subfossil plant remains generally, but special attention may be directed to the excellent section by Dr. Stoller dealing with the investigation of peat deposits from the ecological and phytogeographical point of view.

(8) The labour undertaken by Dr. Jongmans in compiling an annual bibliography of palæobotanical literature has evidently secured the approval and support which it deserved, though one may regret the delay in issuing the third volume of this work, containing the titles for the years 1910 and 1911, with a supplementary list of 1909 publications. The mere citation of titles, however, forms a small part of the work, occupying only forty pages of this volume; the remainder (more than 500 pages) is devoted to the indexing of the plants dealt with in some 800 books and papers, a few words being added in each case to indicate the general nature of the communication made concerning the plant named.

(9) The original plan of the "Icones Plantarum Formosanarum" was to publish in a long series of fascicles, extending over some fifteen years, a flora which should contain full descriptions of all plants found in Formosa. However, even in the first fascicle (1911) this plan had to be altered slightly so as not to exceed the grant made by the authorities, and accordingly only the new species were described, with notes on the others; and in the meantime a further reduction of the grant has unfortunately compelled Dr. Hayata to cut out nearly all references to species in this second fascicle. Even in this somewhat truncated form, the work is of the utmost value; the present instalment contains keys to the families, genera, and species, an enumeration of Formosan plants from Saxifragaceæ to Dipsaceæ, with their localities and geographical distribution, descriptions of new plants, and forty very fine plates. The total number of flowering plant species now known from Formosa is a little more than 3000. For the interesting conifer *Taiwania cryptomerioides* a diagnosis is given of the male flowers, which were first discovered in 1911; in its male flowers this genus shows marked general resemblance to Cunninghamia.

F. CAVERS.

OUR BOOKSHELF.

Einführung in die Spektrochemie. By Prof. G. Urbain. Uebersetzt von Dr. U. Meyer. Pp. viii+213+9 plates. (Dresden and Leipzig: Theodor Steinkopff, 1913.) Price 9 marks.

THIS book is a translation of the French edition which has already been reviewed in these columns. It is based on a course of spectroscopy given by the author at the Sorbonne, and will be found useful in this country to colleges taking a short course in the subject for advanced students.

The book contains an excellent and up-to-date account of the various methods used in the production of spectra. The descriptions of the methods employed are very clear and well illustrated with diagrams, and contain many laboratory details necessary to know in order to repeat the methods with facility, but which are generally omitted from text-books.

Following this, which occupies nearly half the book, are chapters on phosphorescence and absorption spectra. A final chapter is devoted to the analysis of spectra into series and the laws of series, in which the chief facts of the subject are clearly set forth.

A Galla-English, English-Galla Dictionary. Collected and Compiled by E. C. Foot. (Cambridge University Press, 1913.) Price 6s. net.

THE Galla are people living in Abyssinia from Harrar, on the east, to the Sudan frontier on the west, and from Wollo, in the north, down to the southern frontier. Some, too, live in British East Africa, and a detached tribe to the west of Witu, on the north bank of the Tana river. Mr. Foot describes them as "a most industrious, pastoral and agricultural people, who are also keen traders."

Mr. Foot has been studying their language since he went to Abyssinia first, in 1907, and the volume gives the results of his industry. As Sir John Harrington says in his introductory note, the dictionary should be of service not only in Abyssinia, but also on her frontiers with the Sudan, Uganda, and East Africa.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Radium-D and the Final Product of the Radium Disintegration Series.

A RECENT discussion in the columns of NATURE has raised the question of the existence of elements chemically and spectroscopically identical but differing from one another by a few units of atomic weight. Should the far-reaching generalisations of Soddy and of Fajans prove correct, the chemical elements will have to be regarded from an entirely different point of view, and the explanation of the periodic nature of their properties will have to be sought for in the recurrent character of the processes of radio-active disintegration. At present, however, some of the evidence on which those views are based is at least open to question. With the exception of radium, niton, and the parent elements—uranium and thorium—none of the thirty-four radio-active bodies have been isolated, and none of their compounds have been obtained in a state approaching purity. Their properties have only been inferred from their behaviour when mixed with very large amounts, comparatively speaking, of known elements, such as lead, thorium, and tellurium, and when it has been found impossible to alter the proportions of these minute traces of radio-active matter by the usual analytical processes, chemical identity has been inferred. Even admitting the extreme delicacy of radio-active methods of analysis, it might be questioned whether much can be deduced from the inseparability of such minute traces when present along with large amounts of closely related elements. More satisfactory evidence would be furnished if the chemical properties of an equilibrium mixture from a pure radio-active parent could be investigated; and since during the last few months some direct observations have been made on the nature of radium-D and its products it may be of interest to give a preliminary account of the investigation.

The source of the radium-D and its products was highly purified niton (radium emanation) which four years ago had been compressed into fine capillary glass tubes, liquefied, and used for the determination of the vapour pressures of the gas by Sir William Ramsay and myself. Each tube originally contained somewhat less than 0·2 of a curie of emanation, which, when liquefied by pressure, filled a volume of approximately 1/5000 cub. mm. at the sealed end of the tube. Three tubes of the precious material were kindly placed at my disposal by Sir William Ramsay. The emanation was allowed to decay under pressure, and subsequent microscopic examination showed that the liquid had transformed itself into a dark-coloured deposit of submetallic lustre, resembling somewhat a dried colloidal metal, and also into a colourless gas, viz. helium. The total mass of the solid deposit was hence of the order of 1/1000 milligram, and since it had decayed for four years it contained, in addition to the equilibrium quantities of radium-E and radium-F, about 15 per cent. of radium-G, the end point of the series, as well as traces of the branch series derived from radium-C_2. The tube was only weakly radio-active, but when laid on a photographic plate the impression produced by the β-radiation of radium-E corresponded exactly with the visible distribution of the deposit in the tube. By a suitable procedure the mercury sealing the open end of the tube was removed as completely as possible, and after pumping off the helium pure chlorine was admitted. At ordinary temperatures the submetallic deposit remained unattacked, but on gently warming it was seen to change completely into a pure white, apparently homogeneous, crystalline chloride. On heating *in vacuo* to 220° C., the chloride did not volatilise perceptibly, and the photographic impression it produced coincided with that obtained from the submetallic deposit. Hence the chlorides of radium-D, -E, and -G are not appreciably volatile under these conditions.

On introducing water into the tube it was seen that the crystalline deposit dissolved without decomposition, but was only slightly soluble. Even after warming in presence of about ten times its own volume of water only a small proportion of the total solid went into solution.

The chief object, however, of this experiment was to determine whether radium-G, the final product of the series, was similar in chemical character to lead, and also to find out if radium-D approximated closely in behaviour to its longer-lived descendant. That radium-G and lead are identical is supported by much indirect evidence, though no direct proof has been advanced. Now lead is an element which can be detected in very minute quantities by the delicate and characteristic microscopic test of Behrens, viz. by the formation of a characteristically crystalline triple nitrite with the nitrites of copper and potassium. The test is so delicate that 1/100,000 milligram of lead can be detected with certainty if the proper conditions are observed, and, moreover, by determining the number and size of the crystals in a drop of known volume the amount present can be approximately estimated. It was proposed, therefore, to apply the test to a known fraction of the radio-active matter in the tube and to see whether the amount of triple nitrite formed corresponded with radium-G alone or with radium-G + radium-D. The application of the test was complicated, however, by the discovery that the glass of the capillary, and, in fact, soda-glass in general, contained about 0·03 per cent. of lead, and that a detectable fraction of this lead could be dissolved out of the glass with nitric acid. By avoiding the use of strong acids and simply extracting the glass with water no perceptible amount of this element could be found in the concentrated extract. To be quite certain that no lead from the glass could find its way into solution by this procedure, the very stringent test was made of extracting 5 grams of finely powdered glass for some hours with water and testing the residue after evaporation to dryness. The glass used had at some previous time been exposed to the action of radium emanation, and was of a deep purple colour. No lead was found in the extract, though analysis proved its presence in the glass.

Other sources of error lay in the possible presence of lead in the mercury sealing the tube, and in the reagents used for the test. No lead could be detected in the mercury and the reagents were carefully purified beforehand. In order to carry out the test the capillary tube containing the radio-active matter was cut into two portions, a longer one containing most of the solution, and a shorter portion in which the undissolved crystals remained. The solution in the longer portion was allowed to evaporate on a silica microscopic slide, and one portion of the drop obtained was tested for lead by the triple nitrite test and another tested with potassium chromate. In both cases the presence of lead was indubitably proved, but the quantity present was small. The short end containing the crystals was then fractured and the fragments extracted with water to which a drop of acetic acid had been added. The evaporated extract which left a scarcely visible residue was intensely radio-active, and from its solution a minute trace of a dark-coloured sulphide was precipitated by sulphuretted hydrogen. This latter was separated by centrifuging the solution in a capillary tube, dissolved in a drop of nitric acid, and tested by the Behrens method. The drop yielded a copious crop of triple nitrite crystals, and the amount of lead present was estimated at 1/4000 milligram. Now in the whole of the disintegration products in the tube only about 1/7000 milligram of radium-G was contained, and, further, only a fraction of the total matter was used for the test. Hence it seems probable that radium-G and radium-D both form a characteristically crystalline triple nitrite identical with that formed by lead.

An attempt was made to determine what fraction of the whole of the matter originally in the tube was present in the drop tested, by comparing the β-radiation of the various portions, but no great trustworthiness could be placed on the measurements at the time, since the chloride of radium-E has probably a different solubility to the chlorides of D and G. In a few months' time, however, when the β-radiation of E has reached its equilibrium value a repetition of the measurements should lead to a definite conclusion. Hence, excluding the possibility of undetected sources of error, one must conclude that the slow change products of the disintegration of niton contain a body behaving like lead, and, further, that this body is either radium-D alone or a mixture of radium-D and radium-G. Thus the investigation, so far as it has gone at present, tends further to support the theories of Soddy and of Fajans. R. WHYTLAW-GRAY.

University College, London.

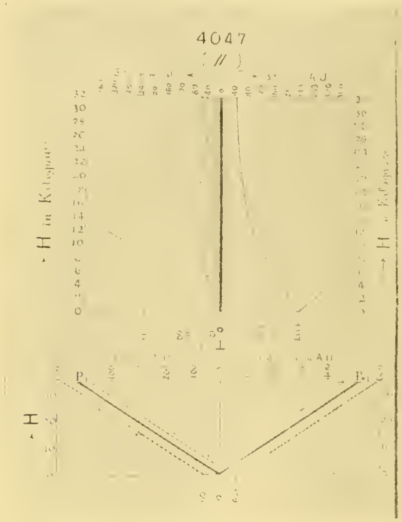
Anomalous Zeeman Effect in the Satellites of Mercury Lines.

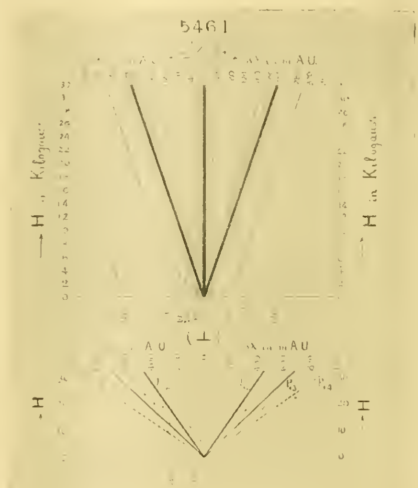
GEHRCKE and Baeyer, Lunelund, and McLennan showed that the satellites of some mercury lines are separated in a regular manner in weak fields; Gmelin found in the yellow line a satellite having anomalous character. Wendt noticed four characteristic lines in strong fields, but the satellites from which these lines proceed could not be identified.

Owing to extreme complexity in the distribution of lines when the field strength is increased, we have as yet no continuous observation indicating the position of satellites of mercury lines in different magnetic fields.

To fill in this gap, we made measurements on the satellites of the violet line 4047 and the green line 5461, up to the field of 30 kilogauss, and arrived at an unexpected result that the satellites show anomalous Zeeman effect, either as regards intensity or the mode of separation, and in nearly all cases both combined.

The instrument used was an echelon grating, but it was sometimes crossed with a Fabry-Perot air plate or a Lummer-Gehrcke plane-parallel plate to eliminate the false lines. From a large number of photographs





of transverse effects obtained in different fields, which were mostly uniform but sometimes heterogeneous, the positions of the satellites were plotted and traced into continuous curves; these are given in the accompanying figures, for components vibrating parallel and perpendicular to the field. The branches of the principal lines are indicated by P, and shaded to show the actual breadth; the positions of satellites in zero field are marked on the axis of abscissa by lines proportional to the intensity.

A glance at the figures for parallel components show that the separation is not generally proportional to the magnetic field. The satellites of 4047 are characterised by approaching the central principal line asymptotically, while in weak fields, the change in wave-length is quite rapid. The most remarkable of them is the satellite at -60 m.A.U. from the principal; the branch towards the positive side is approximately a parabola with vertical axis, and that towards the negative side a similar curve with horizontal axis; consequently the change wrought by magnetic field is proportional to $\sqrt{H}$ for the former branch, and to H^2 for the latter, showing that the singular case discovered by Gmelin is not confined to the satellites of the yellow line 5790. The same remark applies to the satellite -242 of the green line; the $(-)$ branch becomes fainter with increase of the field, and is parabolic in the sense above mentioned, the $(+)$ branch increases in brightness with the field, and the wavelength goes on increasing until it reaches a maximum, whence it gradually returns to the initial value in $H = 24{,}000$, and decreases farther at a constant rate. The $(+)$ branch becomes ultimately parallel to the principal line P_{-1}. The direction taken by this Branch ultimately coincides with that of the $(-)$ branch of the satellite, -74; on approaching the $(+)$ branch of -242, this $(-)$ branch of -74 becomes fainter, and is finally lost to view; the other branch of -74 runs probably parallel to P_{+1}, and increases in intensity.

The satellites -26 and $+78$ have both a curved branch towards the negative side, and a straight branch on the positive side, both being parallel to P_0. Thus in these lines the different branches to which the satellites are divided ultimately run parallel to the principal lines, whether the vibration takes place parallel or perpendicular to the direction of the magnetic force. This stage is reached earlier in the latter than in the former, as an inspection of the figures will show. The same holds good also for the strong satellites of the mercury line 4359. On reaching this stage, the change in wave-length takes place proportional to the corresponding change in magnetic field, and the separation becomes ultimately normal.

It is in the transition from zero field to this final stage that the separation of the satellite takes place in a singularly anomalous manner, that we seldom meet with in the separation of the principal lines.

This fact will have an important bearing on the elucidation of the nature of the satellite, and probably may have an intimate connection with the recent experiments of Paschen and Back. Before entering into theoretical speculation as to the probable origin of the anomalous mode of separation, we think it advisable to extend the investigation to see if such an effect is common to satellites of lines of other elements.

The Piltdown Horse "Grinder."

In the Dawson-Woodward paper on the Piltdown skull of a "hominid" (Q.J.G.S., vol. lxix.) mention is made of a tooth of *Equus*, and an accurate description (so far as it goes) is given. After handling it again at Kensington, and comparing it by measurements with recent finds from this Stort Valley, also with one recently placed in the Sedgwick Museum, and another in the Saffron Walden Museum, I have found that the tooth in question appears to be the *fourth premolar* (p.m. 4) of *Equus robustus*, which Prof. Cossar Ewart has recognised as the true "Solutré Horse" ("Restoration of an Ancient Race of British Horses," Proc. Roy. Soc., Edin., vol. xxx., part 4). The importance of this identification (if it is confirmed by experts) is too obvious to need further comment to those who are familiar with recent advances in our knowledge of the prehistoric horse. It remains to determine the exact horizon in the gravel-deposit at which this tooth was found before we can appraise its precise value as a time-index (see Nature, July 8, 1909, paper to the Royal Soc. by Prof. J. C. Ewart, F.R.S.). But one may venture to assert that the *stratum* of Piltdown gravel, from which this tooth of Equus came, is of far later date than anything belonging to the Pleiocene.

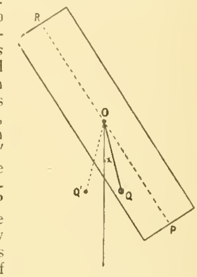
Bishop's Stortford, August 16.

Automatic Stability in Aëroplanes.

Prof. Bryan's explanation of his model illustrating instability due to friction is somewhat obscure, but in any case it is difficult to see how there is not a violation of the principle of conservation of energy in his conclusion.

If θ and ϕ are the angles made with the vertical at any instant by OQ and OP respectively, the potential energy of the controlling mechanism is $k(\theta-\phi)^2$, where k is some constant.



When the system starts to move from the position depicted in the figure, its energy is $C + k(\beta-\alpha)^2$, and when it reaches the position of rest on the other side its energy is $C' + k(\gamma-\alpha)^2$, where C and C′ depend on the position of Q and Q′ relative to O, and therefore are equal, and β and γ denote the angles which OP makes with vertical in the first and last positions. Now Prof. Bryan states that γ is greater than β, in spite of the fact that some energy has been degraded by friction in passing from one position to the other. Where is his concealed source of energy?

J. B. Dale.

The system contemplated in my letter assumes the existence of an external source of energy, and perhaps it might have saved misunderstanding if this fact had been stated at the expense of brevity. If we imagine an aëroplane performing purely lateral oscillations, and suppose it furnished with a pendulum so arranged as to operate on a pair of ailerons, we have a system the action of which might be represented to a first approximation by the model assumed by me. In this case the necessary energy is being supplied by the wind, which, by its action on the ailerons, causes the aëroplane to rotate like a windmill during the interval that the pendulum rotates with the aëroplane, while the inclinations of the ailerons remain constant. The work done in a small displacement is of the form $k(\theta-\phi)d\theta$, but this does not integrate into an expression representing potential energy.

G. H. Bryan.

Physiological Factors of Consciousness.

I wish to ascertain the opinion of physiologists and psycho-physicists on the following point, and I hope some readers of Nature will be good enough to supply me with the information required.

My query is this: What is the true explanation of the fact that stimuli sufficiently strong to arouse vivid sensations in a subject while he is wide awake apparently fail to arouse any sensation at all in a state of unconsciousness? Four explanations appear to be possible, namely:—

(1) The afferent nervous current does not penetrate at all along the conducting paths into the central nervous system.

(2) It penetrates into it, but only up to a little way, and does not reach the highest nervous centres.

(3) It reaches even the highest centres, but simply touches them and does not enter them.

(4) It enters them, but fails to bring about that physical change in them that is the invariable concomitant of every conscious state.

The first of these explanations appears to me the least tenable of all. The last explanation, on the other hand, seems to be relatively the most probable. Indeed, on purely psychological grounds I am inclined to accept it as the final solution, but I must wait and seek an explanation on strictly physiological lines.

ABDUL MAJID.

Ghasiari-Mandi, Lucknow, India.

IN reply to your inquiry for information upon the question raised by Mr. Majid I beg to say that the view of the matter which is, I think, pretty generally accepted and which I have adopted and attempted to develop in several publications (more especially in a series of papers in *Mind*, vol. xv., "Physiological Factors of the Attention Process"), is that the central nervous system consists of series of sensor-motor arcs superimposed on one another to form strata of successively higher function from below upwards; that the synapses or cell-junctions of the higher level arcs offer higher resistance in the resting state than those of arcs of lower level; that the waking state is essentially one in which the generally diffused excitement of the whole system reduces these resistances of the higher levels to such degree that excitations from lower levels can penetrate them, such penetration being impossible in the quiescent state owing to the high degrees of resistance presented by the synapses of these higher levels.

Anæsthetic drugs (as I first suggested in *Mind* in 1898) seem to abolish consciousness through increasing the resistances of the synapses; and fatigue-products probably act on them in a similar manner, thus cooperating with diminution of external stimuli to the sense-organs in predisposing to or inducing normal sleep. I know of no evidence that points towards Mr. Abdul Majid's fourth type of explanation. His letter raises an interesting question, which is by no means settled, although the type of explanation I suggest is, I think, more or less tentatively accepted by a good many physiologists; and it would be of interest to elicit some expressions of opinion.

W. MCDOUGALL.

Oxford, August 7.

FOSSIL MAN.[1]

IN the summer of 1908 the Abbés A. and J. Bouysonnie and L. Bardon, already distinguished for their researches into the Palæolithic industries in France, made an important discovery. At La Chapelle-aux-Saints, a little south of Brive, in the Department of Corrèze, they found buried in a grave of Mousterian age a human skeleton of Neandertal type, with the head more completely preserved than in any previously known example of its kind. An inquest was held on the spot by some of the best-known "prehistorians" in France, who unanimously confirmed the observations of the discoverers. The skeleton, which Messrs. Bouysonnie and Bardon have generously presented to the National Museum of Palæontology in Paris, was entrusted by a fortunate choice to the director, Prof. Boule, and the result of his investigations is the beautiful monograph before us.

The first chapter is devoted to a history of the discovery. The skeleton was found lying in a hollow of the rocky limestone floor of the cave, and was covered by a magna of broken bones, worked flints, and yellow cave-earth, over which followed first a layer of clay and then of loose soil containing pebbles. Among the animals represented by the bones are the woolly rhinoceros, reindeer, bison, hyæna, marmot, and horse—a characteristic Pleistocene fauna. The implements are for the most part Mousterian points and racloirs; there are a few bouchers of Acheulean type, as well as some grattoirs which seem to presage the Aurignacian; but the assemblage as a whole is typical Mousterian.

The skeleton was orientated east and west, the head to the west. Above the head were the bones of a bison's foot (a metatarsal and some phalanges) still in connection—a proof that the deposits had not been disturbed, and suggestive of much else besides.

The skull (Fig. 1), of which a masterly analysis is given, is unusually perfect, and especially in

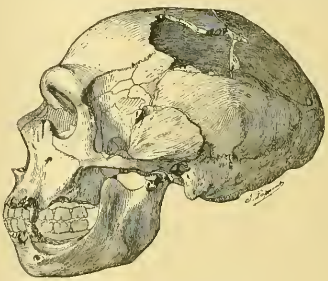


FIG. 1.—Skull of the man of La Chapelle-aux-Saints, with the nasal bones and the dentition restored (× ¼).

those parts which are absent from the Gibraltar skull, so that it is possible to determine the position of such important points of reference as the basion, opisthion, and bregma. The base is unfortunately incomplete, and this is the more to be regretted as the base of the Gibraltar skull, which in some respects is better preserved, presents some peculiar features not yet perhaps fully explained. In general there is a strong resemblance between these two skulls, the most marked difference, apart from size, lying in the extreme prognathism of the skull from La Chapelle-aux-Saints. Prof. Boule suggests that the orthognathism of the Gibraltar skull may be due to distortion consequent on pressure, but in the absence of collateral evidence we should be more inclined to regard it as an individual variation.

The most important characters of the skull are as follows: it is very large, especially for a man whose stature did not exceed 1·6 metres, and its capacity, measured directly by Flower's method, is 1620 c.c. The capacity of the Neandertal skull

[1] "L'Homme Fossile de la Chapelle-aux-Sainte." By Prof. M. Boule. Pp. 275+xvi plates. (Paris: Masson et Cie., 1913.) Price 50 francs.

is estimated at 1408 c.c., of La Quina at 1367 c.c., and of Gibraltar at 1296 c.c.

It is long, almost mesocephalic, and very flat: the frontal torus is enormous, the forehead low and retreating; there is a marked occipital torus, and the foramen magnum is situated far backwards; the squamosal is small, the mastoid process reduced, the tympanic slightly compressed, and there is a rudimentary post-glenoid apophysis. The palate is very large. The face has a remarkably brutal appearance, due partly to the retreating forehead and the frontal torus, the great round orbits, and very broad nose, but above all to the massive maxilla, which is without a canine fossa, and projects forwards, continuing the direction of the jugal, to form a sort of snout. The lower jaw is distinguished by the great thick-

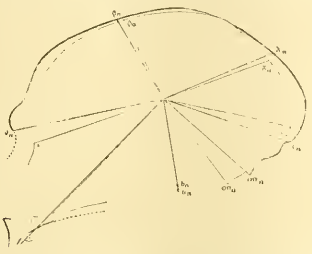

FIG. 2.—Profile of the skull of the man of La Chapelle-aux-Saints (thick line) compared with that of a low Australian aborigine (thin line). (The inions should be interchanged.)

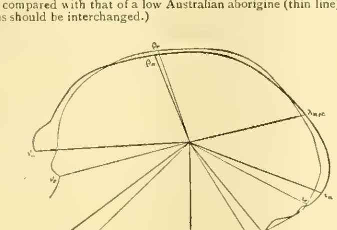

FIG. 3.—Profile of the skull of the man of La Chapelle-aux-Saints (thick line) compared with that of an average European (thin line).

ness of its body, the breadth of the ascending ramus, the obliquity of the symphysis, and the complete absence of a chin. The dentition is megalodont.

As the author justly remarks, it is not so much the occurrence of one or other of these characters which distinguishes the head of Neandertal man (many of them may be found scattered up and down among the members of some existing races); it is rather the association of all of them in one and the same skull, and, so far as we know, in all the skulls of one and the same race.

Very complete measurements are given, but exception might fairly be taken to the use of the glabella-inion line as a base; this is not without value when the Neandertal skulls are compared *inter se*, but it becomes misleading when the comparison is extended to the skulls of existing races. A better method is to superpose sagittal sections on a line drawn from the basion to the centre of form of its cranial area, as in the accompanying illustrations (Figs. 2 and 3).

It was found possible to obtain an internal cast of the skull, and thus to throw some light on the form of the brain, which, notwithstanding its magnitude, presents several simian features. It would be interesting to know what psychological significance may attach to these; Prof. Boule's

FIG. 5.—The skeleton of an Australian aborigine for comparison with Fig. 3 (× 15).

comment is that a small watch may be a better timekeeper than a big clock.

A minute description of the other bones of the skeleton brings to light a number of interesting peculiarities, as in the form of the scapula and the clavicle, the characters of the cervical vertebræ, and others which are summarised in a useful table (pp. 222–6).

In discussing the stature it is pointed out that Manouvrier's rules are founded exclusively on a study of existing white races, and that other factors have to be taken into account when we proceed to extinct races like the Neandertal. Prof. Boule is thus led to assign a stature of from

1·58–1·59 to the man of La Chapelle-aux-Saints, or even perhaps 10 mm. less. The attitude is regarded as having been less habitually erect than in recent races.

The numerous and important differences which we encounter in all parts of the skeleton are sufficient to distinguish Neandertal man from all existing races; he differs more from them than they from one another, and is therefore to be regarded as a distinct species, which, according to the recognised rules of nomenclature, should be named *Homo neandertalensis*.

All anthropologists will welcome the very interesting chapters on fossil Pleistocene man and the evolution of mankind which conclude the work. They are valuable not merely as a compendium of existing knowledge, but above all as an expression of Prof. Boule's personal opinions. We have not space to dwell on these, but we may briefly enumerate one or two points. No very close affinity is admitted between *Homo neandertalensis* and the aborigines of Australia; though they share many primitive characters in common, yet in still more they offer a decided contrast (Figs. 4 and 5). Pithecanthropus is regarded as a gigantic gibbon. The Mauer jaw is assigned to the Chellean stage. Some resemblance is recognised between the Grimaldi skeleton and the Bushmen, and it is admitted that the Aurignacian artists may have been the ancestors of this interesting people. No convincing evidence has yet been adduced of the existence of man before the Pleistocene epoch, and the so-called "rostro-carinates" are rejected.

The whole history of the discovery at La Chapelle-aux-Saints, from the exposure of the skeleton in its tomb down to its lodgment and reconstruction in the museum at Paris and the appearance of this monumental memoir, is a faultless record of skill and foresight. There are no lost opportunities to be regretted, and every significant fact that the material could yield has been elicited and set before us by a master hand.

THE AUSTRALIAN MEETING OF THE BRITISH ASSOCIATION IN 1914.

PROJECTED TOURS BEFORE AND AFTER THE MEETING.

BESIDES numerous excursions, in some cases over long distances, which are being arranged in connection with the meetings in the different capital cities of Australia next year, two more extended tours are projected with the object of giving selected members of the main party an opportunity to see portions of the continent which will otherwise not be touched. The first of these will be in Western Australia, and will be open to a limited advance party composed mainly of geologists, zoologists, anthropologists, and botanists.

The work of the party will lie in various directions from Perth. Geologists will be taken east to the goldfields, and also north to the Irwin River district. The geological relations of the latter (permo-carboniferous glacial beds with good exposures, and with excellent opportunity for collecting specimens) are more readily grasped on a short visit than are those of the goldfields. In addition an excursion will be arranged to Yallingup (south from Perth), and here there will be opportunity for botanists and zoologists to collect. For the latter, also, a marine excursion with dredging will be arranged at Bunbury on the return journey. A shorter trip by motor from Perth to Mundaring Weir will interest the same members, the zoologists visiting the region where Peripatus occurs. Marine dredging excursions in Swan River (for Ascidians), and by Rottnest Island, will also be arranged.

As regards the time that is required for a satisfactory working of the programme, a week is a minimum, and will mean much crowding and hurry. The Government of Western Australia and the committee in charge of matters connected with the visit would welcome a stay of a fortnight, and are prepared to grant railway facilities and find hospitality for that time. The number in the party must be limited, and membership restricted to people who are keenly interested in the work proposed. Twenty-five to thirty would be a convenient number, which might, perhaps, be extended to thirty-five, but must not exceed this.

The second tour would begin after the last meeting of the association in Brisbane, and the proposed itinerary is the following:—Brisbane viâ Rockhampton to Longreach by rail; coach to Winton; rail to Hughenden and Cloncurry; motor to Croydon and rail to Normanton. The party would then be taken to the mouth of the Norman river, and be met by the steamer belonging to the Administration of the Northern Territory (Dr. J. A. Gilruth, Administrator), and conveyed across the Gulf of Carpentaria, and about one hundred miles up the Roper river. They would proceed through the Territory by motor-car (there are no roads) to Pine Creek, and thence by rail to Darwin, where the steamer to England viâ Java, Singapore, and Colombo would be met.

A very considerable portion of Australia would be covered, and fine opportunities offered for the study of botany, geology, agriculture, &c., and, what is of great importance to Australia at the present time, the conditions of white settlement in the tropics. Obviously the party must be small, and it is suggested that it should include a botanist, a geologist, a zoologist, and a physiologist, or persons connected with mining, agriculture, and the development of Empire. Four would be a suitable number, or at the most five. Representative men only would be acceptable, for the trip will be costly; but if a party of sufficient standing and enthusiasm be prepared to undertake it, the Hon. D. F. Denham, Premier of Queensland, has promised, on behalf of his Government, to bear the expenses of the Queensland section, and the Administration of the Northern Territory will be responsible for the later section. A rough estimate of the time that might be spent on the whole trip is one month, but this would need to be adjusted in accordance with the time-table of the boats from Darwin to England.

It is hoped that both of these parties may be arranged by about the middle of November, while the organising secretary for the Australian meeting (Dr. A. C. D. Rivett) is in England. Inquiries should be addressed to the Secretary, British Association, Burlington House, Piccadilly, W.

TWENTY-FIVE YEARS' WORK AT THE PHYSIKALISCH-TECHNISCHE REICHSANSTALT, CHARLOTTENBURG.

THE Physikalisch-Technische Reichsanstalt, which may be aptly termed the German "National Physical Laboratory," plays such an important part in physical science that it may not be without interest to readers of NATURE to indicate briefly a few of the more prominent questions which have been dealt with at the institution since its foundation in 1885, which, by the way, was due in great measure to Werner von Siemens. Considerable information is afforded in two articles[1] recently published by members of the staff, and these papers should make interesting reading to those desiring further particulars of the work.

In addition to carrying out research work of direct interest to science and industry, the Reichsanstalt carries out the verification against standards of all kinds of instruments in the same manner as does the National Physical Laboratory in this country. It is, however, the research work to which we will confine ourselves here. The remarkable growth in the activities of the institution has kept pace with the advancement in scientific research during the last quarter of a century.

Dealing first with heat, the Reichsanstalt has occupied itself with practically every question in this branch of physics. One of its first tasks after getting into working order was the continuation of Regnault's famous work: he had shown that the scale of the mercurial thermometer could not be used as a standard owing to the influence exerted on the readings of the instrument by the expansion of the glass tube, the indications differing considerably in the range above 100° C. with thermometers made of different sorts of glass. Great difficulty had been experienced in finding a glass suitable for high temperatures when the Reichsanstalt commenced operations. Schott and Genossen, of Jena, experimented with different types of glasses and produced thermometer tubes constructed of new types of glass, and the Reichsanstalt tested these tubes as regards their accuracy over the fundamental interval 0–100° C., and their suitability for higher temperatures. The result is that the well-known Jena 59 quality has up to the present proved the most suitable in respect of small thermal expansion and of robustness. Extensive comparisons were afterwards carried out between the mercury thermometer and the air thermometer, owing to the difficulty experienced in realising the hydrogen thermometer scale at temperatures above 100° C. These measurements were carried to 500° C. At the present day nitrogen-filled thermometers are recognised as the most practical for high temperatures, and their success is to no small degree due to the labours of the Reichsanstalt. The institution has also played a not inappreciable rôle in the development of pyrometry, from the introduction of the thermo-couple by Le Chatelier to the more recent progress which resulted in the introduction of radiation pyrometry, based on the early observations of Becquerel, and on the later investigations of Kirchhoff and Wien on the subject of "black body" radiation. Following on Regnault's experiments, the Reichsanstalt has carried out research on the thermal properties of substances: this included experiments on the expansion of water between 0° and 100° by the communicating tube principle, and the determination of the saturation pressure between −60° and +370° C. The determination of the specific heat of gases—a question of high importance in internal combustion engine work—has been carried out with nitrogen, carbonic acid gas, and water vapour up to 1400° C., thus completing the work of Le Chatelier and Mallard in this connection, and the determination of the specific heat of gases at low temperatures has been made by Callendar's continuous flow method, improved by the counter-flow principle.

The electrical side of the work is no less interesting, and the activities of the institution have kept pace with the unceasing progress of this all-embracing science. It is, of course, of prime importance that the electrical units of measurement should be defined and realised as accurately as possible, and in this connection the Reichsanstalt has taken part in international conferences dealing with the subject, as well as cooperating with the State laboratories of other countries in carrying out measurements. Mercury copies of standard resistances had been found to be inconvenient in practice, and resistance boxes of German silver had proved inconstant and shown the resistance to be an intimate function of the temperature. It was Weston, in America, who first paved the way to improvement in this respect by inventing an alloy which showed but slight change of resistance with temperature; but it was left to the Germans to improve on Weston's discovery, the result being the introduction of the alloy (copper eight parts, nickel four, and manganese twelve) known universally as "manganin." Twenty years' experience at the Reichsanstalt with manganin resistances has shown the material to be unsurpassed by any other.

At the time the Reichsanstalt was founded standard cells were scarcely in use: it was only in the 'nineties that the Reichsanstalt, as the result of investigations, produced a practical standard cell, and one capable, moreover, of undergoing transit. This cell has, however, been superseded by the well-known Weston normal cell, which was accepted as the standard of e.m.f. by the London

[1] "Die Physikalisch-Technische Reichsanstalt: Fünfundzwanzig Jahre ihrer Tätigkeit." By Profs. Scheel, Holborn, Jaeger, and Brodhun. *Die Naturwissenschaften*, 1913, Nos. 8, 10, 12, 14.
"Die Physikalisch-Technische Reichsanstalt in Charlottenburg." By Prof. Karl Scheel. *Akademische Rundschau*, January, 1913.

conference on electrical units and standards (1908).

For direct-current measurements in electricity the three fundamental units—the ohm, the ampere, and the volt—are sufficient; but the Reichsanstalt experiments have contributed to a great extent to the improvement and simplification of methods of measurement. It was this institution that helped largely in the development of the potentiometer, which, in conjunction with the standard cell, forms the real basis of very many electrical measurements.

Mention should also be made of the "artificial loading" method introduced by the Reichsanstalt (separate circuit for current and pressure), which enables tests to be carried out, with but a small expenditure of electrical energy, on apparatus intended for the measurement of outputs up to many thousand kilowatts. It was also the Reichsanstalt which introduced the optical method of measuring current densities by means of the optical pyrometer.

Considerable interest attaches to the testing of sheet-iron employed in dynamo and transformer construction, and endeavours have repeatedly been made to keep down the energy losses in the material while augmenting the permeability (magnetisability) of the iron as much as possible. The Reichsanstalt was the first to suggest the use of iron alloyed with silicon for this purpose; and the researches of Barrett, Brown, and Hadfield appear to show the great advantage of this alloyed iron, which results in the reduction of eddy currents.

The optical work of the Reichsanstalt is not discussed quite so fully as that of the other branches. After a mention of pre-existing units of light, a space is devoted to the amyl acetate lamp of Hefner (briefly, the Hefner lamp) as a photometric standard. Whilst recognising its many advantages the Reichsanstalt has not lost sight of its deficiencies, and for this reason has always endeavoured to establish a measure of light to satisfy the broadest requirements of scientific and technical practice. Successful experiments have been conducted to secure a constant radiation of light from incandescent platinum with the aid of the bolometer, and tests now in hand justify the hope of arriving shortly at a mode of realisation of the "black body" which will fulfil all requirements in regard to accuracy and trustworthiness. Through the labours of the Reichsanstalt Germany was the first country to possess a generally recognised, accurately investigated unit of light.

The Charlottenburg establishment has also kept in close touch with practical requirements connected with saccharimetrical work. For ascertaining the value of sugar use is made of its rotation relative to the plane of polarisation, the Germans (and many other countries) using the Ventzke scale of divisions for the saccharimeters. The hundred point of this scale is defined by the rotation of a standard sugar solution (26 grammes in 100 c.c. of water at 20° C.) in a 20 cm. tube. For checking the readings of this apparatus, a quartz plate ground perpendicular to the axis is employed. Extensive experiments had to be made on the rotation of the pure sugar at the concentration of the standard solution, in order to arrive at a basis for test purposes. Great accuracy is necessary, as it is estimated that an error of 0·1 per cent. would make a difference in the sale value of the annual production of sugar in Germany of about 25,000*l*. The Reichsanstalt has, in addition, introduced the Abbe refractometer for determining the percentage of solids or of dry substance in connection with the impure sugar solutions to be investigated in the course of manufacture. Particulars are given of the method employed. Experiments have also been undertaken on the refractivity of other substances with the Abbe-Fizeau dilatometer, such as the refraction of different gases (air, H, N, and He) at room temperature and at very low temperatures; in addition, accurate measurements have been made on the refractive power of quartz and fluorspar—substances of such great importance in radiation measurements.

A series of optical experiments on metals have been made, yielding important results. The reflecting power was first determined by measuring the quantity of light reflected nearly perpendicular (to within $\frac{1}{4}°$) to the surface, for light of different wave-lengths, not only for the visible part of the spectrum, but also for ultra-violet (to wavelengths of $0·25\mu$) and for ultra-red rays (to wavelengths of $1·5\mu$). In the visible range the work was carried out with the spectrophotometer, and in the invisible range with a Rubens thermopile. In addition to pure metals the technically important mirror-alloys were investigated, and, for the visible range, glass mirrors coated with silver and mercury amalgam. It is interesting to note that silver, which in the visible spectrum reflects better (viz. 90–95 per cent.) than all other metals, reflects much less than all other metals in an ultra-violet region (between $0·25$ and $0·3\mu$), namely, only about 4 per cent.—or less even than a quartz surface.

An apparatus has been constructed by the Reichsanstalt for producing sharp interference bands, and having a high capacity. Its main constituent is a plane-parallel glass strip into which the light to be tested is transmitted in such manner as to fall on the bounding planes near to the angle of total reflection, thus emerging striated. With this apparatus a number of spectrum lines, particularly the mercury lines, have been tested as regards their structure and the presence of accompanying lines ("satellites").

In conclusion mention should be made of a series of experiments relative to the luminous phenomena in highly evacuated Geissler tubes. A new kind of ray, similar to the kathode rays, was discovered which was emitted from the anode under certain conditions. These anode rays, which are emitted in particular from hot salt anodes, show magnetic and electric deflection like the kathode rays and the Doppler effect (displacement of the lines in the spectrum). They were conceived as being positively charged metallic atoms of the salts contained in the anode, and are cast off from the anode at great velocity (100 to 1000 kilometres per second). Difficult measurements carried out have had reference to the velocity and to the ratio of the electric charge to the mass of a luminescent particle for different metals. Views, corroborated chiefly by spectroscopic tests, make it probable that the anode rays are identical with the sun's protuberances—that the latter are nothing but anode rays of gigantic dimensions.

The annual report of the Reichsanstalt for the past year, just to hand, gives evidence of continued progress in the various branches of scientific investigation, but space will not permit of touching on the subjects dealt with: readers are referred to the *Zeitschrift für Instrumentenkunde*, March, April, and May, 1913, in this connection.

E. S. HODGSON.

DERIVATION OF POWER FROM TIDAL WATERS.

THOUSANDS of years have been required to evolve the processes by which the energy stored by natural agencies has been made to fulfil our requirements; thousands of years may still be required to evolve processes by which the internal heat of the earth, the phenomena attendant on barometric pressure, and the potential energy of the tidal wave may be similarly utilised.

But with regard to the latter much has in reality been already achieved. Vast fleets of barges and shipping are daily carried to and fro by means of the tidal stream in estuaries and the mouths of rivers. Ships of all sizes are lifted and kept afloat in inland tidal basins. London, Cardiff, Bristol, and numerous seaport towns illustrate the fact that ends impracticable by other means may be attained by the utilisation of the tidal wave; and there is little doubt that as time goes on, the advantages to be derived from the utilisation of the tides in dock work will be manifested by even greater and more important works than have yet been undertaken.

Why, then, should it generally be considered impracticable to utilise some small portion of the potential energy of the tidal wave in the production of energy for other useful purposes? The answer to this question is difficult to find, but it appears that about forty years ago an attempt was made to investigate the matter. An analysis of the initial cost and probable revenue from a tidal installation was made the subject of articles in *The Engineer*. The result of the analysis showed that electricity could be produced at a cheaper rate with gas engines than by a tidal installation. The cumulative result of this weighty opinion was evidently far-reaching, and for many years only half-hearted attempts have been made to prove that the tidal installation is no longer to be considered outside the range of practical engineering problems.

The conditions which obtained forty years ago are no longer in existence. The improvements in plant for carrying out large works are so great that they are difficult to realise. The hydro-electric installations in those days were so few in number and so unimportant in effect, that the vast works which have been executed in the past few years would likewise have been considered impracticable from a commercial point of view, or, at the best, in the light of doubtful experiments. Even so late as 1904, in a paper read before the Institution of Civil Engineers (vol. clvii., session 1903–04, part iii.), Mr. Steiger gives it as his opinion that water power has been chiefly used for driving flour mills, and as the authority of the author is above dispute, it may be safely concluded that an analysis made forty years ago should no longer be allowed to stand without revision.

Perhaps the most important modification of the conditions which obtained until quite recently is the use of ferro-concrete as an auxiliary to the formation of embankments. The strength and durability of structures, such as bridges and landing stages, with struts and braces of ferro-concrete has proved the possibilities of that material in braced structural work, while the small section and great length of ferro-concrete piles has shown the possibility of handling suitably designed beams and girders of this material without risk of injury to them.

Now by constructing braced trestles which can be handled by a crane, and placed so accurately in position that slabs of ferro-concrete, designed for the purpose, may be set between them and fixed, an extremely economical shell may be formed to serve as the matrix of an earthwork embankment.

The present writer has had the privilege of making an exhaustive investigation into modern methods of forming sea walls, wharfs, breakwaters, and other sea works of that kind, and he is in a position to state that where there is no danger from the action of heavy seas, great economy can be effected by forming the face of a sea wall with a skin of concrete slabs, held in position by trestles of the same material.

But even with the saving which can be effected by this method of construction, the tidal installation is only practicable from a commercial viewpoint when the initial cost can be reduced to between 40*l*. and 50*l*. per horse-power; or, stating the matter in another way, unless the sum of the maintenance charges, plus about 10 per cent. on the capital outlay, divided by the capacity of the installation in horse-power, does not exceed 4*l*. per horse-power year.

The financial side of the question is of the first importance, but the difficulties to be overcome on the technical side are also, it is to be presumed, regarded as nearly insuperable as well. To deal with the latter it is necessary briefly to consider the general characteristics of tidal waters in estuaries or similar locations, and to indicate the methods proposed for overcoming them.

When the tidal wave passes from the open sea into the funnel-shaped entrance of a channel or estuary, its volume being constant, the height of the wave increases as the opening narrows, and the particles of water composing it acquire a horizontal motion. In fact, the tidal wave, after entering an estuary, may be considered to be a stream, which, while the crest of the wave is passing, becomes quiescent for a time, and then flows in the opposite direction until the trough of the wave, in its turn, causes another period of quiescence. These periods of quiescence are called the tidal intervals.

Now it has been found that the potential energy of a river may be converted to useful energy by damming the stream at a convenient place to obtain a working head for turbines; the difference in level of the stream above and below the dam being but a few feet. The economy of this method of generating electricity has been established by experience, and it is clear that if the utilisation of the tidal stream could be effected on somewhat similar lines, similar results might reasonably be expected. This in effect constitutes the problem which has to be solved.

The chief difficulty which has to be surmounted in utilising the tidal stream for power purposes is the tidal interval, and this difficulty must be considered as a problem to be solved for every location. In one case it might happen that it would be found cheaper to form one tidal reservoir and another reservoir inshore above the level of the highest tide.

The inshore reservoir would be filled twice daily by means of pumps actuated by the tidal reservoir, to serve as the supply to an ordinary hydro-electric installation which could be operated when required. In another case it might be found that the difficulty could be best dealt with by forming an auxiliary reservoir at a convenient spot higher up a neighbouring river, thus providing a separate unit to carry the load over the tidal intervals. In another case, again, it is possible that the intermittent operation of the turbines would not be found inconvenient. But speaking generally, the difficulty can be surmounted by the formation of two or more reservoirs connected to the tide and to a central turbine chamber by means of sluice valves; the feed to the turbines springing alternately from the main tidal stream and from the reservoirs in such a manner that a working head of water might be continuously maintained.

But it cannot be too strongly insisted upon that the first requirement for a tidal installation is a suitable site, the peculiarities of which will determine the character of the system adopted. For, since the success of such an undertaking depends on the cost per unit of power for structural work and equipment, it is evident that advantage must be taken of every favourable peculiarity, and that the system adopted will be dependent on the site.

In a case where the tidal interval is to be bridged by means of three tidal reservoirs the sequence of flow between the reservoirs and the tidal way is somewhat difficult to follow, but may readily be understood from the tabular description below. The three reservoirs are severally denoted by the letters "a," "b," and "c."

The tide rising from low water to one-third of its range:—

"a" Turbines fed from reservoir	"b" Standing empty	"c" Emptying into the tidal way

The tide rising from one-third of its range to high water:—

"a" Filling to high-water level	"b" Empty	"c" Turbines fed from the tidal way into the reservoir

The tide falling from high water to one-third of range:—

"a" Standing full	"b" Turbines fed from the tidal way into the reservoir	"c" Filled up to tide level

The tide falling from one-third of its range to low water:—

"a" Full	"b" Emptying to low-tide level	"c" Turbines fed from reservoir

It has been practically established that the basis of calculation for the power of a tidal installation should be one-third of the range of the minimum tide; hence when high tide is reached, water flowing from the tidal way may be passed through the turbines into the empty reservoir "b," the capacity of which must be such that the water level inside will have risen to the height of one-third of the range of the tide when the tide has fallen that distance. Similarly at low tide, water impounded in reservoir "a" to the level of the last high tide may be discharged through the turbines into the tidal way, the capacity of reservoir "a" being such that the tide will have risen one-third of its range before the water level inside has fallen an equal distance.

A third reservoir "c" must be provided to receive the water flowing through the turbines from the tidal way, during the time that the tide is rising from one-third of its range to high tide. It must then be filled to high-tide level direct from the tide, so that when the latter has fallen one-third of its range, the contents may be discharged through the turbines into the tidal way.

By an arrangement of valves and sluices all the reservoirs can be controlled automatically to perform their several functions as and when required.

The technical description of the several sluice valves or gates, of the structural details of the supply, or turbine chamber, and of the embankment walls was given in detail in the author's paper on tidal waters as a source of power, which was read and discussed before the Society of Engineers on May 5. It is, however, necessary to state that the cost of these details has been exhaustively considered, and it has been found that though the expense entailed is very heavy, it cannot be considered prohibitive unless the capacity of the installation is less than it should be to justify the outlay. For it will readily be seen that the length of the embankment walls will not increase directly as the area of the reservoirs, and hence that within defined limits, the greater the capacity of the installation the smaller will be its cost per unit of horse-power.

It is hoped that in the near future an opportunity will be found to obtain, not only a close estimate of the cost of a tidal installation, but also a proof in practice of its convenience and economy as a means of reducing the national consumption of fuel. C. A. Battiscombe.

NOTES.

The ninety-sixth annual meeting of the Société Helvétique des Sciences Naturelles is to take place this year at Frauenfeld from September 7 to 10. The programme is an interesting one. Among the lectures announced which are likely to attract considerable attention we notice that by Dr. de Quervain, of Zürich, on the Swiss Expedition to Greenland and its results, and that by Prof. Keller, of Zürich, on the geography of the fauna of the Caucasus, both of which are to be illustrated by lantern slides. Prof. Maillefer, of Lausanne, who will speak of his researches on the laws of geotropism, and Prof. Dutoit, of the same city, who will discourse on recent conquests in the realm of analytical chemistry, are equally certain of an attentive audience. Besides these, Prof. Grubemann's, of Zürich, account of the development of the modern theory of rocks, and Prof. Rikli's geographical studies in the flora of the Caucasus, as well as Prof. Fuhrmann's, of Neuchatel, sketch of his scientific researches during his journey through the Cordilleras of Columbia, will be awaited with interest. Among the men of science who have announced their intention of making communications to the separate sections are Prof. Edouard Fischer, of Bern, and Prof. Ernst, of Zürich, in the botanical section; Dr. Paul Arbenz and Dr. H. Schardt, of Zürich, in the geological section; Prof. C. E. Guye, of Geneva, and Prof. Perrier, of Lausanne, in the physical section, as well as Prof. Einstein and his colleague at Zürich, Prof. M. Grossmann, in a discussion of the physical and mathematical basis of the theory of gravitation, to take place at a common sitting of the physical with the mathematical section. In the latter section, though only added of late years, there is a relatively large number of communications inscribed, of which several are concerned with the more recent theories. In the section for geophysics Prof. P. Mercanton, of Lausanne, and in the section for chemistry, Prof. A. Pictet and Dr. G. Baume, of Geneva, are reading papers.

The third International Congress for Diseases of Occupation will take place under the presidency of Dr. F. von Haberler and Prof. A. Schattenfroh in Vienna in September, 1914. The subjects for discussion will be:—"The Physiology and Pathology of Fatigue, especially with Regard to Professional Work, Overwork, and Nightwork," "work in Hot and Damp Air," "Anthrax," "Pneumoconiosis," "Electrical Industrial Injuries," "Industrial Poisoning, especially by Anilin, Mercury, and Lead," "Industrial Injuries to Hearing," and "Independent Communications." The general secretary is Dr. Ludwig Teleky, Vienna IX., 23, Türkenstrasse.

The fourth International Congress of School Hygiene was opened at Buffalo on Tuesday last, and will continue in session until Saturday next. The president is Dr. C. W. Eliot. The work of the congress is divided amongst three sections, devoted respectively to "The Hygiene of School Buildings, Grounds, Material Equipment, and Upkeep," "The Hygiene of School Administration, Curriculum, and Schedule," and "Medical, Hygienic, and Sanitary Supervision in Schools."

The eleventh International Conference on Tuberculosis will be held in Berlin from October 22 to 25. Among the communications promised are the following:—"Clinical Forms of Koch's Bacillosis at Different Periods of Life," by Prof. Landouzy; "The Surgical Treatment of Pulmonary Tuberculosis," by Dr. Brauer; "Life Insurance," by Dr. K. Frankel; "State Insurance and Schools for Children with a Tendency to Tuberculosis," by Prof. Pannwitz.

The annual meeting of the International Association of Medical Psychology and Psychotherapy will take place at Vienna on September 19 and 20. The general secretary is Dr. L. Frank, 45, Zürichbergstrasse, Zürich.

The death is announced, from Bonn, of Robert Rieder Pasha, the well-known surgeon, at the age of fifty-one years. In 1898 he became a professor in the University of Bonn. Afterwards he became Inspector-General of Medical Schools in Turkey, and received the title of Pasha. He remodelled the system of medical training in Turkey, and was responsible for the establishment of several hospitals and similar institutions in and near Constantinople, and returned to Germany in 1906.

The death is announced, in his fifty-sixth year, of Mr. C. Leslie Reynolds, superintendent of the National Botanic Gardens at Washington. He had been connected with the gardens for nearly forty years.

The death is announced, in his seventy-third year, of Mr. W. Whitehead, president of the British Medical Association in 1902, and from 1894 to 1900 professor of clinical surgery in the Victoria University of Manchester.

The death is announced of Mr. J. R. Sheldon, a well-known agriculturist, at the age of seventy-three years. Mr. Sheldon was appointed to the chair of agriculture at the Royal Agricultural College, Cirencester, in 1877, being subsequently lecturer on dairy farming at Downton Agricultural College. He was the author of "Dairy Farming" and "Live Stock in Health and Disease."

The late Sir Jonathan Hutchinson, F.R.S., left by will the following directions regarding his museums at Selby, Haslemere, and Chenies Street, London:—"I leave the three museums at Haslemere, Selby, and 22 Chenies Street, and their contents to my trustees upon trust to dispose of the same as they in their own absolute discretion shall think best, but my desire is that, without imposing any trust upon my said trustees, they shall dispose of my said museums and their contents in accordance with my wishes expressed to them during my life."

By the will of Prof. Emil Chr. Hansen and his wife a fund bearing his name has been established. At intervals of two or three years, beginning in 1914, a gold medal bearing his effigy and accompanied by a sum of at least 2000 kroner is to be awarded on May 8 to the author of a meritorious publication on some microbiological subject, and recently published in Denmark or elsewhere. In 1914 the medal will be awarded to a worker in the field of medical microbiology. The president of the board of trustees is Prof. S. P. L. Sorensen, the Chemical Department of Carlsberg Laboratory, Copenhagen, from whom all information may be obtained.

On the closing day of the International Congress of Medicine, an address on the relationship between medicine and public health was delivered by the President of the Local Government Board, the Right Hon. John Burns, M.P. He surveyed the saving of life which has been effected by the application of sanitary measures, the decline in such diseases as enteric and typhus fevers, which are due to local insanitary conditions, and the stages in the registration of disease, which has proved so powerful an agent in its control. Finally, a tribute was paid to the nursing profession, and the interesting fact noted that Florence Nightingale, who initiated our present nursing system, received her preliminary training in a German institution, the Deaconess's Institute at Kaiserwörth, on the Rhine.

We see by *The Townsville Daily Bulletin* (Queensland) that the Australian Institute of Tropical Medicine at Townsville was officially opened on June 28 by Sir William MacGregor, the Governor of Queensland, in the presence of many men of science and medical men. In the course of an inspiring address, Sir W. MacGregor traced the evolution of the movement for the foundation of the institute, giving especial credit for work done to the Rt. Rev. Dr. Frodsham, formerly Bishop of North Queensland, and to Prof. Anderson Stuart, dean of the faculty of medicine in the University of Sydney. He then spoke of the work to be done by the institute in the following words:—"The field that lies open to this institute for investigation is vast and varied, covering as it does not only different races of men in health and disease in the tropics of Australia, in Papua, and in the Pacific Islands, but also all other creatures in the same great area, for in these times the transmission of many diseases from other beings to man is well known, typical of which is the 'Rossa Cycle' in malaria; but there are many others, such as the Guinea worm, from a small cyclops; yellow fever, flaria, and dengue, from mosquitoes; tapeworm from domestic animals, &c. Research work in this institute will, however, not be limited to animal organisms, but will also embrace the vegetable kingdom, especially in the forms of foods and poisons; and now, in view of the researches of Dr. Erwin Smith on cancer in plants, caused by the *Bacterium tumefaciens*, and of the remarkable conclusions of Johnson, that the bud rot of the cocoanut palm is caused by *B. coli*, the pathology of the vegetable kingdom will demand much greater attention than has hitherto been given to that subject. The institute will also concern itself with such elementary things as earth, air, water, and sunshine; in short, with everything that influences the physical life of man in the tropics. Researches in this institute will also embrace questions that concern industrial life in our tropics. Dr. Breinl's work on nodules has already been of such a character as to demonstrate that the institute will be of much service to our flocks and herds, and be important in our economic pursuits." He then touched upon the investigations that will be carried out with reference to the effect of climate on the white race in tropical Australia; the proper kind of houses to be erected for their use; the most suitable forms of food and clothing for them; the study of insect and bacterial life in disease; the economic work which will be undertaken, and the value of such an institution to the medical man who has to deal with diseases peculiar to the tropics.

A second report (the first was issued in 1910) on infant and child mortality, by the medical officer of the Local Government Board, Dr. Newsholme, has been issued by the Board. The task of the present report has consisted mainly in setting out the facts as to incidence of mortality, and in attempting to render conspicuous the experience of those towns or parts of towns in which an excessive sacrifice of child-life occurs. A great saving of child-life has been effected in the last few years, and a large portion of this decline has occurred in the towns now under report. It is satisfactory to find that this saving of life cannot be attributed merely to favourable climatic conditions, but to some degree at least is the result of improved sanitary and housing conditions. In the first part of this report the detailed facts as to incidence of infant and child mortality are set out. In its second part the close interrelationship between defective sanitation, poverty and intemperance, and excessive mortality is discussed. In its third part, a preliminary statement as to child welfare work is given.

It is announced in *The Times* that Mr. Peter Waite, of Adelaide, South Australia, is sending a collection of animals to the Scottish Zoological Park. The collection includes two kangaroos, four Bennett's wallabies, four rock wallabies, two emus, two ópossums, two eagles, two Tasmanian devils, two black swans, two magpie geese, and two ibises. The Adelaide Zoological Garden is sending two dingos, and Mr. S. S. Ralli, of Adelaide, two giant kingfishers. Mr. E. J. Robertson Grant, of Edinburgh, who is at present in the Argentine, has also intimated that he is getting together a collection of animals for the Zoological Park, and will bring them with him when he returns to Scotland in November next..

Hungary possesses a Governmental institution for the scientific study of ornithology, the Magyar Királyi Központ, or Königlich Ungarische Centrale, to which has recently been added an anatomical department, the staff of which publishes its researches in the periodical *Aquila*. Dr. Greschik, one of the assistants, has made a renewed study of the microscopic structure of the rectum of some sixty kinds of native birds

The histology of this class is usually treated somewhat cursorily in our text-books, mainly because of the minute size of the avine cells in comparison with those of other vertebrates. A number of good text-figures and a plate illustrate the details, most of which naturally can interest the specialist only, but there are also observations and conclusions, for instance, those concerning leucocytes and the protoplasmic rods of the cylindrical epithelial cells, which are of general physiological importance.

To *The Field* of August 23 Mr. R. I. Pocock contributes an article on the skin-glands of shrew-mice, in which it is pointed out that the gland on the flanks of the British species, which is generally supposed to emit the musky odour characteristic of these animals, is present only in the males. On the other hand, it is developed in both sexes of the Indian musk-shrew (Crocidura), as well apparently as in the Continental representative of that genus. It has been generally stated that the musky odour of all shrews is protective, but, in the members of the typical genus, if it be emitted by the gland, it must be a sexual feature, probably designed to attract the females. Before this can be definitely decided, it has to be ascertained whether the females of British shrew-mice are musky. If they are not, the numerous shrew-mice left dead by cats in gardens in autumn must probably all be males. Quite apart from the question whether the glands be its source, it seems, on the other hand, quite evident that in the Indian musk-shrew and its near relatives the musky odour is highly protective, rendering these animals obtrusive and "self-advertising."

THE current number of *The Quarterly Journal of Microscopical Science* (vol. lix., part 2) contains a very interesting article by Mr. E. S. Goodrich on metameric segmentation and homology. He discusses the well-known difficulty that organs which are undoubtedly homologous, inasmuch as they can be traced back to corresponding parts in a common ancestor, may nevertheless occur on different segments in different representatives of a group. The paired limbs of vertebrates are cited as typical illustrations of the problem. These shift backwards or forwards during the course of evolution in the most perplexing manner. Mr. Goodrich holds that, in order that they may be regarded as strictly homologous, it is not necessary that organs should be developed on corresponding segments in different types, and he accounts for their variation in position by a process of "transposition," rejecting the theories of intercalation and excalation of segments, re-division of the body and migration of the organs in question.

THE August number of *The Museums' Journal* is chiefly devoted to reports of the recent conference of the Museums' Association at Hull, including the presidential address delivered by Mr. E. Howarth. It is illustrated with a portrait of the president, and a photograph of the members of the association at Burton Constable, the seat of Major Chichester-Constable.

IN the second volume on insects in *The Cambridge Natural History* it is stated that the family Fulgoridæ "includes the so-called lantern-flies, in which the front of the head forms a huge proboscis that was formerly believed to be luminous." In the August number of *The Zoologist* Mr. H. W. Bell-Marley records the emission of light by the adult of a Natal species (*Rhinorthra guttata*), as well as by parasitic lepidopterous larvæ with which it is infested.

The Scientific American announces an alteration in the system of issue of publications by the United States Department of Agriculture. The old independent series of bulletins and circulars of the thirteen publishing bureaus, divisions, and offices of the department have been discontinued and will be superseded by a new *Journal of Research* for printing scientific and technical matter, and by a departmental series of bulletins, written in popular language for selected and general distribution. By this plan the confusion that has resulted from the multiplicity of series of publications will be avoided, and the saving of a considerable sum will annually be effected. Under the new plan the department will discontinue the general distribution of matter so scientific or technical as to be of little or no use to the lay reader. It will supply technical information only to those directly interested and capable of using scientific analyses, and of understanding the results of research work couched in scientific terms. A larger amount of information in popular form which the average reader can immediately apply to his own direct advantage will hereafter be distributed.

WE have received from Dr. J. H. Maiden a reprint of the presidential address delivered by him last year to the Royal Society of New South Wales. This address ranges over a wide and varied field, and contains much that is of general interest, including obituary notices and memoirs of Sir Joseph Hooker, Lord Lister, and Baron von Mueller. Reference is made to the forthcoming Melbourne meeting of the British Association and to other scientific matters of Australian interest, such as the Northern Territory Expedition of 1911, the exploration of Antarctica, the centenary of the Sydney Botanic Gardens, &c. After dealing with some botanical matters, such as the teaching of botany, a plea for a botanical survey and a new census of New South Wales plants, Dr. Maiden proceeds to set forth in some detail his views regarding the functions of a botanic garden, with suggestions as to work in phyto-chemistry and other practical proposals for increasing the usefulness of botanic gardens in Australia or elsewhere.

DR. W. A. CANNON, of the Carnegie Institution Desert Laboratory, Tucson, Arizona, has forwarded a reprint of an interesting paper on some features of the root systems of desert plants (*Popular Science Monthly*, vol. lxxxi). Among desert shrubs there are three main types of root system: (1) the superficial type, in which the roots extend horizontally from the plant axis, and lie near the soil surface; (2) the tap root, which goes directly down to a depth determined partly by the character of the soil, partly by the penetration of the rains and partly by the character of the root itself; (3) the generalised type of root, which not only reaches widely, but also penetrates fairly deeply.

The third, or generalised type, is characteristic of the great majority of desert plants; the prevalent idea that the roots of such plants are usually very long has no adequate foundation. The author adds interesting notes on the environment of the roots of desert plants—height of water-table in the soil, soil temperature, soil air, &c.—and indicates the problems which are being investigated at the Desert Laboratory with regard to the relation between desert plants and the soil.

The relative value of strong and weak wheats is a controversial question which has more than once engaged attention in the columns of Nature. The former type of wheat yields flour which is preferred by the professional baker in large cities for a number of reasons, and therefore commands a higher price. It has come to be considered of higher quality, and it is at present the object of wheat breeders all the world over to convert the indigenous weak wheats into stronger varieties. It is generally stated (for example, Humphries, Royal Society of Arts, 1909, 239) that the wheats which yield flour better suited for British consumption (by which the manufacturing centres and towns are implied), do not suit the native Indian requirements so well; indeed, wheat is more often consumed by the natives in the form of coarse cakes toasted by the side of an open fire than in the form of the light, well-risen loaf known to us. However, Mr. and Mrs. Howard, whose work in improving Indian wheats is receiving wide recognition (see Nature for August 7, p. 586), write to say that they do not agree with this view of the question, and they claim that the class of wheat preferred by the people of India for their own food is the same as that in greatest demand in the English markets. Mr. and Mrs. Howard realise fully (*Agric. Journal of India*, iii., p. 31) that any improvement in the quality of wheat to be of importance must satisfy both the people of India and the home millers.

The cultivation of tobacco in the Nyasaland Protectorate would appear to be full of promise, if one may judge from the report of the director of agriculture for the past year. During the period 1902–12 the total export of tobacco has increased from 60 lb. to $2\frac{1}{4}$ million lb., and the locally grown material so strongly resembles Virginian-grown tobacco that it is readily absorbed by the trade. In view of the large grants which have been made from the Treasury towards the cultivation of small quantities of inferior tobacco in Ireland, it is certainly striking that so much progress has been made in Nyasaland, even without the assistance of a tobacco expert. The claim is made that the possibilities of the Protectorate for tobacco-growing are probably greater than those of any other part of the British Empire.

A useful note on "Thunderstorm Statistics of Egypt" is contributed by Mr. E. W. Bliss to *The Cairo Scientific Journal* for June. The data are summarised from a list of all available records of storms prepared by request of the Cairo Department of Ordnance by the Meteorological Service, and refer chiefly to observations at Abbasia between 1868 and 1912. A table including both slight and severe storms, and also many cases where only lightning was observed, shows that during the above period electrical discharges were experienced on 180 days only. Cases occurred in each month except July, the majority being in October and November, and their rarity bears out a statement previously made that in Egypt thunderstorms are comparatively few in number. Storms accompanied by hail or heavy rain, or which did damage to buildings, only amounted to twenty-eight in the forty-five years, an average of rather more than one in two years. The discharges appear to occur most frequently during the evening hours.

The Canadian Department of the Naval Service, Ottawa, has issued a useful pamphlet on "The currents in the entrance to the St. Lawrence," from investigations of the tidal and current survey in the seasons of 1895, 1911, and 1912. The most modern methods were employed in the investigation; the temperature and density of the water, and complete meteorological observations were also taken. Between the Gaspé coast and Anticosti the currents present a complete contrast in their behaviour; on the one shore there is a current flowing always in the same direction. while on the other the set is weak and continually veering. One of the chief endeavours has been to reduce these currents to law, and in the case of the Gaspé current it has been largely successful. Although the veering currents are weak, and at times irregular, it has been possible to prove that the tide has a dominating influence upon them, and that their directions during flood and ebb are fairly definite as a rule. The features of both currents are discussed in considerable detail.

The July number of *Himmel und Erde* contains the address delivered by Dr. M. Laue on taking up his professorship at Zürich in December last. Naturally, it deals with the new field of research opened up by his own experiments on the reflection of Röntgen rays by crystals. From the results obtained by himself, and by others who have repeated his experiments, he concludes that the wave theory of the constitution of Röntgen rays is in much closer accord with the facts than the form of emission theory advocated by Prof. Bragg. The difficulties in the way of its general acceptance are not greater than those with which the wave theory of light has to deal, and the rejection of the wave theory in one case would necessitate its equal rejection in the other.

In a paper read before the American Institute of Electrical Engineers in March last, Mr. C. Fortescue showed how the excessive concentration of electrical stress which is to be found at certain parts of the insulation of electrical apparatus could be replaced by a uniform stress of much smaller amount. A short account of the electrostatic theories which underlie Mr. Fortescue's method is given by Prof. W. S. Franklin, of Lehigh University, in the July number of the Journal of the Franklin Institute. Prof. Franklin shows that the two propositions—an equipotential surface may be to any extent replaced by a thin metal sheet without disturbing the field, and a closed metal shell screens its inside from outside effects—form the basis for most of the devices suggested. Taking the field round a charged wire or that between two charged wires as his starting point, he builds up by simple processes the most important practical cases. His paper concludes with a warning against the frequent use of the idea of potential in cases in which the simpler one of the electric field will give all the required information.

OUR ASTRONOMICAL COLUMN.

THE ORIGIN OF SOLAR ELECTRICITY.—Among the many interesting papers concerning astrophysical matters which appear in No. 8 of the *Monthly Notices* of the Royal Astronomical Society, attention may be directed to a convincing contribution to our knowledge of the agencies originating the vast solar electrical phenomena demonstrated by the brilliant researches effected at Mount Wilson. In a paper under the above title Dr. J. A. Harker applies the results of laboratory work conducted in collaboration with Dr. G. W. C. Kaye at the National Physical Laboratory to the explanation of cosmical phenomena. This experimental work has shown that at very high temperatures the vapours in the tube resistance furnace become highly conducting, and that under the same condition most refractory substances emit electricity carried by particles many times the mass of an atom of the substance. Calculations show that the measured emissivity of carbon at about 3000° C. would be ample to account for solar currents of magnitude sufficient to give rise to the intense magnetic fields Professor Hale has shown to be probably found in sun-spots.

THE TRUE FORM OF THE EARTH AND ITS INTERNAL CONSTITUTION.—Dr. A. Veronnet contributes a discussion of these subjects to No. 13 of the *Revue Générale des Sciences*. It is now known that this "somewhat irregular round body" on which we live has a rough sort of tetrahedral shape, but mathematicians must have a more generalised form, and thus for them the geoid is an ellipsoid of rotation of which the inverse of the eccentricity is about 297. Dr. Veronnet criticises the various formulæ which have been suggested to represent the hypothetical generating curve, and has himself proposed a new one. By considering the effect of variations of density and velocity of rotation limits are determined for the above-mentioned ratio, and it is shown that if the above value, found by Helmert, is supported, then the earth rotates as one piece. The author is also led to make some interesting conclusions regarding the effect of tides and causes of earthquakes.

COSMOLOGICAL HYPOTHESES.—At the Science Congress held at Lourenço Marques, Mr. R. T. A. Innes, of the Transvaal Observatory, dealt with this subject, and added one hypothesis more which he referred to as "the explosion hypothesis." He assumes that matter will not indefinitely submit to continued reduction of volume under indefinitely increasing gravitational pressure, but that a time will come when this pressure will "break into the atomic structure of its matter and cause explosions." By such explosions the sun threw off the planets and the latter their satellites; in other stars they caused the formation of multiple systems; new stars are due to the eruptive outbursts accompanying the explosions, and when on a smaller scale and rhythmical they are responsible for the phenomena of variable stars. Mr. Innes, we may remark, has shown an inexplicable eclecticism in choosing his foundation facts; for example, he has ignored the harmonious results obtained by modern workers on the temperatures of the individual stars, but has selected a contrary opinion to the effect that solar type stars are hotter than the white stars.

MAGNETIC SURVEYS.[1]

THE introduction tells us that this is the first of a series of volumes to be published dealing with the researches of the department of terrestrial magnetism of the Carnegie Institution of Washington, founded in April, 1904. These volumes, while principally on terrestrial magnetism, will contain memoirs on allied subjects, such as atmospheric electricity. The present volume treats of all the magnetic observations made *on land* by the department from the beginning of its observational work in 1905 up to the end of 1910. These observations are directed towards the accomplishment of one of the principal objects which the department has in view, viz. the acquisition of the data necessary for a general magnetic survey of the earth.

The first fifty pages deal with the general methods of work, the selection and description of stations, and especially with the field instruments and the taking and reducing of observations. The observational instruments—magnetometers, dip circles, and dip inductors—and auxiliary apparatus are handsomely illustrated in plates 2 to 6. Much experience of field-work has accumulated of late years at Washington, and the instructions to observers merit the careful attention of all interested in survey work. Pp. 51–6 introduce us to the results of the observations, which are chronicled in the later part of the volume. On p. 53 is a list of thirty-five observers whose work is included. Amongst them are several eminent foreigners, including Prof. Palazzo, of Rome, and Profs. Beattie and Morrison, of South Africa, who have observed for a time under the auspices of the Carnegie Institution. The stations observed at number almost 1300, of which more than 1200 are outside the bounds of the United States.

Of the continents, Africa shows the largest number of stations, 386, the great majority of which were occupied in 1907 and 1908 by Profs. Beattie and Morrison. Of the 328 stations in North America, 189 were in Canada or Newfoundland, fifty-nine in Central America, and nine in Greenland. In Asia there were 308 stations. Of these 142 were in China—occupied mainly by Messrs. Edmunds and Sowers—thirty-seven in Persia, thirty-two in Russian and eighty-one in Turkish territory. The observations in Asiatic Turkey were due mainly to Mr. Sligh, but partly to Mr. J. C. Pearson. The latter gentleman seems to have taken all the observations in Persia and in Asiatic and European Russia, and most of those in Egypt. He also observed in Canada, in European Turkey, at Pola, Potsdam, and Kew Observatories, and was amongst the crew of the surveying ship *Galilee*, who observed in Japan, Australia, and New Zealand. His experiences as a traveller should be of interest. Of the remaining stations, 111 were in South America, and 119 in numerous islands in the Pacific and Atlantic Oceans.

The tables of results, pp. 58–100, give for each station the geographical coordinates, the date and hours of observation, the observed values of magnetic declination, inclination, and horizontal force, the instruments used, and the observer's initials. Pp. 101–120 contain interesting extracts from the reports made by the several observers. The rest of the volume is occupied by minute descriptions of the stations, to facilitate their identification. An artistically attractive feature is the reproduction in plates 1 and 7–10 of a number of fine photographs, showing a selection of the stations occupied or scenes in their neighbourhood.

[1] "Researches of the Department of Terrestrial Magnetism. Land Magnetic Observations 1905–10." By L. A. Bauer, Director of the Department. Pp. 185+10 plates. (Washington, D.C.: Published by the Carnegie Institution of Washington, 1912.)

The work is a striking example of what can be done when scientific zeal and business capacity have behind them resources such as those of the Carnegie Institution. Dr. Bauer and the staff of the department of terrestrial magnetism—both those who took the observations and those who did the necessary office work—are to be congratulated on the progress made towards the achievement of one of their principal objects of ambition, a general magnetic survey of the globe.

C. CHREE.

ADVANCE IN ECONOMIC ENTOMOLOGY.

A NOTABLE feature of recent biological research is the attention paid by medical experts to the study of insects. Capt. F. W. Cragg, of the Indian Service, has lately published two Scientific Memoirs (Nos. 54 and 55) of the Medical and Sanitary Departments of the Government of India, which are of importance to students of the anatomy of Diptera. Both memoirs deal with blood-sucking species, No. 54 with *Philaematomyia insignis*, and No. 55 with *Haematopota pluvialis*. The excessively small number of males of the latter fly is believed by Capt. Cragg, after examination of the genitalia of the female insect, to be explained by heavy mortality as the result of pairing. We notice that the bibliography of this paper contains some remarkable misprints, of which "Verh. yool-bat. Gas. Wein" is worthy of record as a piece of unconscious humour! The last published part of the Bulletin of Entomological Research (vol. iii., part 4, December, 1912) contains valuable systematic papers on blood-sucking Diptera, by Mr. E. E. Austen and Prof. R. Newstead, and some very useful diagnoses of the larval stages of African mosquitoes, by Messrs. F. W. Edwards and A. T. Stanton.

The same number of the bulletin is noteworthy for a suggestive paper by Dr. J. Dewitz on the bearing of physiology on economic entomology. The author points out, for example, the importance of a precise knowledge of the effect of stimuli due to light of varying intensity and wave-length if luminous traps for destructive moths are to be used to the best advantage. Temperature is also found to be a factor in the working of this reaction; "the colder the night the fewer the females (and in particular females with eggs) that are caught by acetylene trap-lamps."

In a lately issued bulletin (Entomology, No. 113) of the U.S. Department of Agriculture, Messrs. W. D. Hunter, F. C. Pratt, and J. D. Mitchell describe the principal cactus insects of the United States. The "prickly pears" (Opuntia) are well known as furnishing food and habitation for the cochineal insect; since the decline of the cochineal industry, however, these plants were regarded rather as noxious weeds until the recent recognition of the fact that they furnish valuable fodder for cattle. Insects which injure them are therefore regarded as economically important, and in this short memoir a number of species of various orders are described and figured.

Some very important observations are contained in a small bulletin (No. 203) issued by the Maine Agricultural Experiment Station in 1912. Miss Edith M. Patch has apparently shown that the aphid causing "leaf-curl" on the elm (*Schizoneura americana*) migrates in spring to the apple and other Rosaceæ, and becomes the parent of the aërial colonies of the notorious woolly aphid, *S. lanigera*. The elm is thus the normal host of the sexual forms in autumn, and the apple is to be regarded as an "intermediate" host. The extreme rarity of sexual forms of *S. lanigera* on apple in these countries may perhaps be explained by a similar unsuspected migration here, though our native elm "leaf-curl" aphid (*Schizoneura ulmi*) is generally regarded as distinct from *S. americana*, and identical with the polyphagous root-feeding form, *S. fodiens*.

The gipsy moth (*Porthetria dispar*) and the brown-tail moth (*Euproctis chryssorhoea*) are well-known examples of European insects which, having been introduced into America, have become there very serious pests. From among the voluminous writings of forest entomologists on these species, one or two recent papers are worthy of especial notice. A. F. Burgess gives an account (U.S. Dept. Agric., Entom. Bull. 119, 1913) of the means by which the gipsy moth extends its range. On account of the excessive weight of the female's body, she is unable to fly, though provided with wings, and the spread of the insect from place to place is carried on mostly during the larval stage. The caterpillars are often artificially though unwittingly transported by farm carts, and it appears that one generally unrecognised evil result of automobile traffic is that these destructive insects are carried far more widely and rapidly than formerly by the passage of motors along main roads which are bordered by infested woods. The young larvæ, however, are provided with a natural means of dispersal in form of long hairs, which enable them to be carried by wind for considerable distances. Some ingenious experiments on this subject have been made by erecting tall platforms provided with traps in which the little caterpillars are caught on their aërial journeys.

As these destructive insects were introduced from Europe, the American entomologists have naturally tried the experiment of importing some of their natural enemies, and an exhaustive report on this subject has been published by Dr. L. O. Howard and W. F. Fiske (U.S. Dept. Agric., Entom. Bull. 91, 1912). To summarise the mass of material in this bulletin is impossible, but the magnitude of the work undertaken may be judged from such a fact as that 11,000 egg-clusters of the brown-tail moth were imported from Europe in the autumn of 1906, and 40,000 specimens of a single species of hymenopterous egg-parasite, *Pteromalus egregius*, reared from these were turned out in New England woodlands during the succeeding spring. Many valuable bionomic details with regard to the parasites are recorded, and reference is made to attempts—successful or otherwise—to introduce predaceous enemies of other harmful insects into countries where the latter have themselves obtained a foothold. A short special paper on a cognate subject is R. S. Woglum's report on a trip to India and the Orient in search of the natural enemies of the Citrus white-fly (*Aleyrodes citri*); this forms Bull. 120 of the Entomological Bureau of the U.S. Dept. Agric.

A much-needed systematic monograph of the "white-flies," or "snowy-flies" (Aleyrodidæ) is commenced by A. L. Quaintance and A. C. Baker in the Technical Series, No. 27, of the same bureau. These insects are allied to the Coccidæ and Aphididæ, but have received far less attention from entomologists than those two families. In the work now begun their structure, classification, and bionomics are dealt with as fully as possible in the present state of knowledge; ultimately the authors think that the family may prove as rich in species as the Coccidæ or Aphids.

Another valuable systematic paper of economic interest is Prof. M. Bezzi's memoir on Indian Trypaneids, or fruit-flies (Memoirs Indian Museum, vol. iii., No. 3, 1913). These are small Diptera included in what used to be known as the "acalypterate" series of the Muscidæ. The careful, systematic study of such insects is of importance, and Dr. Annandale, the director of the Indian Museum, is to be congratulated on having obtained the help of such an eminent European student as Prof. Bezzi, of Turin.

The Imperial Bureau of Entomology begins this year to supplement the Bulletin of Entomological Research by a *Review of Applied Entomology*, issued in two series—A, Agricultural, and B, Medical and Veterinary. Containing records of recent literature, with full summaries, these publications cannot fail to be valuable to students of insect life.

G. H. C.

METEOROLOGICAL REPORTS.

We have received the meteorological observations made at the Hamburg Astronomical Observatory for 1910–12. This institution was established in the town of Hamburg in 1825, and was for many years under the able superintendence of Dr. Rümker; it is now situated at Bergedorf, 19 km. E.S.E. of its former position, and is under the superintendence of Dr. Schorr. Very complete and careful observations are made five times daily; the amount of cloud is also given for each hour between 6h. p.m. and 6h. a.m. The sunshine is recorded by Campbell-Stokes (burning) and Jordan (photographic) instruments. The average annual difference in the possible percentage for 1910–12 is 6·7 in favour of the Jordan recorder. Although the observations are not strictly comparable, we should not have expected so much difference. An interesting comparison of temperature and humidity in English and French screens is made with the readings of an Assmann's aspiration psychrometer. The hourly means of temperature in both screens are generally higher than those of the psychrometer; the greatest differences occur in daytime, especially in the French screen (open at bottom), but at the 9h. p.m. observation the reverse obtains. Humidity in the screens is generally higher than the readings of the psychrometer, especially during summer.

The report of the Sonnblick Society for the year 1912 contains the results of the meteorological observations on the summit of the Sonnblick, Salzburg (3105 metres), for twenty-five years, 1887–1911, prepared by Hofrat Dr. J. v. Hann. The mean monthly temperatures were:—January, $-13·3°$ C. (February, $-14·0°$); July, $0·9°$; year, $-6·6°$; mean of absolute extremes, $9·5°-29·7°$. Mean yearly precipitation, 1715 mm., on 216·7 days. Fog was observed on 251·5 days. The mean yearly sunshine was 1496·9 hours, being 35 per cent. of the possible amount. The duration of sunshine varies greatly in different years; September, 1895, had 241 hours, August, 1896, only eighteen hours! November and January have relatively the most sunshine, May and June the least. Winter and late autumn are the brightest seasons, April to June the dullest months. Among other useful summaries contained in the report we may mention the observations at the summit of the Donnersberg, Bohemia (835 metres), for the years 1905–9. The observatory is attached to the German University at Prague, under the direction of Prof. R. Spitaler.

The report and meteorological observations at the Royal Observatory, Hong Kong, for the year 1912 have reached us; the results have been carefully prepared by Mr. T. F. Claxton, formerly director of the Mauritius Observatory. The tables include hourly values of the principal elements, five-day means, and results of magnetic observations. The mean annual air-temperature, 71·9°, was about normal; maximum, 92·5°, in September; minimum, 45·3°, in December. The rainfall, 63·9 in., was about 20·5 in. below the average. The colony was not actually visited by a typhoon, but the tracks of those and of the more important depressions which occurred in the Far East during the year are shown on two plates. A weather map and reports from about forty stations are issued daily; the forecasts drawn from these data for various districts show a very high percentage of success. A large amount of data is extracted from ships' logs; this is utilised in determining typhoon tracks, and to some extent for the eventual publication of pilot charts of the Pacific for the area 9° S. to 45° N. latitude, and 100° to 180° E. longitude, divided into two-degree squares.

HORTICULTURAL INVESTIGATIONS AT THE WOBURN EXPERIMENTAL FRUIT FARM.[1]

In a flower, such as that of an apple-tree, there is a tubular structure in the centre, forming the female portion of the flower, and that is surrounded and overtopped by a number of rods, bearing at their extremities sacs of pollen, this constituting the male element. When a grain of pollen, either of the same or another flower, enters the central tube, or pistil, fertilisation occurs, and a seed, or pip, begins to form near the base of the pistil. As it develops, the woody substance surrounding it, which is really a portion of the stalk of the tree, gradually swells to a remarkable extent, and eventually forms the fleshy or edible portion of the fruit. We commonly call it the fruit, but it is only a metamorphosed portion of the mother-tree: the real fruit of the tree, the progeny of male and female elements, is the pip. When this is sown in the ground, it germinates, and eventually forms a new tree, which, though probably showing some resemblance to its two parents, will be a new variety, and will not bear apples of the same sort as the mother-tree. One reason which makes it all the more improbable that a pip will give rise to a tree bearing fruit like that of the mother-tree, is that in many cases the female portion of the flower cannot be fertilised except by pollen from a tree of a different variety.

As it is impossible to reproduce a fruit-tree of any given variety from seed, other methods of multiplication must be adopted, namely budding or grafting. A young tree of a similar character is taken (the stock), and in the one case a bud, or in the other case a twig (scion), from the tree to be propagated is united with the stem of the stock. All the growth arising from this bud, or buds, is similar to that of the tree from which it was taken; the stock acts as little else than a channel for conveying nourishment to the ingrafted buds; yet it does exert a certain influence on the character of the growth of scion. For apples we use two classes of stocks; the one, the crab stock, is obtained by sowing the seeds of crab-apples, and is characterised by forming a scanty number of roots, but these are stout, and have a tendency to obtain deep hold of the ground; the other, the paradise stock, is derived from a French variety of apple, and forms a much larger number of roots, but smaller, and tending to spread out near the surface of the ground. The grafted tree partakes of the character of the roots of the stock; on the paradise stock it becomes more spreading in its habit, and grows less vigorously than on the crab stock, and, whilst the former is more suitable for growing trees in the bush form, the crab stock is more suited for standard trees.

In the case of pears, the corresponding stocks are: the pear stock for standard trees, and the quince stock for bush trees.

It must be remembered, however, that the effect of the stock on the growth of a tree is a subsidiary

[1] From a discourse delivered at the Royal Institution on Friday, February 21, by Mr. Spencer U. Pickering, F.R.S.

matter; the characteristics of the growth are mainly dependent on the nature of the scion.

During removal of a tree from the nursery to the plantation many of the roots are destroyed, and nearly all of them are injured. The seat of growth of a root is situated at the extreme tip of the root, the power of multiplication being confined to a few meristematic cells which are centred there, these being protected only by some layers of outer cells, known as the root-cap, which are continually being rubbed off and reproduced from the meristematic cells, as the root forces its way through the earth. The whole root-tip is very minute, and when it is destroyed, growth becomes impossible; but there are certain cells situated at intervals along the roots which are capable of becoming modified and giving rise to new root-tips, just as there are cells in the branches capable of developing into buds if all the visible buds of a tree are destroyed.

When a tree is removed from the soil, most of the root-tips will inevitably be broken off, and the rest will become dried up by exposure to the air, so that the damage to the roots must be serious. But the well-being of a tree depends on the balance between roots and branches, both of which supply certain, but different, elements necessary for growth, and this serious damage to the roots can only be counterbalanced by damaging the branches to a corresponding extent. This is done by severely pruning the branches, cutting them back, as it is termed, to about one-third of their length. The effect of omitting this operation is often disastrous; the tree may become permanently stunted, and even, in the case of plums, which tend to bear heavily after moving, it may be fatal.

Though good horticulturists agree as to the necessity of cutting back after transplanting, they differ as to the time when this should be done. The results of our experiments on a large number of trees show that the time of cutting back makes little difference to the ultimate size of the tree, so long as it is not performed while the tree is in active growth. If it is done in the summer, however, the tree receives a serious check, from which it does not recover for at least the next seven years. Deferring the cutting back until the following winter does not give the tree any such check as regards its growth, but it affects its fruiting. Such deferred cutting back is generally followed in the second year by vigorous growth, the tree making up for the absence of growth during the first year, and it perseveres in this habit of growing in subsequent years, when it ought to be growing and fruiting as well.

Passing on to the question of the annual pruning of a tree; it is a common belief that the more you prune a tree the more it will grow. It seems fairly obvious that, even if true at all, this must be true only within certain limits; and, as applied to young, freely growing trees, it appears to be quite untrue. Various plantations of similar trees at Woburn have been systematically pruned to different extents during the seventeen years since they were first planted, and the photographs of average specimens from these plantations are sufficient to show that, as regards the general size, the trees which have never been pruned are larger than those which have been pruned moderately, and these again are larger than those which have been pruned hard. What may be noticed as to the latter is that it is a sturdier tree than that pruned moderately, the trunk and main branches having gone on swelling, while the extension of the branches was prevented by the severe pruning. On the other hand, the unpruned tree, as might naturally be expected, is somewhat straggly and not well shaped.

Another experiment will illustrate the extent to which pruning is opposed to growth. Four strictly similar twigs, 36 in. long, were selected on the same tree: one was not cut back, the others were shortened to 24, 12, and 6 in., respectively. At the end of the following season the weight of these twigs (taking the average of many series) was in the proportion of 562 : 310 : 178 : 100, and from every point of view the growth of the twigs had been greater in proportion as they had been less pruned (Fig. 1). In addition to this, it was found that there were more fruit-buds, and, therefore, a greater promise of fruit, the less the twigs were pruned; the relative proportions of fruit-buds in these cases were 314 : 238 : 165 : 100. That this promise is actually fulfilled in practice is proved by the records of the crops borne by plantations of similar trees which have for many years been pruned to different extents. In one case these plantations contained three different varieties of apples; it was found that during the first five years, and also during the second five years, the unpruned trees bore twice as much, and the hard-pruned ones little more than half as much, as the trees which had been pruned moderately. These trees were on the paradise stock; but the same was found to be the case with apples on the crab stock, for we have another plantation where 117 different varieties of apples are grown, four trees on the one stock, and four on the other; in each case one-half of them have been pruned lightly, and one-half heavily, and in both cases the crops from the latter have been less than one-half of those from the former.

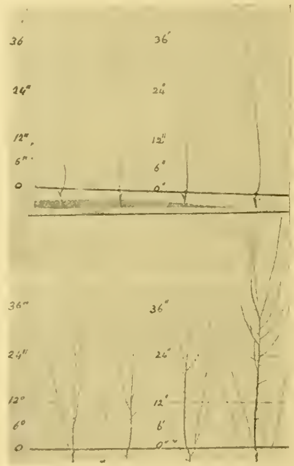

Fig. 1.—Four similar shoots cut back to different extents, showing the different growth made by them.

What has surprised us is that the heavier crops in these cases have not been accompanied by any serious diminution in the size of the individual fruits.

It is thus established as a fundamental principle, that the less pruning there is, the more will a tree grow, and the more fruit will it bear. But this does not mean that we should dispense with pruning altogether. The chief object in training a young tree is to make it sturdy and well-shaped, so that it will be capable of bearing a heavy crop when it comes to full maturity; to effect this, the extension of the branches must be checked so as to give the stem and main branches time to fill out, and occasionally a branch will have to be removed altogether, either to admit light and air into the tree, or to prevent it rubbing against other branches. To what extent this pruning should be carried, and for how long it should be continued, must depend on the habit of the tree. Instances of injury through the absence of pruning may be seen in nearly any farm orchard throughout the country; but examples of over-pruning are almost as general, and are to be found in most private gardens, where the stunted trees throw out every year thickets of twigs, serving no other purpose than that of feeding the bonfire.

Besides the annual branch-pruning there are other operations included under the term pruning, but the only one to which I can now allude is root-pruning. In this the roots are unearthed and cut back, with the view of increasing the fruitfulness of the tree. The check which such an operation gives to the growth is very severe, and if carried to excess, will kill the tree entirely. It is evidently one which should be undertaken only in very exceptional circumstances, such as where the tree is showing rampant growth, and will neither flower nor fruit. We hear little of root-pruning except in private gardens, and we should scarcely ever hear anything of it there if a more rational system of branch-pruning were adopted. When the branches are cut away to an excessive extent, the balance between branch and root can only be restored by cutting the roots away too. But to injure the tree in one way, and to attempt to correct matters by injuring it in another way, is not a very intelligent procedure.

Passing to the problems connected with the transplanting of a tree; during this operation many of the old root-tips are torn off in lifting the tree, but others are killed by becoming dried up on exposure to the air. Some exposure is always inevitable, and in most cases several days elapse between the lifting and the planting of a tree. It is of great importance, however, that this exposure should be reduced to the narrowest limits. A number of trees were lifted at Woburn, and some of them were replanted at once, whilst others were left in a shed for four days before doing so, and it was found that the latter made only four-fifths as much growth as the former during the following season. It is on this account that planting trees in the spring should be discountenanced, as drying winds are then more prevalent; but if this drying effect is avoided, it is immaterial when the planting is carried out: similar trees planted at different times between November 28 and March 3 were found to do equally well.

Much stress is always laid by horticulturists on the importance of selecting trees with a good supply of fibrous roots, and of taking the utmost care of these roots, spreading them out, and shaking the earth lightly between them. But such precepts are based on ignorance as to the principles of root-growth. Nine-tenths of these roots have lost their tips, they are useless, and as good as dead, for they certainly will die in a very short time. Anyone can satisfy himself on this point; it is only necessary to mark a few of these roots by tying strands of silk round them, and on lifting the tree again at the end of the season it will be found that the rootlets have all, or nearly all, died, and that in their place a new system of rootlets has arisen from the thicker portions of the older roots. In fact, we have found that trees do better if the smallest of the fibrous roots are removed before planting, and also if all the roots are shortened to a certain extent. The reason of this is, not only that it is well to remove parts of the tree which are bound to die, but that the new rootlets which form will be more vigorous if they originate from the thicker portions of the old roots, where the store of material for their nourishment is greater. The practice of leaving the roots as long as possible, and carefully trimming their ends, is quite a mistaken one, for the ends of these roots, having lost the root-tip, cannot start into growth again, and it has been found that of the new rootlets which originate, only some 15 per cent. arise from the neighbourhood of the ends of the old roots, the rest originating from higher up towards the stem, or even from the stem itself.

Two other conclusions may also be drawn from what has been mentioned, namely that it can make little or no difference to the future welfare of the tree whether the ends of the old roots are trimmed, or left jagged and torn as they are when removed from the nursery, nor whether these roots are carefully spread out in the ground, instead of being huddled into the hole prepared for them; for it is the new rootlets which are to be formed, and not the old ones, on which the future life of the tree depends. Both these conclusions have been verified by actual experiment. Even when the roots were twisted and tied together in a bundle, the tree did just as well as when they were spread out in the orthodox fashion.

It is thus seen that all these practices which are supposed to be essential to the proper planting of a tree are really immaterial, and, in fact, that the violation of them within certain limits is beneficial. But the benefit was not sufficient to explain certain results which we obtained, and which puzzled us for many years. We had made a plantation in which, by way of demonstration, the trees had been planted in violation of all the accepted canons, and we expected that these trees would afford an awful lesson to the careless planter. But instead of that, they flourished rather better than their carefully planted neighbours. The results were naturally set aside as accidental, and a repetition, and subsequently many repetitions, were made; but the roughly planted trees refused to behave badly, and flourished so much more than their neighbours that they often showed two or three times more growth than these did. The principal cause of this was eventually traced to the fact that the soil round these trees had been heavily rammed at the planting, instead of being shaken over the roots and merely pressed down. When we consider that the welfare of the transplanted tree depends on its sending out new rootlets from the old roots, it is evident that anything which brings the soil into intimate contact with these roots will be beneficial, and ramming the soil down, especially if it is in a wet condition at the time, will do this more effectually than could ever be done by the gentler method of planting. These somewhat surprising results, therefore, receive a simple explanation, and it is easy to satisfy ourselves, by lifting the trees at the end of a year, that the rammed trees have actually formed more new roots than those carefully planted. Such novel methods of planting naturally excited the wrath of horticulturists, who, as a body, are inclined to carry the veneration for traditional procedure to excess, and we were careful to obtain overwhelming evidence as to the facts before publishing our results. Some seventy sets of experiments were made, in which about 2000 trees were used; the soils in which the trees were planted being of every variety, and situated in eight different counties. Naturally, the results varied, but the average of them showed that ramming might be expected to increase the growth of the tree by nearly 50 per cent., during the first or first two years, at any rate in heavy or fairly heavy soils. In a light sandy soil it naturally had no effect, for the obvious reason that, by the time the tree started into growth, any consolidation of the soil caused by the ramming would have disappeared. In one case only were the results of ramming very bad, and that was in the London clay, where the absence of aëration caused sulphuretted hydrogen to be developed. In other clay soils, no such results ensued (the Woburn farm itself is on the Oxford clay).

That trees will not flourish unless the soil in which they are growing is sufficiently aërated, is well known.

And this is the reason why a tree, when planted, should not be buried deeply in the soil; but a latitude of a good many inches in the depth at which it is planted has been found to make no difference, because the new roots, on which the life of the tree depends, form most readily at whatever depth is most suited to their development, or if they form at other depths, they soon make their way to the most favourable level.

The fact that roots flourish best at some particular level not far below the surface (the depth varying in different soils) is the explanation of some results which appeared to show the exact contrary. A number of paradise stocks were planted with their roots at various depths from 6 to 24 in. below the surface, and it was found that those which had been buried deepest, although they were the most backward at first, rapidly outstripped the others, and in two years had made twice as much growth as these had done. On lifting the trees the reason of this was apparent; in the case of those which had been planted at the ordinary depth, the root-system of the trees was the same as that which they had possessed when planted, though more developed (Fig. 2), whereas, with the buried trees, the original roots, finding themselves at an unsuitable depth, had not developed, but in their place numerous fresh roots had developed from the stem of the tree itself (Fig. 3), and these, finding ample food-material stored in the stem, had developed strongly, and formed a vigorous root-system, with the natural accompaniment of vigorous branch growth. Such results, depending as they do on the ability of the tree to send out new roots from its stem, would not be obtained if a grafted tree were buried in the same way, for roots do not easily arise from the stem of such a tree; indeed, when the experiment was made with crab-stocks instead of paradise-stocks, the results were unfavourable, for the crab-stock does not root so easily from the stem as does the paradise-stock. Thus, these experiments are the reverse of showing that an ordinary fruit-tree should be planted at a great depth.

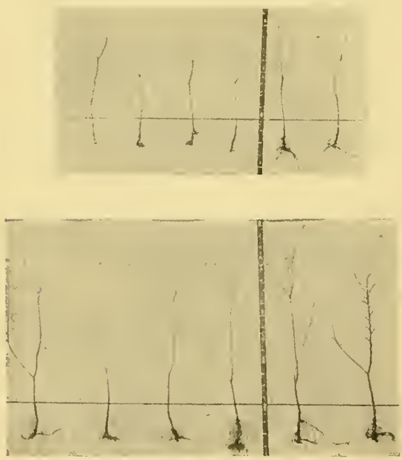

FIG. 2.—Apple stocks planted 6 inches below the surface, and lifted two years afterwards.

It will be seen that all the anomalous results which have been obtained on the subject of planting are easily explained by, and are the natural consequences of, the fact that a tree when transplanted has to form a new root-system before it can begin to grow again, and if this is but kept in view, the whole subject becomes simplified, and the reason becomes evident why many of the practices supposed to be essential to the proper planting of a tree do not bear the test of actual experiment.

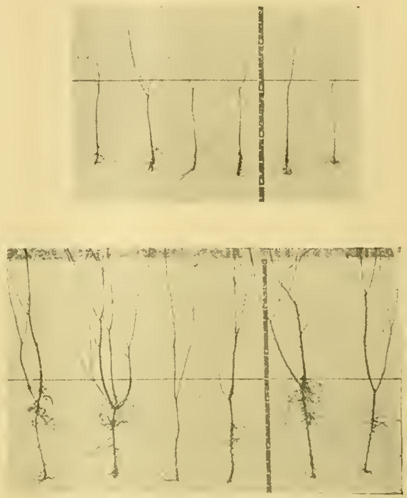

FIG. 3.—Apple stocks planted 24 inches below the surface, and lifted two years afterwards.

EXPLORATIONS AND FIELD-WORK OF THE SMITHSONIAN INSTITUTION IN 1912.

FOLLOWING the custom established in 1911, the Smithsonian Institution has issued an illustrated pamphlet dealing with the scientific expeditions conducted under its direction, or in which its representatives participated. The pamphlet describes the work of about twenty different parties.

The institution was represented by two small parties in Borneo—those of Mr. H. C. Raven, who has been collecting mammals and ethnological material in Dutch East Borneo for the past two years, and Mr. Daniel D. Streeter, of Brooklyn, N.Y., who has served as a collaborator for the National Museum in the collecting of mammals, in a trip through Sarawak and Dutch Borneo.

Dr. W. L. Abbott, who financed the Dutch East Borneo Expedition under Mr. Raven, and has presented many large collections to the National Museum, has been carrying on a personal investigation in Cashmere, where he has been trapping and studying the smaller mammals of that country, specimens of which have been sent to the museum.

Through the invitation of Dr. Theodore Lyman, of Harvard University, the institution was enabled to cooperate with the Museum of Comparative Zoology in an expedition to the Altai Mountains of Siberia and Mongolia. Mr. N. Hollister represented the National

Museum. The party spent nearly five months in the field, returning with fine series of mammals and birds from this little-known part of Central Asia. Of especial interest in the series of big-game are four rams of the largest known of the wild sheep, as well as specimens of two forms of ibex, and a gazelle. Out of a total of about 650 mammals in the collection, eleven forms are new to science, and some twenty were not previously represented in the National Museum. Mr. George Mixter also visited Siberia, where he secured certain mammals from the region about Lake Baikal, among them bear and seal.

Of particular interest was a trip made by Dr. Ales Hrdlička to Siberia and Mongolia, to study the physical anthropology of the natives. His main object was a search for data concerning the race which is supposed to have peopled America. He gathered extensive information and collections, from which he draws the conclusion that there exist in several places in Siberia, Mongolia, and Tibet numerous remains of an ancient population which was physically identical with, and in all probability gave rise to, the American Indian.

The hunting trip carried on by Mr. Paul J. Rainey in British East Africa, in which the institution was represented by Mr. Edmund Heller, was very successful; nearly 4000 mammals, 1000 reptiles, and 400 birds were obtained, as well as many land shells and botanical specimens. From the collection, which supplements that of the Smithsonian African Expedition, there have been as many as forty new species and twelve new genera described.

The Astrophysical Observatory of the Smithsonian Institution again sent an expedition to Bassour, Algeria, for the continuation of the observations relative to the heat of the sun, an investigation on which the observatory has been working for the past seven years, with observing stations on Mt. Wilson, California, and during two seasons in Algeria. Mr. Abbot, the director of the observatory, states that the results of the work of 1911 and 1912 thoroughly establish the supposed variability of the sun.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—The scheme for the administration of the East London College, a school of the University of London in the faculties of arts, science, and engineering, was sealed by the Board of Education on August 15. It establishes a governing body of nineteen members, nine of whom are representatives of the Drapers' Company, the body from which the college derives rather more than half its annual income; three representatives of the University, one of whom must be a woman, with the principal of the college *ex officio*, two of the Academic Board, which consists of the principal members of the teaching staff, one of the London County Council, and three coopted members. The representatives of the University are Lady Busk, Principal Sir Henry Miers, F.R.S., and Mr. F. D. Acland, M.P., Under-Secretary for Foreign Affairs, who is a member of the Senate of the University.

MR. HAROLD PEALING, Liverpool, has been appointed lecturer in physics in the South African College, Cape Town.

PROF. W. H. YOUNG, F.R.S., has been appointed Hardinge professor of mathematics in the University of Calcutta, for the purpose of organising a new school of higher mathematical thought and research. Prof. Young is retaining his chair in Liverpool University.

WE learn from the Allahabad *Pioneer Mail* that at a meeting of the Bombay University Senate on July 26 Sir Alfred Hopkinson, K.C., until recently Vice-Chancellor of the Victoria University of Manchester, was appointed expert adviser on university teaching to the University for a period of six months.

THE calendar for the session 1913–14 of the Merchant Venturers' Technical College, Bristol, is now available. It will be remembered that the faculty of engineering of the University of Bristol is provided and maintained by this college, which, in addition, includes a secondary school for boys and a comprehensive series of evening classes in science, technology, and commercial and other subjects. The evening courses of work in technology have been arranged to meet the special needs of engineers, men engaged in the building trades in general, carpenters and joiners, plumbers, and painters and decorators. Saturday afternoon classes for miners have been arranged by the Gloucestershire and Bristol Education Committees and are given in the college. In addition special courses of instruction for women in domestic subjects are provided.

THE Education Committee of the Staffordshire County Council has published its "Directory for Higher Education, 1913–14." The booklet contains the regulations of the committee and details of schemes of work in operation throughout the county. Instruction in mining is provided by means of lecturers, whose whole time is devoted to the work, and their assistants. For this purpose the county is divided into two portions, comprising the North Staffordshire coalfields and the South Staffordshire coalfields respectively. Classes in metallurgy and iron and steel manufacture are conducted in accordance with the regulations of the Board of Education and the City and Guilds of London Institute. Classes in pottery and porcelain manufacture have been arranged at Burslem, Hanley, Longton, Stoke, and Tunstall. Boot and shoe manufacture, silk manufacture, horticultural and smaller agricultural industries are each to be taught in suitable centres. The directory also gives particulars of the numerous scholarships awarded by the committee, the holiday courses arranged, and the steps taken to provide suitable technological instruction in the rural districts.

PARTICULARS have been issued by the Royal Horticultural Society with reference to the examinations for the national diploma in horticulture, which, so far as possible, will be held in the latter part of June of each year. The scheme, which has been approved by the Board of Agriculture and Fisheries, sets forth that candidates for the diploma must (*a*) register themselves with the society, and (*b*) pass two examinations, a preliminary and a final. The examinations are open to both men and women. The preliminary examination will be based upon the general principles of plant-growing, an elementary knowledge of botany, chemistry, and physics, so far as acquaintance with these subjects is essential to an understanding of garden practice. Care will be taken to ascertain that the candidate is able to perform the operation of gardening with proper skill, and also that he understands the reasons for the methods employed. The syllabus for the final examination will be divided into sections each dealing with one particular branch of horticulture. Candidates may enter for the branch in which they feel themselves most proficient. All particulars, forms, &c., may be obtained from the secretary of the Royal Horticultural Society, Vincent Square, S.W.

THE calendar of the Royal Technical College, Glasgow, for the coming session contains details of the scheme affiliating the college to the University of

Glasgow. The college retains its autonomy in all matters relating to its internal affairs—finance, appointment of staff, and so on—but it has no representation in the Court of the University. An advisory committee has been set up, consisting of members of the University Court and representatives of the college, which will consider all matters affecting their joint interests. A joint board of studies in the faculty of applied science is provided, and will consider all matters relating to the subjects and standard of the several courses. The degree examinations will be conducted by a board of examiners representative of both institutions, with external examiners appointed by the University Court. Students will be free to attend the classes constituting the courses of study in either the University or the college, or in both, the fees being the same. The combination and coordination of the resources of the University with those of the college should be to the advantage of both. The University of Edinburgh, too, has recognised the day classes of the college as qualifying for its degree of bachelor of science under certain regulations.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 18.—M. A. Chauveau in the chair.—M. **Borrelly**: Notes on Hind's nebula. This nebula is now at a maximum period of brightness.—M. **Aries**: The formula for the velocity of sound. Reply to M. Duhem.—MM. **Massol** and **Faucon**: The presence of absorption bands in the ultra-violet spectrum of some abnormal alcohols of the fatty series. The study of pentane and some derivatives of methylpropane and methylbutane shows that the two absorption bands previously found in the three primary alcohols do not appear in the corresponding hydrocarbons; the halogen derivatives are also free from bands. The aldehydes give one large absorption band intermediate in position between the two alcohol bands.—Paul **Godin**: Free thoracic and abdominal respiration in the course of growth.—De Montessus de **Ballore**: Remarks on the earthquake at Gallipoli, August 9, 1912.
