Page 240 *insert* **METEORIC STONES.** See METEORITES.
,, 517 ,, **PAVEMENT.** See BITUMEN.
,, 628 ,, **PREHNITE.** A hydrous silicate of alumina and lime. See Bristow's 'Glossary of Mineralogy.'
,, ,, ,, **PRESERVED MEATS.** See PUTREFACTION: *Curing of Provisions.*
,, 682 ,, **PYROMORPHITE.** A chlorophosphate of lead. See LEAD.

Bread-fruit order. This is the Indian *jaca*, a native of Southern Asia. Its fibres are employed for many purposes by the natives, and the wood is used for furniture. A yellow dye, derived from the inner bark is employed in India for dyeing the robes of the Buddhist priests.

JACKSONITE. A name applied by Whitney to a mineral from Keweenaw Point, Lake Superior. It appears to be nothing more than ordinary prehnite. See PREHNITE.

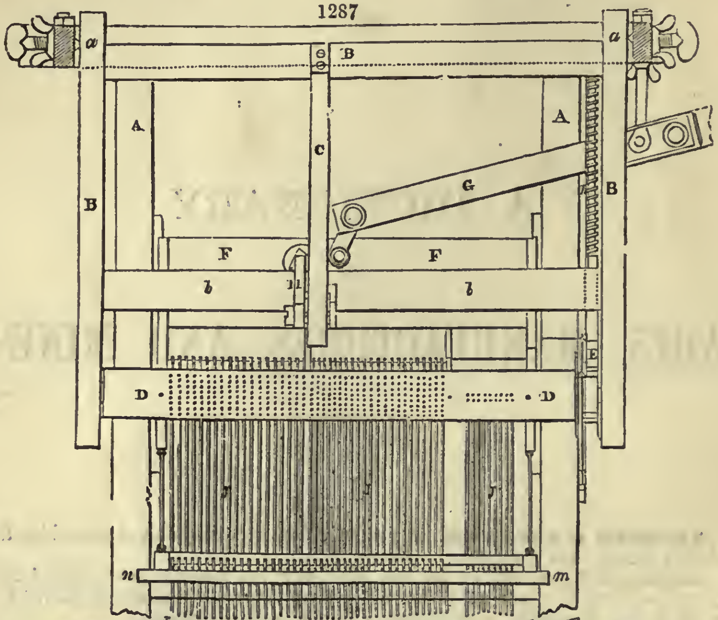
JACQUARD-LOOM. A peculiar and most ingenious mechanism, invented by M. Jacquart of Lyons, to be adapted to a silk and muslin loom for superseding the employment of draw-boys, in weaving figured goods. Independently of the ordinary play of the warp threads for the formation of the ground of such a web, all those threads which should rise simultaneously to produce the figure, have their appropriate healds, which a child formerly raised by means of cords, that grouped them together into a system, in the order, and at the time desired by the weaver. This plan evidently occasioned no little complication in the machine, when the design was richly figured; but the apparatus of Jacquart, which subjects this manœuvre to a regular mechanical operation, and derives its motion from a simple pedal put in motion by the weaver's feet, was generally adopted soon after its invention in 1800. Every common loom is susceptible of receiving this beautiful appendage. It costs in France 200 francs or 8*l*. sterling, and a little more in this country.

Fig. 1287 is a front elevation of this mechanism, supposed to be let down. *Fig.* 1288 is a cross section, shown in its highest position. *Fig.* 1289, the same section as the preceding, but seen in its lower position.

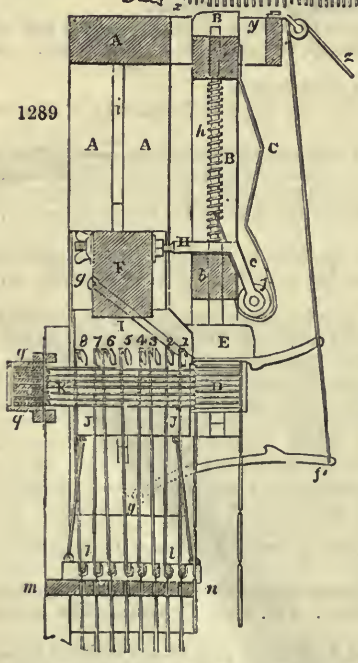
A is the fixed part of the frame, supposed to form a part of the ordinary loom; there are two uprights of wood, with two cross-bars uniting them at their upper ends, and leaving an interval x y between them, to place and work the moveable frame B vibrating round two fixed points *a a*, placed laterally opposite each other, in the middle of the space *x y*, *fig.* 1287.

C is a piece of iron with a peculiar curvature, seen in front, *fig.* 1287, and in profile,

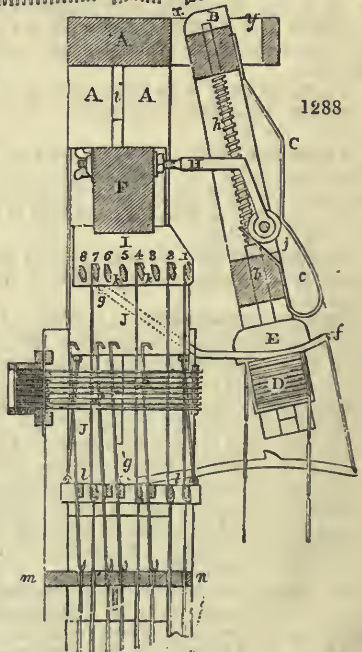
1287



1289



1288



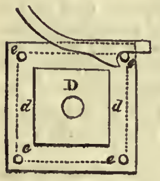
figs. 1288 and 1289. It is fixed on one side upon the upper cross-bar of the frame B, and on the other, to the intermediate cross-bar *b* of the same frame, where it shows an inclined curvilinear space *c*, terminated below by a semicircle.

D is a square wooden axis, moveable upon itself round two iron pivots, fixed into its two ends; which axis occupies the bottom of the moveable frame B. The four faces of this square axis are pierced with three round, equal, truly-bored holes arranged in a quincunx. The teeth *a*, *fig.* 1291, are stuck into each face, and correspond to holes *a*, *fig.* 1294, made in the cards which constitute the endless chain for the healds; so that in the successive application of the cards to each face of the square axis, the holes pierced in one card may always fall opposite to those pierced in the other.

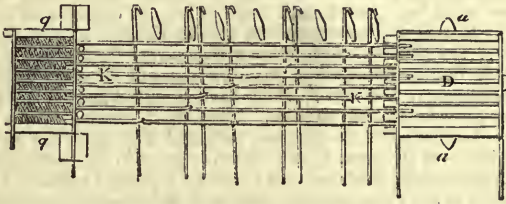
The right-hand end of the square axis, of which a section is shown in double size, *fig.* 1290, carries two square plates of sheet iron *d*, kept parallel to each other and a little apart, by four spindles *e*, passed opposite to the corners. This is a kind of lantern, in whose spindles the hooks of the lever *f f'*, turning round fixed points *g g'* beyond the right-hand upright A, catch hold, either above or below at the pleasure of the weaver, according as he merely pulls or lets go the cord *z*, during the vibratory movement of the frame B.

E is a piece of wood shaped like a T, the stem of which, prolonged upwards, passes freely through the cross-bar *b*, and through the upper cross-bar of the frame B, which serve as guides to it. The head of the T-piece being applied successively against the two spindles *e*, placed above in horizontal position, first by its weight, and then by the spiral spring *h*, acting from above downwards, keeps the square axis in its position, while it permits it to turn upon itself in the two directions. The name *press* is given to the assemblage of all the pieces which compose the moveable frame B B.

1290



1291



F is a cross-bar made to move in a vertical direction by means of the lever G, in the notches or grooves *i*, formed within the fixed uprights A.

H is a piece of bent iron, fixed by one of its ends with a nut and screw, upon the cross-bar F, out of the vertical plane of the piece C. Its other end carries a friction roller J, which, working in the curvilinear space *c* of the piece C, forces this, and consequently the frame B, to recede from the perpendicular, or to return to it according as the cross-bar F is in the top or bottom of its course, as shown in *figs.* 1288 and 1289.

I, cheeks of sheet iron attached on either side to the cross-bar F, which serve as a safe to a kind of claw K, composed here of eight small metallic bars, seen in section, *figs.* 1288 and 1289, and on a greater scale in *fig.* 1291.

J, upright skewers of iron wire, whose tops bent down hookwise naturally place themselves over the little bars K. The bottom of these spindles likewise hooked in the same direction as the upper ones, embraces small wooden bars *l*, whose office is to keep them in their respective places, and to prevent them from twirling round, so that the uppermost hooks may be always directed towards the small metallic bars upon which they impend. To these hooks from below are attached strings, which after having crossed a fixed board *m n*, pierced with corresponding holes for this purpose, proceed next to be attached to the threads of the loops destined to lift the warp threads.

K K, horizontal spindles or needles, arranged here in eight several rows, so that each spindle corresponds both horizontally and vertically to each of the holes pierced in the four faces of the square axis D. There are, therefore, as many of these spindles as there are holes in one of the faces of the square.

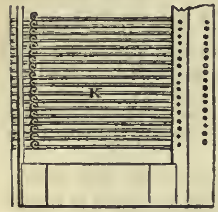
Fig. 1292 represents one of these horizontal spindles. *n* is an eyelet through which the corresponding vertical skewer passes. *o*, another elongated eyelet, through which a small fixed spindle passes to serve as a guide, but which does not hinder it from

1292

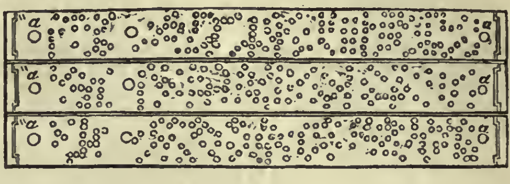
moving lengthwise, within the limits of the length of the eyelet. *p*, small spiral springs placed in each hole of the case *q q*, *fig.* 1291. They serve the purpose of bringing back to its primitive position every corresponding needle as soon as it ceases to press upon it.

Fig. 1293 represents the plan of the upper row of horizontal needles. *Fig.* 1294 is a fragment of the endless chain, formed with perforated cards, which are made to circulate or travel by the rotation of the shaft D. In this movement, each of the perforated cards, whose position, form, and number are determined by the operation

1293



1294



of tying-up of the warp, comes to be applied in succession against the four faces of the square axis or drum, leaving open the corresponding holes, and covering those upon the face of the axis which have no corresponding holes upon the card.

Now let us suppose that the *press* B is let down into the vertical position shown in *fig.* 1289; then the card applied against the left face of the axis, leaves at rest or untouched the whole of the horizontal spindles (skewers), whose ends correspond to these holes, but pushes back those which are opposite to the unpierced part of the card; thereby the corresponding upright skewers, 3, 5, 6, and 8, for example, pushed out of the perpendicular, unhook themselves from above the bars of the claw, and remain in their place, when this claw comes to be raised by means of the lever G; and the skewers 1, 2, 4, and 7, which have remained hooked on, are raised along with the warp threads attached to them. Then by the passage across of a shot of the colour, as well as a shot of the common weft, and a stroke of the lay after shedding the warp and lowering the press B, an element or point in the pattern is completed.

The following card, brought round by a quarter revolution of the axis, finds all the needles in their first position, and as it is necessarily perforated differently from the preceding card, it will lift another series of warp threads; and thus in succession for all the other cards, which compose a complete system of a figured pattern.

This machine, complicated in appearance, and which requires some pains to be understood, acts however in a very simple manner. Its whole play is dependent upon the movement of the lever G, which the weaver himself causes to rise and fall, by means of a peculiar pedal; so that without the aid of any person, after the piece is properly read in and mounted, he can execute the most complex patterns as easily as he could weave plain goods; only attending to the order of his weft yarns, when these happen to be of different colours.

If some warp yarns should happen to break without the weaver observing them, or should he mistake his coloured shuttle yarns, which would so far disfigure the pattern, he must undo his work. For this purpose, he makes use of the lower hooked lever *f*', whose purpose is to make the chain of the card go backwards, while working the loom as usual, withdrawing at each stroke the shot both of the ground and of the figure. The weaver is the more subject to make mistakes, as the figured side of the web is downwards, and it is only with the aid of a bit of looking-glass that he takes a peep of his work from time to time. The upper surface exhibits merely loose threads in different points, according as the pattern requires them to lie upon the one side or the other.

Thus it must be evident, that such a number of pasteboards are to be provided and mounted as equal the number of throws of the shuttle between the beginning and end of any figure or design which is to be woven; the piercing of each pasteboard individually will depend upon the arrangement of the lifting rods, and their connection with the warp, which is according to the design and option of the workman; great care must be taken that the holes come exactly opposite to the ends of the needles; for this purpose two large holes are made at the ends of the pasteboards, which fall upon conical points, by which means they are made to register correctly.

It will be hence seen, that, according to the length of the figure, so must be the number of pasteboards, which may be readily displaced so as to remount and produce the figure in a few minutes, or remove it, or replace it, or preserve the figure for future use. The machine, of course, will be understood to consist of many sets of the lifting rods and needles, shown in the diagram, as will be perceived by observing the disposition of the holes in the pasteboard; those holes, in order that they may be accurately distributed, are to be pierced from a gauge, so that not the slightest variation shall take place.

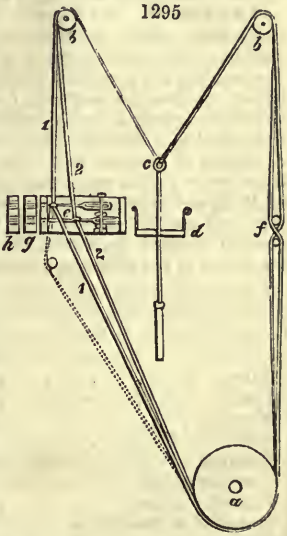
To form these card-slips, an ingenious apparatus is employed, by which the proper steel punches required for the piercing of each distinct card are placed in their relative situations preparatory to the operation of piercing, and also by its means a card may be punched with any number of holes at one operation. This disposition of the punches is effected by means of rods connected to cords disposed in a frame, in the nature of a false simple, on which the pattern of the work to be performed is first read in.

These improved pierced cards, slips, or pasteboards, apply to a weaving apparatus, which is so arranged that a figure to be wrought can be extended to any distance along the loom, and by that means the loom is rendered capable of producing broad-figured works; having the long lever G placed in such a situation that it affords power to the foot of the weaver, and by this means enables him to draw the heaviest morintures and figured works, without the assistance of a draw-boy.

The machinery for arranging the punches consists of a frame with four upright standards and cross-pieces, which contains a series of endless cords passing under a wooden roller at bottom, and over pulleys at the top. These pulleys are mounted on axles in two frames, placed obliquely over the top of the standard frame, which pulley-frames constitute the table commonly used by weavers.

In order better to explain these endless cords, *fig.* 1295 represents a single endless cord, 1 1, which is here shown in operation, and part of another endless cord, 2 2, shown stationary. There must be as many endless cords in this frame as needles in the weaving-loom. *a* is the wooden cylinder, revolving upon its axis at the lower part of the standards; *b b*, the two pulleys of the pulley-frames above, over which the individual endless cord passes; *c* is a small transverse ring. To each of these rings a weight is suspended by a single thread, for the purpose of giving tension to the endless cord. *d* is a board resembling a common comber-bar, which is supported by the cross-bars of the standard frame, and is pierced with holes, in situation and number corresponding with the perpendicular threads that pass through them; which board keeps the threads distinct from each other.

1295



At *e*, the endless cord passes through the eyes of wires resembling needles, which are contained in a wooden box placed in front of the machine, and shown in this figure in section only. These wires are called the *punch-projectors*; they are guided and supported by horizontal rods and vertical pins, the latter of which pass through loops formed at the hinder part of the respective wires. At *f* are two horizontal rods extending the whole width of the machine, for the purpose of producing the cross in the cords; *g* is a thick brass plate, extending along in front of the machine, and lying close to the box which holds the *punch-projectors*; this plate *g*, shown also in section, is called the *punch-holder*; it contains the same number of apertures as there are punch-projectors, and disposed so as to correspond with each other. In each of these apertures, there is a punch for the purpose of piercing the cards, slips, or pasteboards with holes; *h* is a thick steel plate of the same size as *g*, and shown likewise in section, corresponding also in its number of apertures, and their disposition, with the punch-projectors and the punch-holder. This plate *h*, is called the *punch-receiver*.

The object of this machine is to transfer such of the punches as may be required for piercing any individual card from the punch-holder, *g*, into the punch-receiver, *h*; when they will be properly situated, and ready for piercing the individual card or slip with such holes as have been read in upon the machine, and are required for permitting the warp threads to be withdrawn in the loom, when this card is brought against the ends of the needles. The process of transferring the patterns to the punches will be effected in the following manner:—

The pattern is to be read in, according to the ordinary mode, as in a false simple, upon the endless cords below the rods *f*, and passed under the revolving wooden cylinder *a*, to a sufficient height for a person in front of the machine to reach conveniently. He there takes the upper threads of the pattern, called the *beard*, and draws them forward so as to introduce a stick behind the cords thus advanced, as shown by dots, for the purpose of keeping them separate from the cords which are not intended to be operated upon. All the punch-projectors which are connected with the cords brought forward will be thus made to pass through the corresponding apertures of the punch-holder *g*, and by this means will project the punches out of these apertures, into corresponding apertures of the punch-receiver *h*. The punches will now be properly arranged for piercing the required holes on a card or slip, which is to be effected in the following manner:—

Remove the punch-receivers from the front of the machine; and having placed one of the slips of card or pasteboard between the two folding plates of metal, completely pierced with holes corresponding to the needles of the loom, lay the punch-receiver upon those perforated plates; to which it must be made to fit by mortises and blocks, the cutting parts of the punches being downwards. Upon the back of the punch-receiver is then to be placed a plate or block, studded with perpendicular pins, corresponding to the above described holes, into which the pins will fall. The plates and the blocks thus laid together, are to be placed under a press, by which means the pins of the blocks will be made to pass through the apertures of the punch-receiver; and wherever the punch has been deposited in the receiver by the above process, the said punches will be forced through the slip of pasteboard, and pierced with such holes as are required for producing the figured design in the loom.

Each card being thus pierced, the punch-receiver is returned to its place in front of the machine, and all the punches forced back again into the apertures of the punch-holder as at first. The next sort of cords is now drawn forward by the next *beard*, as above described, which sends out the *punch-projectors* as before, and disposes the punches in the punch-receiver, ready for the operation of piercing the next card. The process being thus repeated, the whole pattern is by a number of operations, transferred to the punches, and afterwards to the cards or slips, as above described.

JACYNTH. See JACINTH—HYACINTH.

JADE. Under the common name of Jade two or three distinct minerals, resembling one another in many of their physical characters, but differing in chemical composition, are popularly confounded. The true jade, or *nephrite*, is an anhydrous silicate of lime and magnesia, related to the non-aluminous varieties of hornblende. *Jadeite* is a mineral closely resembling true nephrite in external characters, but distinguished as a separate species by Damour, whose analyses show that it is essentially a silicate of alumina and soda. A third mineral, originally described by H. B. de Saussure as a jade, was termed *Saussurite* by T. de Saussure: this was the *jade tenace* of Haüy and the early French mineralogists. It is mainly a silicate of alumina and lime, and may be classed with the species termed *zoisite*. The differences in composition between the several minerals comprehended under the general name of jade are shown in the following selected analyses:—

	I.	II.	III.	IV.
Silica	54·68	57·10	59·17	43·59
Lime	16·06	13·48	2·68	19·71
Magnesia	26·01	23·29	1·15	2·98
Soda	...	...	12·93	3·08
Alumina	...	0·72	22·58	27·72
Peroxide of iron	...	...	...	2·61
Protoxide of iron	2·15	3·39	1·56	...
Protoxide of manganese	1·39	...	...	...
Water	0·68	2·50	...	0·35
Total	100·97	100·48	100·07	100·04

I. Nephrite, from China, by Rammelsberg.
II. Nephrite, from New Zealand, by Scheerer.
III. Jadeite, from China, by Damour.
IV. Saussurite, from Lake of Geneva, by T. Sterry Hunt.

It may be useful to give the means of discriminating these minerals by their behaviour before the blowpipe. *Nephrite* is difficult of fusion, does not colour the flame, but when moistened with solution of nitrate of cobalt assumes a rose colour, due to the presence of magnesia; *jadeite* is readily fusible to a transparent glass, and gives with cobalt a blue colour, due to the alumina; *Saussurite* is more fusible than nephrite, but less so than jadeite, it colours the flame blue, and becomes blue with cobalt.

None of the varieties of jade have been found crystallised, but they usually occur in compact tough masses, breaking with a splintery fracture. The specific gravity varies from 2·9 to 3·1, rising to 3·38 in Saussurite. All the jades are hard stones, being nearly as hard as quartz, but it is said that some varieties when first broken, are so soft as to be readily cut with a knife. The colours are various shades of green, occasionally passing into a greenish white tint.

Like most green stones, jade has always been a favourite material for amulets. It formerly possessed special repute for curing diseases of the kidneys, whence the mineralogical name *nephrite* (*νεφρός*, the kidneys), and the popular name *kidney-stone* (*pierre néphritique*, Fr.; *pietra di hijada*, Sp.; *Nierenstein*, Ger.).

Jade is largely used in China as an ornamental stone under the name of *yu*. Mr. Pumpelly has shown that the jade of the province of Yunnan, known as *fetsui*, is really jadeite. The Chinese appear to have formerly obtained considerable supplies of jade from Eastern Turkestan, where it is found in the chain of the Kuen-lun Mountains. The jade-quarries on the Kara-kash River have been visited and described by Dr. Cayley and by Hermann von Schlagintweit. According to the latter traveller, jade is always known in Khotan under the name of *yashm*.

Jade is found extensively in New Zealand, and is employed by the natives for making *tikis*, or the grotesque ornaments worn on the breast, and for the peculiar instruments of war, called *pattoo-pattoos* or *meres*. The use of jade for these axe-like weapons has led to the popular name of *axe-stone* (*Beilstein*, Ger.). The New Zealand jade is known to the Maories as *punamu* or 'greenstone;' and, according to Von Hochstetter's map it is found along the west coast of the South Island; indeed, this island is called, from the occurrence of jade, *Te Wahi Punamu*, or 'The place of the greenstone.'

Jade also occurs in Siberia, and fine specimens have been brought by M. Alibert, with his graphite, from the Government of Irkutsk.

In prehistoric times, jade and jadeite were used for amulets and ornaments, and specimens have been found among the relics of the old pile-buildings, or *Pfahlbauten*, of the Swiss lakes. It is curious to conjecture whence this material could have been derived; for, with the exception of an erratic block found at Schwemsal in Germany, true jade is not known to occur in western Europe. The so-called jade pebbles of Iona are nothing more than serpentinous marble.—F.W.R.

JADEITE. See JADE.

JAGGERY. Palm-sugar, prepared from *Saguerus saccharifer*

JALAP. The root of the *Exogonium purga*, Bth., a member of the *Convolvulaceæ*, or Bindweed order. It takes its name from Xalapa, a city of Mexico. Its uses as a common purgative are well known.

JAMAICA PEPPER. One of the names given to ALLSPICE.

JAMESONITE. A sulphide of lead and antimony, containing about 40 per cent. of lead and 34 of antimony. It occurs in several mines in the north-east of Cornwall, and in Devonshire, but has not hitherto been available as an ore of lead.

JANAPUM. *Crotalaria juncea*, a vegetable fibre used for ropes. See FIBRES.

JAPAN EARTH. *Terra Japonica.* See GAMBIR.

JAPAN LACQUER. A hard black varnish prepared from the *Stagmaria verniciflua*.

JAPAN PEPPER. A condiment prepared in China and Japan by bruising the capsules of the *Xanthoxylon piperitum*, D.C. From this plant, or from a closely-allied species, Stenhouse obtained two peculiar principles, which he called *Xanthoxylene* and *Xanthoxylin*.

JAPAN SAGO. A starch obtained from the stem of the *Cycas revoluta*.

JAPAN WAX. A vegetable wax obtained from the fruits of *Rhus succedanea*, L., and perhaps other species. It has been imported from Japan for use in candle-making.

JAPANNING is a kind of varnishing or lacquering, practised with excellence by the Japanese, whence the name.

The only difference between varnishing and japanning is that after the application of every coat of colour or varnish, the object so varnished is placed in an oven or stove at as high a temperature as can safely be employed without injuring the articles or causing the varnish to blister or run.

For black japanned works, the ground is first prepared with a coating of black, made by mixing dross ivory black to a proper consistence with dark coloured *anime* varnish, as this gives a blacker surface than could be produced by japan alone. If the surface is required to be polished, five or six coats of japan are necessary to give sufficient body to prevent the japan from being rubbed through in polishing.

Coloured japans are made by mixing with some hard varnishes the required colour, and proceeding as described. See VARNISH.

JARGOON, the name given to a variety of Zircon from Ceylon. It is seldom perfectly transparent, and is either colourless or grey, with tinges of green, blue, red, and yellow of various shades, but generally smoky and ill-defined. It occurs in worn angular pieces, or in small detached crystals, rarely exceeding 6 or 8 carats in weight, chiefly in the sand of a river in Ceylon. The surfaces of the crystals are smooth, and possess a lustre more nearly approaching that of the diamond than any other gem. At the present day, though out of fashion and in no request, it is still occasionally sold for inferior diamonds.

Davy says that the light grey varieties of the zircon are sold by the inhabitants of Ceylon as imperfect diamonds, the natives being altogether ignorant of the true nature of the mineral. It is most abundant in the district of Matura, whence it has its common name in Ceylon of *Matura diamond.* The colourless zircon is also cut and sold as a false diamond in the bazaars of India.—H.W.B.

JAROSITE. A hydrous sulphate of peroxide of iron, with an alkaline sulphate. It takes its name from Barranco Jaroso, in the Sierra Almagrera, in Spain.

JASPER (*Jaspe calcédoine*, Fr.; *Jaspis*, Ger.) is a sub-species of quartz, of which there are five varieties:—1. The Egyptian red and brown, forming nodules with ring or tendril-shaped delineations. 2. Porcelain jasper, or clay altered by heat, and differing from true jasper by being fusible on the edges, before the blowpipe. 3. Striped or riband jasper. 4. Common jasper. 5. Agate jasper. The prettiest specimens are cut for seals, and for the inferior kinds of jewellery ornaments. See LAPIDARY.—H.W.B.

JATROPHA MANIHOT. A plant belonging to the *Euphorbiaceæ*, from which the *Cassava meal* is prepared, and from the expressed juice of which are obtained *Cassava starch* and *Tapioca.* See TAPIOCA.

The seeds of *Jatropha purgans* yield jatropha oil, and the nuts of this and some other species of *Jatropha* are known as 'Physic nuts.'

JEAN. A twilled cotton, usually stripped. Satin-jeans are woven so as to present a smooth glossy appearance. It is used for stays, &c.

JELLY, ANIMAL. See GELATINE; GLUE; and ISINGLASS.

JELLY, VEGETABLE. A great many vegetable productions yield upon infusion or decoction gelatinous solutions. These vary very much in character. The jelly of ripe currants and other berries is a compound of mucilage and acid, which loses its power of gelatinising by prolonged ebullition.

JEMMIES. A woollen cloth made in Scotland.

JERKED BEEF. Beef dried in the sun: much of this has been introduced from the South American States, but it has not hitherto been much used, although sold at a very low price.

JERUSALEM ARTICHOKE. The edible tubers of the *Helianthus tuberosus.* The epithet of 'Jerusalem' is a corruption of the Italian *girasol.*

JESSAMINE or **JASMINE.** A well-known family of plants. The *Jasmium fruticans*, a native of the southern parts of France, *J. odoratissimum*, a native of India, and *J. sumbac*, a native of India and Arabia, are used to obtain the essential oil or jasmine. See PERFUMERY.

JET. (*Jaiet*, or *jais*, Fr.) Jet occurs in the upper lias shale in the neighbourhood of Whitby, in Yorkshire, in which locality this beautiful substance has been worked for many hundred years. The jet-miner searches with great care the slaty rocks, and finding the jet spread out, often in extreme thinness between the laminations of the rock, he follows it with great care, and frequently he is rewarded by its thickening out to two or three inches.

The best jet is obtained from a lower bed of the upper lias formations. This bed has an average thickness of about 20 feet, and is known as jet rock. An inferior kind, known as soft jet, is obtained from the upper part of the upper lias, and from the sandstone and shale above it. The production of jet in this country appears to be limited to the coast of Yorkshire, from about nine miles south of Whitby to Boulby, and about the same distance to the north; the estates of Lord Mulgrave being especially productive. There is a curious allusion to this in Drayton's 'Polyolbion':—

> The rocks by Moultgrave, too, my glories forth to set,
> Out of their crannied rocks can give you perfect jet.

Dr. Young, in his 'Geology of the Yorkshire Coast,' writes—'Jet, which occurs here in considerable quantities in the aluminous bed, may be properly classed with fossil wood, as *it appears to be wood in a high state of bitumenisation.* Pieces of wood impregnated with silex are often found completely crusted with a coat of jet about an inch thick. But the most common form in which the jet occurs is in compact masses of from half an inch to 2 inches thick, from 3 to 18 inches broad, and of 10 or 12 feet long. The outer surface is always marked with longitudinal striæ, like the grain of wood, and the transverse fracture, which is conchoidal, and has a resinous lustre, displays the annular growth in compressed elliptical zones.'

It does not appear to us that the 'ligneous origin' of jet is by any means established; indeed, we think the amount of evidence is against it. There is no example, as far as we can learn, of any discovery of true jet having a strictly ligneous structure, or showing anything like the conversion of wood into this coal-like substance. There appears, however, to have been some confusion in the observation of those who have written on the subject. Mr. Simpson, the intelligent curator of the Whitby Museum, who has paid much attention to the subject, says, 'Jet is generally considered to have been wood, and in many cases it undoubtedly has been so; for the woody structure often remains, and it is not unlikely that comminuted vegetable matter may have been changed into jet. But it is evident that vegetable matter is not an essential part of jet, for we frequently find that bone, and the scales of fishes also have been changed into jet. In the Whitby Museum there is a large mass of bone, which has the exterior converted into jet for about a quarter of an inch in thickness. The jetty matter appears to have first entered the pores of the bone, and there to have hardened; and during the mineralising process, the whole bony matter has been gradually displaced, and its place occupied by jet, so as to preserve its original form.' After an attentive examination of this specimen, we are not disposed to agree entirely with Mr. Simpson.

Jet certainly incrusts a mass which has something the structure of a bone, but, without a chemical examination of its constituents, we should hesitate even to say it was bone. Wood without doubt has been found *encrusted* with jet, as fragments of animal matter may also have been. But it is quite inconsistent with our knowledge of physical and chemical changes, to suppose that both animal and vegetable matter would undergo this change. By *process of substitution*, we know that silica will take the place occupied by carbon, or woody matter; as, for example, in the fossil palms of Trinidad, and the silicified forests of Egypt; but we have no example within the entire range of the coal-formations of the world of carbon taking the place of any of the earths.

Jet is found in plates, which are sometimes penetrated by belemnites. Mr. Ripley, of Whitby, has several curious examples,—two plates of jet, in one case enclose water-worn quartz pebbles; and in another jet partially invests an angular fragment of quartz rock. 'This is the more remarkable,' says Mr. Simpson, 'as quartz rock, or, indeed, any other sort of rocky fragment, is rarely found in the upper lias.'

The very fact that we find jet surrounding belemnites, casing adventitious masses of stone, and investing wood, seems to show, that a liquid, or at all events, a plastic condition, must at one time have prevailed. We have existing evidence of this. Dr. Young, in the work already quoted, says:—'In the cavities of nodules containing petrifactions, we sometimes meet with *petroleum*, or *mineral oil*. When first exposed, it is *generally quite fluid* and of a dark green colour; but it soon becomes viscid and black, and at last hardens into a kind of pitch, which generally melts with heat, and when ignited burns with a crackling noise, and emits a strong bituminous smell.' One more sample of evidence in favour of the view that jet has been formed from wood. It is stated (Reed's 'Illustrated Guide to Whitby') that in front of the cliff-work of Hailburne Wyke existed a petrified stump of a tree, in an erect posture, 3 feet high and 15 inches across, having the roots of coaly jet in a bed of shale; whilst the trunk in the sandstone was partly petrified, and partly of decayed sooty wood. Even in this example it would appear, that after all, a coating of jet was all that really existed upon this example of the equisetum, which probably stands where it grew. Mr. Simpson, in a valuable little publication, 'The Fossils of the Yorkshire Lias described from Nature, with a short Outline of the Geology of the Yorkshire Coast,' says:—'From all we know respecting this beautiful mineral, it appears exceedingly probable that it has its origin in a certain bituminous matter, or petroleum, which abundantly impregnates the jet-rock, giving out a strong odour when it is exposed to the air. It is frequently found in a liquid state in the chambers of ammonites and belemnites and other cavities, and, whilst the unsuspicious operator is breaking a lias nodule, it flies out and stains his garment. This petroleum, or mineral oil, also occurs in nodules which contain no organic remains; and I have been informed by an experienced jet-miner that such nodules are often associated with a good seam of jet, and are therefore regarded as an omen of success.'

Jet is supposed to have been worked in this country long before the time of the Danes in England, for the Romans certainly used jet for ornamental purposes. Lionel Charltan, in the 'History of Whitby,' says, that he found the ear-ring of a lady having the form of a heart, with a hole in the upper end for a suspension from the ear; it was found in one of the Roman tumuli, lying close to the jaw-bone. There is no doubt that when the abbey of Whitby was the seat of learning and the resort of pilgrims, jet rosaries and crosses were then common. The manufacture was carried on till the time of

Elizabeth, when it seems to have ceased suddenly, and was not resumed till the year 1800, when Robert Jefferson, a painter, and John Carter made beads and crosses with files and knives:—a neck guard, made in this manner, fetched one guinea. A stranger coming to Whitby saw them working in this rude way, and advised them to try to turn it; they followed his advice and found it answer; several more then joined them, and the trade has been gradually increasing since.

In 1860 the jet-trade of Whitby realised about 45,000*l.*; but since that time it has doubled itself. In 1870 the value amounted to 84,000*l.*; in 1871 to 86,000*l.*; in 1872 to 88,000*l.*; and in 1873 it probably exceeded 90,000*l.*

Two kinds of jet occur at Whitby—the hard and the soft. The hard jet, which alone is now worked, is found in layers of varying extent and thickness; the largest known specimen having measured 6 feet 4 inches in length, about 5 inches in width, and 1½ inch in thickness; it weighed 11½ lbs. Formerly, the hard jet was worked in the cliffs by a dangerous process called 'dessing'; but the cliff-workings are now almost entirely abandoned, and most of the jet is obtained from mines in the Cleveland hills, the most extensive workings being those of Bilsdale, near Broughton. About 20 mines are at present open, giving employment to about 200 miners. Rough hard jet varies in value from 4*s.* to 21*s.* per lb.; but the soft jet realises only 5*s.* 6*d.* to 30*s.* per stone, and it is now rarely worked at Whitby, since Spanish jet can be imported at the same price. The Spanish does not stand wear so well as the Whitby jet, nor does it bear exposure to the weather. The two kinds may be distinguished by scratching them with a knife, the Spanish giving a very irregular scratch, whilst the Whitby gives a fine groove.

In working jet, the first operation is to remove the skin, or outer surface, which is chipped off with an iron chisel; the denuded pieces are then sawn up into sizes adapted for the required articles, and are worked into form by carving and turning; finally, the objects are polished with rouge on a board covered with hide, by which means a fine velvety lustre is obtained. There are at present upwards of 200 workshops in Whitby, the largest being that of Mr. Charles Bryan, which gives employment to about 120 hands. Most of the jet ornaments are sent to London; the inferior ones are mostly purchased for the American market. A trade is also carried on with the Continent and with most of our colonies.

The jet workers complain of the great scarcity of designs in jet. Several designs have been sent them; but the artists not being acquainted with the peculiarities of the material, their designs are not generally applicable, and the manufacturer is much more successful in the imitation of natural objects than any artificial combination.

For recent information on jet, we are indebted to a paper on *Whitby Jet and its Manufacture*, by Mr. J. A. Bower, F.C.S., 'Journal of the Society of Arts,' December 19, 1873.

JETSAM. Goods *cast into the sea* from a ship in stress of weather; *flotsam* being the portion of a ship and cargo which *remains floating upon the waters*; and *lagan*, or *ligan-goods*, being merchandise which is cast overboard, and sunk with a buoy attached, so that they may be possibly discovered.

JEWELLER'S GOLD. Usually an alloy of about 25 per cent. of copper with 75 of gold. See Alloy.

JEWELLER'S ROUGE. A carefully-prepared peroxide of iron, used for polishing.

JEWELLERY. See Bijoutry; Gem; and Lapidary.

JEW'S PITCH. A fine variety of asphalt from the Dead Sea. See Asphalt.

JIGGING, *a mining term.* Separating the ore with a griddle, or wire-bottomed sieve, the heavier substances passing through to the bottom or lower part of the sieve, the lighter substance remaining on the upper part.

JINTA WAN. A substance somewhat resembling caoutchouc, imported from India. See Caoutchouc.

JOHANNITE. Uranium-vitriol, or hydrous sulphate of uranium and copper, found at Joachimstahl in Bohemia, and Johanngeorgenstadt in Saxony.

JUJUBE. The fruit of the *Lizyphus vulgaris* and *L. jujuba*, about the size of, and nearly resembling, a small plum. The French confectioners prepare a lozenge from the juice of the fruit, but nearly all the jujubes sold by our druggists and confectioners are merely dried mucilage, flavoured and sweetened.

JUMPER, *a mining term.* A large borer, steeled at each end like chisel bits. It is worked by the hand.

JUNIPER. A genus of plants belonging to the order *Coniferæ.* About twenty species are known. This plant is cultivated mostly for its berries, which, when distilled with water, yield a volatile essential oil. The berries are largely employed in the manufacture of Hollands and gin. The French name of the plant is *Genièvre*, and hence our English words 'gin' and 'geneva.'

The *Juniperus Bermudiana*, the Bermuda red cedar, is a large tree with soft and fragrant wood, and is what is used in making pencils, and by cabinet-makers.

The *J. Virginia*, L., is also used as the so-called cedar for lead-pencils.

JUTE consists of the fibres of two plants, called the chonch and isbund (*Corchorus olitorus* and *Corchorus capsularis*), extensively cultivated in Bengal, and forming, in fact, the material of which gunny-bags and gunny-cloth are made. It fetches nearly, though not quite, so high a price as sunn. See SUNN. It comes into competition with flax, tow, and codilla, in the manufacture of stair and other carpets, bagging for cotton and other goods, and such like fabrics, being extensively used for these purposes in Dundee. But it is unsuitable for cordage or other articles into which hemp is manufactured, from its snapping when twisted, and rotting in water.—*M'Culloch.*

The importance of jute as an article of manufacture is shown by the following statement of the *Exports* from India from 1850, when it first began to attract attention in this country, to 1863:—

	Cwts.	Total Value £
1850	391,098	88,980
1851	584,461	196,936
1852	535,027	180,976
1853	340,797	112,017
1854	509,507	214,768
1855	699,566	220,241
1856	882,715	329,076
1857	673,416	274,957
1858	788,820	303,292
1859	317,890	525,099
1860	761,201	290,018
1861	1,092,668	409,372
1862	1,232,279	537,610
1863	1,266,884	750,456

The rapid progress of the jute manufacture in this country is thus shown. The following Tables show the increase since 1869; which is to be accounted for by the low cost of the material, and its possessing a considerable amount of spinning quality.

Imports: nearly all from British India.

Years	Cwts.
1869	2,467,000
1870	2,376,000
1871	3,454,020
1872	4,041,018
1873	4,543,000

The following quantities of yarn and waste of jute were imported in 1871 and 1872:—

	1871		1872	
	lbs.	£	lbs.	£
From Russia	29,000	400	...	...
„ Holland	249,285	4,914	261,844	4,891
„ Belgium	178,787	6,363	28,132	1,347
„ France	2,739,981	50,913	2,285,166	49,631
„ Other countries	...	...	56,929	1,644
Total	3,197,053	62,590	2,632,071	57,513

The President of the Chamber of Commerce, Dundee, at a meeting (1873) stated that great prosperity had attended the Dundee trade during the past year, that the whole machinery had been in operation, and that full employment had been obtained by all. The importation of jute had never been greater than in this year, being some 20,000 tons more than last. It was mentioned as another indication of the prosperity, that the deposits of the working classes engaged in the jute manufacture in the savings-bank during the present year had increased by 36,000*l.* or 37,000*l.*

It is in Scotland especially where goods made from jute represent a large branch of industry. This very cheap raw material is employed there, either pure or mixed, to make ordinary brown cloth, but more especially sacking, packing-cloth, and carpets. The jute yarns used for carpets are of the richest and most varied colours, and are sometimes used in conjunction with cocoa-nut fibre. Even the Brussels and velvet-pile carpets are imitated with success in appearance, but not in durability. Dundee and its surrounding neighbourhood are the principal seats of this fast-increasing manufacture. The number of spindles acting on jute in Dundee is considerably above 50,000. A very beautiful cloth for binding books is made from jute.

The bulk of the raw jute exported is sent to France. About 30,000 cwts. are annually returned in the shape of jute-yarn.

The amount of British-made jute-yarn and manufactures exported was as follows during the last five years:—

	Yarns lbs.	Manufactures yds.
1869	8,041,000	50,127,000
1870	12,669,000	57,920,000
1871	13,710,000	62,310,000
1872	12,715,000	84,452,000
1873	12,275,000	96,539,000

This is exclusive of jute bags and sacks, which are not separately classified in the trade returns.

The following Parliamentary return of the jute *Exports* in 1872 shows the countries to which our manufactures were sent:—

Jute Yarn:	lbs.	£
To Germany	1,684,272	33,521
,, Holland	2,866,952	54,448
,, Belgium	792,540	19,640

Total	84,452,457	1,486,484

K

KABOOK. A name for a clay-ironstone in Ceylon.—*Simmonds.*

KAINITE. A hydrous sulphate of potash and magnesia, occurring in the great saline deposits overlying the rock-salt at Stassfurt, in Prussian Saxony. It has become an important commercial source of sulphate of potash.

KAL. *A mining term.* 'Wild iron; a coarse, false kind of iron.'—*Borlase.* In St. Just, in Cornwall, a *callan lode* is a lode containing much iron.

KALEIDOPHON. An instrument devised by Professor Wheatstone. An elastic thin bar is fixed by one of its extremities, and at its free end it carries a silvered or polished ball; a ray of light is reflected from this ball, and when the thin plate is put in vibration, the fine point of light describes various curves, corresponding with the musical notes produced by the vibrations.

KALEIDOSCOPE. A well-known instrument invented by Sir David Brewster. It has been much employed in arts of design. The leading conditions are that the angle at which the reflectors are placed is a submultiple of 360°, that the only positions in which a body can be placed to form perfectly symmetrical images are between the ends of the mirrors, or in contact with the ends, and the eye must be as near as possible to the angular point.

KALI. The Arabs gave this name to an annual plant which grows near the sea-shore, now known under the name of *Salsola soda,* and from whose ashes they extracted a substance, which they called *alkali,* for making soap. The term *Kali* is used by German chemists to denote caustic potash, and *Kalium,* its metallic basis, instead of our *potash* and *potassium.*

KALINITE. Dana's name for native potash-alum. See ALUM.

KAMALA, or **KAMILA DYE.** An Indian yellow dye for silks, obtained from the *Rottlera tinctoria,* Rxb. The red powder which covers the fruit is mixed with alum or with carbonate of soda, and yields an orange dye. Kamala is also employed medicinally in the East.

KAMPTULICON. This article was first made in the year 1843, but, like most new productions, it remained for some time unappreciated. At length it was used by Sir Charles Barry for the corridors of the Houses of Parliament.

At first it was produced in its unstained colour, but subsequently it has been stained of many different colours. It is also impressed with surface-colour designs of varied and appropriate subjects. It is an admirable recipient of colour, which penetrates throughout its substance, and remains permanent. Kamptulicon is composed of gutta-percha, India-rubber, and ground cork.

Other materials have been tried, such as prepared oil and ground cork; but this has not been very successful. In some, sawdust has been substituted for cork.

One of the great advantages of kamptulicon is its property of deadening sound. The Kamptulicon Elastic Floor-Cloth Company, who have extensive works at Bow Common, furnish the following notice of this manufacture:—

The first part of the manufacturing process is the purification of the native caoutchouc or India-rubber. It is first put to soak into large water tanks heated by steam, and when sufficiently softened, is placed before a circular knife of cast steel, revolving at the rate of 3,000 times a minute, and cut into small blocks; and is then taken to a pair of powerful cast-steel rollers, which seize it, and grind it with immense force; and, aided by a jet of water, all the clay and foreign ingredients are expelled and washed away; it is passed several times through this machine, till it is perfectly free from all impurities, when it is taken to a formidable apparatus, called the masticator, which consists of a massive structure of iron, fitted with cylinders, of which every part, being subject to a violent straining, is rendered as strong as possible. The material having been of a loose though tough mass on entering this machine, is gradually crushed and worked down into a body of consistent substance, and has altered to a light brown colour. This process is attended with the evolution of much heat, caused by the immense friction in the working of the material, and any water yet remaining in the mass is actually converted into steam, a succession of explosions constantly being heard in the apparatus from the disengaged air or steam; it is then removed and worked into the proper consistency, by being passed through deeply-indented rollers, which further grind and incorporate it with the different colours, &c., for spreading upon cloth and rolling into sheets for steam packing; this is the most tedious and expensive part of the manufacture, at it goes through several pairs of similar rollers, which require great mechanical power. After being brought to this state, which is varied according to the purpose for which it is required, it is taken to a still larger set of rollers, which consists of four cast-steel cylinders, each of 22 inches diameter, and 62 inches on the face; these rollers are beautifully turned and polished, fitted with steam connections, as well as for hot and cold water, and are estimated to have cost upwards of 1,500*l.*, there being great difficulty in obtaining rollers of so large a size.

The material forms a sheet upon the first roller, and, as it passes over, is pressed into the cloth through the other rolls, and wound off in front of the machine on a roller connected with it, the average speed of the machine being such as to produce 1,500 to 2,000 yards per day. After leaving the machine, the fabric or rubber is subjected to the vulcanising process by being placed with sulphur at temperatures of from 300° to 370° Fahr., which renders the India-rubber highly elastic, and gives it the properties of resisting the influence of grease or acids. The whole of the machinery is worked by a pair of horizontal double-cylinder engines of 66 horse-power, and one engine of 30 horse-power. Space will not permit us to describe the further machinery for making all the various articles in detail.

KANEITE. An arsenide of manganese, probably from Saxony; named after Sir Robert Kane, by whom it was first described.

KANGAROO. A marsupial animal, native of Australia. Its tail makes excellent soup; and its skin, when tanned, becomes a soft and durable leather.

KAOLIN. A name derived from the Chinese, which is sometimes applied to porcelain clay. See CLAY, PORCELAIN.

KARABE', a name of amber, of Arabic origin, in use upon the Continent.

KARN or **CARN.** A Cornish miner's term, frequently, according to Borlase, used to signify the solid rock—more commonly a pile of rocks.

KARSTENITE. The name given by Hausmann to anhydrous sulphate of lime, in compliment to the German mineralogist Karsten. See ANHYDRITE.

KÂT, or **KHAT.** An Arabian drug, obtained from the *Catha edulis* and *C. spinosa.* It is said to be chewed by the Arabs for the sake of its exhilarating effects; whilst a decoction prepared from it is used as tea.

KATTIMUNDOO or **CUTTEMUNDOO.** A caoutchouc-like substance obtained from the *Euphorbia antiquorum* of Roxburgh. It was first exhibited in this country in the Great Exhibition of 1851, being sent by Mr. W. Elliott from Vizagapatam.

It was of a dark brown colour, opaque except in thin pieces, hard and somewhat brittle at common temperatures, but easily softened by heat. Perfectly insoluble in boiling water, but becoming soft, viscid, and remarkably sticky and adhesive like bird-lime, reassuming, as it cools, its original character.

It is said to be used for joining metal, fastening knife-handles, &c.

KAURIE or **KAWRIE RESIN.** See DAMMAR.

KAVA ROOT. The root of the *Piper methysticum*, Forst., used in the South Sea Islands for preparing a disgusting beverage.

KEDGE ANCHOR. A small anchor with an iron stock used for warping.

KEEL. A barge used on the Tyne to carry coal. These barges are constructed to carry 21 tons. The keel 'is worked by means of *one oar* at the gunwale and a *sweep* at the stern. Of late years the build and rig of these vessels have been so greatly improved, that they can now work to windward in as good a style as a sloop.' Dunn, *Winning and Working of Collieries.*

KEELER. A manager of coal barges and colliers in the Durham and Northumberland district.

KEEVE, *a mining term.* A large vat used in dressing ores: also a *brewer's term* for a mash tub.

KEG. A cask containing five gallons.

KEIR. A boiler used in bleaching establishments. See BLEACHING.

KELP (*Varec*, Fr.; *Wareck*, Ger.) is the crude alkaline matter produced by incinerating various species of fuci, or *sea-weed.* They are cut with sickles from the rocks in the summer season, dried and then burned, with much stirring of the pasty ash. Dr. Ure analysed many specimens of kelp, and found the quantity of soluble matter in 100 parts of the best to be from 53 to 62, while the insoluble was from 47 to 38. The soluble consisted of:

Sulphate of soda	8·0	19·0
Soda, as carbonate and sulphuret	8·5	5·5
Muriate of soda and potash	36·5	37·5
	53·0	62·0

The insoluble matter consisted of:

Carbonate of lime	24·0	10·0
Silica	8·0	0·0
Alumina, tinged with iron oxide	9·0	10·0
Sulphate of lime	0·0	9·5
Sulphur and loss	6·0	8·5
	47·0	38·0

The first of these specimens was from Heisker, the second from Rona, both in the Isle of Skye, upon the property of Lord Macdonald. From these, and many other analyses which were made by Dr. Ure, it appears that kelp is a substance of very variable composition, and hence it was very apt to produce anomalous results, when employed as the chief alkaline flux of crown glass, which it was for a very long period. The *Fucus vesiculosus* and *F. nodosus* are reckoned to afford the best kelp by incineration; but all the species yield a better product when they are of two or three years' growth than when cut younger. The *varec* made on the shores of Normandy contains almost no carbonate of soda, but much sulphate of soda and potash, some hyposulphite of potash, chloride of sodium, iodide of potassium, and chloride of potassium; the average composition of the soluble salts being, according to Gay-Lussac, 56 of chloride of sodium, 25 of chloride of potassium, and a little sulphate of potash. The very low price at which soda-ash, the dry crude carbonate from the decomposition of sea salt, is now sold, has superseded the use of kelp for this purpose.

Mr. E. C. C. Stanford has introduced a process for preparing kelp by simply carbonising the weeds. The sea-weeds are collected during the winter, and, when dried and compressed, are distilled in retorts at a comparatively low temperature. See ALGÆ; IODINE; POTASH.

KENTISH RAG. See RAG and RAGSTONE.

KERATIN. An animal principle obtained from hairs, nails, horn, feathers, and other integumentary tissues.

KERMES GRAINS, ALKERMES, are the dried bodies of the female insects of the species *Coccus ilicis*, which lives upon the leaves of the *Quercus ilex* (prickly oak). Kirby and Spence, and also Stephens, state that the *Coccus ilicis* is found on the *Quercus coccifera*. The word *kermes* is Arabic, and signifies 'little worm.' In the middle ages, this dye-stuff was therefore called *vermiculus* in Latin, and *vermeil* and *vermilion* in French. It is curious to consider how the name *vermilion* has been since transferred to red sulphuret of mercury.

Kermes has been known in the East since the days of Moses; it has been employed from time immemorial in India to dye silk; and was used also by the ancient Greek and Roman dyers. Pliny speaks of it under the name of *coccigranum*, and says that there grew upon the oak in Africa, Sicily, &c., a small excrescence like a bud, called *cusculium*; that the Spaniards paid with these grains half of their tribute to the Romans; that those produced in Sicily were the worst; that they served to dye purple; and that those from the neighbourhood of Emerita in Lusitania (Portugal) were the best.

In Germany, during the ninth, twelfth, thirteenth, and fourteenth centuries, the rural serfs were bound to deliver annually to the convents a certain quantity of kermes, the *Coccus Polonicus*, among the other products of husbandry. It was collected from the trees upon St. John's-day, between eleven o'clock and noon, with religious ceremonies, and was therefore called *Johannisblut* (St. John's blood), as also German cochineal. At the above period, a great deal of the German kermes was consumed in Venice, for dyeing the scarlet to which that city gives its name. After the discovery of America, cochineal having been introduced began to supersede kermes for all brilliant red dyes.

The principal varieties of kermes are the *Coccus quercus*, the *Coccus Polonicus*, the *Coccus fragariæ*, and the *Coccus uva ursi.*

The *Coccus quercus* insect lives in the south of Europe upon the kermes oak. The female has no wings, is of the size of of a small pea, of a brownish-red colour, and is covered with a whitish dust. From the middle of May to the middle of June the eggs are collected, and exposed to the vapour of vinegar, to prevent their incubation. A portion of eggs is left upon the tree for the maintenance of the brood. In the department of the Bouches-du-Rhône, one half of the kermes crop is dried.

The kermes of Poland, or *Coccus Polonicus*, is found upon the roots of the *Scleranthus perennis* and the *Scleranthus annuus*, in sandy soils of that country and the Ukraine. This species has the same properties as the preceding; one pound of it, according to Wolfe, being capable of dyeing 10 pounds of wool; but Hermstaedt could not obtain a fine colour, although he employed 5 times as much of it as of cochineal. The Turks, Armenians, and Cossacks dye with kermes their morocco leather, cloth, silk, as well as the manes and tails of their horses.

The kermes called *Coccus fragariæ* is found principally in Siberia, upon the root of the common strawberry.

The *Coccus uva ursi* is twice the size of the Polish kermes, and dyes with alum a fine red. It occurs in Russia.

Kermes is found not only upon the *Lycopodium complanatum* in the Ukraine, but upon a great many other plants.

Good kermes is plump, of a deep red colour, of an agreeable smell, and a rough and pungent taste. Its colouring matter is soluble in water and alcohol: it becomes yellowish or brownish with acids, and violet or crimson with alkalis. Sulphate of iron blackens it. With alum it dyes a blood-red; with copperas, an agate-grey; with sulphate of copper and tartar, an olive-green; with tartar and salt of tin, a lively cinnamon-yellow; with more alum and tartar, a lilac; with sulphate of zinc and tartar, a violet. Scarlet and crimson dyed with kermes were called *grain colours*. The red caps for the Levant are dyed at Orleans with equal parts of kermes and madder, and occasionally with an addition of Brazil-wood. Kermes is but little used in England at present as a dyeing substance.

KERMES, MINERAL. Pure mineral kermes is regarded by Berzelius, Fuchs, and Rose, as an amorphous tersulphuret of antimony. As the preparation has but little use in the arts except as an artist's colour, for its mode of preparation and its chemical constitution, we refer to Watts's 'Dictionary of Chemistry.'

KERMESITE. Red antimony ore, composed of oxygen, 5·29; antimony, 74·45; sulphur, 20·49. It occurs in the form of tufts of cherry-red hair-like crystals, at Bräunsdorf, near Freiberg, in Saxony, and at a few other localities.

KERNEL ROASTING. See COPPER.

KEROSINE. A name given to one of the mineral oils, obtained from the oil-wells and oil-shales of America, and other places.

KERSEY. A coarse stuff woven from long wool, chiefly manufactured in the north of England.

KERSEYMERE. Commonly spelt *cassimere*. A fine fabric woven plain from the finest wools; a manufacture of the west of England principally.

KETCHUP. A name derived from the Japanese *kitjap*. It is prepared from mushrooms, especially from the *Agaricus campestris*, by sprinkling them with salt, letting them drain, and boiling the juice with spices. Walnut-ketchup is made from green walnuts in a similar manner.

KETONES. A class of organic bodies derived from aldehydes by substitution of one atom of hydrogen for one atom of an alcohol-radical. For example, acetone is acetic ketone; that is, it may be regarded as acetic aldehyde in which one atom of hydrogen is replaced by the radical methyl. See Watts's 'Dictionary of Chemistry.'

KHAYA. One of the largest and handsomest trees growing on the western coast of Africa. The wood is of fine quality, and of a reddish colour like mahogany.

KIABOCCA WOOD, called also Amboyna wood. This wood is said to be the excrescence or burr of the *Pterospermum indicum*, or of the *Pterocarpus draco*, from the Moluccas, the Island of Borneo, Amboyna, &c.

KIBBLE, *a mining term*. A bucket usually made of iron, in which the ore is drawn to the surface from the depths of the mine.

KIDDERMINSTER-CARPET. A carpeting so called from the place of its early manufacture. This kind of carpet is now principally made in Scotland. Kidderminster is composed of two webs, each consisting of a separate warped woof. The two are interwoven at intervals to produce the figures. The two webs being passed at intervals through each other, each part being at one time above and the other below, it will be evident, when the webs are of different colours, that the figures will be the same on both sides, only the colours will be reversed. These carpets should be made entirely of wool.

KIESERITE. A hydrous sulphate of magnesia, containing $MgO . SO^3 + HO$ (**$MgSO^4 + H^2O$**). It occurs in large quantities in the upper part of the great saline deposits overlying the rock-salt of Stassfurt, near Magdeberg, in Prussian Saxony. The kieserite is specially characteristic of a zone of the deposits, known as the *kieserite region*, which occurs below the carnallite, and above the polyhalite region. Kieserite forms about 17 per cent. of the salts in that portion of the deposit to which it gives its name. It is separated from the associated salts by solution and crystallisation. Large quantities of sulphate of magnesia prepared from kieserite are now sent into the market by the Stassfurt manufacturers.

The first attempts to economise kieserite were made in 1864, when it was proposed to employ it in the preparation of sulphate of potash. Since that time the applications have greatly increased, and it has now become an important article of commerce.

The largest quantity of the raw material is sent to this country, where it takes the place of the sulphate of magnesia, formerly manufactured from dolomite, or from Grecian magnesite, in cotton printing. Another portion of kieserite is converted into Glauber salts, which, on account of its freedom from iron, are highly prized by gas manufacturers.

Manufacturers of '*blanc fixe*' employ kieserite, instead of sulphuric acid, to precipitate the sulphate of baryta from chloride of barium, and in all similar cases where it is proposed to prepare a difficultly-soluble sulphate, the kieserite can be advantageously used. Kieserite is recommended as a substitute for gypsum in agriculture, as a top-dressing for clover, and is largely employed in England for this purpose. It is proposed to use kieserite in the manufacture of alum. There is a mineral called bauxite, which chiefly consists of the hydrated oxide of aluminium; this is easily dissolved in hydrochloric acid; cheap potash salts and the calculated quantity of kieserite are added; alum crystallises out of the solution, and chloride of magnesium remains in the mother-liquid.

The uses indicated above are wholly inadequate to consume the enormous quantities now obtained from the Stassfurt mines, Millions of pounds of kieserite are annually brought to the surface, and it is becoming a serious question to know what to do with it. If it could be used as a substitute for gypsum in building materials and cements, its cheapness would at once commend it to notice. Experiments looking to this application have been tried.

Two equivalents of kieserite and one equivalent of caustic lime were stirred to a paste in water: the mass hardened, but remained granular and brittle. On calcining it, however, again pulverising and moistening with water, it set to a solid marble-like mass, which could be applied to many useful purposes. It is proposed to employ this material for ornamental decorations in the interior of houses, and in general for the manufacture of cements, and as a substitute for plaster-of-Paris.

Kieserite appears likely to prove a valuable accession to our supply of useful minerals, to be ranked by the side of kainite, a potash mineral also found at Stassfurt, and now largely imported into the United States.

KILBRICKENITE. A variety of Geocronite from Kilbricken, Clare county, Ireland.

KILKENNY COAL. A variety of anthracite.

KILLAS. The name given by the Cornish miners to the *clay slate* of that district. It varies very much in colour and character, being sometimes clay-white, and at other times grey or blue. It is in one district soft; in another compact and hard.

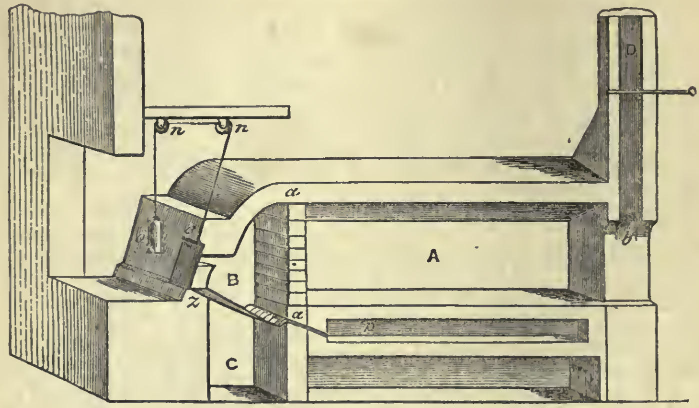
KILN, (*Four*, Fr., *Ofen*, Ger.) is the name given to a certain variety of furnace in which substances can be submitted to the influence of heat. In general, a kiln may be described to be a structure of some considerable size, in which limestones, iron-ores, or the like, can be calcined, bricks and cement stones burnt, pottery baked, or glass annealed.

The ordinary brick-kiln has been already described in the article BRICKS; there are, however, a few modern arrangements which demand some more especial description.

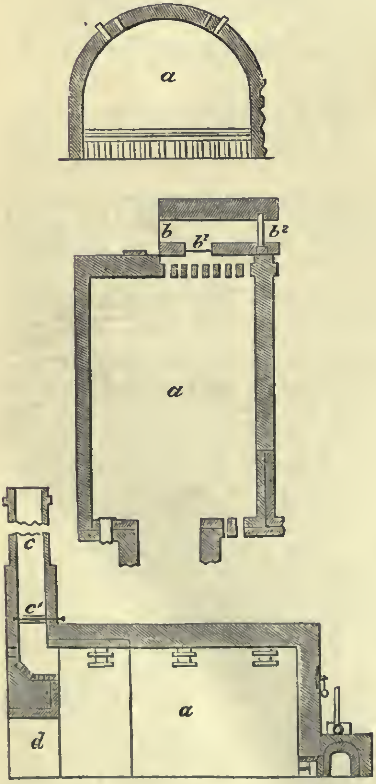
Horizontal Close Kilns.—These are employed very extensively on the Continent. One is represented in *fig.* 1296. Although intended for bricks, it is often advantageously used as an ordinary potter's kiln. A is the firing kiln; B is the fuel-grate; C the ash-pit, and D the chimney. The fire proceeds from the narrow end through the whole length of the kiln to the chimney. Below the flue is the door *b*, which is bricked up during every operation. The perforated wall *a a* separates the fire-hearth from the burning chamber, and diffuses the flame uniformly over the whole front part of the chamber; the position of the fire-grate is found in practice to be exceedingly good, and is recommended. The grate is inclined towards the kiln for the purpose of facilitating the addition of fuel. The curve in the roof conducts the flames, without interruption, into the burning chamber. The fire-door, *e*, can be easily drawn up by means of the weight *o*, and the chains passing over the pulleys *n n*. The flue *p*, and a few others in the side of the kiln, tend to keep the brickwork dry, which is an important point in getting up the heat. The heat in all furnaces thus constructed is greatest in the neighbourhood of the wall *a a*; and to prevent the vitrification of the bricks, a certain quantity of lime is thrown into the front part of the kiln. In such a furnace as this, the firing chamber is 3½ feet high and 10 feet long, and a full charge is 6,000 bricks.

Newcastle Kilns are arched kilns or ovens. These have been improved by Mr. C. G. Johnson, who constructs a flue running along the back of a range of these kilns, and instead of placing the chimney at the end farthest from the fire, he places it near the fire. A communication is formed between the kilns of the flue running along the back of the range. Suitable dampers regulate the heat, which can be drawn through any kiln from back to front by the chimney. *Fig.* 1297 is a front elevation of a portion of a range of kilns thus constructed. *a* is the body of the kiln, where the bricks are stacked

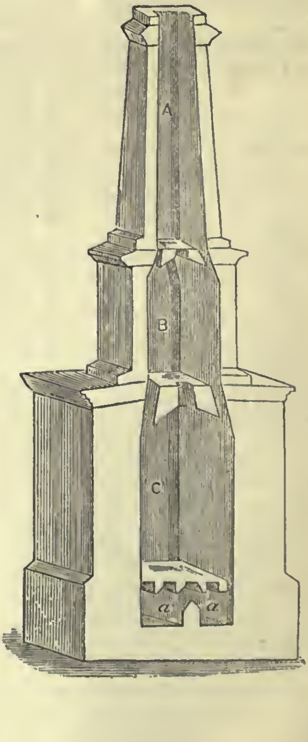
1296



1297



1298



on a plane floor; *b*, a flue that connects any two or more kilns with each other, the communication being regulated by means of dampers b^1 b^2; *c*, chimney with damper *c'*;

d, an archway for setting and drawing the kilns, made up with bricks daubed with clay, so as to be air-tight while the bricks are burning. The system of firing is the same as in the ordinary end firing ovens. The mode of working is simple: No. 1 kiln when fired, is put into communication with No. 2, this kiln having had the opening in front closed up, and the damper in the chimney opened. No. 2 kiln acts as a chimney to No. 1 during the time that the moisture is being driven off from the bricks in it. While this operation is going on, No. 3 kiln can be set, and as soon as the moisture is expelled from the bricks in the first kiln, communication can be closed with No. 2, and that with No. 3 opened. The waste heat will then pass into No. 3. This can be repeated as many times as there are kilns, and the firing up of the kiln with the dried bricks effected.

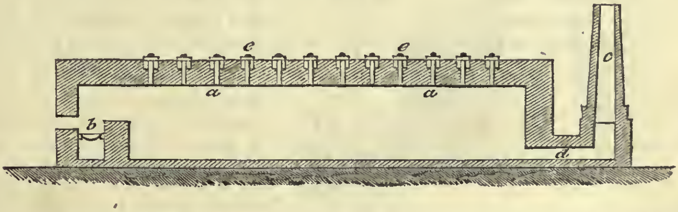
In Hellmann's brick-kiln, at his works near Hanover, the firing-chamber is 8 feet from side to side, 12 feet 8 inches to the top of the arch, and 20 feet 4 inches in length. This space, which is much larger than that in the kiln just described, will contain 24,000 bricks. The mean quantity of coal consumed in firing this kiln is 260 cwts. The kiln is heated from 4 grates, which join in the centre.

The open Dutch kilns are much larger. Heren describes one 51 feet wide, 110 feet long, and 25 feet high, containing 56 layers of bricks, one above the other, consisting of more than 3,000,000 bricks, which are burnt in 36 days by the flames from 10 fires. The *Bihl* kiln (*fig.* 1298) used in Waiblingen is of a similar character. This kiln is heated by two fires; between the fires and the chimney A there are two working chambers, a lower chamber C for burning, and an upper chamber B for drying the bricks. The working chambers and chimney are separated from each other by perforated arches; the lower arch *a a* above the fire being perforated with 25 apertures for the passage of the flames, while between the drying chamber and the chimney there are 13 similar passages. The fuel is placed below the chief chamber C and in front of it, in a prolongation of the fire channels *a a*, in which the grates are set. Several modifications of these kilns have been from time to time introduced, and they have been specially varied to meet the conditions for burning roofing tiles, pipes, &c., but in principle they are essentially the same.

Hoffmann's Straight Kiln.—The following *fig.* (1299) represents in section a kiln on Hoffmann's system as arranged by Chamberlain and Wedekind.

a a is the brick-work of the kiln; *b*, the fire-place at one end, the opposite end opening with a chimney *c*, by a flue *d*; a number of openings *e e*, provided with closely-fitting covers are constructed along the roof of the kilns for the introduction of small fuel. The entire length of the kilns having been filled with bricks, in a fit state for burning, a fire is lighted in the fire-place *b*, and air is allowed to enter freely through the fire-door. When the heat at this end of the kiln is sufficiently high, fuel is intro-

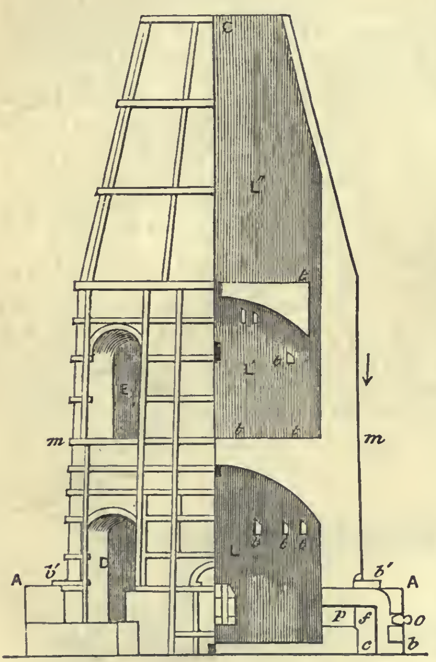
1299



duced through the openings *e e* on the top. The hot air and products of combustion pass along the entire length of the kiln, between the goods stacked in it, gradually heats it, and finally passes off by the flue *d* to the chimney *c*. So soon as that portion of the stacked bricks, into and amongst which the fuel has been supplied, has become sufficiently burnt, the further supply of fuel is stopped, and the supply is then carried on through other openings *e* in advance, so as to mingle the fuel with the adjoining bricks, which by this time will be sufficiently heated to ensure the combustion of such fuel. Those bricks which have been thoroughly burnt are now allowed to cool gradually by the action of the cold air which passes amongst them and takes up the caloric, which is transferred to the succeeding bricks on its way to the chimney. In this manner the process of burning is continued until the extreme end of the kiln has been reached, some of the goods having, in the meantime, been drawn and replaced by fresh ones, so that the kiln will be ready for relighting by the time the last of the goods is withdrawn. These kilns may be provided at intervals with sliding doors, which extend across the kiln, and subdivide it into a number of separate compartments, facility is thus afforded for making use of these compartments as drying chambers, whilst the other portion of the kiln is burning. The drying may be facilitated by bringing hot air from the cooling portions of the kiln into the drying chamber for the time being, by means of a moveable pipe or flue, which may be adjusted to any of the holes, *e*, in roof. When the bricks are sufficently dry, the doors and flue are removed so as to bring them within the direct range of the hot air and products of combustion from the burning bricks, preparatory to their being fired from above. In this arrangement flues provided with dampers should be employed, leading from each compartment to separate chimneys, or to one common flue leading to a single chimney, and each compartment should have near its upper part a flue for carrying off the steam and vapour, evolved during the process of drying.

Pottery-kilns are sometimes constructed upon this principle, in compartments; the number varying considerably according to the conditions required: these are not usually continuous. The greatest possible heat is required for baking porcelain. The porcelain kiln consists of a round chamber, on the floor of which the porcelain vessels, enclosed in *seggars*, are arranged in columns. The flames fill the whole space, circulating between the columns, and escaping through different apertures in the top of the chamber; from thence they enter a second chamber, and their heat is still sufficient for baking biscuit-ware. *Fig.* 1300 represents the Sèvres porcelain kiln. The kiln is surrounded by four separate fires A A, which first heat the space L, which is intended for completely burning the porcelain; the upper chamber L′ being used for baking the biscuit; while the third space L″ may be used for the same purpose, or for drying the seggars, the flame escaping through the chimney C. The hearths of the porcelain kiln are peculiar; they are constructed without any grate, and built in such a manner that the draught is forced to take a contrary direction to that which it usually takes in other kilns. The space C is filled with red-hot fuel, which is passed in through the aperture *b*, and completely fill the space *f*. The draught in the first instance is downward, in the direction of the arrow, through b', and the spaces between the fuel in *f* and *c*; this creates a long flame, which escapes through *p* into the chamber L. The round aperture *o* is usually closed with a clay stopper; through this opening the fire is stirred; *b*, at the foot of the hearth is used for removing the ashes when necessary, the draught being always regulated by the lid b'. The flue is divided by three tongues into three channels *p*, in order that the flame may be dispersed; D and E are the doors for the insertion of the goods. In the arched covering of the space L twenty-five apertures *t t* are left to conduct the flame into the chamber L′. Any single opening would draw all the flame together—the object is to spread it. Half the number of openings are made in the roof of L′ t' t', for a similar purpose. Small openings are made in the walls of the chamber L, through which the colour of the fire may be watched. The whole of the kiln is bound together with iron bands to prevent its falling to pieces. Such furnaces are usually 20 feet in diameter, they are constructed internally with fire-stone, aud surrounded on the outside with bricks.

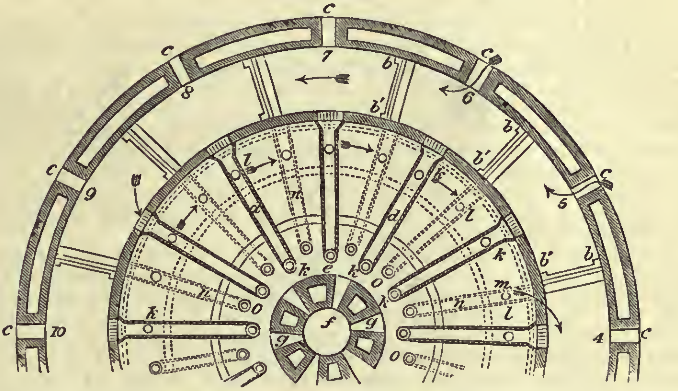
1300



Hoffmann's Continuous Kiln.—Fig. 1302 represents a vertical section, and *fig.* 1301 a sectional plan of a continuous kiln, combined with a second or inner chamber, by which dry or warm air may be taken from any of the heated chambers of the kiln to any of the other chambers, for the purpose of drying green bricks or other articles from which it is desired to drive off the moisture. *a*, the brickwork of the kiln, a portion of the annular burning and drying space of which may be shut off or separated from the rest by two moveable diaphragms, *b*, *b′*, to form a drying chamber. The entire kiln is capable of being subdivided into a number of compartments, numbered in *fig.* 1301 from 4 to 10 inclusive, although any other number may be used. Each compartment is provided with a door at *c*, through which the goods are introduced and removed. From the upper part of the several compartments extend a series of flues, *d d*, converging towards, and opening into, an annular smoke-chamber, *e*, which surrounds the chimney, *f*, and communicates therewith by the passages or openings, *g*. The inner ends of these flues inside the smoke chamber are closed or left open by means of conical plugs, *k k*, which, by being elevated, will regulate the amount of opening of the flues. A closed man-hole, *i*, *fig.* 1302, is made in each of these flues for the facility of cleaning. Valves, *k* (*fig.* 1301), connect any one of these flues, when open, with the annular passage, *l*, for dry or warm air, the bottom of the passage communicating, by means of valve *m*, with the flues, *n*, which lead from the lower portion of the compartments of the kiln to the smoke chamber, *e*, before referred to. These flues, *n*, are also provided with conical plugs or dampers, *o*, similar to those which are fitted on to the inner ends of the flues, *d*.

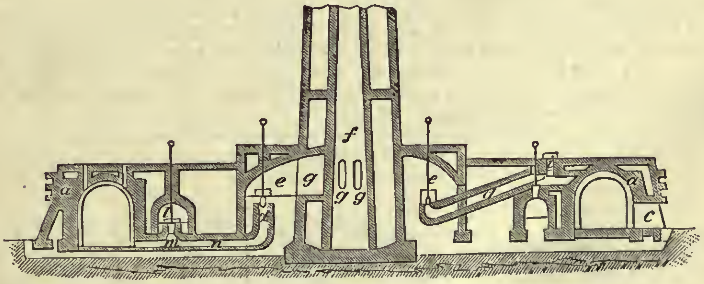
In *fig.* 1301 the chambers 4 and 5 are represented as being shut off from the doors, *b*, *b′*, and are supposed to contain green bricks; the chamber 6 is being filled whilst

1301



the goods are being removed from chamber 7; the chambers 8, 9, and 10, all contain burnt goods in the act of cooling; whilst the other chambers are being fired, the hot air therefrom passing through the goods in the chambers 1 and 2 (not shown), and being obstructed by the door, *b*, from entering the drying-chambers 4 and 5 direct, it passes

1302



by the bottom flue, *n*, of the series direct to the smoke-chamber, *e*, and thence to the chimney, the plug or damper, being more or less open for that purpose according to the draught required. The fresh air enters by the doors, *c c*, passes through the heated goods in the chambers 7, 8, and 9, thereby cooling the goods, and at the same time taking up the caloric. A portion of this air so heated passes onwards through the chambers 10, 11, 12, 1, 2, and thence by the flue, *n*, to the chimney, whilst another portion enters one of the flues, *d*, at the mouth thereof, and as the plug or valve, *h*, on the inner end of this flue is closed, the heated air enters by the open valve, *k*, in the annular chamber or passage, *l*. The warm air then traverses the chamber, *e*, passes through the only open valve, *m*, of the series into the flue, *n*, of the series, the end of which in the smoke chamber is closed by the valve, *o*, and thence to the drying-chamber, 4, and chamber, 3, and finally escaping at *d* by the flue and open plug or valve, *h*, into the smoke chamber, *c*, and chimney, *f*; the whole of the valves, *h*, *o*, *k*, and *m*, are kept closed, except those which are in connection with the flues for the time being; and, so soon as the goods in the drying-chambers 3 and 4 are sufficiently dry for burning, the doors, *b*, are removed, and replaced at *b'*, exposing the bricks in the chamber 3 to the direct action of the heat from the kiln-fires, whilst the chamber 5, just filled with green bricks, forms, with the chamber 4, a drying-chamber. A fresh set of valves or dampers is now opened, and the operations of burning and drying proceed in a continuous manner.

Kilns for special purposes demand especial contrivances; but, usually, they are in principle like one or other of those which have been described. For Malt-Kiln, see MALT.

KIMERIDGE CLAY or **SHALE.** The sands which underlie the Portland stone of Dorsetshire and the south-west of England are based upon a considerable thickness of dark brownish- or bluish-grey clay, to which the term Kimeridge Clay has been given by geologists from the circumstance of its being largely developed and well displayed in the neighbourhood of the village of that name.

Throughout the Isle of Purbeck, but especially in the part of it in question, the clay assumes a very shaly and bituminous character, sometimes passing into more massive beds of brownish shaly coal, possessing a conchoidal fracture.

The Romans, and also the Celts who inhabited the country previously to its invasion by the former nation, appear to have manufactured the harder portions of the shale into cups and other articles, but chiefly into beads, armlets, and bracelets, specimens of which last have been found in the neighbouring barrows, in some cases still encircling the wrists of skeletons.

Circular discs of shale, about the size of a penny piece, have also been dug up in great numbers in this part of the Isle of Purbeck: as many as 600 were, upon one occasion, found closely packed together.

Authorities have been much divided in opinion as to the origin and use of these circular pieces of shale. By some they are supposed to have passed current as money or tokens, whence the name of Kimeridge coal-money, by which they are commonly known, has been applied to them; but the most probable supposition is, that they were the portions of the material fixed to the lathe, and left adhering to it after the armlets or other ornaments of a similar description had been turned from their outer circumferences, and that at some subsequent period these refuse pieces of the turner were worn as amulets or charms by the superstitious.

The shale around Kimeridge abounds in animal and vegetable matter, the former consisting of the shells of oysters, ammonites, &c., together with the bones and teeth of large saurians and fish; while the latter is in so finely divided a state as not to be distinguishable to the eye. Much carbonate of lime and pyrites are also present, especially in those portions in which animal remains are most abundant.

The variation in the external character of the shale is accompanied by a corresponding variation in the relative proportions of mineral and organic matter contained in it; those portions which are the mose fissile and slaty containing a large proportion of mineral matter combined with a relatively small proportion of organic matter; while, on the other hand, in the harder and more massive portions which break with a conchoidal fracture, the organic matter is greatly in excess of the mineral matter, as is shown by the following analyses:—

	Greyish-green delicately fissile shale A		Brown shale with conchoidal fracture B
Amount of volatile matter . . .	19·51	52·8	73·3
„ „ mineral matter . . .	80·49	47·2	26·7
	100·00	100·0	100·0

When heated the shale gives off copious fumes of a disagreeable odour resembling that of petroleum; and when ignited it burns of itself with a dull smoky flame, leaving, when freely exposed to the atmosphere, a reddish ash, which generally retains the form of the original fragment.

The shale has long been used for fuel by the people of the district where it occurs, and the ashes left after combustion have long been known to the farmers on the coast to exercise a beneficial influence upon their crops, especially turnips; but the unpleasant smell given out by it when burning has prevented it from being used, except by the poorer inhabitants.

The composition of this gas, freed from carbonic acid and sulphuretted hydrogen by passing through an ordinary lime purifier, was as follows:—

Olefiant gas and congeners	10·0
Light carburetted hydrogen and hydrogen	79·0
Carbonic oxide	11·0
	100·0

The composition of the coke produced was:—

Carbon	73·4	72·8
Ash	34·3	30·3
	107·7	103·1

The excess above 100 arises from the presence of sulphides in the coal, which during the process of incineration absorb oxygen, and are converted into sulphates.

A ton of shale furnished 11,300 cubic feet of this purified gas, the illuminating power of which, used in the argand burner, consuming 5 cubic feet per hour, equalled that of 20 sperm candles, while the percentage of coke remaining was 36·5.

The liquid and solid products obtained by the distillation of the shale at a low temperature, are an offensively smelling, dark brown oil, suspended in an aqueous liquid, charged with sulphuretted hydrogen, carbonic acid, and ammonia.

This oil, purified and distilled with water, furnished an oily liquid heavier than water; a tar-like residue being left in the retort.

The oily liquid which, when purified, gives out the odour of the finest varieties of coal-gas naphtha, is a mixture of several chemical substances.

When treated with concentrated nitric acid, this oily liquid is divided into two portions, one of which is dissolved by the acid, while the other insoluble portion floats on the surface of the solution in the form of a light colourless oily liquid, resembling in its general character the hydrocarbons of Boghead coal-tar, and of petroleum. The nitric solution which forms the larger proportion of the oily liquid, when mixed with water, furnishes a dense, heavy, yellowish oil, with the odour of nitro-benzol.

Hence it appears that the oily liquid obtained by the distillation of the shale consists chiefly of benzol and its homologues, mixed with small quantities of petroleum hydrocarbons. When sufficiently purified it is applicable for all the purposes for which benzol is employed, for dissolving India-rubber and gutta-percha, for removing stains from fabrics, for preparing varnishes, for making artificial oil of almonds, &c.

On subjecting to distillation without water, and at a rather high temperature, the oily tar-like residue remaining in the retort after the crude volatile oil is obtained by heat from the shale, had been distilled with water, other volatile products are obtained.

The first portion of the oil obtained during the distillation is of an amber colour when first distilled, and much less limpid than the oil produced by distillation with water. It also possesses an offensive sulphurous smell, which, however, is lost on exposure to the air, while the oil assumes a much darker colour. This oil is acted upon by sulphuric, nitric, and hydrochloric acids, by which, especially by the first, a portion of it is resinified.

The remaining portion of the oil, when washed with water and afterwards distilled with steam, furnishes a perfectly colourless oil with the properties of paraffine. This last oil, which forms but a small portion of the original oil, behaves in all respects like the paraffine oil obtained from Boghead cannel coal, and is applicable to the lubrication of machinery, and all the other purposes to which that liquid is applied.

The black, pitch-like, coky residue left in the retort resembles in general character the coke produced from coal in the manufacture of gas.

The ash of the incinerated coke contains nearly the same proportions of silica, alumina, and iron, as Portland cement. The following is an analysis of the ash left by the shale, which contains the larger amount of mineral matter:—

	Ash of Dorsetshire shale	Portland cement
Insoluble residue	29·01	
Peroxide of iron	7·10	5·30
Silica	21·75	22·23
Alumina	10·60	7·75
Lime	20·62	54·11
Carbonic acid	10·92	2·15
	100·00	91·54

Some few years since works were established at Wareham, for the purpose of extracting naphtha, and other products, from the shale by distillation; but the manufacture was abandoned in consequence of the impossibility of destroying the smell given out by the naphtha. We learn (1874) that the works are to be resumed.

The treatment of the shale at Wareham, according to Mr. John C. Mansel, was conducted in the following manner:—

The retorts were charged with about 5 cwts. of shale, prevously broken into pieces about 2 inches square, and the temperature was maintained as nearly uniform as possible. In order to obtain the required uniform temperature the retorts were constructed so as to have backs of lead. The gas formed in the retorts was then condensed by means of a leaden worm, and the product was a crude oil; a large quantity of gas was made during this operation, which was not condensed, but used for ordinary purposes. The crude oil was allowed to stand in long tanks for 48 hours, for the purpose of letting the ammoniacal water (of which there is a large quantity) subside. The oil was then put into a still and rectified once or twice as the case might be. The first product was a light oil, making overproof 75°; the next products were heavy oils, containing paraffine.

The shale, on being taken out of the retorts, was placed in close vessels, and when cool was ground in a mill for manure. In its unmanufactured state the shale was not sufficiently rich in ammonia for this purpose; but at this stage the artificial manure was said to be as valuable as Ichaboe guano, both having been recently analysed for the purpose of comparison. By keeping the temperature low in the retorts, neither the phosphates nor the organic matter were destroyed.

KIMERIDGE COAL. See Kimeridge Clay or Shale.

KING'S BLUE. See Blue Pigments.

KINGSTON'S METAL. An alloy which is known as Kingston's metal is much used for the bearings and packings of machinery. James Pole Kingston patented in 1853 the use of an alloy which he specified as prepared in the following manner:—

An alloy, consisting of copper 9 lbs. and tin 24 lbs., is first melted; then 9 lbs. of mercury are added, and the whole combined. When cooled, it is ready to be used.

KING'S YELLOW. A mixture of arsenious acid and orpiment, used as a pigment.

KING-WOOD is imported from the Brazils, and is sometimes called violet wood. This is one of the most beautiful of the hard woods, and is used in small cabinet work.

KINIC ACID. A peculiar acid extracted by Vauquelin from cinchona.

KINO is an extract obtained most probably from the *Pterocarpus marsupium*, which grows on the Malabar coast. In India kino is used for dyeing cotton a nankeen colour. It is of a reddish-brown colour, has a bitter styptic taste, and consists of tannin and extractive, 75 parts, and a red gum 25 parts. It is used only as an astringent in medicine. Kino is often called a gum, but most improperly so.

KIP. A Malacca weight for tin, of 40 lbs. 11 oz. avoirdupois.—*Simmonds.*

KIPS. The tanners call the skins of young animals kips. The skins of full-grown cattle of small breed are also so called. See Leather.

KIRSCHWASSER is an alcoholic liquor obtained by fermenting and distilling bruised cherries, called *Kirschen* in German. The cherry usually employed in Switzerland and Germany is a kind of morello, which on maturation becomes black, and has a kernel very large in proportion to its pulp. When ripe, the fruit, being made to fall by switching the trees, is gathered by children; thrown promiscuously, unripe, ripe, and rotten into tubs; and crushed either by hand, or with a wooden beater. The mashed materials are set to ferment; and, whenever this process is complete, the whole is transferred to a still, and the spirit is run off, by placing the pot over the common fireplace.

The fermented mash is usually mouldy before it is put into the alembic, the capital of which is luted on with a mixture of mud and dung. The liquor has accordingly, for the most part, a rank smell, and is most dangerous to health, not only from its own crude essential oil, but from the prussic acid derived from the distillation of the cherry-stones.

There is a superior kind of *Kirschwasser* made in the Black Forest, prepared with fewer kernels, from choice fruit, properly pressed, fermented, and distilled.

KIRWANITE. A mineral found in basalt on the north-eastern coast of Ireland, consisting of silica, lime, alumina, and protoxide of iron.

KISH. A workman's name for the crystalline scales of graphite, which separate from certain kinds of cast iron on cooling.

KNIFE-CLEANING MACHINES. Mr. Kent's machine for this purpose consists of a box or case, containing a couple of wooden discs, fixed near to each other upon a horizontal iron rod or spindle, which passes through the case, and is caused to rotate by means of a winch-handle. Each disc is, for about three-fourths of the area of its inner face, covered with alternate rows of bristles and strips of leather; and the remaining fourth part is covered with bristles only. The knife-blades to be cleaned are introduced through the openings in the case, between the rubbing surfaces of the discs; and rotatory motion being given to the discs by a winch-handle, the knives are rapidly cleaned and polished.

Mr. Masters constructed knife-cleaning machines upon the same plan as the above; but the rubbing-surface of each disc is formed of strips of buff leather, with only a narrow circle of bristles around the edge of each surface, to clean the shoulders of the knives; small brushes are fixed beneath the holes in the case, through which the blades of the knives are inserted, to prevent the exit of dust from the apparatus.

Mr. Price has also devised a machine for cleaning knives, and another for cleaning forks. The knife-cleaner consists of a horizontal drum, covered with pieces of leather or felt, and fixed within another drum or circular framing, lined with leather or felt. The knives are introduced through openings, in a moveable circular plate, at the front of the outer casing, and enter between the surfaces of the two drums. The plate is fixed upon a horizontal axis, which extends through the case, and is furnished at the back with a handle; by turning which the disc is caused to rotate and carry round the knives between the surfaces of the drums. The fork-cleaner consists of a box, with a long rectangular opening in the side; behind which two brushes are fixed, face to face. Between these brushes the prongs of the forks are introduced, and the handles are secured in a carrier, which is made to advance and recede alternately by means of a throw-crank, and thereby thrust the prongs into and draw them out of contact with the brushes. The carrier consists of two metal plates, the lower one carrying a cushion of vulcanised India-rubber for the fork handles to rest upon, and the upper being lined with leather; they are hinged together at one end, and are connected at the other, when the handles have been placed between them, by a thumb-screw.

KNOLLS. A mining term in Germany for lead ore separated from the smaller parts.

KNOPPERN are excrescences produced by the puncture of an insect upon the flower-cups of several species of oak. They are compressed or flat, irregularly-pointed, generally prickly and hard; brown when ripe. They abound in Styria, Croatia, Sclavonia, and Natolia; those from the latter country being the best. They contain a great deal of tannin, are much employed in Austria for tanning, and in Germany for dyeing fawn, grey, and black. See Galls.

KOFFO-HEMP. The name in the Moluccas for the Manilla hemp, or rather for the fibres of the wild plantain of those islands, the *Musa textilis*.

KOHL-RABBI. A variety of cabbage (*Brassica oleracea*), in which the stem enlarges into a fleshy excrescence, resembling a turnip.

KOLA NUTS. The bitter seeds of certain species of *Sterculia*, highly esteemed for their medicinal properties by the tribes on the Niger.

KOUMISS is the name of a liquor which the Kalmucks make by fermenting mare's milk, and from which they distil a favourite intoxicating spirit, called *rack* or *racky*.

The milk is kept in bottles made of hide till it becomes sour, is shaken till it casts up its cream, and is then set aside in earthen vessels, in a warm place to ferment, no yeast being required, though sometimes a little old koumiss is added. 21 lbs. of milk put into the still afford 14 oz. of low wines, from which 6 oz. of pretty strong alcohol, of an unpleasant flavour, are obtained by rectification.

KOURIE WOOD. The wood of the New Zealand pine, *Dammara Australis*, one of the most magnificent of the coniferous woods. It is also called *cowdie* and *kaurie* wood. It is much used for the masts of ships.

KRAMERIA. A shrub, which is a native of Peru, yielding the well-known rhatany root, often used as a dentifrice.

KREOSOTE. See Creosote.

KRYOLITE. See Cryolite.

KUKUI OIL. An oil expressed from the seeds of the *Aleurites triloba*, or candle-nut tree. It is used as an artist's oil.

KUSS-KUSS. This is the tough fibrous rhizome of an Indian grass. It is woven into a fabric called *tatty* in India; it has an extensive use in the manufacture of awnings, blinds, and sunshades; these are often sprinkled with water during the hot seasons, which, by evaporation, cools the air in the apartment, and at the same time imparts an agreeable odour.

KYANITE. A stone, which is sometimes blue and transparent. It is then employed as a gem; it resembles sapphire. Its chemical composition is, silica, 37·0; alumina, 63·0.

KYANIZING. A process for preserving wood, successfully carried out by the late Mr. Kyan of New York. A solution of corrosive sublimate is forced into the pores of the timber. This chloride of mercury combines with, and coagulates the vegetable albumen, and thus renders the wood impervious to air or moisture.

KYANOL. The old name of aniline. It was applied by Runge to the base from coal-tar.

KYROSITE. A sulphide of copper containing traces of arsenic, from Briccius, near Annaberg, in Saxony.

L

LABARRAQUE'S FLUID. A solution of chloride of soda, occasionally used in bleaching. See Chloride of Lime.

LABDANUM. A resin found on the leaves of the *Cistus Creticus*, in Candia. It is used in perfumery and for pastiles.

LABRADORITE, or **LABRADOR FELSPAR,** is a beautiful mineral, with brilliant changing colours, blue, red, and green, &c. Spec. grav. 2·70 to 2·75. Scratches glass; affords no water by calcination; fusible at the blowpipe into a frothy bead; soluble in muriatic acid; solution affords a copious precipitate with oxalate of ammonia. Cleavages of 93½° and 86½°; one of which is brilliant and pearly. Its constituents are, silica, 55·75; alumina, 26·5; lime, 11; soda, 4; oxide of iron, 1·25; water, 0·5.

Labradorite receives a fine polish, and the beauty of its chatoyant reflections recommends it as an article of ornament.—H.W.B.

In addition to the play of iridescent colours exhibited on the brachydiagonal cleavage-plane of labradorite, the mineral usually presents an aventurine-like appearance due to the enclosure of microscopic scales and crystals (*microliths*). The minute structure of labradorite has recently been studied by Schrauf, of Vienna, and other microscopists. See Felspar.

LABRADOR TEA. An infusion of the leaves of *Ledum palustre* and *L. latifolium*, drunk in parts of North America.

LABURNAM. *Cytisus Laburnam.* (*Arbois commun*, Fr.; *Goldregen*, Ger.) The wood of the laburnam-tree is sometimes used in ornamental cabinet-work and in marquetry. 'In the laburnam there is this peculiarity, namely, that the medullary plates, which are large and very distinct, are white, whereas the fibres are a dark brown—a circumstance which gives an extraordinary appearance to this wood.'—*Aikin.*

LABYRINTH, in *Metallurgy*, means a series of canals distributed from the lead of a stamping-mill; through which canals a stream of water is transmitted for suspending, carrying off, and depositing, at different distances, the ground ores. See Dressing of Ores.

LAC. (*Laque*, Fr.; *Lack, Lackfarben*, Ger.) A resinous substance produced by the puncture of a peculiar female insect, called *Coccus lacca* or *ficus*, upon the branches of several plants; as the *Ficus religiosa* or the pepel tree, the *F. Indica*, the *Rhamnus jujuba*, the *Croton lacciferum* or bihar tree, and the *Butea frondosa*, the Dhak, which grow in Siam, Assam, Pegu, Bengal, and Malabar. The twig becomes thereby incrusted with a reddish mammillated resin, having a crystalline-looking fracture.

The female lac-insect is of the size of a louse; red, round, flat, with 12 abdominal circles, a bifurcated tail, antennæ, and 6 claws, half the length of the body. The male is twice the above size, and has 4 wings; there is one of them to 5,000 females. In November or December the young brood makes its escape from the eggs, lying beneath the dead body of the mother; they crawl about a little way, and fasten themselves to the bark of the shrubs. About this period the branches often swarm to such a degree with this vermin, that they seem covered with a red dust; in this case, they are apt to dry up, by being exhausted of their juices. Many of these insects, however, become the prey of others, or are carried off by the feet of birds, to which they attach themselves, and are transplanted to other trees. They soon produce small nipple-like incrustations upon the twigs, their bodies being apparently glued, by means of a transparent liquor, which goes on increasing to the end of March, so as to form a cellular texture. At this time the animal resembles a small oval bag, without life, of the size of cochineal. At the commencement, a beautiful red liquor only is perceived, afterwards eggs make their appearance; and in October or November, when the red liquor gets exhausted, twenty or thirty young ones bore a hole through the back of their mother, and come forth. The empty cells remain upon the branches. These are composed of the milky juice of the plant, which serves as nourishment to the insects, and which is afterwards transformed or elaborated into the red colouring matter that is found mixed with the resin, but in greater quantity in the bodies of the insects, in their eggs, and still more copiously in the red liquor secreted for feeding the young. After the brood escapes, the cells contain much less colouring matter. On this account, the branches should be broken off before this happens, and dried in the sun. In the East Indies this operation is performed twice in the year; the first time in March, the second in October. The twigs encrusted with the radiated cellular substance constitute the *stick-lac* of commerce. It is of a red colour more or less deep, nearly transparent, and hard, with a brilliant conchoidal fracture. The stick-lac of Siam is the best; it often forms an incrustation fully one quarter of an inch thick all round the twig. The stick-lac of Assam ranks next; and, last, that of Bengal, in which the resinous coat is scanty, thin, and irregular. There are three kinds of lac in commerce: stick-lac, which is the substance in its natural state, seed-lac, and shell-lac. According to the analysis of Dr. John, stick-lac consists of–

An odorous common resin	80·00
A resin insoluble in ether	20·00
Colouring matter analogous to that of cochineal	4·50
Bitter balsamic matter	3·00
Dun yellow extract	0·60
Acid of the stick-lac (laccic acid)	0·75
Fatty matter, like wax	3·00
Skins of the insects, and colouring matter	2·50
Salts	1·25
Earths	0·75
Loss	4·75
	120·00

According to Franke, the constituents of stick-lac, are, resin, 65·7; substance of the lac, 28·3; colouring matter 0·6.

Seed-lac.—When the resinous concretion is taken off the twigs, coarsely pounded, and triturated with water in a mortar, the greater part of the colouring matter is dissolved, and the granular portion which remains being dried in the sun, constitutes *seed-lac*. It contains of course less colouring matter than the stick-lac, and is much less soluble. Mr. Hatchett's analysis of seed-lac was as follows:—

Resin	68
Colouring matter	10
Wax	7
Gluten	5·5
Foreign bodies	6·5
Loss	4
	100

John found in 100 parts of it, resin, 66·7; wax, 1·7; matter of the lac, 16·7; bitter balsamic matter, 2·5; colouring matter, 3·9; dun yellow extract, 0·4; envelopes of insects, 2·1; laccic acid, 0·0; salts of potash and lime, 1·0; earths, 6·6; loss, 4·2.

Shell-lac.—In India the *seed-lac* is put into oblong bags of cotton cloth, which are held over a charcoal fire by a man at each end, as soon as it begins to melt, the bag is twisted so as to strain the liquefied resin through its substance, and, to make it drop upon smooth stems of the banyan-tree (*Musa paradisa*). In this way, the resin spreads into thin plates, and constitutes the substance known in commerce by the name of *shell-lac*.

The Pegu stick-lac, being very dark coloured, furnishes a shell-lac of a corresponding deep hue, and therefore of inferior value. The palest and finest shell-lac is brought from the northern *Circar*. It contains very little colouring matter. A stick-lac of an intermediate kind comes from the Mysore country, which yields a brilliant lac-dye and a good shell-lac.

Shell-lac, by Mr. Hatchett's analysis, consists of resin, 90·5; colouring matter, 0·5; wax, 4·0; gluten, 2·8; loss, 1·8; in 100 parts.

The resin may be obtained pure by treating shell-lac with cold alcohol, and filtering the solution in order to separate a yellow grey pulverulent matter. When the alcohol is again distilled off, a brown, translucent, hard, and brittle resin, of specific gravity 1·139, remains. It melts into a viscid mass with heat, and diffuses an aromatic odour. Anhydrous alcohol dissolves it in all proportions. According to John, it consists of two resins, one of which dissolves readily in alcohol, ether, the volatile and fat oils; while the other is little soluble in cold alcohol, and is insoluble in ether and the volatile oils. Unverdorben, however, has detected no less than four different resins, and some other substances in shell-lac. Shell-lac dissolves with ease in dilute muriatic and acetic acids, but not in concentrated sulphuric acid. The resin of shell-lac has a great tendency to combine with salifiable bases; as with caustic potash, which it deprives of its alkaline taste.

This solution, which is of a dark red colour, dries into a brilliant, transparent reddish brown mass; which may be re-dissolved in both water and alcohol. By passing chlorine in excess through the dark-coloured alkaline solution, the lac-resin is precipitated in a colourless state. When this precipitate is washed and dried, it forms, with alcohol, an excellent pale-yellow varnish, especially with the addition of a little turpentine and mastic.

With the aid of heat, shell-lac dissolves readily in a solution of borax.

The substances which Unverdorben found in shell-lac are the following:—

1. A resin, soluble in alcohol and ether;
2. A resin, soluble in alcohol, insoluble in ether;
3. A resinous body, little soluble in cold alcohol;
4. A crystallisable resin;
5. A resin, soluble in alcohol and ether, but insoluble in petroleum, and uncrystallisable.
6. The unsaponified fat of the *coccus* insect, as well as oleic and margaric acids.
7. Wax.
8. The *laccine* of Dr. John.
9. An extractive colouring matter.

Shell-lac is largely used in the manufacture of sealing-wax and varnishes, and for japanning.

LAC-DYE, *Lac-Lake*, or *Cake-lac*, is the watery infusion of the ground stick-lac, evaporated to dryness, and formed into cakes about two inches square and half an inch thick. Dr. John found it to consist of colouring matter, 50; resin, 25; and solid matter, composed of alumina, plaster, chalk, and sand, 22.

Dr. Macleod, of Madras, states that he prepared a very superior lac-dye from stick-lac, by digesting it in the cold in a slightly alkaline decoction of the dried leaves of the *Menecylon tinctorium* (perhaps the *M. capitellatum*, from which the natives of Malabar and Ceylon obtain a saffron-yellow dye). This solution being used along with a mordant consisting of a saturated solution of tin in muriatic acid, was found to dye woollen cloth of a very brilliant scarlet hue.

The cakes of *lac-dye* imported from India, stamped with peculiar marks to designate their different manufacturers (*the best* DT, the second JMcR, the third CE), are now employed in England for dyeing scarlet cloth, and are found to yield an equally brilliant colour, and one less easily affected by perspiration than that produced by cochineal. When the lac-dye was first introduced, sulphuric acid was the solvent applied to the pulverised cakes, but as muriatic (hydrochloric) acid has been found to answer, it has to a great extent supplanted it. A good *solvent* (No. 1) for this dye-stuff may be prepared by dissolving 3 pounds of tin in 60 pounds of muriatic acid, of specific gravity 1·19. The proper *mordant* for the cloth is made by mixing 27 pounds of muriatic acid of sp. gr. 1·17, with 1½ pound of nitric acid of 1·19; putting this mixture into a salt-glazed stone bottle, and adding to it, in small bits at a time, grain tin, till 4 pounds be dissolved. This solution (No. 2) may be used within twelve hours after it is made, provided it has become cold and clear. For dyeing; three quarters of a pint of the solvent No. 1 is to be poured upon each pound of the pulverised lac-dye, and allowed to digest upon it for six hours. The cloth before being subjected to the dye-bath, must be scoured in the mill with fuller's earth. To dye 100 pounds of pelisse cloth, a tin boiler of 300 gallons capacity should be filled nearly brimful of water, and a fire kindled under it. Whenever the temperature rises to 150° Fahr., a handful of bran, and half a pint of the solution of tin (No. 2) are to be introduced. The froth, which rises as it approaches ebullition, must be skimmed off; and when the liquor boils, 10½ pounds of lac-dye, previously mixed with 7 pints of the solvent No. 1, and 3½ pounds of solution of tin No. 2, must be poured in. An instant afterwards, 10½ pounds of tartar, and 4 pounds of ground sumach, both tied up in a linen bag, are to be suspended in the boiling-bath for five minutes. The fire being now withdrawn, 20 gallons of cold water, with 10½ pints of solution of tin being poured into the bath, the cloth is to be immersed in it, moved about rapidly during ten minutes; the fire is to be then re-kindled, and the cloth winced more slowly through the bath, which must be made to boil as quickly as possible, and maintained at that pitch for an hour. The cloth is to be next washed in the river; and lastly with water only, in the fulling-mill. The above proportions of the ingredients produce a brilliant scarlet tint, with a slightly purple cast. If a more orange hue be wanted, white Florence argal may be used, instead of tartar, and some more sumach. Lac-dye may be substituted for cochineal in the orange-scarlets.

To determine the tinctorial power of lac-dye by comparison with proved samples, a dye-bath is prepared as follows:—5 grains of argal, 20 grains of flannel or white cloth, 5 grains of lac-dye, 5 grains of chloride of tin, 1 quart of water. Heat the water to the boiling point in a tin or china vessel; add thereto the argal, and then the piece of cloth or flannel. Weigh off 5 grains of the lac-dye and pulverise it in a Wedgwood mortar, with the 5 grains by measure of chloride of tin, and pour the whole into the hot liquor containing the cloth, taking care to rinse the mortar with a little of the hot liquor; keep the whole boiling for about half an hour, stirring the cloth or flannel about with a glass rod; then withdraw the cloth, wash and dry it for comparison.

LACCIC ACID crystallises, has a wine-yellow colour, a sour taste, is soluble in water, alcohol, and ether. It was extracted from stick-lac by Dr. John.

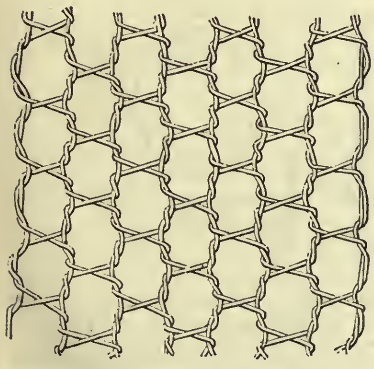
LACCINE is the portion of shell-lac which is insoluble in boiling alcohol. It is brown, brittle, translucid, consisting of agglomerated pellicles, more like a resin than anything else. It is insoluble in ether and oils. It has not been applied to any use.

LACE BARK. The reticulated bark of the *Lagetta lintearia*. This splits into fibres, which resemble lace. Lagetta cloth has been imported into this country under the name of *guana*. The fibres of the lagetta bark possess great strength, and have been used in the West Indies for making ropes, whips, &c.

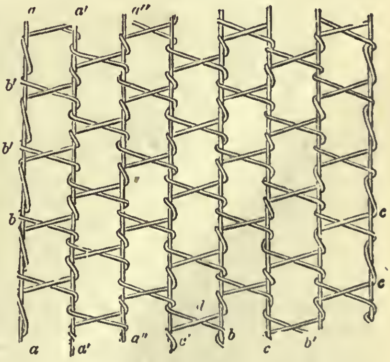
LACE MANUFACTURE. The pillow-made, or bone-lace, which formerly gave occupation to multitudes of women in their own houses, has, in the progress of mechanical invention, been nearly superseded by the bobbin-net lace, manufactured at first by hand-machines, but recently by the power of water or steam. Bobbin-net may be said to surpass every other branch of human industry in the complex ingenuity of its machinery; one of Fisher's spotting frames being as much beyond the most curious chronometer in multiplicity of mechanical device, as that is beyond a common roasting-jack.—*Ure.*

The threads in bobbin-net lace form, by their intertwisting and decussation, regular hexagonal holes or meshes, of which the two opposite sides, the upper and under, are

1303



1304



directed along the breadth of the piece, or at right angles to the salvage or border. *Fig.* 1303 shows how, by the crossing and twisting of the threads, the regular six-sided mesh is produced, and that the texture results from the union of three separate sets of threads, of which one set proceeds downwards in serpentine lines, a second set proceeds from the left to the right, and a third from the right to the left, both in slanting directions. The oblique threads twist themselves round the vertical ones, and also cross each other betwixt them, in a peculiar manner. This may be readily understood by examining the representation. In comparing bobbin-net with common web, the perpendicular threads in the figure, which are parallel to the border, may be regarded as the warp, and the two sets of slanting threads as the weft.

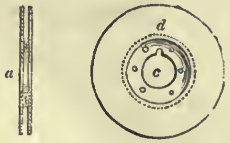
These warp threads are extended up and down, in the original mounting of the piece between a top and bottom horizontal roller or beam, of which one is called the *warp beam*, and the other the *lace beam*, because the warp and finished lace are wound upon them respectively. These straight warp threads receive their contortion from the tension of the weft threads twisted obliquely round them alternately to the right and the left hand. Were the warp threads so tightly drawn that they became inflexible, like fiddle-strings, then the lace would assume the appearance shown in *fig.* 1304; and although this condition does not really exist, it may serve to illustrate the structure of the web. The warp threads stand in the positions *a a*, *a′ a′*, and *a″ a″*; the one half of the weft proceeds in the direction *b b*, *b′ b′*, and *b″ b″*; and the second crosses the first by running in the direction *c c*, or *c′ c′*, towards the opposite side of the fabric. If we pursue the path of a weft thread, we find it goes on till it reaches the outermost or last warp thread, which it twists about; not once as with the others, but twice; and then returning towards the other border, proceeds in a reverse direction. It is from this double twist, and by the return of the weft threads, that the selvage is made.

The ordinary material of bobbin-net is two cotton yarns, of from No. 180 to No. 250, twisted into one thread; but sometimes strongly twisted single yarn has been used. The beauty of the fabric depends upon the quality of the material, as well as the regularity and smallness of the meshes. The number of warp threads in a yard in breadth is from 600 to 900; which is equivalent to from 20 to 30 in an inch. The size of the holes cannot be exactly inferred from that circumstance, as it depends partly upon the oblique traction of the threads. The breadth of the pieces of bobbin-net varies from edgings of a quarter of an inch to webs 12 or even 20 quarters, that is, 2 yards wide.

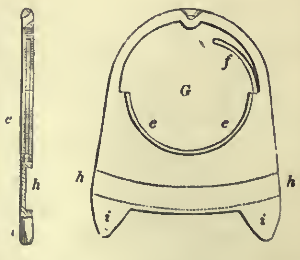
Bobbin-net lace is manufactured by means of very complicated and costly machines, called *frames*. The limits of this Dictionary will admit of an explanation of no more than the general principles of the manufacture. The threads for crossing and twisting round the warp being previously gassed, that is, freed from loose fibres by singeing with gas, are wound round small pulleys, called bobbins, which are, with this view, deeply grooved in their periphery. *Figs.* 1305, 1306, exhibit the bobbin alone, and with its carriage.

In the section of the bobbin *a*, *fig.* 1305, the deep groove is shown in which the thread is wound. The bobbin consists of two thin discs of brass, cut out in a stamp-press, in the middle of each of which there is a hollow space *c*. These discs are riveted together, leaving an interval between their edge all round, in which the thread is coiled. The round hole in the centre, with the little notch at top, serves for spitting

1305

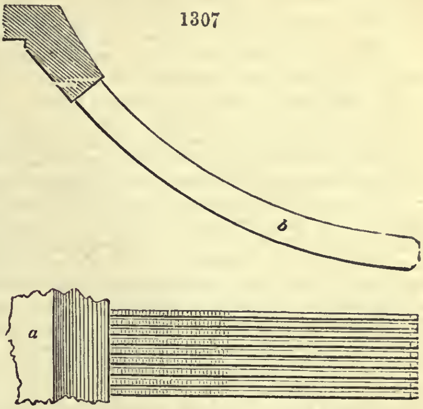


1306



them upon a feathered rod, in order to be filled with thread by the rotation of that rod in a species of reel, called the bobbin-filling machine. Each of these bobbins (about double the size of the figure) is inserted into the vacant space G of the carriage, *fig.* 1306. This is a small iron frame (also double the size of the figure), which, at *e e*, embraces the grooved border of the bobbin, and by the pressure of the spring at *f*, prevents it from falling out. This spring serves likewise to apply sufficient friction to the bobbin, so as to prevent it from giving off its thread at *g* by its rotation, unless a certain small force of traction be employed upon the thread. The curvilinear groove *h h*, sunk in each face or side of the carriage, has the depth shown in the section at *h*. The groove corresponds to the interval between the teeth of the comb, or bars of the bolt, in which each carriage is placed, and has its movement. A portion of that bolt or comb is shown at *a*, *fig.* 1307 in plan, and one bar of a circular bolt machine at *b*, in section. If we suppose two such combs or bolts placed with the ends of the teeth opposite each other, but a little apart, to let the warp threads be stretched, in one vertical plane, between their ends or tips, we shall have an idea of the skeleton of a bobbin-net machine. One of these two combs, in the double bolt machine, has an occasional lateral movement called *shogging*, equal to the interval of one tooth or bolt, by which, after it has received the bobbins, with their carriages, into its teeth, it can shift that interval to the one side, and thereby get into a position to return the bobbins, with their carriages, into the next series of interstices or gates in the other bolt. By this means the whole series of carriages receives successive side steps to the right in one bolt, and to the left in the other, so as to perform a species of counter-march, in the course of which they are made to cross and twist round about the vertical warp threads, and thus to form the meshes of the net.

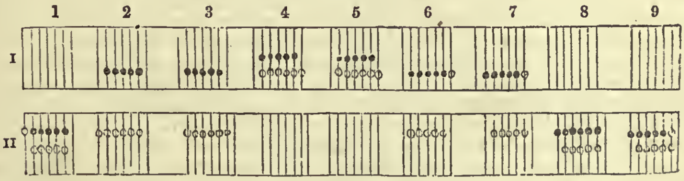
1307



The number of movements required to form a row of meshes in the double tier machine, that is, in a frame with two combs or bars, and two rows of bobbins, is six; that is, the whole of the carriages (with their bobbins) pass from one bar or comb to the other six times, during which passages the different divisions of bobbing and warp threads change their relative positions twelve times.

This interchange or traversing of the carriages with their bobbins, which is the most difficult thing to explain, but at the same time the most essential principle of the lace-machine, may be tolerably well understood by a careful study of *fig.* 1308, in which the simple line | represents the bolts or teeth, the sign ⏀ the black line of carriages, and

1308



the sign ϕ the front line of carriages. II is the front comb or bolt bar, and I the back bolt bar. The former remains always fixed or stationary, to receive the carriages as they may be presented to it by the shogging of the latter. There must be always one odd carriage at the end; the rest being in pairs.

No. 1 represents the carriages in the front comb or bar, the odd carriage being at the left end. The black line of carriages is first moved on to the back bar I, the odd carriage as seen in No. 1, having been left behind, their being no carriage opposite to drive it over to the other comb or bar. The carriages then stand as in No. 2. The bar I now shifts to the left, as shown in No. 3; the front carriages then go over into the back bar or comb, as is represented by No. 4. The bar I now shifts to the right, and gives the position No. 5. The front carriages are then driven over to the front bar, and leave the odd carriage on the back bar at the right end, for the same reason as before described, and the carriages stand as shown in No. 6. The bar I next shifts to the left, and the carriages stand as in No. 7 (the odd carriage being thereby on the back bar to the left). The back carriages now come over to the front bar, and stand as in No. 8. The back bar or comb I shifts to the right as seen in No. 9, which completes the traverse. The whole carriages with their bobbins have now changed their position, as will be seen by comparing No. 9 with No. 1. The odd carriage, No. 1, φ has advanced one step to the right, and has become one of the front tier; one of the back tier or line φ has advanced one step to the left, and has become the odd carriage; and one of the front ones φ has gone over to the back line. The bobbins and carriages throughout the whole width of the machine have thus crossed each other's course, and completed the mesh of net.

The carriages with their bobbins are driven a certain way from the one comb to the other, by the pressure of two long bars (one for each) placed above the level of the comb, until they come into such a position that their projecting heels or catches *i i*, *fig.* 1306, are moved off by two other long flat bars below, called the locker plates, and thereby carried completely over the interval between the two combs.

There are six different systems of bobbin-net machines:—1. Heathcoate's patent machine. 2. Brown's traverse warp. 3. Morley's straight bolt. 4. Clarke's pusher principle, single tier. 5. Leaver's machine, single tier. 6. Morley's circular bolt. All the others are mere variations in the construction of some of their parts. It is a remarkable fact, highly honourable to the mechanical judgment of the late Mr. Morley of Derby, that no machines except those upon his circular-bolt principle have been found capable of working successfully by mechanical power.

The circular-bolt machine (comb with curved teeth) was used by Mr. Morley for making narrow breadths or edgings of lace immediately after its first invention; and it has been regularly used by the trade for that purpose ever since, in consequence of the inventor having declined to secure the monopoly of it to himself by patent. At that time the locker bars for driving across the carriages had only one plate or blade. A machine so mounted is now called 'the single-locker circular bolt.' In the year 1824, Mr. Morley added another plate to each of the locker bars, which was a great improvement on the machine for making plain net, but an obstruction to the making of narrow breadths upon them. This machine is now distinguished from the former by the term 'double locker.'

A rack of lace is a certain length of work counted perpendicularly, and contains 242 meshes or holes. Well-made lace has the meshes a little elongated in the direction of the selvage.

Mr. Heathcoate's machine, invented in 1809, was the first successful lace-making machine.

Mr. Morley patented his in 1811; and in the same year Messrs. Marl and Clarke invented the pusher machine, and Messrs. Leaver and Turton, of New Radford, brought forward the lever machine. In 1817, Mr. Heathcoate applied the rotatory movement to the circular-bolt machine, and mounted a manufactory at Tiverton on this plan, where the lace manufacture is still carried on extensively.

LACQUER is a varnish, consisting chiefly of a solution of pale shell-lac in alcohol, tinged with saffron, annotto, or other colouring matters. 'That commonly employed is made by dissolving shell-lac in proof spirit, and colouring with the resinous substance called *dragon's blood.* The lacquer heightens the colour of brass, or renders it more golden in tint. Lacquer may be pale or deep in tint, when it is known as pale or bronze lacquer, or it may be variously coloured. A transparent colourless lacquer is a desideratum for German silver. A substance called bleached shell-lac is sold, and I believe used for very pale lacquer. The lacquer is warmed and brushed over the articles, which have been also previously warmed on stoves. If the temperature is too cold, a dulness of surface is produced, which is not removed by re-heating. The surface of brass is frequently coloured or *bronzed* after 'dipping,' and before lacquering. A dark grey coating is produced by dipping the article in a solution of arsenious acid in hydrochloric acid, by applying a dilute aqueous solution of bichloride of platinum, by applying an aqueous solution of corrosive sublimate mixed with vinegar, or by rubbing plumbago over the surface. By the application of lacquer to the surface of brass, which has received a dark grey coating by any of these processes, a bronze-like tint is produced, due to the light reflected, through the coloured stratum of varnish produced by lacquering, from the bright surface underneath. Precisely the same effect may be obtained by rubbing plumbago over a piece of writing-paper, and then lacquering the surface, as in the case of brass. For common work, the corrosive sublimate method is extensively used; it is said to cause trouble when it comes in contact with softer solder, with which the reduced mercury amalgamates. The platinum process is used for instruments, such as theodolites, levels, &c.; and in these the bronze is much blacker, as pale is employed instead of yellow lacquer. These methods I know are employed, and probably there may be many others. The beautiful colours of brass foils are communicated by variously-coloured lacquers. The coating of resinous matter adheres with remarkable tenacity, and is not detached by bending the foil backwards and forwards repeatedly. The manufacture of these foils is, I believe, quite an art, and formerly there was only one person in Birmingham who knew how to practise it successfully.'—*Percy's Metallurgy.*

LACTIC ACID, $C^{12}H^{12}O^{12}$ ($C^6H^{12}O^6$). *Syn.* Nanceic acid. (*Acide lactique*, Fr.; *Milchsäure*, Ger.) Discovered by Scheele in sour milk. Subsequently, M. Braconnot examined the sour liquid which floats above starch during its manufacture, also the acidified decoctions of various vegetables, including beet-root, carrots, peas, &c., and found an acid which he considered to be peculiar, and consequently named the nanceic. The acid formed under all these circumstances turns out to be the same; it is, in fact, lactic acid, which modern researches show to be a constant product of the fermentation of sugar, starch, and bodies of that class. The acidity of sauerkraut is due to the presence of the same substance. Liebig extended and confirmed the experiments made many years ago by Berzelius, on the presence of lactic acid in the juice of flesh, but he denied its existence in urine, as asserted by MM. Cap and Henry, and others.

Preparation.—Lactic acid can be prepared easily in any quantity by the fermentation of sugar. Care must be taken, however, that the process does not go too far, because lactic acid undergoes with facility another decomposition, by which it becomes converted into butyric acid. The following process of M. Bensch for the preparation of lactate of lime can be recommended by the author of this article as yielding at a small trouble and expense a very large quantity of product. In fact, he has prepared with facility upwards of 3 pints of butyric acid from lactate of lime obtained in this manner. Dissolve 6 lbs. of lump-sugar, and ½ oz. of tartaric acid in 2½ gallons of boiling water. Leave for a day or two, and then add 2 oz. of rotten cheese, and a gallon of skimmed milk stirred up with 3 lbs. of well-washed prepared chalk. The temperature should not fall below 86° F. nor rise above 95°. The water lost by evaporation must be made up by adding a little every few days. After a time, varying from 10 days to a month, according to the temperature and other circumstances, the whole becomes a magma of acetate of lime. Two gallons of boiling water must then be added, and ½ oz. of quicklime, and the whole, after being boiled for half an hour, is to be filtered through a linen or flannel bag. The filtered liquid is to be evaporated until it begins to get somewhat syrupy, the fluid in this state being put aside to allow the salt to crystallise. The crystals, after being slightly washed with cold water, are to be recrystallised two or three times. To obtain lactic acid from the lactate of lime, it is necessary, in the first place, to convert the latter salt into that of zinc. For this purpose a crude lactic acid is first obtained thus: to every 2 lbs. 3 oz. of lactate of lime dissolved in twice its weight of boiling water, 7 oz. of oil of vitriol previously diluted with twice its volume of water are to be added. The boiling fluid is to be strained through a linen bag to remove the precipitate of gypsum, and the filtered liquid is to be boiled for 15 minutes with 8¾ oz. of carbonate of zinc. The boiling must not be continued longer, or a subsalt of sparing solubility would be produced. The liquid, which is to be filtered boiling, will deposit on cooling the lactate of zinc in colourless crystals, which are to be washed with a little cold water, and after being drained are to be dried by exposure to the air on frames covered with filtering paper. The mother-liquid will yield a fresh quantity of lactate if it be boiled with the salt remaining on the filter and evaporated.

From the lactate of zinc the acid is to be separated by passing sulphuretted hydrogen through the solution of the salt in eight times its weight of boiling water. The gas is to be expelled by heat, and the fluid on evaporation yields pure syrupy lactic acid.

Lactic acid is a colourless syrupy liquid of a powerful pure acid taste. Its specific gravity is 1·215. It is bibasic.

The most important salts of lactic acid are those of zinc and lime. The former salt is that generally formed in examining animal or vegetable fluids with a view to the isolation of the acid. It is found with two different quantities of water according to the circumstances under which it is prepared, and it is worthy of remark that the amount of water of crystallisation remarkably affects the solubility of the salt in water and alcohol.

All the butyric acid employed for the preparation of butyric ether, or pine-apple essence, is now prepared by the fermentation of lactate of lime.—C.G.W.

LACTOMETER is the name of an instrument for estimating the quality of milk, called also a *Galactometer*. The most convenient form of apparatus would be a series of glass tubes each about 1 inch in diameter, and 12 inches long, graduated through a space of 10 inches, to tenths of an inch, having a stopcock at the bottom, and suspended upright in a frame. The average milk of the cow being poured in to the height of 10 inches, as soon as the cream has all separated at top, the thickness of its body may be measured by the scale; and then the skim-milk may be run off below into a hydrometer glass, in order to determine its density or relative richness in caseous matter, and dilution with water.

LACUSTRINE FORMATION, *a geological term.* Belonging to a lake.

LADANUM. A fragrant gum-resin obtained from several species of *Cistus,* as *C. ladaniferus* and *C. Ledon.* It is used in Turkey as a perfume.

LAGAN GOODS. See Jetsam.

LAKES. Under this general title are included all those pigments which are prepared by combining vegetable or animal colouring matter with earths or metallic oxides. The general method of preparation is to make an infusion of the substance, and to add thereto a solution of common alum; or sometimes, when it has been necessary to extract the colouring matter by the agency of an acid, a solution of alum saturated with potash. At first, a slight precipitate falls, consisting of alumina and the colouring matter; but if some alkali is added, the precipitate is increased. Some colouring matters are brightened by alkalis; then the decoction of the dye-stuff is made in an alkaline liquor, and being filtered, a solution of alum is poured into it. Where the affinity of the colouring matter for the subsulphate of alumina is great, alumina recently precipitated is agitated with the decoction of the colouring body. The manufacture of lakes depends on the remarkable property possessed by alumina, of combining with, and separating the organic colouring matters from their solutions.

Red Lakes.—The finest of these is Carmine, which, as carminated lakes, called lake of Florence, Paris, or Vienna, is usually prepared by taking the liquor decanted from the carmine, and adding freshly-precipitated alumina to it. The mixture is warmed a little, briskly agitated, and allowed to settle. Sometimes alum is dissolved in the decoction of cochineal, and then the alumina precipitated by potash; but the colour is not good when lakes are thus prepared, and to improve it the dyer's solution of tin is often added. A red lake may be prepared from kermes in a similar manner.

Brazil-wood yields a red lake. The wood is boiled in a proper quantity of water for 15 minutes, and then alum and solution of tin being added, the liquor is to be filtered, and solution of potash poured in as long as it occasions a precipitate. This is separated by a filter, the powder well washed, and being mixed with a little gum-water, made into cakes. Sometimes the Brazil-wood is boiled with vinegar, instead of water. An excess of potash produces a lake of a violet colour, and cream of tartar gives it a brownish hue.

Madder is much used in the preparation of lakes.

The following process is recommended:—

Diffuse 2 lbs. of ground madder in 4 quarts of water, and after a maceration of 10 minutes strain and squeeze the grounds in a press. Repeat this maceration, &c., twice upon the same portion of madder. It will now have a fine rose colour. It must then be mixed with 5 or 6 lbs. of water and ½ lb. of bruised alum, and heated upon a water-bath for 3 or 4 hours, with the addition of water, as it evaporates; after which the whole must be thrown on a filter-cloth. The liquor which passes through is then to be filtered through paper, and precipitated by carbonate of potash. If potash be added in three successive doses, three different lakes will be obtained of diminishing beauty. The precipitates must be washed until the water comes off colourless, then with gum-water made into cakes.

Yellow Lakes are made with decoctions of Persian or French berries, to which some potash or soda is added; into the mixture a solution of alum is to be poured so long as any precipitate falls. Quercitron will yield a yellow lake, provided the decoction is purified by either butter-milk or glue. Annotto lake is formed by dissolving this substance in a weak alkaline lye, and adding a solution of alum to the solution.

Lakes of other colours can be prepared in a similar manner; but true lakes of other colours are not usually manufactured.

LAMINABLE is said of a metal which may be extended by passing between steel or hardened (chilled) cast-iron rollers.

In the manufacture of rail and bar iron, laminated iron is rolled together at a welding heat, until the required bar or rail is formed (see Rails). This is, even under the best possible circumstances, a defective manufacture. The union of the bars is never absolutely complete, and the result of the long-continued action of trains of carriages upon all rails is the development of the laminated plates, which frequently *peel* off, layer after layer, to the destruction of the rail, and to the great danger of the traveller. Railway iron should be rolled into form from perfectly homogeneous masses of metal. This lamination of iron rails has been laid hold of by those who advocate the hypothesis that the slate rocks owe their lamination to mechanical pressure, whereas it is evidently the result of an imperfect manufacture. See Rolling Mills.

LAMING'S MIXTURE. A mixture of porous hydrous peroxide of iron with sawdust, used for absorbing sulphuretted hydrogen in the purification of coal-gas. The sulphur accumulated in this mixture may be recovered by calcination, or by means of steam.

LAMIUM ALBUM, or the dead nettle, is said by Leucus to afford from its leaves a greenish-yellow dye. The *L. purpureum* dyes a reddish-grey with salt of tin, and a greenish tint with iron-liquor.

LAMP-BLACK. Every person knows that when the combustion of oil in a lamp is imperfect it pours forth a dense volume of black soot. According to the quantity of carbon contained in the material employed, so is the illuminating power of the flame produced by combustion. If, therefore, we have a very brilliant flame, and we subject it to any conditions which shall impede the progress of the combination of the carbon with the oxygen of the air, the result is at once the formation of solid carbon, or lamp-black. This is exhibited in a remarkable and often an annoying manner by the camphine lamp. If oil of turpentine, resin, pitch-oil, or fat-oil, be burnt in lamps under a hood, with either a rapid draught or an insufficient supply of air, the lamp-black collects on the hood, and is occasionally removed. Sometimes a metallic roller, generally of tin, is made to revolve in the flame, and rub against a brush. By the cooling influence of the metal, the heat of the flame is diminished, the combustion retarded, and the carbon deposited, and in the revolution of the cylinder swept off. Camphor burning forms a very beautiful black, which is sometimes used as a pigment.

The common varieties of lamp-black are made from all sorts of refuse resinous matters, and from the rejected fragments of pine-trees, &c. In Germany, a long flue is constructed in connection with the furnace in which the resinous substances are burnt, and this flue communicates with a hood, composed of a loose woollen cloth, held up by a rope passing over a pulley. Upon this the soot collects, and is from time to time shaken down. In the best-conducted manufactories about 3 cwts. of lamp-black is collected in each hood in about twelve hours. In England, lamp-black is sometimes prepared from the refuse coking coal, or it is obtained in connection with coke-ovens. The lamp-black, however, obtained from the combustion of coal or woody matter is never pure. See Animal Black; Bone Black; Ivory Black.

LAMP, DAVY. See Safety Lamp.

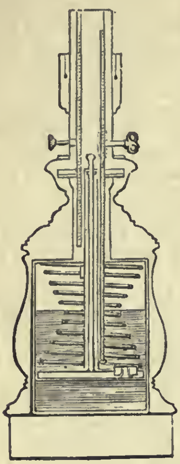
LAMPS. Under Illumination, will be found some notices of several kinds of lamps, with especial reference to the quantity of light produced by them.

Lamps are very varied in form, and equally varied in the principles involved. A brief description, however, of a few of the modern varieties is necessary.

The Moderator Lamp.—The spiral spring has been introduced into the moderator lamps, for the purpose of forcing the oil up the wick of the lamp. This will be understood by the following description and drawings:—The distinguishing character of the moderator lamp is the direct transmission of the power, in the reservoir of oil, to the resistance offered by the weight of the column of oil, as it rises to the cotton;—and secondly, the introduction of a rectangular regulator, which equilibrates constantly by the resistance of the oil and the force applied to raise it. In the reservoir (*fig.* 1309), is a spiral spring which presses on the disc or piston, *fig.* 1310, which is furnished with a valve opening downwards. This spring is attached to a tooth-rack, worked by a pinion wheel, by means of which it is wound up. The mechanical force of the spring is equal to from 15 to 20 pounds; and as this force is exerted upon the disc, floating on the oil, this is forced up through the tube, and it overflows to the argand burner, thoroughly saturating the cotton, and supplying a constant stream of oil. This oil falls back into the reservoir, and is, of course, above the disc. When the spring has run down, it is again wound up; and then the valve opening downward allows the oil to flow back beneath the disc, to be again forced up through the tube. As the pressure employed is so great, the oil would, but for the 'moderator,' flow over with too much rapidity. This *moderator*, or regulator, is a tapering rod of iron-wire, which is placed in the ascending tube; and, as the pressure increases, it is forced more into it, and checks the flow of oil; whereas as it diminishes it falls, and being tapering, allows more oil to rise. Several ingenious adjustments are introduced into these lamps, as manufactured by the Messrs. Tylor of Warwick Lane, with which we need not at present deal. The cylinders containing the oil are covered with cases in metal or sometimes of porcelain. Two drawings of these are shown (*fig.* 1311 and *fig.* 1312). These lamps admit evidently of yet more elegant forms than have been given them. The urn-shaped, from the antique, in very pure taste, is the last introduction of the house above named.

It would be tedious to enumerate the various modifications of form and action to which the oil lamp has been subject, previous to its arrival at what may be deemed its perfect construction by Argand. The discovery of the mode of applying a new principle by this individual not only produced an entire revolution in the manufacture of the article, but threatened with ruin all those whom the patent excluded from participation in the new trade; so much so indeed, that Argand, who had not been apprenticed to the business, was publicly persecuted by the tinners, locksmiths, and ironmongers, who disputed his right by any improvements to infringe the profits of their chartered vocation. 'This invention,' to quote a description of the lamp pub-

1309



1311

1312

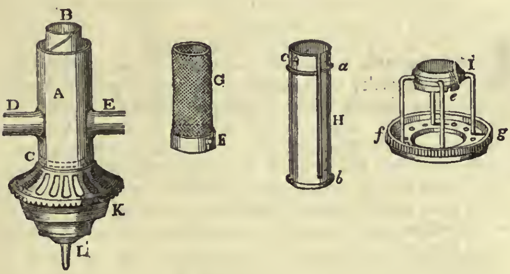
1310

lished some years ago, 'embraces so many improvements upon the common lamp, and has become so general throughout Europe, that it may be justly ranked amongst the greatest discoveries of the age. As a substitute for the candle, it has the advantage of great economy and convenience, with much greater brilliancy; and for the purpose of producing heat, it is an important instrument in the hands of the chemist. We may, with some propriety,' continues this authority, 'compare the common lamp and the candle to fire made in the open air, without any forced method of supplying it with oxygen; while the Argand lamp may be compared to a fire in a furnace, in which a rapid supply of oxygen is furnished by the velocity of the ascending current. This, however, is not the only advantage of this valuable invention. It is obvious that, if the combustible vapour occupies a considerable area, the oxygen of the atmosphere cannot combine with the vapour in the middle part of the ascending column. The outside, therefore, is the only part which enters into combustion; the middle constituting smoke. This evil is obviated in the Argand lamp, by directing a current of atmospheric air through the flame, which, instead of being raised from a solid wick, is produced from a circular one, which surrounds the tube through which the air ascends.

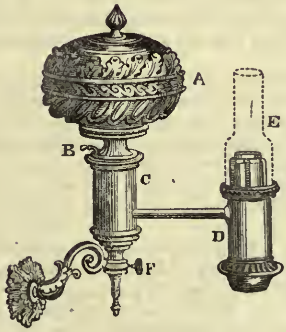
The mechanism of the Argand burner, in its improved state, will be clearly understood from the annexed figures and explanation, which apply equally to each description of the lamps hereafter described.

A, *fig.* 1313, is a brass tube, about 3¼ inches in length, and 1¼ inch wide; within this tube is placed another, B, which is soldered fast inside by the flange at C: the space between these tubes contains the oil surrounding the wick, and which, being freely admitted from the reservoir by the side pipes D E, rises in the tubular space, either to a height corresponding with its level in the reservoir, or at least so as to maintain the wick in a state of constant saturation. The tube B is of considerable thickness, having a spiral groove cut about it from top to bottom; F is a metallic ring made to slip over the tube B, it contains a short pin inside, which fits exactly into the spiral groove just mentioned; G is the circular woven cotton wick, the lower end of which is drawn tight upon the neck of the ring; H is a copper tube, with a slit nearly from top to bottom; it admits the ring F, and being dropped over the inner tube B, exactly fits the inside of the wider tube A, by means of a narrow rim near the top at *a*, and another at the bottom *b*; between the upper rim and the margin there is a small projecting pin *c*, which, when the whole apparatus is combined, fits into the cavity *e* of the collar I. To prepare the lamp for use, the tube H is placed between A and B, as just described; the ring F, with its charge of cotton, is next inserted, the pin in the inside falling into the spiral groove, and that on the outside entering the slit in the tube H, which, on being turned about, moves the ring F down upon the screwed inner tube, until the wick only just rises above the superior edges of the tubes, in the interval between which it lies in the oil. In this stage the frame I is placed on the nick in the collar at *e*, falling upon the pin near the top of H; the lower disc *f g*, passing over the tube A, at once presents a convenient support for the glass chimney, and a finger-hold for raising the wick. The central tube is open throughout, communicating, at its lower end, with the brass receptacle K; the latter is perforated at top, to admit the air which, by circulating through the above tube, and the hollow flame which surrounds it, causes the lamp to burn with that peculiar freedom and brilliancy which distinguish the Argand construction. This last-mentioned receptacle likewise catches any small quantity of oil which may pass over the inner tube during the combustion of the wick. L is the brass peg, which fits into the upper part of the pillar, in the table-lamp.

1313



1314



1315

In addition to the endless variety of small portable lamps, the peculiarities of which it would be tedious to particularise, and the merit of which, as compared with those on the Argand principle, consists, for the most part, in their cheapness, the more important articles, and those generally in demand, may be distinguished as fixed or bracket lamps, supended or chandelier lamps, and table or French lamps—all these having burners on the principle above described. The former sort were, previous to the introduction of gas, very common in shops. The globe A (*fig.* 1314), which is sometimes made plain and sometimes embossed, as in the cut, screws off, when the oil is poured in at an opening in the lower part, which is afterwards closed by means of a slide attached to the stem B, and the globe, thus replenished, is inverted and screwed into the part C. When the lamp is used, the stem B is raised a little, and the oil is suffered to flow through the intermediate tube into the cistern D, only at the rate at which it is consumed by the burning of the wick. The peculiar form of the glass chimney is admirably calculated to assist in the more complete combustion of the matter drawn up to the wick when impure oil is used, a desideratum originally in part secured by placing over the central tube, and in the midst of the flame, a circular metal plate, by means of which the ascending column of air was turned out of its perpendicular course, and thrown immediately into that part of the flame where the smoke is formed, and which by this ingenious contrivance is effectually consumed; this application, however, is not necessary, nor the form of much moment, when purified sperm-oil is used. These lamps being usually made to move on a pivot at F, attached to the wall or other support, are very convenient in many situations, as being easily advanced over a desk or counter, and afterwards turned aside when not in use.

The sinumbral lamp having passed out of use need not be described.

The use of spirit lamps followed, and we have the naphtha and camphine lamps of this order. The accompanying woodcut (*fig.* 1315) shows the peculiarity of the camphine lamp, where the reservoir of spirit (turpentine deprived of smell) is far below the burner, to which it ascends by capillary attraction, through the tubes of the cotton wick. Lamps to burn naphtha (*Belmontine*, &c.) are constructed on the same principle, as are all the paraffine and mineral-oil lamps.

One of the best oil lamps is that known as Carcel's lamp.

In this lamp the oil is raised through tubes by clockwork, so as continually to overflow at the bottom of the burning wick; thus keeping it thoroughly soaked, while the excess of the oil drops into the cistern below. Lamps of this description will burn most satisfactorily for many years; but it can hardly be trusted in the hands of a servant, and when it gets at all deranged, it must be sent to its constructor, in Paris, to be repaired. The light of this lamp, when furnished with an appropriate tall glass chimney, is very brilliant, though not perfectly uniform; since it fluctuates a little, but always perceptibly to a nice observer, with the alternating action of the pump-work; becoming dimmer after every successive jet of oil, and brighter just before its return. The flame, moreover, always flickers more or less, owing to the powerful draught, and rectangular reverberatory shoulder of the chimney. The mechanical lamp is, however, remarkable for continuing to burn, not only with unabated but with increasing splendour for 7 or 8 hours; the vivacity of the combustion increasing evidently with the increased temperature and fluency of the oil, which, by its ceaseless circulation through the ignited wick, gets eventually pretty warm. In the comparative experiments made upon different lights by the Parisian philosophers, the mechanical lamp is commonly taken as the standard. It is not entitled to this pre-eminence, for it may be made to emit very different quantities of light, according to differences in the nature and supply of the oil, as well as variations in the form and position of the chimney.

The following experiments by Dr. Ure are well worth preserving:—

The great obstacle to the combustion of lamps lies in the viscidity, and consequent sluggish supply, of oil to the wicks; an obstacle nearly insuperable with lamps of the common construction during the winter months. The relative viscidity or relative fluency of different liquids at the same temperature, and of the same liquid at different temperatures, has not, I believe, been hitherto made the subject of accurate researches. I was, therefore, induced to make the following experiments with this view.

Into a hemispherical cup of platinum, resting on the ring of a chemical stand, I introduced 2,000 water-grain measures of the liquid whose viscidity was to be measured, and ran it off through a glass siphon, $\frac{1}{8}$th of an inch in the bore, having the outer leg $3\frac{1}{2}$ inches, and the inner leg 3 inches long. The time of efflux became the measure of the viscidity; and of two liquids, if the specific gravity and consequent pressure upon the siphon were the same, that time would indicate exactly the relative viscidity of the two liquids. Thus, oil of turpentine and sperm-oil have each very nearly the same density; the former being, as sold in the shops, =0·876, and the latter from 0·876 to 0·880, when pure and genuine. Now I found that 2,000 grain-measures of oil of turpentine ran off through the small siphon in 95 seconds, while that quantity of sperm-oil took 2,700 seconds, being in the ratio of 1 to $28\frac{1}{2}$; so that the fluency of oil of turpentine is $28\frac{1}{2}$ times greater than that of sperm-oil. Pyroxilic spirit, commonly called naphtha, and alcohol, each of specific gravity 8·125, were found to run off respectively in 80 and 120 seconds; showing that the former was 50 per cent.

more fluent than the latter. Sperm-oil, when heated to 265° Fahr., runs off in 300 seconds, or ⅛th of the time it took when at the temperature of 64°. Southern whale oil, having a greater density than the sperm-oil, would flow off faster were it not more viscid. 2,000 grain-measures of water at 60° run off through the said siphon in 75 seconds, but when heated to 180° they run off in 61 seconds. Concentrated sulphuric acid, though possessing the great density of 1·840, yet flows off very slowly at 64°, on account of its viscidity, whence its name of oil of vitriol. 2,000 grain-measures of it took 660 seconds to discharge.

For a continuation of this subject, and a further description of lamps of various kinds, see also SILBER LIGHT; SAFETY LAMP.

LAMPIC ACID. *Syn.* Aldehydic acid; Acetylous acid. (*Acide lampique*, Fr.) If a little ether be placed at the bottom of a glass, and some spongy platinum attached to a wire of the same metal be ignited and suspended about an inch from the fluid, it will glow and continue to do so for a long time. On the other hand, if a spiral of platinum wire be placed over the wick of a spirit-lamp, and the latter be first ignited and then blown out, the wire will continue at a red heat until all the spirit is exhausted. Numerous sesquioxides, when placed warm on wire-gauze over capsules containing alcohol, will glow in the same manner. Under all these circumstances, a powerful odour resembling aldehyde is evolved, which strongly affects the eyes. If this experiment be made in such a manner that the volatile product may be condensed, it will be found to be strongly acid. It is powerfully reducing in its tendency, and if heated with the oxides of silver or gold, converts them into the metallic state, and the liquid is found to contain acetic acid and resin of aldehyde. If, however, the acid liquid be only very gently warmed with oxide of silver, a portion of the latter is dissolved; but when baryta is added to precipitate the silver as oxide, and the fluid is warmed, the metal instead of the oxide comes down, and the fluid, when tested for the nature of the acid, is found to contain nothing but acetate of baryta. These phenomena are explained by some chemists by supposing the fluid to contain an acid which they, following the late Professor Daniell, call the lampic, and supposed to contain $C^4H^4O^3$ (**$C^4H^8O^3$**). When lampic acid is treated first with oxide of silver, and then with baryta-water, and heated, they consider that the oxygen of the oxide of silver is transferred to the lampic acid, and converting it into acetic acid, which combines with the baryta, while the metallic silver is precipitated. The following equation explains the reaction supposed to take place:—

$$\underbrace{C^4H^4O^3}_{\text{Lampic acid.}} + BaO + AgO = \underbrace{C^4H^3O^3{,}BaO}_{\text{Acetate of baryta.}} + Ag + HO.$$

$$\mathbf{C^4H^8O^3 + BaO + Ag^2O = (C^2H^3O^2)^2Ba + Ag^2 + H^2O.}$$

The conversion of the lampic acid into acetic acid is therefore attributed to the oxidising tendency of the oxide of silver. Those who regard the decomposition from the above point of view, consider lampic acid to be acetylous acid, that is to say, to bear the same relation to acetylic acid (acetic acid) that sulphurous acid does to sulphuric acid.

LAMBSKINS. With the fleece on, these are extensively used for clothing, for door-mats, and the like. *Prussian lambskins* are used for linings, for coat collars and cuffs. *Astracan lamb*, which is a rich, glossy, black skin, with short fur, is used for many ornamental costumes. *Hungarian lamb:* this skin forms the national coat of Hungary. *Spanish lamb:* the short jacket of the Spaniard is made of this skin. It is said that upwards of a million lambskins are imported annually into this country for glove-making.

LANARKITE. A sulphato-carbonate of lead occurring at Leadhills in Lanarkshire, whence the name.

LANCE WOOD. *Uvaria lanceolata* or *Guatteria virgata.* This wood is imported from Jamaica and Cuba, in long poles from 3 to 6 inches diameter. Lance wood is paler in colour than box; it is selected for elastic works, as gig-shafts, archery bows, springs, &c. These are bent into the required form by boiling or steaming. Surveyor's rods, ordinary rules, and billiard cues are made of lance wood.

LANDER. In mining, the man who attends at the mouth of the shaft to receive the 'kibble of ore' as it reaches the surface.

LANGITE. A basic sulphate of copper, from Cornwall, described a few years ago by Prof. Maskelyne.

LANTHANUM. A metal discovered by Mosander in 1841. It occurs associated with didymium and cerium, in certain rare Swedish minerals.

LAPIDARY, *Art of.* The art of the lapidary, or that of cutting, polishing, and engraving gems, was known to the ancients, many of whom have left admirable specimens of their skill. The Greeks were passionate lovers of rings and engraved stones; and the most parsimonious among the higher classes of the Cyrenians are said to have worn rings of the value of ten minæ (about 30*l.* of our money). By far the greater part of the antique gems that have reached modern times may be considered as so many models for forming the taste of the student of the fine arts, and for inspiring his mind with correct ideas of what is truly beautiful. With the cutting of the diamond, however, the ancients were unacquainted, and hence they wore it in its natural state. Even in the middle ages, this art was still unknown; for the four large diamonds which enrich the clasp of the imperial mantle of Charlemagne, as now preserved in Paris, are uncut, octahedral crystals. But the art of working diamonds was probably known in Hindostan and China in very remote periods. After Louis de Berghen's discovery, in 1476, of polishing two diamonds by their mutual attrition, all the finest diamonds were sent to Holland to be cut and polished by the Dutch artists, who long retained a superiority, now no longer admitted by the lapidaries of London and Paris. See DIAMOND.

The operation of gem-cutting is abridged by two methods: 1, by cleavage; 2, by cutting off slices with a fine wire, coated with diamond-powder, and fixed in the stock of a hand-saw. Diamond is the only precious stone which is cut and polished with diamond-powder, soaked with olive oil upon a mill plate of very soft steel.

Oriental rubies, sapphires, and topazes, are cut with diamond-powder soaked with olive oil, on a copper wheel. The facets thus formed are afterwards polished on another copper wheel, with tripoli, tempered with water.

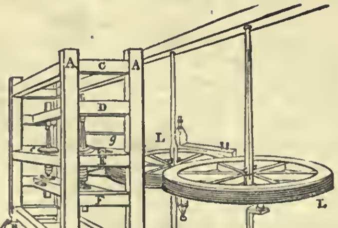
Emeralds, hyacinths, amethysts, garnets, agates, and other softer stones, are cut at a lead wheel, with emery and water; and are polished on a tin wheel with tripoli and water, or, still better, on a zinc wheel, with putty of tin and water.

The more tender precious stones, and even the pastes, are cut on a mill-wheel of hard wood, with emery and water; and are polished with tripoli and water on another wheel of hard wood.

Since the lapidary employs always the same tools, whatever be the stone which he cuts or polishes, and since the wheel discs alone vary, as also the substance he uses with them, we shall describe, first of all, his apparatus, and then the manipulations for diamond-cutting, which are applicable to every species of stone.

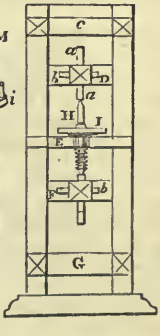
The lapidary's mill, or wheel, is shown in perspective in *fig.* 1316. It consists of a strong frame made of oak carpentry, with tenon and mortised joints, bound together with strong bolts and screw nuts. Its form is a parallelopiped, of from 8 to 9 feet long, by from 6 to 7 feet high; and about 2 feet broad. These dimensions are large enough to contain two cutting wheels alongside of each other, as represented in the figure.

1316



1317

1318



Besides the two sole bars B B, we perceive in the breadth, 5 cross bars, C, D, E, F, G. The two extreme bars C and G, are a part of the frame-work, and serve to bind it. The two cross-bars D and F, carry each in the middle of their length, a piece of wood as thick as themselves, but only 4½ inches long (see *fig.* 1316), joined solidly by mortises and tenons with that cross-bar as well as with the one placed opposite on the other parallel face. These two pieces are called *summers* (lintels); the one placed at D is the upper; the one at F the lower.

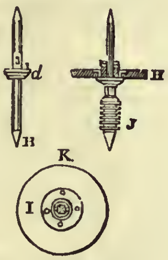
In *fig.* 1318 this face is shown inside, in order to explain how the mill wheel is placed and supported. The same letters point out the same objects, both in the preceding and the following figures.

In each of these *summers* a square hole is cut out, exactly opposite to the other in which are adjusted by friction a square piece of oak, *a a*, *fig.* 1318, whose extremities are perforated with a conical hole, which receives the two ends of the arbor H of the wheel I, and forms its socket. This square bar is adjusted at a convenient height by a double wooden wedge, *b b*. The cross-bar in the middle E, supports the table *c c*, a strong plank of oak. It is pierced with two large holes, whose centres coincide with the centres of the conical holes hollowed out at the end of the square pins. These holes of about 6 inches diameter each, are intended to let the arbor pass freely through, bearing its respective wheel. (See one of these holes at I, in *fig.* 1320 below).

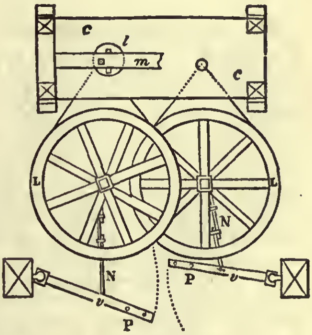
Each wheel is composed of an iron arbor H, *fig.* 1318, of a grinding wheel I, which differs in substance according to circumstances, as already stated, and of the pulley J, furnished with several grooves (see *fig.* 1320), which has a square fit upon the arbor. The arbor carries a collet *d*, on which are four iron pegs or pins that enter into the wheel to fasten it.

The wheel plate, of which the ground plan is shown at K, is hollowed out towards its centre to half its thickness; when it is in its position on the arbor, as indicated in *fig.* 1320, a washer or ferrule of wrought iron is put over it, and secured in its place by a double wedge. In *fig.* 1320 the wheel-plate is represented in section, that the connection of the whole parts may be seen.

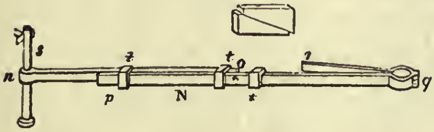
1319 1320



1321



1322



A board *g* (see *fig.* 1316 and *fig.* 1324) about 7½ inches high, is fixed to the part of the frame opposite to the side at which the lapidary works, and it prevents the substances made use of in the cutting and polishing from being thrown to a distance by the centrifugal force of the wheel-plate.

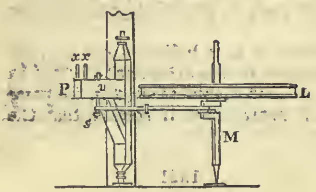
Behind the apparatus is mounted for each grinding-plate, a large wheel L (see *fig.* 1316), similar to a cutler's, but placed horizontally. The wheel is grooved round its circumference to receive an endless cord or band, which passes round one of the grooves of the pulley J, fixed below the wheel-plate. Hence, on turning the fly-wheel L, the plate revolves with a velocity relative to the velocity communicated to the wheel L, and to the difference of diameter of the wheel L, and the pulley J. Each whee. L, is mounted on an iron arbor, with a crank (see M, *fig.* 1317).

The lower pivot of the arbor *h* is conical, and turns in a socket fixed in the floor. The great wheel L rests on the collet *i*, furnished with its 4 iron pins, for securing the connection. Above the wheel an iron washer is laid, and the whole is fixed by a double wedge, which enters into the mortise *l*, *fig.* 1317.

Fig. 1321 exhibits a ground-plan view of all this assemblage of parts, to explain the structure of the machine. Everything that stands above the upper *summer-bar* has been suppressed in this representation. Here we see the table *c c*; the upper *summer* *m*; the one-wheel plate *l*, the other having been removed to show that the endless cord does not cross; the two large wheels L L, present in each machine, the crank bar N, seen separate in *fig.* 1322, which serves for turning the wheel L. This bar is formed of three iron plates *n*, *o*; *p*, *q*; and *q*, *r* (*fig.* 1322). The first is bent round at the point *n*, to embrace the stud *s*; the second *p q*, is of the same breadth and thickness as the first; and the third, is adjusted to the latter with a hinge joint, at the point *q*, where they are both turned into a circular form, to embrace the crank M. When all these pieces are connected, they are fixed at the proper lengths by the buckles or square rings *t t t*, which embrace these pieces, as is shown in *fig.* 1322.

The stud *s*, seen in *fig.* 1322, is fixed to the point *v*, by a wedge-key upon the arm P, represented separately, and in perspective, in *fig.* 1323. The labourer seizes the two upright pegs or handles *x x*; by the alternate forward and backward motion of his arm, he communicates the same motion to the crank-rod, which transmits it to the crank of the arbor M, and impresses on the arbor, and the wheel which it bears, a rotatory movement.

1323



1324

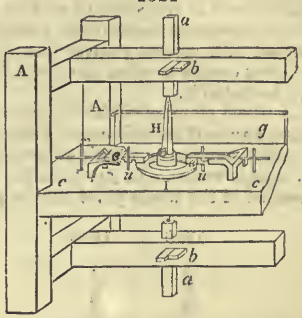


Fig. 1324 shows piece-meal and in perspective a part of the lapidary's wheel-mill. There we see the table *c c*, the grind plate I, whose axis is kept in a vertical position by the two square plugs *a a*, fixed into the two *summers* by the wedges *b b*. On the two sides of the wheel-plate, we perceive an important instrument called a *dial*, which serves to hold the stone during the cutting and polishing. The instrument has received lately important ameliorations, to be described in *fig.* 1325. The lapidary holds this instrument in his hand, he rests upon the iron pins *u u*, fixed in the table lest he should be affected by the velocity of the revolving wheel-plate. He loads it sometimes with weights *e e*, to make it take better hold of the grinding-plate.

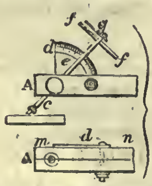
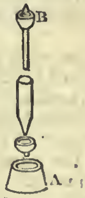
Fig. 1325, shows an improvement made by one of the most expert lapidaries of Geneva, whereby he cuts and polishes the facet with extreme regularity, converting it into a true dial. Each of the two jaws bears a large conchoidal cavity, into which is fitted a brass ball, which carries on its upper part a tube *e*, to whose extremity is fixed a dial-plate *f f*, engraved with several concentric circles, divided into equal parts, like the toothed-wheel cutting engine-plate, according to the number of facets to be placed in each cutting range. The tube receives with moderate friction the handle of the cement-rod, which is fixed at the proper point by a thumb-screw, not shown in the figure, being concealed by the vertical limb *d*, about to be described.

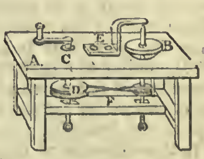
1325



1326



1327



A needle or index *g*, placed with a square fit on the tail of the cement-rod, marks by its points the divisions on the dial-plate *f f*. On the side *m n*, of the jaw A, there is fixed by two screws, a limb *d*, forming a quadrant, whose centre is supposed to be at the centre of the ball. The quadrant is divided as usual into 90 degrees, whose highest point is marked 0, and the lowest would mark about 70; for the remainder of the arc down to 90 is concealed by the jaw. The two graduated plates are used as follows:—

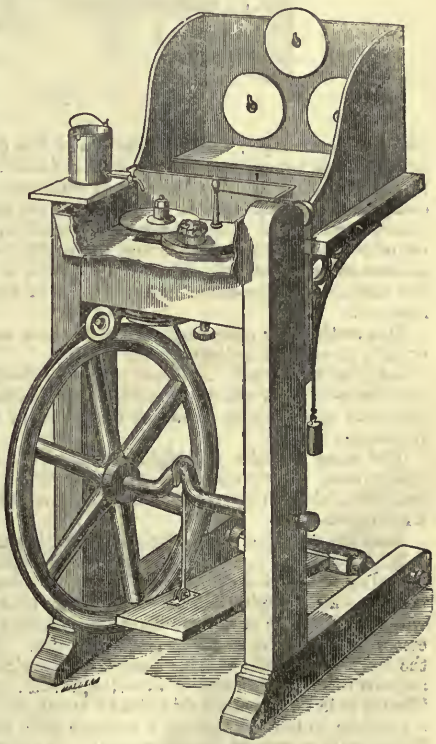
When the cement-rod conceals zero or 0 of the limb, it is then vertical, and serves to cut the table of the brilliant; or the point opposite to it, and parallel to the table, On making it slope a little; 5 degrees, for example, all the facets will now lie in the same zone provided that the inclination be not allowed to vary. On turning round the cement-rod and the index *g* marks the divisions so that by operating on the circle with 16 divisions, stopping for some time at each, 16 facets will have been formed, of perfect equality, and at equal distances, as soon as the revolution is completed.

In cutting the stones, they are mounted on the cement-rod B, *fig.* 1326, whose stem is set upright in a socket placed in a middle of a sole piece at A, which receives the stem of the cement-rod. The head of the rod fills the cup of A. A melted alloy of tin and lead is poured into the head of the cement-rod, in the middle of which the stone is immediately plunged; and wherever the solder has become solid, a portion of it is pared off from the top of the diamond, to give the pyramidal form shown in the figure at B.

There is an instrument employed by the steel polishers for pieces of clock-work, and by the manufacturers of watch-glasses for polishing their edges. It consists of a solid oaken table, *fig.* 1327. The top is perforated with two holes, one for passing through the pulley and the arbor of the wheel-plate B, made either of lead or of hard wood, according to circumstances; and the other C for receiving the upper part of the arbor of the large pulley D. The upper pulley of the wheel-plate is supported by an iron prop E, fixed to the table by two wooden screws. The inferior pivots of the two pieces are supported by screw sockets, working in an iron screw-nut sunk into the summer-bar F. The legs of the table are made longer or shorter, according as the workman chooses to stand or sit at his employment. Emery with oil is used for grinding down, and tin-putty or colcothar for polishing. The workman lays the piece on the flat of the wheel-plate with one hand, and presses it down with a lump of cork, while he turns round the handle with the other hand.

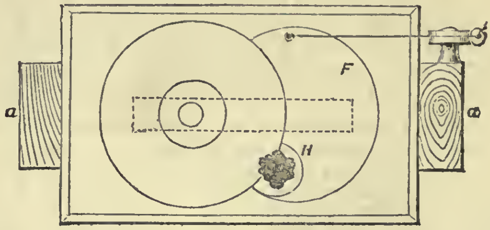
A very convenient form of apparatus has been devised by Mr. James B. Jordan, and manufactured by Messrs. Cotton and Johnson, of Grafton Street, Soho, for the purpose of preparing thin sections of minerals, rocks, and other hard substance for microscopical observation. This machine is represented in *figs.* 1328, 1329, and 1330. It consists of a wooden frame-work, *a a*, supporting a crank-axle and driving-wheel, two feet diameter; the top part of this frame consists of two cross-pieces *a′*, fixed about an inch apart, as in the bed of an ordinary turning-lathe; into the slot between them is placed a casting B, carrying the bracket for the angle-pulleys C; this casting is bored to receive the spindle D, which, by means of the treadle, is made to revolve at the rate of 400 or 500 revolutions per minute. It is also bored to receive another spindle E, to the top of which is fixed a metal plate F, for carrying the small cup H, to which the specimen is attached by means of prepared wax. This means of mechanically applying the work to the slicer is far preferable to holding it in the hand in the ordinary way; the requisite pressure against the cutting disc is regulated by the weight G, and the thickness of the slice by the thumb-screw K, on which the spindle rests. By this means it is possible to cut tolerably thin and parallel slices, of from $\frac{1}{10}$th to $\frac{1}{8}$th of an inch in thickness; the thinness of course varying according to the strength of the rock which is being operated upon. The slitting disc is made of soft iron, eight inches diameter, and about $\frac{1}{50}$th of an inch in thickness, and it is fixed on the spindle D, between two brass plates 4 inches diameter, charged with diamond-powder in the usual way.

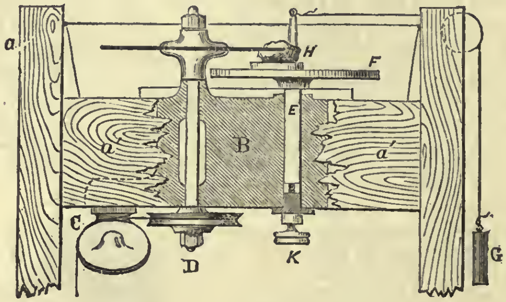
1328



The slices are still further reduced in thickness by grinding with fine emery and water on a lead 'lap,' which is made to revolve on the spindle D. The lap is 8 inches diameter, and about ⅝ths of an inch thick in the centre, cast with rounded edges and

1329





1330

slightly convex sides; this form facilitates the grinding of a uniform thinness, there being always a tendency on a flat surface (which soon wears hollow) for the edges of the section to grind away before it is sufficiently thin. One side of the section can easily be ground and finished by holding in the hand; and this being done, it must be cemented with hard Canada balsam to a small square of plate glass, in order to grind the other side, which operation must be carefully carried on until the structure appears distinct and well defined. The finish requisite is best given by careful rubbing on the flat surface of a hone-stone until all traces of the lines of grinding and scratches are removed.

Thin sections for microscopic study are then usually re-mounted in Canada balsam under a glass cover in the ordinary way.

LAPIS LAZULI. A silicate of soda, lime, and alumina, with the sulphide of iron and sodium in minute quantities. This beautiful mineral is found in crystalline limestone of a greyish colour, on the banks of the Indus, and in granite in Persia, China, and Siberia.

The finest varieties are highly esteemed, being employed in the manufacture of costly vases. It was also the source from which the beautiful pigment ultramarine, was obtained, but this colour is now prepared artificially at a very cheap rate. See Ultramarine.

LAPIS OLLARIS, or *Pot-stone.* An impure form of steatite.

LAPS. Metal polishing-wheels. Metal wheels or laps made of nearly every metal and alloy in common use, have been more or less employed in the mechanical arts as vehicles for the application of several of the polishing-powders. But of all laps, notwithstanding their variety, those of lead, slightly alloyed, and supplied with powdered emery, rendered the most conspicuous service. Generally the plane, or flat surface of the lap, is employed; at other times the cylindrical edge, as by cutlers; but the portion actually used in either case is called the *face* of the lap. There are several kinds of laps. The lap is in some cases a thin disc of metal, fixed by means of a screwed nut against a shoulder on the spindle, but it is better with lead laps to employ an iron plate cast full of holes to support the softer metal. The casting mould may in this case be either an iron disc, with a central screw to fix the iron centre plate at the time of pouring, or the mould may be made of sand and in halves, after the usual manner of the foundry.

In either case the iron plate should be made as hot as the fluid metal, which, by entering the holes, becomes firmly united to the iron, especially if the holes are largest on the reverse side, or that away from the lead.—*Holtzapffel.*

Lap is also a roll or sliver of cotton for feeding the cards of a spinning machine.

LARD. The fat of the pig.

LARD OIL. Lard being subjected to a pressure, an oil, *oleine*, is expressed, *stearine* being left. This lard oil is much used for lubricating machinery, and it has been employed for the adulteration of olive oil.

LARDERELLITE. A borate of ammonia, from the boracic-acid lagoons of Tuscany.

LASKS. All Indian cut stones are called *lasks.* They are in general ill-shaped or irregular in their form, their depth ill-proportioned, and the table, or face, seldom in the centre of the stone, sometimes too broad or too small, and none properly polished. The chief thing regarded is saving the size and weight of the stone. These stones are always new wrought when brought to Europe.

LATHE-CORDS. Cords for turning lathes. These cords are made of intestines of horses, cleaned and prepared by the separation of the mucous membrane in the manner described under GOLD BEATERS' SKIN. A wooden ball, armed in its lower part with four cutting blades, at equal distances from each other, is fixed by an upright piece of wood to a bench. The end of an intestine is then drawn over this ball, and as the gut is pulled downwards it is divided into four equal bands or strips.

Four or eight of these strips, according to the thickness which it is intended to give to the cord, are tied with a peculiar knot to one end of a thick piece of cord. The end is passed around a peg introduced into a hole in a solid post, to the side of which a number of pegs are attached. At a distance of ten or eleven yards from the first one, another post is fixed, similarly provided with pegs, and over one of these latter the middle of the assemblage of strips is passed, the other end being brought back, and attached to the first peg by means of another knotted cord. The tied end of the strisp is then attached to the wheel by a hook connected with the *whirl*, which is made to revolve until the strips are sufficiently twisted. The twisted end is then kept stretched by attaching it to the peg, and any projecting filaments are cut off. After being stretched for some time, the cords are then twisted again, and a third and a fourth time are twisted by hand, being each time rubbed with and drawn through a bunch of moistened horsehair after the twisting, and again stretched out between the two posts. If the cord is not smooth and even after the twisting is completed, it is made so by rubbing with a piece of dog-skin. It is then dried, and by some makers is exposed to the vapours of sulphur. At last the ends are cut off, and the cord is rolled in a coil.

In order to avoid the putrid emanations, from the intestines, which are generally in an incipient state of decomposition, Labarraque recommends to clean them at once, turn the inside out, and put them to soak over night in a cask containing, for fifteen or twenty intestines, chloride of potash, at 13° or 18°, 1 lb.; water, 4 gallons. The mucous membrane is ready to be detached the next day; and after its removal, and a thorough washing, the intestines can at once be prepared, as has been already described.

LATH WOOD. The outside cuttings of fir-trees, used for being split into laths.

LATTEN is a somewhat antiquated term, which was applied to several kinds of sheet metal. 'Mines of *latten*, whatever may have been meant by the word, are mentioned in the time of Henry VI., who made his chaplain, John Botteright, comptroller of all his mines of gold, silver, copper, *latten*, lead, within the counties of Devon and Cornwall.' Is tin meant by the term ?—*Watson's Chemical Essays.*

In the reigns of Henry VIII. and Edward VI., several acts of parliament were passed, prohibiting the exportation of brass, copper, *latten*, bell-metal, gun-metal, schrof metal, &c. Windows framed with lead are called *lattice* windows in the West of England.

The term is now applied to sheet or plate brass. *Black latten* is rolled sheets; *shaven latten* is in *thinner sheets*; and *roll latten* is polished on both sides.

LAUGHING GAS. The popular name of *nitrous oxide* or *nitrogen monoxide*, NO (**N^2O**). It is best prepared by heating solid nitrate of ammonia, this salt being resolved by heat into laughing gas and water. The gas, when inhaled, produces a peculiar intoxicating effect, usually without being followed by any ill consequences. Of late years laughing gas has been largely used by dentists as an anæsthetic. Care, however, is needed in administering it, as it may produce serious results on individuals suffering from certain affections of the heart.

LAUMONTITE, or *Efflorescing zeolite.* A hydrous silicate of alumina and lime, occurring in cavities in amygdaloidal trap rocks and in metalliferous veins. It is common in some of the copper deposits of Lake Superior.

LAUNDER. A miner's term for a wooden tube or gutter to convey water. A long shallow trough, carrying off the ore from the stamps.

LAUREL OIL. This oil is known also under the name of '*oil of bays,*' and is obtained from either the fresh or dried berries of the *bay tree* (*Laurus nobilis*), which grows principally in the south of Europe; and is also cultivated in our gardens, the leaves being used by the cook on account of their flavour. The berries were analysed by Bonastre in 1824, and amongst other things, were volatile oil, 0·8, laurin (camphor of the bay berry), 1·0, and fixed oil, 12·8, in 100 parts of the berries. Duhamel states that the fixed oil is obtained from the fresh and ripe berries by bruising them in a mortar, boiling them for three or four hours in water, and then pressing them in a sack. The expressed oil is mixed with the decoction, and on cooling is found floating on the surface of the water. When the dried berries are used, they are first subjected to the vapour of water until they are well soaked, and are then rapidly pressed between heated metallic plates. By the latter process they yield one-fifth of their weight of oil. It is imported in barrels from Trieste. It has a butyraceous consistence and a granular appearance. Its colour is greenish, and its odour like that of the berries. Cold alcohol extracts from it the essential oil and green colouring matter, leaving the *lauro-stearine*, which composes the principal part of it. With alkalis it forms soaps. But its principal use is in medicine, and more particularly in veterinary medicine. It has been used as a stimulating liniment in sprains and bruises, and in paralysis.

Native Oil of Laurel (*Hancock*); *Laurel Turpentine* (*Stenhouse*).—Imported from Demerara; obtained by incisions in the bark of a large tree, called by the Spaniards '*Azeyte de sassafras,*' growing in the vast forests between the Orinoco and the Parime. This oil is transparent, slightly yellow, and smells like turpentine, but more agreeable, and approaching to oil of lemons. Its specific gravity at 50° Fahr. is 0·8645. It consists of two or more oils isomeric with each other, and with oil of turpentine. Its colour is due to a little resin. It is an excellent solvent for caoutchouc.—*Pereira.*

LAURIC ACID. An acid obtained from the fat of the bay tree (*Laurus nobilis*), and from the oil of pichurim beans (*Faba pichurim maj.*)

LAURITE. A sulphide of osmium and ruthenium, found in the platinum washings in Borneo.

LAVA. The ejected matter of volconoes. 'The stone which flows in a melted state from a volcano.'—*Lyell.* M. Abich obtained from the Etna lava of 1669, 48·83 silica. He found the lava to consist of 54·80 labradorite, 34·16 augite, 7·98 olivine, and 3·08 magnetic iron.

Bischoff gives the following two analyses of lava:—

	Hecla	Etna
Silica	54·76	49·63
Alumina	13·61	22·47
Peroxide of iron	15·60	10·80
Lime	6·14	9·05
Magnesia	1·35	2·68
Potash	3·41	3·07
Soda	1·21	0·98

LAVA-WARE. A peculiar stoneware, manufactured and coloured to assume the semi-vitreous appearance of lava.

LAVER. *Porphyra laciniata* and *Ulva latissima.* See ALGÆ.

LAVENDER, OIL OF. See PERFUMERY.

From the flowers of the *Lavandula spicata* the oil of spike is obtained, which is used by painters on porcelain, and by artists in the preparation of some varnishes.

LAWN. A fine linen fabric.

LAZULITE (Eng. and Fr.; *Lazulith,* Ger.), from an Arabic word, *azul,* meaning *heaven.* It is a blue vitreous mineral, found massive and crystalline, traversing clay slate, and sometimes associated with spathic iron; spec. grav. 2·76 to 2·94; scratches glass; affords a little water by calcination; fusible into a white glass; dissolves in acids with loss of colour; the solution leaves an alkaline residuum, after being treated with carbonate of ammonia, filtered, evaporated, and calcined. By analysis it is found to consist of:—

	1	2
Phosphoric acid	43·88	46·79
Alumina	31·77	27·10
Protoxide of iron	8·90	7·10
Magnesia	9·89	11·87
Water	5·56	7·12

LEAD. (*Plomb*, Fr.; *Blei*, Ger.) This metal appears to have been known at a very early period. It is mentioned by Moses, as a metal in common use. Job describes mining for lead, and the metallurgic processes of refining and separating silver from lead are very clearly described by both Job and Jeremiah. Lead has a bluish-grey colour, and, when recently cut, it exhibits considerable lustre, which, however, it speedily loses. It is one of the softest of the ordinary metals, is easily cut with a knife, may be scratched with the nail, and marks paper with a grey stain. Lead is malleable, and may be beaten into thin leaves, but these are of very imperfect tenacity; hence, it cannot be drawn into thin wire; a wire of $\frac{1}{12}$th of an inch in diameter will not support 20 lbs.

If lead be prepared in a very finely divided state, it is *pyrophoric*. This is usually prepared from the tartrate of lead, by heating it in a glass tube as long as any fumes are evolved; consequently, it is finely-divided lead, combined with some carbon. As soon as the fumes cease, the tube must be closed at the blowpipe-lamp. If at any time the tube is broken, and the powder scattered in the air, it burns with a red flash.

If lead is heated in closed vessels, it fuses at 635° F. (335° C.), and at a red heat, it gives off vapours. If fused lead is allowed to cool slowly, it crystallises in a somewhat peculiar manner; the crystals are referrible to the cubic system, but they group themselves in a very complicated and interesting way. By the electro-chemical action of zinc on a solution of the acetate of lead, crystals of that metal are obtained in an arborescent form. This experiment is usually spoken of as the formation of *Saturn's tree*, Saturn being the alchemic name for this metal.

When fused in the air, lead oxidises rapidly, and it becomes covered with an iridescent pellicle, often of great beauty. It then passes into a yellow powder (litharge), protoxide of lead.

Pure lead is not affected by perfectly pure water free from air; but if air be present, the metal is oxidised at its expense, and the oxide thus formed, combining with carbonic acid, is deposited on the lead in minute crystals as a basic carbonate of lead. The water will then be found to contain lead in solution, and such waters drawn from impure cisterns often produce very distressing consequences. If the water contains any sulphates, the lead is thrown down as a sulphate of lead, which is insoluble.

The Ores of Lead.

1. *Native lead.*—Mr. Greg appears to doubt the existence of native lead in this country. He says, however, 'Native lead has been recently discovered in undoubtedly genuine specimens in the province of Guanaxuato in Mexico.' Some equally genuine specimens of native lead have been found in the Grassington mines and examined by the Editor; these are in the cabinets of the Duke of Devonshire, and of the late Stephen Eddy, and it is now we presume in the possession of his son.

2. *Minium. Native oxide of lead.*—This rare ore has been found in Anglesea, at Alston Moor, the Snailbeach Mine in Shropshire, at Grassington, the Leadhills in Scotland, and Wicklow in Ireland. Its composition is—lead, 90·66, oxygen, 9·34.

3. *Cerussite. Carbonate of lead. White Lead ore* (*Bleispath*, Ger.).—This ore occurs in crystals, in fibrous, compact, and earthy masses. It is found at several of the lead mines of Cornwall and Devonshire; remarkably fine specimens have been obtained from Frank Mills Mines in Devonshire, one of which is in the Museum of Practical Geology. In nearly all the mines producing the ores of lead, *cerussite* is formed, varying much in its character with the different conditions under which it has been formed.

This ore, in its purest state, is colourless and transparent like glass. It may be recognised by the following characters: Its specific gravity is from 6 to 6·7; it dissolves with more or less ease, and with effervescence, in nitric acid; becomes immediately black by the action of sulphuretted hydrogen, and melts on charcoal before the blowpipe into a button of lead. According to Klaproth, the carbonate of Leadhills contains 82 parts of oxide of lead, and 16 of carbonic acid, in 98 parts. This mineral is tender, scarcely scratches calcspar, and breaks easily with a waved conchoidal fracture. It possesses the double refracting property in a very high degree; the double image being very visible on looking through the flat faces of the prismatic crystals. Its crystalline forms are very numerous, and are referrible to the rhombic system. It is also found in an earthy state.

4. *Anglesite. Sulphate of lead*, or *Vitreous lead* (*Bleivitriol*, Ger.).—This mineral closely resembles carbonate of lead; so that the external characters are inadequate to distinguish the two. But the following are sufficient. It does not effervesce with nitric acid; it is but feebly blackened by sulphuretted hydrogen; it first decrepitates and then melts before the blowpipe into a transparent glass, which becomes milky as it cools. By the combined action of heat and charcoal, it passes first into a red pulverulent oxide,

and then into metallic lead. It consists, according to Klaproth, of 71 oxide of lead, 25 sulphuric acid, 2 water, and 1 iron. The prevailing form of crystallisation is the rectangular octahedron, whose angles and edges are variously modified. This mineral was first recognised in Anglesea, hence its name. It was found in the Channel Islands at Sark Mine, and is occasionally met with in the Leadhills and at Wanlockhead in Scotland, at Glemalure in Wicklow, and at Ballycorus Mine, Co. Dublin.

5. *Phosphate of lead. Pyromorphite.*—This, like all the combinations of lead with an acid, exhibits no metallic lustre, but a variety of colours. Before the blowpipe, upon charcoal, it melts into a globule externally crystalline, which by a continuance of the heat, with the addition of iron and boracic acid, affords metallic lead. Its constituents are 80 oxide of lead, 18 phosphoric acid, and 1·6 hydrochloric acid, according to Klaproth's analysis of the mineral from Wanlockhead. The crystalline forms are derived from an obtuse rhombohedron. Phosphate of lead is a little harder than white lead; it is easily scratched, and its powder is always grey. Its specific gravity is 6·9. It has a vitreous lustre, somewhat adamantine. Its lamellar texture is not very distinct; its fracture is wavy, and it is easily frangible. The phosphoric and arsenic acids being, according to M. Mitscherlich, isomorphous bodies, may replace each other in chemical combinations in every proportion, so that the phosphate of lead may include any proportion, from the smallest fraction of arsenic acid to the smallest fraction of phosphoric acid, thus graduating indefinitely into arsenate of lead. The yellowish variety indicates, for the most part, the presence of arsenic acid. It is found in Cornwall, Devonshire, Yorkshire, Derbyshire, and Cumberland, very fine specimens being found in the Alston Moor mines.

6. *Arsenate of lead. Mimetesite.*—The name is derived from μιμητής, *imitator*, the species so nearly resembling pyromorphite. The colour of this ore varies from straw-yellow and wax-yellow to brown, reddish-brown, orange, yellow, and red. Before the blowpipe, on charcoal, it emits arsenical fumes, and yields a bead of lead. The analysis by Dufrenoy gives the following as its composition:—

Arsenate of lead	84·55
Phosphate of lead	4·50
Chloride of lead	9·05

At Drygill, in Cumberland, this ore has been met with in sufficient abundance to be worked to some extent as an ore of lead. The mimetesite from this mine was at one time used in the manufacture of flint-glass, to which it gave great brilliancy. The form of the arsenate of lead, when it is crystallised, is a prism with six faces, of nearly the same dimensions as that of phosphate of lead. When pure, it is reducible upon charcoal, before the blowpipe, into metallic lead, with the copious exhalation of arsenical fumes; but only in part, and leaving a crystalline globule, when it contains any phosphate of lead. The arsenate of lead is tender, friable, sometimes even pulverulent, and of specific gravity 5·04. That from the Saxon mines of Johann-Georgenstadt, consists, according to Rose, of oxide of lead, 77·5; arsenic acid, 12·5; phosphoric acid, 7·5; and chlorine, 1·5.

7. *Sulphide of lead. Galena* (*Bleiglanz*, Ger.).—This is the most abundant ore of lead; it may be indeed regarded as the only commercial ore of value, if we except the carbonates, which are probably formed by the decomposition of galena. Its prevailing forms are the cube and a combination of the cube and octahedron; lustre metallic, opaque, colour and streak *lead grey*. Fracture conchoidal, but difficult to obtain, owing to the readiness with which it cleaves. The localities of galena need not be named here, as the lead-producing districts, of which a list will be presently given, will include them, galena occurring in them all. Thomson's analysis of galena gives—

Lead	85·13
Sulphur	13·02
Iron	0·50

'It is a remarkable fact that silver should invariably be present in galena, sometimes, indeed, in very minute proportion; and the same generalisation may now be received as established with respect to the presence of gold. The silver, it is certain, usually exists in galena in the state of sulphide; and so, probably, does the gold. The mode of existence of sulphide of silver in galena is not always the same, as may be inferred from the fact that by *washing*, nearly the whole of the silver is carried away from some kinds of galena; while by the *same treatment* of other kinds of galena the loss of silver is inconsiderable. It is an error to suppose that largely-crystalline galena is generally poor in silver.'—*Percy*.

8. *Jamesonite* is a combination of lead, antimony, and sulphur. It occurs in acicular crystals, or in parallel or diverging groups, and more frequently in fibrous masses. It is found in many places in Cornwall and Devon. Rose's analysis gives the following as its composition:—

Lead	38·71
Antimony	34·90
Iron	2·96
Copper	0·21
Zinc	0·74
Sulphur	25·53
	103·05

Some *Jamesonite* found near Bampton in Devon contained 15 per cent. of silver.

9. *Bournonite* is found near Liskeard in Cornwall, not far from Kingsbridge, and close to Beer Alston in Devonshire. It occurs in many places on the Continent, and is found in both North and South America. Rammelsberg gives it the following composition:—

Lead	42·54
Antimony	24·71
Copper	13·03
Sulphur	19·72
	100·00

This mineral may be regarded as a double sulphide of lead and antimony, analogous to the double sulphide of copper and iron.

The following ores of lead are only of mineralogical interest:—

10. *Chloro-carbonate of lead. Cromfordite. Phosgenite. Horn-lead.*—This ore has a pale yellow colour, is reducible to metallic lead by the agency of soda, and is not altered by the hydrosulphides. Before the blowpipe it melts first into a pale yellow transparent globule, with salt of phosphorus and oxide of copper, and manifests the presence of chlorine. It is fragile, tender, softer than carbonate of lead, and is sometimes almost colourless, with an adamantine lustre. Spec. grav. 6·06. Its constituents, according to Berzelius, are, lead, 25·84; oxide of lead, 57·07; carbonate of lead, 6·25; chlorine, 8·84; silica, 1·46; water, 0·54, in 100 parts.

11. *Plattnerite. Super-* or *binoxide of lead.* A doubtful species.

12. *Linarite. Cupreous sulphate of lead.* Found at Leadhills, and in Cumberland.

13. *Susannite. Sulphato-carbonate of lead.* Occurs at Leadhills.

14. *Lanarkite. Sulphato-carbonate of lead.* Ditto.

15. *Leadhillite. Sulphato-tricarbonate of lead.* Ditto.

16. *Caledonite. Cupreous sulphato-carbonate of lead.* Ditto.

17. *Vanadinate. Vanadate of lead.*

18. *Wulfenite. Molybdate of lead.*

19. *Geocronite. Sulphantimonide of lead.*

20. *Mendipite. Oxychloride of lead.*

21. *Matlockite,* *ditto.*

22. *Crocoisite. Red lead ore* or *Chromate of lead.*

23. *Vauquelinite. Chromate of lead and copper.*

A few other lead-bearing minerals might have been named, but from their having no commercial value, it has not been thought necessary to do so.

The ores of lead, which may be represented by galena, or the sulphide of lead, that being the truly commercial variety, are found in rocks of different ages from the granite and clay-slates to the Triassic formations. In the Devonian slate rocks, in the neighbourhood of Liskeard in Cornwall are many most productive lead mines. To the north of Truro is the abandoned lead mine Huel Rose, which from its long celebrity gave its name to the district; and again to the south of Helstone there have been some valuable workings for lead. These formations of lead ore have all been in the clay-slate, or 'killas' rocks of Cornwall. In Devonshire many most valuable lead mines have been worked in similar rocks. In these the celebrated mines of Beer Alston on the Tamar existed. With a very few exceptions, but little lead has been discovered in the black slates,—the carboniferous series of Devonshire. Some lead ore has, however, been discovered in the New Red Sandstone and in the slate rocks immediately adjoining them near Newton St. Cyres. To the north of the carboniferous rocks of Devonshire we have a renewal of clay-slate rocks, similar in all respects to those which are found near Liskeard in Cornwall; in these rocks are the once famous argentiferous lead mines of Combe Martin, from which Edward the Black Prince derived an immense revenue.

The lead mines of the Mendip Hills, which were at one time very productive, are in the mountain-limestone formation. The lead which is now obtained from the Mendips is smelted from the refuse slimes and slags left by the old miners. Those of

Cardiganshire are found in clay-slates and gritstones, correspondent with or underlying the lowest beds described by Sir R. Murchison in his Silurian System.

In Shropshire we have lead ore occurring in the original Silurian rocks, the Llandeilo formation. 'In that lofty and rugged district of Shropshire which lies around the village of Shelve and the Corndon mountains, and which extends west of the Stiper Stones range into Montgomeryshire' (*Murchison*), lead lodes are abundant. In Derbyshire, in Yorkshire, in Cumberland, Northumberland, and Durham, the lead mines prove the most productive in the mountain-limestone formations, although there are some instances in which good lead mines have been worked in the sandstones and shales. In addition to these, we have the mines in the Leadhills and at Wanlockhead, consisting chiefly of the Silurian slates, in Scotland; Luganure, &c., in the granite districts of Wicklow, Newtonards in County Down, with a few others in Ireland, and the lead mines in the Silurian rocks of the Isle of Man,—these are the principal districts from which our large supplies of lead ore are obtained.

The principal lead mines at present worked in other parts of the world are the following :—1. Poullaouen and Huelgöet, near Carhair in France, department of Finisterre, being veins of galena, which traverse a clay-slate resting on granite. They have been known for upwards of three centuries; the workings penetrate to a depth of upwards of 300 yards, and in 1816, furnished 500 tons of lead per annum, out of which 1,034 pounds avoirdupois of silver were extracted. 2. At Villefort and Viallay, department of Lozère, are galena mines said to produce 100 tons of lead per annum, 400 kilogrammes of silver (880 lbs. avoird.). 3. At Pezey and Macot, to the east of Moutiers in Savoy, a galena mine exists in talc-schist, which has produced annually 200 tons of lead, and about 600 kilogrammes of silver (1,230 lbs. avoird.). 4. The mine of Vedrin near Namur in the Low Countries, is opened upon a vein of galena, traversing compact limestone of a transition district; it has furnished 200 tons of lead, from which 385 pounds avoirdupois of silver were extracted. 5. In Saxony the galena mines are so rich in silver as to make the lead almost overlooked. They are enumerated under Silver Ores. 6. The lead mines of the Hartz have been likewise considered as silver ones. 7. Those of Bleyberg in the Eifel are in the same predicament. 8. The galena mines of Bleyberg and Villach in Carinthia are in compact limestone. 9. In Bohemia to the south-west of Prague. 10. Mines of Joachimsthal and Bleistadt on the southern slope of the Erzgebirge, produce argentiferous galena. 11. There are numerous lead mines in Spain, the most important being in the granite hills of Linarès, upon the southern slope of the Sierra Morena, and in the district of the small town of Caujagar. Sometimes enormous masses of galena are extracted from the mines of Linarès. There are also mines of galena in Catalonia, Granada, Murcia, and Almeira, the ore of the last locality being generally poor in silver. 12. The lead mines of Sweden are very argentiferous, and worked chiefly with a view to the silver. 13. The lead mines of Daouria are numerous and rich, lying in a transition limestone, which rests on primitive rocks; their lead is neglected on account of the silver.

There have been a few lead mines in this country, which have been equally productive of silver. This was especially the case with the lead mine which was formerly worked near Combe Martin, and the mines formerly worked at Beer Alston in Devonshire. One of the most remarkable of recent examples, is a small mine known as Huel Florence, near Tavistock, from which some lead ore has been sold at upwards of 90*l.* a ton, on account of the large quantity of silver it contained. At the conclusion of this article some tables will be given, showing the argentiferous character of the different lead-producing districts of the United Kingdom.

Before proceeding to the consideration of the metallurgy of lead, a few brief notices of the history of lead mining may not be out of place.

As we have already stated, mining for lead must have been one of the earliest of man's subterranean labours, and at all periods of history we learn that lead mines have been worked. The Romans, especially, worked lead mines in Spain, and, after the conquest of this country, in many of our lead-producing districts, especially in Cardiganshire, Shropshire, and Flintshire.

Lead mining appears to have been carried on from a very early period in Alston Moor, and some other of the northern districts. But in the west of England, lead mining must be regarded as a somewhat recent industry.

Borlase mentions, in 1758, that lead mines had anciently and lately been worked in Cornwall, and that those most noted formerly were Penrose, Penwerty, Trevascus, Relestian, and Guarnek (Garras). He states that Penrose mines (near Helstone) had been wrought for about 200 years—that is, from about the middle of the sixteenth century—and that they had yielded tolerable profit within thirty years. The only lead mine worthy of note at work in his time, was at St. Issy, near Padstow. Pryce describes the lead ore of Garras, near Truro, to have been so argentiferous, that when wrought about 1720, it produced 100 oz. of silver in the ton of lead. Huel Pool, near Helstone, about 1790, yielded from 40 to 50 oz. of silver per ton of lead, and works were erected for extracting the silver. The lead ore of Wheal Rose contained 60 oz. of silver per ton.

In Devonshire, the Combe Martin and Beer Alston mines have long been celebrated for their argentiferous lead ores. It is stated that the produce of these mines was unusually great in the reigns of Edward I. and Edward II. In 1293, William de Wymundham accounted at the Treasury for 270 lbs. of silver raised in Devon. In 1294, it amounted to 521*l.* 10*s.* weight; and in 1294, to 704*l.* 3*s.* 1*d.* weight. In 1296, great profit is stated to have been derived from the Devon mines; and 360 miners were impressed out of Derbyshire and Wales to work in them. In 1360, a writ was issued, authorising certain persons to take up as many miners and workmen as should be necessary to work in the king's mines in Devon, allowing them reasonable wages according to the custom of the country; to arrest and imprison such as should resist, till they should give security to serve the king in the said mines, and to buy and provide timber at a competent price.

Henry, bishop of Winchester and cardinal of England, as one of the executors of John, duke of Bedford, who had a grant from the king of the gold and silver mines of Devon and Cornwall, rendered 26 lbs. and 2 oz. weight of pure silver as the 15th part of the pure silver raised in those counties from 15th December, 21st, to 16th August, 23rd of the same king's reign.

The Combe Martin mine was re-opened in the reign of Elizabeth. The working of this mine was strongly recommended to the Long Parliament in 1659; but Lysons observes that it does not appear to have been again worked until the close of that century, and then without success. In 1813 it was again opened and worked for four years, producing only 208 tons of ore in that time. In 1837 they were again worked, and it was evident that the previous mining operations had been very unskilfully managed. The two lodes near Beer Alston have produced large quantities of argentiferous galena, often containing from 80 to 120 oz. of silver per ton of lead. According to Mr. Hitchings, the greatest quantity which occurred in that part of them named the South Hooe mine was 140 oz. of silver per ton of lead. In 1784 and 1785 the silver produce of these mines amounted to 6,500 oz. From Huel Betsy, near Tavistock, which was re-opened in 1806, from 300 to 400 tons of lead, and from 4,000 to 5,000 oz. of silver, were annually obtained. Lead mines were worked at a very early period in the Isle of Man, but the recent workings only date from the commencement of the present century. The mines of Cardiganshire were evidently worked by the Romans. In the reigns of Henry VII. and of Elizabeth they attracted much attention, and German miners were invited to work them.

The English lead-miners distinguish three different kinds of deposits of lead ore: *rake-veins*, *pipe-veins*, and *flat-veins*. The English word 'vein' corresponds to the French term *filon*; but miners make use of it indifferently in England and France, to indicate all the deposits of this ore, adding an epithet to distinguish the different forms; thus, *rake-veins* are true veins in the geological acceptation of the word vein; *pipe-veins* are masses usually very narrow, and of oblong shape, most frequently parallel to the plane of the rocky strata; and *flat-veins* are small beds of ores interposed in the middle of these strata.

In the north of England, which, on account of its great preponderance in produce, we take as the basis of our description of lead mining, the ores are for the most part found in *veins* (*lodes* in Cornish) and flats. Although different names have been assigned to occasional varieties, the usual occurrence of lead ore is in rake-veins, or direct running veins, usually named as *veins*, with some distinctive appellation prefixed, as, for example, Rampgill Vein, Hudgillburn Vein. Other veins, lying parallel, receive a similar prefix, with the addition of the words north, east, or south; but for the last-named the word *sun* is often used; as, for instance, Hudgillburn Sun Vein, and 2nd and 3rd Sun Vein if further discoveries are made of other parallel veins. Considerable quantities of ore are also raised from horizontal extensions of portions of the vein called *flats*, and these are interposed between the strata adjacent to the vein.

Rake-veins are the most common form in which lead ore occurs in Cumberland. They are in general narrower in the sandstone which covers the limestone than in the calcareous beds. A thickness of less than a foot in the former becomes suddenly 3 or 4 feet in the latter; in the rich vein of Hudgillburn, the thickness is 17 feet in the *Great limestone*, while it does not exceed 3 feet in the overlying *Watersill* or sandstone. This influence exercised on the veins by the nature of the enclosing rock, is instructive; it determines at the same time almost uniformly their richness in lead ore, an observation similar to what has been made in other countries, especially in the veins of Kongsberg in Norway. The Cumberland veins are constantly richer, the more powerful they are, in the portions which traverse the calcareous rocks, than in the beds of sandstone, and more particularly the schistose rocks. It is rare in the rock called *plate* (a solid slaty clay) for the vein to include any ore; it is commonly filled with a species of potter's earth. The upper calcareous beds are also in general more productive than the lower ones. In most of these mines, the veins were not worked till lately below the fifth calcareous bed (the four-fathom limestone), which is 307 yards beneath the Millstone-Grit; and as the first limestone stratum is 108 yards beneath it, it follows that the thickness of the part of the ground where the veins are rich in lead does not in general exceed 200 yards. It appears, however, that veins have been mined in the neighbourhood of Alston Moor downwards to the eleventh calcareous stratum, or Tyne bottom limestone, which is 418 yards under the Millstone-Grit of the coal formation, immediately above the whinsill; and that they have been followed above the first limestone stratum, as high as the grindstone sill, which is only 83 yards below the same stratum of Millstone-Grit; so that in the total thickness of the plumbiferous formation is there more than 836 yards. It has been asserted that lead veins have been traced even further down, into the Memerby scar-limestone; but they have not been mined.

The greatest enrichment of a vein takes place commonly in the points where its two sides, being not far asunder, belong to the same rock; and its impoverishment occurs when one side is calcareous and the other a schistose clay. The minerals which most frequently accompany the galena are carbonate of lime, fluoride of calcium, sulphate of baryta, quartz, and pyrites.

The *pipe-veins* (*amas* in French) are seldom of great length; but some have a considerable width; their composition being somewhat similar to that of the rake-veins. They meet commonly in the neighbourhood of the two systems, sometimes being in evident communication together; they are occasionally barren; but when a wide pipe-vein is metalliferous, it is said to be very productive.

The *flat-veins*, or *strata-veins*, seem to be nothing else than expansions of the matter of the vein between the planes of the strata; and contain the same ores as the veins in their vicinity. When they are metalliferous, they are worked along with the adjacent rake-vein, and are productive to only a certain distance from that vein, unless they get enriched by crossing a rake-vein. Some examples have been adduced of advantageous workings in *flat-veins* in the *great limestone* of Cumberland, particularly in the mines of Coalcleugh and Nenthead. The *rake-veins*, however, furnish the greater part of the lead which Cumberland and the adjacent counties send every year into the market.

The metalliferous limestone occupies, in Derbyshire, a length of about 25 miles from north-west to south-east, under a very variable breadth, which towards the south amounts to 25 miles. Castleton to the north, Buxton to the north-west, and Matlock to the south-east, lie nearly upon its limits. It is surrounded on almost all sides by the Millstone-Grit, which covers it, and which is, in its turn, covered by the coal strata. The nature of the rocks beneath the limestone is not known. In Cumberland the metalliferous limestone includes a bed of trap, designated under the name of *whinsill*. In Derbyshire the trap is much more abundant, and it is thrice interposed between the limestone. These two rocks constitute of themselves the whole mineral mass, through a thickness of about 550 yards, measuring from the Millstone-Grit; only in the upper portion, that is near the Millstone-Grit, there is a pretty considerable thickness of argillo-calcareous schists.

Four great bodies or beds of limestone are distinguishable, which alternate with three masses of trap, called *toadstone*. The lead veins exist in the calcareous strata, but disappear at the limits of the toadstone. It has, however, been ascertained that they recur in the limestone underneath. See Mines and Mining.

Metallurgy of Lead.

Although lead forms an essential element in a large number of minerals, the ores of this metal are, strictly speaking, far from numerous. Of these the most important is sulphide of lead, or galena. This mineral, which possesses a metallic brilliancy, and has a lighter colour than metallic lead, presents, in its cleavage, all the variations from large facettes and laminæ indicating a cubic crystallisation to a most minutely granular structure. It is extremely brittle, and its powder presents a brilliant blackish-grey appearance.

The specific gravity of galena is 7·5 to 7·8, and its composition, when absolutely pure, is—

Lead	86·55
Sulphur	13·45
	100·00

The next most important ore of lead is the carbonate, which is a brittle mineral, of a white or greyish-white colour, having a specific gravity varying from 6·46 to 6·50. Its composition is—

Carbonic acid	16·05
Oxide of lead	83·56
	99·61

Large quantities of this substance occur in the mines of the Mississippi Valley in the United States of America, where they were formerly thrown away as useless, but have since been collected and smelted. Vast deposits of this substance have also been found in the Bunter sandstone, near Düren in Prussia, and at Freyung in Bavaria.

The extraction and mechanical preparation of ores is the business of the miner, and not of the metallurgist who receives them from the former freed as perfectly as possible from foreign matters.

The metallurgic processes, by the aid of which lead is obtained from galena, may be divided into two classes. The first of these is founded on the following reactions:—If one equivalent of sulphide of lead and two equivalents of the oxide of the same metal are fused together, the result is three equivalents of metallic lead and one equivalent of sulphurous acid, which is evolved.

This reaction is represented by the following equation:—

$$PbS + 2PbO = 3Pb + SO^2.$$

When, on the other hand, one equivalent of sulphide of lead and one equivalent of sulphate of lead are similarly treated, two equivalents of lead are obtained, and two equivalents of sulphurous acid are evolved. Thus:—

$$PbS + PbO,SO^3 = 2Pb + 2SO^2.$$

The process, founded on the foregoing reactions, and which we will distinguish as the *method by double decomposition*, consists in roasting the galena in a reverberatory furnace until a certain amount of oxide and sulphate has been formed, and subsequently, after having intimately mixed the charge, and closed the doors of the furnace causing the whole to enter into a state of fusion.

During this second stage of the operation, the reaction between the sulphides, sulphates, and oxides takes place, and metallic lead is eliminated. The roasting of the ore is, in some cases, conducted in the same furnace in which the fusion is effected, whilst in others two separate furnaces are employed.

The process by double decomposition is best adapted for the richer varieties of ore, and such as are least contaminated by siliceous or earthy impurities, and is consequently that which is almost universally employed for smelting the ores of this country.

By the second method, which we will call the *process by affinity*, the ore is fused with a mixture of metallic iron, which by combining with the sulphur liberates the metallic lead. This reaction will be understood by reference to the following equation:—

$$PbS + Fe = Pb + FeS.$$

In practice, however, metallic iron is not always employed for this purpose; cast iron is also frequently used, and in some instances the ores of iron and hammer-slags are substituted, as are also tap-cinder and other secondary products containing a considerable percentage of this metal. None of these substances are, however, found to be so efficacious as metallic iron, since cast iron requires to be decarburised before it can readily decompose the sulphide of lead; and the ores of iron require the introduction of various fluxes, and the consequent expenditure of an additional amount of fuel. In all cases, however, it is judicious to subject the ore to a preliminary roasting, in order to eliminate a portion of the sulphur, and thereby reduce the expenditure of iron, as well as to agglutinate the ore and render it better adapted for its subsequent treatment in the blast-furnace.

We will not attempt to describe the different forms given to roasting furnaces employed for the ores treated by this process, but would remark that they frequently resemble the kilns used for the preparation of lime, whilst in some instances the ores are roasted in heaps interstratified with wood or other fuel.

The method of treating ore by *affinity* is particularly adapted to those varieties that contain a considerable amount of silica, since such minerals, if treated by double decomposition, would, by the formation of oxide of lead, give rise to silicates, from which it would be exceedingly difficult to extract the metal.

English Process. Treatment by double decomposition.—Galena, if placed in a close vessel which protects it from the action of the air, and exposed to a gradually increasing temperature, becomes fused without the elimination of any lead taking place, but ultimately a portion of the sulphur is driven off, and a subsulphide is formed, which at a very elevated temperature is volatilised without change.

If, however, the vessel be uncovered, and the air allowed to act on its contents, oxygen combines with the sulphur, sulphurous acid is evolved, and the desulphuration of the mineral is slowly effected.

When galena is spread on the hearth of a reverberatory furnace, and is so placed as to present the largest possible amount of surface to oxidising influences, it will be found that the surface slowly becomes covered with a yellowish-white crust of sulphate of lead. The oxygen of the air, by combining with the two elementary bodies of which galena is composed, will evidently produce this effect. This is not, however, the only chemical change which takes place in the charge under these circumstances; oxide of lead is produced at the same time as the sulphate, or rather the formation of the oxide is prior to that of the sulphate.

In fact, during the first stage of the operation of roasting, sulphurous acid is evolved, the sulphur quits the lead, and a portion of that metal remains in a free state. This becomes oxidised by the air passing through the furnace, and subsequently a part of it combines with sulphuric acid, formed by the oxidation of sulphurous acid, and sulphate of lead is the result. In this way, after the expiration of a certain period, both oxide and sulphate of lead are present in the furnace.

During the early period of the roasting, when the temperature of the furnace is not very elevated, the proportion of sulphate is larger than that of the oxide formed, but in proportion as the heat of the apparatus increases, the production of oxide becomes more considerable, whilst that of the sulphate diminishes.

The sulphate and oxide thus formed re-act in their turn on the undecomposed galena, whilst a portion of the latter, by combining with the sulphide of lead, gives rise to the formation of oxysulphide.

This last compound has no action on galena, except to dissolve it in certain proportions, but is readily decomposed by the aid of carbonaceous matter.

It is therefore evident that the addition of carbon, at this stage of the operation, will have the effect of reducing the oxide and oxysulphide of lead.

Every process then that has for its object the reduction of lead ores by double decomposition, comprises two principal operations: 1st. The reduction of galena, by the aid of heat and atmospheric air, to a mixture of sulphide, oxide, and sulphate, which mutually decompose each other, with the elimination of metallic lead; 2nd. The reduction of the oxysulphide by the addition of carbonaceous matter.

The Reverberatory Furnace.—The reverberatory furnace employed for the treatment of galena is composed, like all other furnaces of this description, of three distinct parts,—the fire-place, the hearth, and the chimney.

The hearth has to a certain extent the form of a funnel, of which the lowest point is on the front side of the furnace immediately below the middle door. The molten metal, descending from every side along the inclined bottom or sole, is collected in this receptacle, and is ultimately run off by means of a proper tap-hole. This tap-hole is, during the operation, closed by a pellet of clay.

The inclination of the hearth is more rapid in the vicinity of the fire-bridge than towards the chimney, in order that the liquid metal may not be too long exposed to the oxidising and volatilising influences of a current of strongly-heated air.

The dimensions given to these furnaces, as well as the weight of the charge operated on at one time, vary considerably in different localities, but in the north of England the following measurements are usually employed:—The fire-grate is 5 feet 9 inches × 1 foot 10 inches, and the thickness of the fire-bridge 1 foot 6 inches; the length of the sole is 9 feet, and its average width 7 feet. The depth of the tap is about 2 feet 6 inches below the top of the inclined sole. The height of the roof at the fire-end may be 1 foot 4 inches, and at the other extremity 11 inches.

The introduction of the charge is in some cases effected by the doors of the furnace, whilst in other instances a hopper, placed over the centre of the arch, is made use of.

On the two sides of the furnace are placed three doors, about 11 inches × 9 inches, which are distinguished as 1, 2 and 3, counting from the fire-bridge end. The three doors on the one side are known as the front doors, whilst those on the other side are called the back doors. Immediately beneath the door on the front side of the furnace is situated the iron pan into which the molten lead is tapped off.

The bottom of this arrangement is in most cases composed of fire-bricks, covered by a layer of vitrified slags, of greater or less thickness. In order to form this bottom, the slags are introduced into the furnace, the doors closed, and the damper raised. An elevated temperature is thus quickly obtained, and as soon as the scoriæ have become sufficiently fused, they are, by means of rakes and paddles, made to assume the required form. The charge employed, as before stated, varies in almost every establishment. In the North, however, smaller charges are used than in most other localities. At Newcastle, and in the neighbourhood, the charge varies from 12 to 14 cwts.; in Wales, and near Bristol, 21-cwt. charges are treated; whilst in Cornwall, charges of 30 cwts. are not unfrequently worked. The time required for smelting a charge varies with its weight and the nature of the ores, from 6 to 24 hours.

In some cases the ore is introduced raw into the furnace, whilst in others it undergoes a preliminary roasting previous to its introduction. Rich ores are generally smelted without being first calcined; but the poorer varieties, and particularly those which contain large quantities of iron pyrites, are, in most instances, subjected to roasting in a separate furnace.

In order to understand more clearly the operation of smelting in furnaces of this description, we will suppose that a charge has just been tapped off, and that, after thoroughly clearing the hearth, a fresh charge of raw ores has been introduced. During the first part of the operation of roasting, which usually occupies about two hours, the doors are taken off to admit free access of air, and also for the purpose of cooling the furnace, which has been strongly heated at the close of the preceding operation. No fuel is at this period charged upon the grate, since the heat of the furnace is of itself sufficient to effect the elimination of the first portions of sulphur. The ore is carefully stirred, for the purpose of constantly presenting a fresh surface to oxidising influences, and when white fumes are no longer observed to pass off in large quantities, a little coal may be thrown on the grate, and the temperature gradually elevated until the charge becomes slightly clammy and adheres to the rake. When the roasting is considered as being sufficiently advanced, the smelter turns his attention to the state of the fire, taking care to remove the clinkers and get the grate into proper condition for the reception of a fresh supply of fuel. The furnace doors are now closed, and a strong heat is kept up for about a quarter of an hour, when the smelter examines the condition of his charge by removing one of the doors. If the operation is progressing satisfactorily, and the lead flowing freely and passing without obstruction into the tap, the firing is continued a little longer; but when the ores have been found to have taken fire, or are lying unevenly on the bottom of the furnace, the position of the charge is changed by the use of an iron paddle. During this operation the furnace becomes partially cooled, and the reduction of temperature thus obtained is frequently found to produce decompositions, which facilitate the reduction of the charge. In the case of extremely refractory ores, this alternate heating and cooling of the furnace is sometimes almost indispensable, whilst, in other instances, their being once or twice raked over is all the manipulation that is required.

We will suppose that four hours have now elapsed since the charging of the furnace, and that the charge has run down the inclined sole towards the tap. The smelter now examines the condition of the scoriæ, and adds a couple of shovelfuls of lime and three or four shovelfuls of small coals, the amount and relative proportions of these being regulated in accordance with the aspect of the slags. The charge is now, by means of proper tools, again raised to the breast of the furnace, and the firing continued until the charge has run down into the tap-hole. The foreman now takes his rake and feels if any lumps remain in an unfused condition, and if he finds all to be in a fluid state he calls his assistant from the other side, and by the addition of a small quantity of lime and fine coal, makes the slag assume a pasty or rather doughy consistency. By the aid of his paddle he now pushes this compound up to the opposite side of the furnace, where it is drawn by an assistant through the back door into a trough containing water. Whilst the assistant is doing this, the foreman is busily engaged in tapping off the metal into the iron pan in front of the furnace, from which, when sufficiently cooled, it is laded out into suitable moulds.

The total duration of the operation may be about six hours.

To build a furnace of the above description, 5,000 common bricks, 2,000 fire-bricks, and 2½ tons of fire-clay are required. In addition to this, must be reckoned the iron-work, the expense of which will be much influenced by the nature of the armatures employed and the locality in which the furnace is constructed.

The amount of fuel employed for the treatment of a ton of lead ore varies not only in relation to the richness of the mineral, but is also much influenced by the nature of the associated matrix and the calorific value of the fuel itself. The loss of metal experienced during the operation is mainly dependent on the richness of the ore treated and the skill and attention of the foreman.

In the North about 12 cwts. of coal are consumed in the elaboration of 1 ton of ore, and the loss of metal on 60 per cent. ore may be estimated at about 12 per cent., of which about 6½ per cent. is subsequently recovered from the slag and fumes. At a well-conducted smelting works, situated in the west of England, in which the average assay of the ores smelted during the year was 75½, the yield from the smelting furnaces was 68½ per cent., and the coal used per ton of ore was 13¾ cwts. The lead recovered from the slag and fumes amounted to 2¾ per cent., making the total yield of metal 71¼ per cent., and the loss on the assay produce 4¼ per cent.

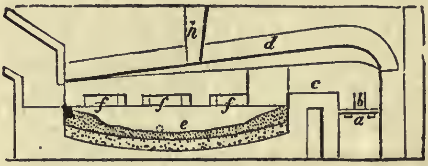
In this establishment the men are paid from 7*s*. 6*d*. to 12*s*. 6*d*. per ton of lead, in accordance with the nature of the ores operated on.

In one establishment the process before described is somewhat varied. The charge employed is 21 cwts. This is run down and tapped off at the expiration of 6 hours, and about 9 pigs of 1¼ cwt. each usually obtained. A second charge of 21 cwts. is then dropped in, and, as soon as it is roasted, mixed with the slags of the former operation. The whole is then run down in the ordinary way, the slags drawn and the lead tapped off in 9 hours. The produce of the second or double charge is from 14 to 15 pigs.

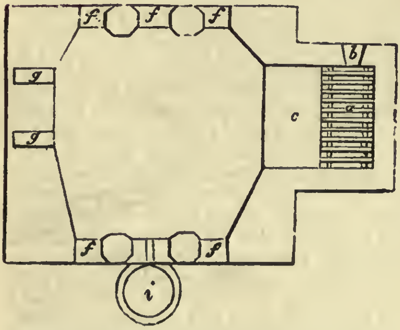
If the ores are difficult to flow, 16 to 16½ hours are required for the two charges. A small quantity of black slag from the slag hearth is employed for drying up.

Figs. 1331, 1332, 1333, represent the reverberatory furnace at the Marquis of Westminster's lead-smelting works, two miles from Holywell. The hearth is hollowed out below the middle door of the furnace; it slopes from the back and ends towards this basin. The distance from the lowest point of this concavity up to the sill of the door, is usually 24 inches, but it is sometimes a little less, according to the quality of the

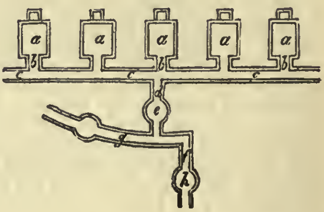
1331



1332



1333



ores to be smelted. This surface has no hole for running off the slag, above the level of the tap-hole for the lead, like the smelting furnace of Lea, near Matlock. A single chimney stack serves for all the establishment; and receives all the flues of the various roasting and reducing furnaces. *Fig*. 1333 gives an idea of the distribution of these flues. *a a a*, &c., are the furnaces; *b*, the flues, 18 inches square; these lead from each furnace to the principal conduit *c*, which is 5 feet deep by 2½ wide; *d* is 6 feet deep by 3 wide; *e* is a round chamber, 15 feet in diameter; *f* is a conduit, 7 feet high by 5 wide; *g* another, 6 feet high by 3 wide. The chimney at *h* has a diameter at bottom of 30 feet, at top of 12 feet, including the thickness of its sides, forming a truncated cone 100 feet high; whose base stands upon a hill a little way from the furnaces, and 62 feet above their level.

a, *figs*, 1331, 1332, is the grate; *b*, the door of the fire-place; *c*, the fire-bridge; *d*, the arched roof; *e*, the hearth; *f f f*, &c., the working doors; *g g*, flues running into one conduit, which leads to the subterranean condensing-chamber *e*, and thence to the general chimney; *h*, a hopper-shaped opening in the top of the furnace, for supplying it with ores.

This magnificent structure is not destined solely for the reduction of the ores, but also for dissipating all the vapours which might prove noxious to the health of the work-people and to vegetation

The ores smelted at Holywell are very refractory galenas, mixed with blende, calamine, pyrites, carbonate of lime, &c., but without any fluoride of calcium. They serve mutually as fluxes to one another. The coal is of inferior quality. The sole of each furnace is formed of slags obtained in the smelting, and they are all of one kind. In constructing it, 7 or 8 tons of these slags are first thrown upon the brick area of the hearth; are made to melt by a brisk fire, and in their stiffening state, as they cool, they permit the bottom to be sloped and hollowed into the desired shape. Four workmen, two at each side of the furnace perform this task.

The ordinary charge of ore for one smelting operation is 20 cwts., and it is introduced through the hopper. An assistant placed at the back doors spreads it equally over the whole hearth with a rake; the furnace being meanwhile heated only with the declining fire of a preceding operation. No regular fire is made during the first two hours, but a gentle heat merely is kept up by throwing one or two shovelfuls of small coal upon the grate from time to time. All the doors are closed, and the register-plate of the chimney lowered.

The outer basin in front of the furnace is at this time filled with the lead derived from a former process, the metal being covered with slags. A rectangular slit above the tap-hole is left open, and remains so during the whole time of the operation, unless the lead should rise in the interior basin above the level of that orifice; in which case a little mound must be raised before it.

The two doors in front furthest from the fire being soon opened, the head-smelter throws in through them, upon the sole of the furnace, the slags swimming upon the bath of lead, and a little while afterwards he opens the tap-hole, and runs off the metallic lead reduced from these slags. At the same time his assistant turns over the ore with his paddle, through the back doors. These being again closed, while the above two front doors are open, the smelter throws a shovelful of small coal or coke cinder upon the lead-bath, and works the whole together, turning over the ore with the paddle or iron oar. About three quarters of an hour after the commencement of the operation, he throws back upon the sole of the hearth the fresh slags which then float upon the bath of the outer basin, and which are mixed with coaly matter. He next turns over these slags, as well as the ore with the paddle, and shuts all the doors. At this time the smelter lades off the lead into the pig-moulds.

The assistant now turns over the ore once more through the back doors. A little more than an hour after the operation began, a quantity of lead proceeding from the slag last remelted is run off by the tap; being usually in such quantity as to fill one half of the outer basin. Both the workmen then turn over the ore, with the paddles, at the several doors of the furnace. Its interior is at this time of a dull red heat; the roasting being carried on rather by the combustion of the sulphurous ingredients, than by the action of the small quantity of coal in the grate. The smelter, after shutting the front doors, with the exception of that next the fire-bridge, lifts off the fresh slags lying upon the surface of the outside bath, drains them, and throws them back into the furnace.

An hour and a half after the commencement, the lead begins to ooze out in small quantities from the ore; but little should be suffered to flow before two hours have expired. About this time the two workmen open all the doors, and turn over the ore, each at his own side of the furnace. An hour and three quarters after the beginning, there are few vapours in the furnace, its temperature being very moderate. No more lead is then seen to flow upon the sloping hearth. A little coal being thrown into the grate to raise the heat slightly, the workmen turn over the ore, and then close all the doors.

At the end of two hours, the *first fire* or roasting being completed, and the doors shut, the register is to be lifted a little, and coal thrown upon the grate to give the *second fire*, which lasts during 25 minutes. When the doors are now opened, the inside of the furnace is of a vivid red colour, and the lead flows down from every side towards the inner basin. The smelter with his rake or paddle pushes the slags upon that basin back towards the upper part of the sole, and his assistant spreads them uniformly over the surface through the back doors. The smelter next throws in by his middle door, a few shovelfuls of quicklime upon the lead-bath. The assistant meanwhile for a quarter of an hour works the ore and the slags together through the three back doors, and then spreads them out, while the smelter pushes the slags from the surface of the inner basin back to the upper part of the sole. The doors being now left open for a little, while the interior remains in repose, the metallic lead, which had been pushed back with the slags, flows down into the basin. This occasional *cooling* of the furnace is thought to be necessary for the better separation of the products, especially of the slags from the red bath.

In a short time the workmen resume their rakes, and turn over the slags along with the ore. Three hours after the commencement a little more fuel is put into the grate, merely to keep up a moderate heat of the furnace during the paddling. After three hours and ten minutes, the grate being charged with fuel for the *third fire*, the register is completely opened, the doors are all shut, and the furnace is left in this state for three quarters of an hour. In nearly four hours from the commencement, all the doors being opened, the assistant levels the surfaces with his rake, in order to favour the descent of any drops of lead; and then spreads the slags, which are pushed back towards him by the smelter. The latter now throws in a fresh quantity of lime, with the view not merely of covering the lead-bath and preventing its oxidation, but of rendering the slags less fluid.

Ten minutes after the third fire is completed, the smelter puts a new charge of fuel on the grate, and shuts the doors of the furnace to give it the *fourth fire*. In four hours and forty minutes from the commencement, this fire being finished, the doors are opened, the smelter pierces the tap-hole to discharge the lead into the outer basin, and throws some quicklime upon the slags in the inner basin. He then pushes the slags thus *dried up* towards the upper part of the hearth, and his assistant rakes them out by the back doors.

The whole operation of a *smelting shift* takes about four hours and a half, or at most five hours, in which four periods may be distinguished:—

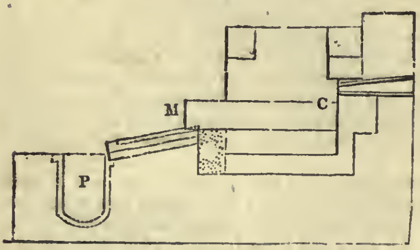
1. The *first fire* for roasting the ores requires very moderate firing, and lasts two hours.

2. The *second fire*, or smelting, requires a higher heat, with shut doors; at the end the slags are *dried up* with lime, and the furnace is also allowed to cool a little.

3, 4. The last two periods, or the *third* and *fourth fires*, are likewise two smeltings or foundings, and differ from the first only in requiring a higher temperature. The heat is greatest in the last. The form and dimensions of the furnace are calculated to cause a uniform distribution of heat over the whole surface of the hearth. Sometimes billets of green wood are plunged into the metallic lead of the outer basin, causing an ebullition which favours the separation of the slags, and consequently the production of a purer lead; but no more metallic metal is obtained.

Ten cwts. of coal are consumed at Holywell in smelting one ton of the lead-ore *schlich* or sludge; but at Grassington, near Skipton in Yorkshire, with a similar furnace worked with a slower heat, the operation taking from seven hours to seven hours and a half, instead of five, only $7\frac{1}{2}$ cwts. of coal are consumed. But here the ores are less refractory, have the benefit of fluor-spar as a flux, and are more exhausted of their metal, being smelted upon a less sloping hearth.

1334



C, Tuyère. M, Workstone. P, Lead-pot.

The ore-hearth.—This furnace, called by the French *fourneau écossais*, is from 22 to 24 inches in height and 1 foot by $1\frac{1}{2}$ in area inside; but its horizontal section, always rectangular, varies much in its dimensions at different levels, as shown in *fig.* 1334.

Treatment of lead ores by the Scotch furnace or ore-hearth.—This furnace is generally employed in the counties of Northumberland, Cumberland, and Durham for the smelting of lead ores, which were formerly carried to them without any preparation, but they are now often exposed to a preliminary calcination. The roasted ore yields in the Scotch furnace a more considerable product than the crude ore, because it forms in the furnace a more porous mass, and at the same time *it works drier*, to use the founder's expression; that is, it allows the stream of air impelled by the blast to diffuse itself more completely across the matters contained in the furnace.

In proceeding to smelt by means of an ore-hearth, two workmen are required to be in attendance from the beginning to the end of each smelting shift, the duration of which is from 12 to 15 hours. The first step in commencing a smelting shift is to fill up the hearth-bottom, and space below the workstone with *peats*, placing one already kindled before the nozzle of the bellows. The powerful blast very soon sets the whole in a blaze, and by the addition of small quantities of coal at intervals, a body of fire is obtained, filling the hearth. Roasted ore is now put upon the surface of the fire, between the forestone and pipestone, which immediately becomes heated red hot and reduced; the lead from it sinking down and collecting in the hearth bottom. Other portions of ore of 10 or 12 lbs. each are introduced from time to time, and the contents of the hearth are stirred and kept open, being occasionally drawn out and examined upon the workstone, until the hearth bottom becomes full of lead. The hearth may now be considered in its regular working state, having a mass of heated fuel, mixed with partly-fused and semi-reduced ore, called *Brouze*, floating upon a stratum of melted lead. The smelting shift is then regularly proceeded with by the two workmen, as follows :—The fire being made up, a stratum of ore is spread upon the horizontal surface of the *brouze*, and the whole suffered to remain exposed to the blast for the space of about five minutes. At the end of that time, one man plunges a poker into the fluid lead, in the hearth bottom below the *brouze*, and raises the whole up, at different places, so as to loosen and open the brouze, and in doing so, to pull a part of it forwards upon the workstone, allowing the recently-added ore to sink down into the body of the hearth. The poker is now exchanged for a shovel, with a head 6 inches square, with which the brouze is examined upon the workstone, and any lumps that may have been too much fused, broken to pieces; those which are so far agglutinated by the heat, as to be quite hard, and further known by their brightness, being picked out, and thrown aside, to be afterwards smelted in the slag hearth. They are called 'grey slags.' A little slaked lime, in powder, is then spread upon the brouze, which has been drawn forward upon the workstone, if it exhibit a pasty appearance; and a portion of coal is added to the hearth, if necessary, which the workman knows by experience. In the mean time, his fellow workman, or shoulder fellow, clears the opening, through which the blast passes into the hearth, with a shovel, and places a peat immediately above it, which he holds in its proper situation, until it is fixed, by the return of all the brouze, from the workstone into the hearth. The fire is made up again into the shape before described, a stratum of fresh ore spread upon the part, and the operation of stirring, breaking the lumps upon the workstone, and picking out the hard slags repeated, after the expiration of a few minutes, exactly in the same manner. At every stirring a fresh peat is put above the nozzle of the bellows, which divides the blast, and causes it to be distributed all over the hearth; and as it burns away into light ashes, an opening is left for the blast to issue freely into the body of the brouze. The soft and porous nature of dried peat renders it very suitable for this purpose; but, in some instances, where a deficiency of peats has occurred, blocks of wood of the same size have been used with little disadvantage. As the smelting proceeds, the reduced lead, filtering down through all parts of the brouze into the hearth bottom, flows through the channel, out of which it is laded into a proper mould, and formed into pigs.

The principal particulars to be attended to in managing an ore-hearth properly during the smelting shift are these: First.—It is very important to employ a proper blast, which should be carefully regulated, so as to be neither too weak nor too powerful. Too weak a blast would not excite the requisite heat to reduce the ore, and one too powerful has the effect of fusing the contents of the hearth into slags. In this particular no certain rules can be given; for the same blast is not suitable for every variety of ore. Soft free-grained galena, of great specific gravity, being very fusible, and easily reduced, requires a moderate blast; while the harder and lighter varieties, many of which contain more or less iron, and are often found rich in silver, require a blast considerably stronger. In all cases, it is most essential, that the blast should be no more than sufficient to reduce the ore, after every other necessary precaution is taken in working the hearth. Second.—The blast should be as much divided as possible, and made to pass through every part of the brouze. Third. —The hearth should be vigorously stirred, at due intervals, and part of its contents exposed upon the workstone; when the partially-fused lumps should be well broken to pieces, as well as those which are further vitrified, so as to form slags, carefully picked out. This breaking to pieces, and exposure of the hottest part of the brouze upon the workstone, has a most beneficial effect in promoting its reduction into lead; for the atmospheric air immediately acts upon it, and, in that heated state, the sulphur is readily consumed, or converted into sulphurous acid, leaving the lead in its metallic state; hence it is that the reduced lead always flows most abundantly out of the hearth immediately after the return of the brouze, which has been spread out and exposed to the atmosphere. Fourth.—The quantity of lime used should be no more than is just necessary to thicken the brouze sufficiently; as it does not in the least contribute to reduce the ore by any chemical effect: its use is merely to render the brouze less pasty, if, from the heat being too great, or from the nature of the ore, it has a disposition to become very soft. Fifth.—Coal should also be supplied judiciously; too much unnecessarily increasing the bulk of the brouze, and causing the hearth to get too full.

When the ore is of a description to smelt readily, and the hearth is well managed in every particular, it works with but a small quantity of brouze, which feels dry when stirred, and is easily kept open and permeable to the blast. The reduction proceeds rapidly with a moderate degree of heat, and the slags produced are inconsiderable; but, if in this state, the stirring of the brouze and exposure upon the workstone are discontinued, or practised at longer intervals, the hearth quickly gets too hot, and immediately begins to agglutinate together; rendering evident the necessity of these operations to the successful management of the process. It is not difficult to understand why these effects take place, when it is considered, that in smelting by means of the ore-hearth, it is the oxygen of the blast and of the atmosphere which principally accomplishes the reduction ; and the point to be chiefly attended to consists in exposing the ore to its action, at the proper temperature, and under the most favourable circumstances. The importance of having the ores free from impurities is also evident ; for the stony or earthy matter it contains impedes the smelting process, and increases the quantity of slags. A very slight difference of composition of perfectly-dressed ore may readily be understood to affect its reducibility; and hence it is, that ore from different veins, or the same vein in different strata, as before observed, is frequently found to work very differently when smelted singly in the hearth. It happens, therefore, that with the best workmen, some varieties of ore require more coal and lime, and a greater degree of heat than others ; and it is for this reason that the forestone is made moveable, so as to answer for ore which works either with a large or a small quantity of brouze.

It has been stated that the duration of a smelting shift is from 12 to 15 hours, at the end of which time, with every precaution, the hearth is apt to become too hot, and it is necessary to stop for some time, in order that it may cool. At mills where the smelting shift is 12 hours, the hearths usually go on 12 hours, and are suspended 5 ; four and a half or five bings[1] of ore (36 to 40 cwts.) are smelted during a shift, and the two men who manage the hearth work each four shifts per week ; terminating their week's work at 3 o'clock on Wednesday afternoon. They are succeeded by two other workmen, who also work four 12-hour shifts ; the last of which they finish at 4 o'clock on Saturday. In these eight shifts, from 36 to 40 bings of ore are smelted, which, when of good quality, produce from 9 to 10 fodders[2] of lead. At other mills where the shift is 14 or 15 hours, the furnace is kindled at 4 o'clock in the morning, and worked until 6 or 7 in the evening each day, six days in the week ; during this shift 5 or 5½ bings of ore are smelted, and two men at one hearth, in the early part of each week, work three such shifts, producing about 4 fodders of lead—two other men work each three shifts in the latter part of the week, making the total quantity smelted per week, in one hearth, from 30 to 33 bings.

Hearth-ends and Smelter's fume.—In the operation of smelting, as already described, it happens that particles of unreduced and semi-reduced ore are continually expelled from the hearth, partly by the force of the blast, but principally by the decrepitation of the ore on the application of heat. This ore is mixed with a portion of the fuel and lime made use of in smelting, all of which are deposited upon the top of the smelting-hearth, and are called hearth-ends. It is customary to remove the hearth-ends from time to time, and deposit them in a convenient place until the end of the year, or some shorter period, when they are washed to get rid of the earthy matter they may contain, and the metallic portion is roasted at a strong heat, until it begins to soften and cohere into lumps, and afterwards smelted in the ore-hearth, exactly in the same way as ore undergoing that operation for the first time, as already described.

It is difficult to state what quantity of hearth-ends are produced by the smelting of a given quantity of ore, but in one instance the hearth-ends produced in smelting 9,751 bings, on being roasted and reduced in the ore-hearth, yielded of common lead 315 cwts., and the grey slags separated in this process gave, by treatment in the slag-hearth, 47 cwts. of slag-lead ; making the total quantity of lead 362 cwts., which is at the rate of 3 cwts. 2 qrs. 23 lbs. from the smelting of 100 bings of ore.

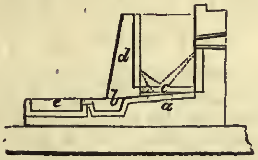
Slag-hearth.—The various slags obtained from the different operations of lead smelting are divided into two classes. Those which do not contain a sufficient amount of metal to pay for further treatment are thrown away as useless, whilst those in which the percentage of lead is sufficiently large are treated by the slag-hearth.

Figs. 1335, 1336, represent a slag-hearth, the *fourneau à manche* (elbow furnace) of the French, and the *Krummofen* (crooked furnace) of the Germans ; such as is used at Alston Moor, in Cumberland, for the reduction of the lead-slag. It resembles the Scotch furnace. The shaft is a parallelopiped, whose base is 26 inches by 24 inches in area inside, and whose height is 3 feet ; the sole-plate *a*, of cast iron, slopes slightly down to the basin of reception, or the fore-hearth, *b*. Upon both of the long sides of the sole-plate there are cast-iron beams, called *bearers*, *c*, *c*, of great strength, which support the side walls built of a coarse-grained sandstone, as well as the cast-iron plate *d* (*forestone*), which forms the front of the shaft. This stands 7 inches off from the sole-plate, leaving an empty space between them. The back side is made of cast

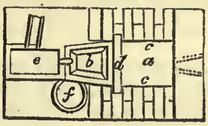
[1] 1 bing=8 cwts. [2] 1 fodder=21 cwts.

iron, from the sole-plate to the horizontal tuyère in its middle; but above this point it is made of sandstone. The tuyère is from 1½ to 2 inches in diameter. In front of the fore-hearth *b*, a cistern, *e*, is placed, through which water continually flows, so

1335



1336

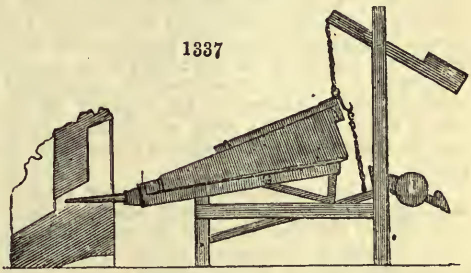


that the slags which spontaneously overflow the fore-hearth may become inflated and divided, whereby the lead disseminated through them may be readily separated by washing. The lead itself flows from the fore-hearth *b*, through an orifice into an iron pot, *f*, which is kept over a fire. The metal obtained from this slag-hearth is much less pure than that extracted directly from the ore.

The whole bottom of the furnace is filled to a height of 17 inches, that is, to within 2 or 3 inches of the tuyère, with the rubbish of coke reduced to coarse powder and beat strongly down. At each *smelting shift*, this bed must be made anew, and the interior of the furnace above the tuyère repaired, with the exception of the front, consisting of cast iron. In advance of the furnace there is a basin of reception, which is also filled with coke rubbish. Farther off is the pit, full of water, replenished by a cold stream, which incessantly runs in through a pipe. The scoriæ, in flowing out of the furnace, pass over the coke bed in the basin of reception, and then fall into the water, whose coolness makes them fly into small pieces, after which they are easily washed, so as to separate the lead that may be entangled amoug them.

These furnaces are urged sometimes by fans or by wooden bellows, *fig.* 1337. But at the smelting works of Lea, near Matlock, the blowing-machine consists of two casks, which move upon horizontal axes. Each of these casks is divided into two equal parts by a fixed plane that passes through its axis, and is filled with water to a certain height. The water of one side communicates with that of the other by an opening in the lower part of the division. Each cask possesses a movement of oscillation, produced by a rod attached to a crank of a bucket-wheel. At each demi-oscillation one of the compartments, being in communication with the external air, is filled; whilst the other, on the contrary, communicates with the nozzle, and supplies wind to the furnace.

1337



Instead of being blown by a cold blast, these furnaces are sometimes supplied with heated air. When smelting with cold air, it is often found difficult to proportion the quantity of slag or other substance operated on, so as to preserve the nose or cone of slag which forms at the end of the tuyère from growing too long, to the prejudice of the operation. When the substance operated on is poor for metal, and very refractory, it frequently happens that the smelter is obliged to break the nose, or introduce some very fusible substance in order to melt it off. By the introduction of hot air this inconvenience is removed, since by increasing or lowering the temperature of the blast, the nose may be allowed to lengthen or shorten, according as the nature of the slags may require. The temperature found to answer best is from 250° to 300° Fahr.; since when it is heated to from 500° to 600°, it is found impossible to form a nose of sufficient length to convey the blast to the front of the hearth, and therefore the back, which is expensive to rebuild, is quickly destroyed.

The advantage to be derived from the use of the hot blast will be evident, from the result of two experiments which were tried some years since:—

Twenty-eight tons of slag smelted with cold blast consumed 392 cubic feet of air per minute.

Labour cost	£3 7 8
Coke, 7 tons, at 24*s*. 6*d*.	8 11 6
Total .	£11 19 2

Thirty-five tons of similar slag smelted with hot blast consumed 300 cubic feet of air per minute.

Labour cost	£3	7	8
Coke, 5 tons, 17 cwts., at 24*s.* 6*d.*	7	3	4
Turf for heating air, 11 loads, 1*s.* 8*d.*	0	18	4
Total .	£11	9	4

From which it will be seen that, with one-quarter part less air, a quarter part more slag was melted per week, and a saving of expense of nearly 10*s.* effected.

The loss of lead experienced in smelting by the slag-hearth is, however, very great, even under the most favourable circumstances; and it has, consequently, of later years been gradually superseded by the Castilian furnace, which will be shortly described. Many large and well-conducted establishments still however continue to employ the slag-hearth, and when well constructed and skilfully managed, the loss arising from volatilisation may be considerably reduced.

Castilian Furnace.—Within the last few years a blast-furnace has been introduced into the lead-works of this country which possesses great advantages over every other description of apparatus which has been hitherto employed for the treatment of lead ores of low produce. This apparatus, although first employed in Spain, was invented by an Englishman (Mr. W. Goundry) who was employed in the reduction of rich slags in the neighbourhood of Carthagena.

This furnace is circular, usually about 2 feet 4 inches, or 2 feet 6 inches in diameter, and is constructed of the best fire-bricks, so moulded as to fit together, and allow all the joints to follow the radii of the circle described by the brick-work. Its usual height is 8 feet 6 inches, and the thickness of the masonry invariably 9 inches. In this arrangement the breast is formed by a semicircular plate of cast iron, furnished with a lip for running off the slag, and has a longitudinal slot, in which is placed the tapping-hole.

On the top of this cylinder of brick-work a box-shaped covering of masonry is supported by a cast-iron framing, resting on four pillars, and in this is placed the door for feeding the furnace, and the outlet by which the various products of combustion escape to the flues. The lower part of this hood is fitted closely to the body of the furnace, whilst its top is closed by an arch of 4½-inch brick-work laid in fire-clay. The bottom is composed of a mixture of coke-dust and fire-clay, slightly moistened, and well beaten to the height of the top of the breast-pan, which stands nearly 3 feet above the level of the floor. Above the breast-pan is an arch so turned as to form a sort of niche, 18 inches in width, and rather more than 2 feet in height.

When the bottom has been solidly beaten, up to the required height, it is hollowed out so as to form an internal cavity, communicating freely with the breast-pan, which is filled with the same material, and subsequently hollowed out to a depth slightly below the level of the internal cavity. The blast is supplied by three water tuyères, 3 inches in diameter at the smaller end, 5½ inches at the larger, and 10 inches in length. Into these the nozzles are introduced, by which a current of air is supplied by means of a fan or ventilator making about 800 revolutions per minute. The blast may be conveniently conducted to the nozzles through brick channels formed beneath the floor of the smelting-house.

The ores treated in this furnace ought never to contain more than 30 per cent. of metal, and when richer, must be reduced to about this tenure by the addition of slags and other fluxes. In charging this apparatus, the coke and ore are supplied stratum super stratum, and care must be taken so to dispose the coke as not to heat too violently the brickwork of the furnaces. In order to allow the slags which are produced to escape freely into the breast-pan, a brick is left out of the front of the furnace at the height of the fore-hearth, which, for the purpose of preventing the cooling of the scoriæ, is kept covered by a layer of coke-dust or cinders. From the breast-pan the slags flow constantly off over a spout into cast-iron waggons, where they consolidate into masses, having the form of truncated pyramids, of which the larger base is about 2 feet square. As soon as a sufficient amount of lead is accumulated in the bottom of the furnace, it is let off into a lateral lead-pot, by removing the clay-stopper of the tap-hole situated in the slot of the breast-pan, and, after being properly skimmed, it is laded into moulds. When, in addition to lead, the ore treated likewise contains a certain portion of copper, this metal will be found in the form of a matt floating on the surface of the leaden bath. This, when sufficiently solidified, is removed, and, after being roasted, is operated on for the copper it contains.

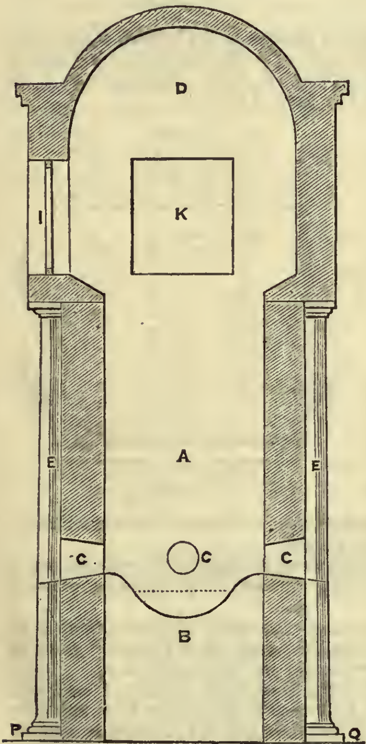
The waggons in which the liquid slag runs off are frequently made to traverse small railways, by which, when one mass has been removed, its place may readily be supplied by an empty waggon. When nearly cold, the casings of the waggons are turned over, and the blocks of slag easily made to drop out. In addition to the facility for transport obtained in this way, one of the great advantages obtained by this method of manipulation arises from the circumstance that should the furnaces at any time run lead or matt, without its being detected by the smelter, the whole of it will be collected at the bottom of the block, from which, when cold, it may be readily detached.

In working these furnaces care must be taken to prevent flame from appearing at the tunnel-head, since, provided the slags are sufficiently liquid, the cooler the apparatus is kept the less will be the loss of metal through volatilisation. In addition to the greatest attention being paid to the working of the furnace, it is necessary, in order to obtain the best results, that all establishments in which this apparatus is employed should be provided with long and capacious flues, in which the condensation of the fumes takes place, previous to arriving at the chimney-shaft. These flues should be built at least 3 feet in width, and 6 feet in height, so as readily to admit of being cleaned, and are often made of several thousand yards in length. The value of the fumes so condensed, amounts to many hundreds, and in some instances thousands per annum.

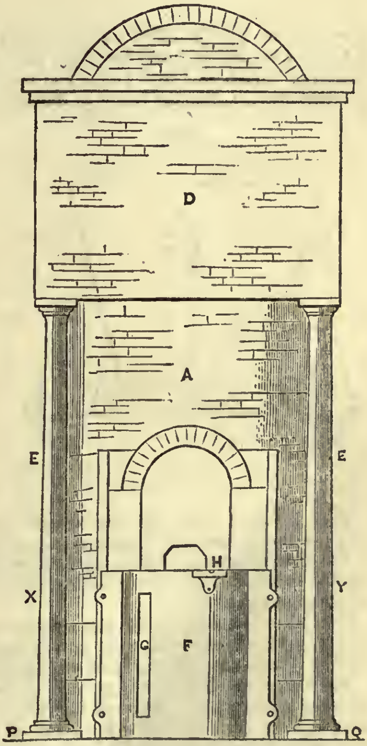
In order to be advantageously worked in these furnaces, the ores should be first roasted, and subsequently agglomerated into masses, which, after being broken into fragments of about the size of the fist, and mixed with the various fluxes, are charged as before described.

In an establishment in which the average assay produce of the roasted ore for lead is 42$\frac{4}{5}$ths, the furnace yield is 38$\frac{13}{14}$ths, and the weight of coke employed to effect the reduction 22 per cent. of the roasted ore operated on. The mixture charged into the

1338



1339



furnace, in this instance, is composed of 100 parts of roasted ore, 42 parts of slags from a previous operation, 8 parts of scrap iron, and 7 parts of limestone. Each furnace works off about seven tons of roasted ore in the course of 24 hours; the weight of slags run off is about double that of the lead obtained, and the matt removed from the surface of the pan is nearly 5 per cent. of the lead produced. The ores treated in this establishment consist of galena, much mixed with spathose iron, and are therefore somewhat refractory. A furnace of this kind requires for its construction about 1,000 segmental fire-bricks, and the same number of ordinary fire-bricks of second quality.

Figs. 1338, 1339, 1340, and 1341 represent respectively a vertical section, an elevation, a ground plan, and an horizontal section of a Castilian furnace. The section *fig.* 1341

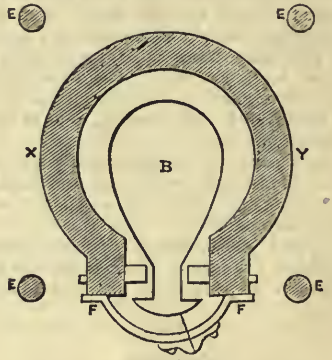
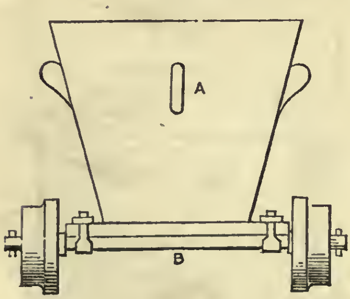
1341

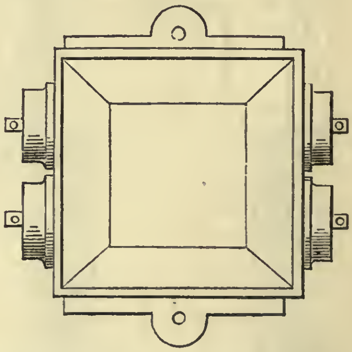


is on the line X Y, *fig.* 1339. A is the body of the furnace, B, the bottom, composed of a mixture of coke-dust and fire-clay; C C C, the tuyères; D, the rectangular covering of masonry; E E E E, cast-iron pillars; F, the breast-pan; G, slot for tapping hole; H, lip of breast-pan; I, feeding-door; K, flue-hole; P, Q, ground line.

1342



1343



Figs. 1342, 1343 are the slag-waggons, A being a moveable case without a bottom, and B a strong cast-iron plate running on four wheels.

The desulphuration of the ores to be treated in these furnaces may be effected either by the aid of an ordinary reverberatory roasting furnace, or in heaps, or properly constructed kilns.

The kilns best adapted for this purpose consist of rectangular chambers, having an arched roof, and provided with proper flues for the escape of the evolved gases, as well as a wide door for charging and withdrawing the ore to be operated on.

Each of these chambers is capable of containing from 25 to 30 tons of ore; and, in order to charge it, a layer of faggots and split wood is laid on the floor, and this, after having been covered by a layer of ore about two feet in thickness, is ignited, care being at the same time taken to close, by means of loose brick-work, the opening of the door to the same height. When this first layer has become sufficiently ignited, a fresh stratum of ore, mixed with a little coal or charcoal, is thrown upon it, and when this layer has in its turn become sufficiently heated, more ore is thrown on. In this way ore is from time to time added, until the kiln has become full, when the orifice of the doorway is closed by an iron plate, and the operation proceeds regularly and without further trouble until the greater portion has become eliminated.

This usually happens at the expiration of about four weeks from the time of first ignition, and the brick-work front is then removed, and the ores broken out, and after being mixed with proper fluxes, passed through the blast-furnace.

The proportion of wood necessary for the roasting of a ton of ore by this means must necessarily depend on the composition of the minerals operated on; but with ores of the description above-mentioned, and in a neighbourhood where wood is moderately cheap, the desulphuration may be effected at a cost of about 5*s.* per ton.

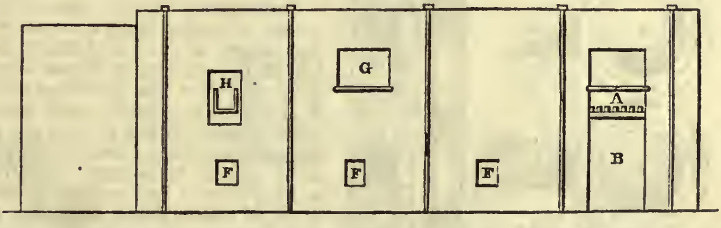
Calcining.—The lead obtained by the various processes above described generally contains a sufficient amount of silver to render its extraction of much importance; but, in addition to this, it is not unfrequently associated with antimony, tin, copper, and various other impurities, which require to be removed before the separation of the silver can be effected.

This operation consists in fusing the hard lead in a reverberatory furnace of peculiar construction, and allowing it to remain, when in a melted state, exposed to the oxidising influences of the gases passing through the apparatus. By this treatment the antimony, copper, and other impurities become oxidised, and on rising to the surface of the metallic bath are skimmed off, and removed with an iron rake. The hearth of the furnace in which this operation is conducted consists of a large cast-iron pan, which may be 10 feet in length, 5 feet 6 inches in width, and 10 inches in depth. The fire-place, which is 1 foot 8 inches in width, has a length equal to the width of the pan, and is separated from it by a fire-bridge 2 feet in width. The height of the arch at the bridge-end is 1 foot 4 inches above the edge of the pan, whilst at the outer extremity it is only about 8 inches.

The lead to be introduced into the pan is first fused in a large iron pot fixed in brick-work at the side of the furnace, and subsequently laded into it through an iron gutter adapted for that purpose. The length of time necessary for the purification of hard lead obviously depends on the nature and amount of the impurities which it contains; and, consequently, some varieties will be sufficiently improved at the expiration of twelve hours, whilst in other instances it is necessary to continue the operation during three or four weeks. The charge of hard lead varies from eight to eleven tons.

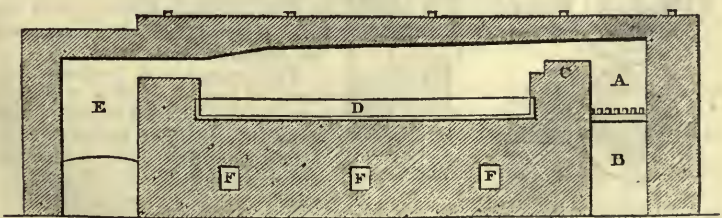
When the metal is thought to be in a fit state for tapping, a small portion taken out with a ladle, and poured into a mould used for this purpose, is found on cooling to

1344



assume at the surface a peculiar crystalline appearance, which when once seen is readily again recognised. As soon as this appearance presents itself, an iron plug is

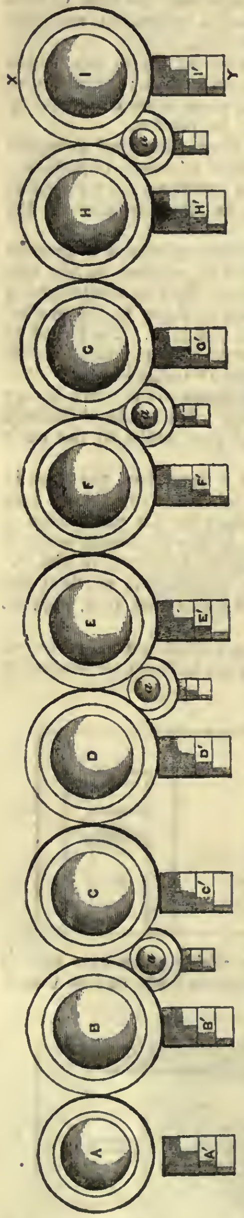
1345



withdrawn from the bottom of the pan, and the lead run off into an iron pan, from which it is subsequently laded into moulds.

The construction of a furnace of this description requires 5,000 common bricks, 3,500 fire-bricks, and 2 tons of fire-clay.

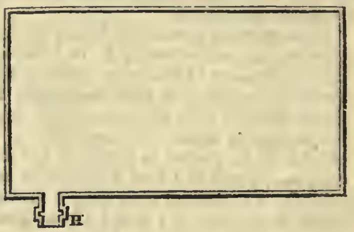
1347



1348

Figs. 1344 and 1345 represent an elevation and vertical section of the calcining furnace. A is the fire-place; B, ash-pit; C, fire-bridge; D, cast-iron pan; E, flue; F F F, channels for allowing the escape of moisture; G, one of the working doors; H, spout for running off calcined metal. *Fig.* 1346 represents the pan removed from the masonry, and shows a groove in the

1346



lip for the introduction of a sheet-iron dam, tightened with moistened bone-ash for keeping in the fused metal.

In the more modern furnaces of this description, the corners are usually rounded to prevent breakage from expansion, whilst the tapping is effected by means of a hole through the bottom near one of the sides. This, when closed, is stopped by means of an iron plug kept in its place by a weighted lever.

Concentration of the silver.—This process is founded on the circumstance, first noticed in the year 1829, by the late H. L. Pattinson, of Newcastle-on-Tyne, that when lead containing silver is melted in a suitable vessel, afterwards slowly allowed to cool, and at the same time kept constantly stirred, at a certain temperature near the melting point of lead, metallic crystals begin to form. These, as rapidly as they are produced, sink to the bottom, and on being removed are found to contain much less silver than the lead originally operated on. The still fluid portion, from which the crystals have been removed, will at the same time be proportionally enriched.

This operation is conducted in a series of 8 or 10 cast-iron pots, set in a row, with fire-places beneath. These are each capable of containing about 6 tons of calcined lead, and, on commencing an operation, that quantity of metal, containing, we will suppose, 20 oz. of silver per ton, is introduced into a pot (say F, *fig.* 1347) about the centre of the series. This, when melted, is carefully skimmed with a perforated ladle, and the fire immediately withdrawn. The cooling of the metal is also frequently hastened by throwing water upon its surface, and whilst cooling it is kept constantly agitated by means of a long iron stirrer or slice. Crystals soon begin to make their appearance, and these as they accumulate and fall to the bottom are removed by means of a large perforated ladle, in which they are well shaken, and afterwards carried over to the next pot to the left of the workman. This operation goes on continually until about 4 tons of crystals have been taken out of the pot F, and have been placed in pot E, at which time the pot F may contain about 40 oz. of silver to the ton, whilst that in E will only yield 10 oz. The rich lead in F is then laded into the next pot G, to the right of the workman, and the operation repeated in F, on a fresh quantity of calcined lead.

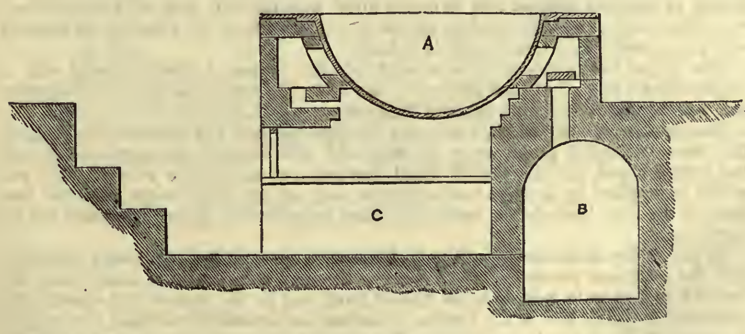
In this way calcined lead is constantly introduced, and the resulting poor lead passes continually to the left of the workman, whilst the rich is passing towards his right. Each pot in succession, when filled with lead of its proper produce for silver, is in its turn crystallised, the poor lead passing to the left of the workman, and the enriched lead to his right. By this method of treatment it is evident that the crystals obtained from the pots to the left of the workman must gradually be deprived of their silver, whilst the rich lead passing to his right becomes continually richer. The final result is, that at one end of the series the poor lead contains very little silver, whilst at the other an exceedingly rich alloy of lead and silver is obtained.

The poor lead obtained by this process should never contain more than 12 dwts. of silver per ton, whilst the rich lead is frequently concentrated to 500 oz. to the ton. This rich lead is subsequently cupelled in the refining furnace.

The ladle employed for the removal of the crystals, when manual labour is made use of, is about 16 inches in diameter, and 5 inches in depth, but when cranes are used, much larger ladles are easily managed. A form of crane has been invented which effects considerable economy of labour in this operation. When, during the operation of crystallisation, the ladle becomes chilled, it is dipped into a small vessel containing lead of a higher temperature than that which is being worked, and known by the name of a temper-pot. The pot containing the rich lead is generally called the No. 1 pot; in some establishments, however, the last pot in which the poor lead is crystallised obtains this appellation.

Figs. 1347 and 1348 represent a plan and elevation of a set of Pattinson's pots, arranged in the most approved way. A is the 'market pot,' from which the desilverised lead is laded out. B, C, D, E, F, G, H, and I, are the working pots, whilst A′, B′, C′, D′, E′, F′, G′, H′, and I′, are their respective fire-places. The 'temper pots,' *a a a a*, are employed for heating the ladles when they have become too much reduced in temperature.

1349



The *figs.* 1349 and 1350 are sections showing the manner of setting and the arrangement of the pots and flues. A, pot; B, main flue; C, ash-pit.

The erection of nine six-ton pots requires 15,000 common bricks, 10,000 fire-bricks, 160 feet of quarles, 80 fire-clay blocks, and 5 tons of fire-clay.

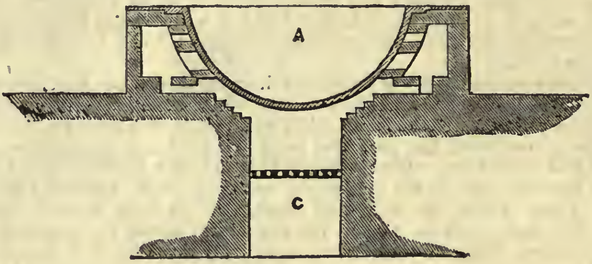
In some establishments ten-ton pots are employed, and where cranes are made use of they are found to be advantageous.

Refining.—The extraction of the silver contained in the rich lead is conducted in a cupel forming the bottom of a reverberatory furnace called a refinery.

In this operation the litharge produced, instead of being absorbed by the substance of the cupel, is run off in a fluid state, by means of a depression called a gate.

The size of the fire-place varies with the other dimensions of the furnace, but is usually nearly square, and in an apparatus of ordinary size may be about 2 feet × 2 feet 6 inches. This is separated from the body of the furnace by a fire-bridge 18 inches in breadth, so that the flame and heated air pass directly over the surface of

1350



the cupel, and from thence escape by means of two separate apertures into the main flues of the establishment. The cupel or test consists of an oval iron ring, about 5 inches in depth, its greatest diameter being 4 feet, and its lesser nearly 3 feet. This frame, in order to better support the bottom of the cupel, is provided with cross-bars about 4½ inches wide and ½ inch in thickness. In order to make a test, this frame is beaten full of finely-powdered bone-ash, slightly moistened with water, containing a small quantity of pearlash in solution, which has the property of giving consistency to the cupel when heated.

The centre of the test, after the ring has been well-filled with this mixture, and solidly beaten down, is scooped out with a small trowel, until the sides are left 2 inches in thickness at top, and three inches at the bottom, whilst the thickness of the sole itself is about 1 inch.

At the fore part or wide end of the test the thickness of the border is increased to 6 inches, and a hole is then cut through the bottom, which communicates with the openings or gates by which the fluid litharge makes its escape.

The test, when thus prepared, is placed in the refinery furnace, of which it forms the bottom, and is wedged to its proper height against an iron ring firmly built into the masonry. When this furnace is first lighted, it is necessary to apply the heat very gradually, since if the test were too strongly heated before it became perfectly dry, it would be liable to crack. As soon as the test has become thoroughly dry, it is heated to incipient redness, and is nearly filled with the rich lead to be operated on, which has been previously fused in an iron pot at the side of the furnace, and beneath which is a small grate where a fire is lighted.

The melted lead, when first introduced into the furnace, becomes covered with a greyish dross, but on further increasing the heat, the surface of the bath uncovers, and ordinary litharge begins to make its appearance.

The blast is now turned on, and forces the litharge from the back of the test up to the breast, where it passes over the gate, and falls through the aperture between the bone-ash and the ring into a small cast-iron pot running on wheels. The air, which is supplied by a small ventilator, not only sweeps the litharge from the surface of the lead towards the breast, but also supplies the oxygen necessary for its formation.

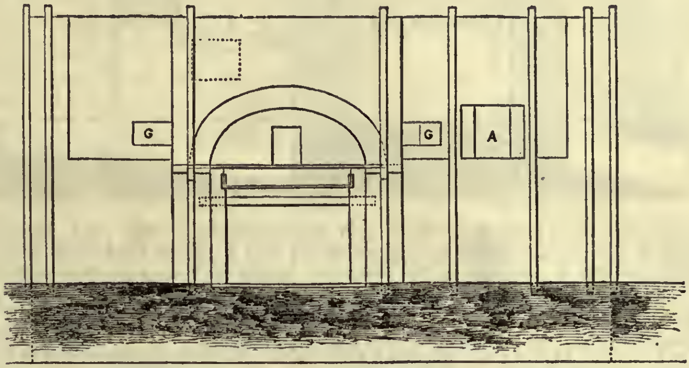
In proportion as the surface of the lead becomes depressed by its constant oxidation, and the continual removal of the resulting litharge, more metal is added from the melting pot, so as to raise it to its former level, and in this manner the operation is continued until the lead in the bottom of the test has become so enriched as to render it necessary that it should be tapped. The contents of the test are now so far reduced in volume that the whole of the silver contained in the rich lead operated on remains in combination with a few hundred-weights only of metal, and this is removed by carefully drilling a hole in the bone-ash forming the bottom of the test. The reason for the removal of the rich lead, is to prevent too large an amount of silver from being carried off in the litharge, which is found to be the case when lead containing a very large amount of that metal is operated on.

When the rich lead has been thus removed, the tapping hole is again closed by a pellet of bone-ash, and another charge immediately introduced.

As soon as the whole of the rich lead has been subjected to cupellation, and has become thus further enriched, the argentiferous alloy is itself similarly treated, either in a fresh test, or in that employed for the concentration of the rich lead. The brightening of pure silver at the moment of the separation of the last traces of lead, indicates the precise period at which the operation should be terminated, and the blast is then turned off, and the fire removed from the grate. The silver is now allowed to set, and as soon as it has become hardened, the wedges are removed from beneath the test, which is placed on the floor of the establishment. When cold, the silver plate is detached from the test, and any adhering particles of bone-ash removed by the aid of a wire-brush.

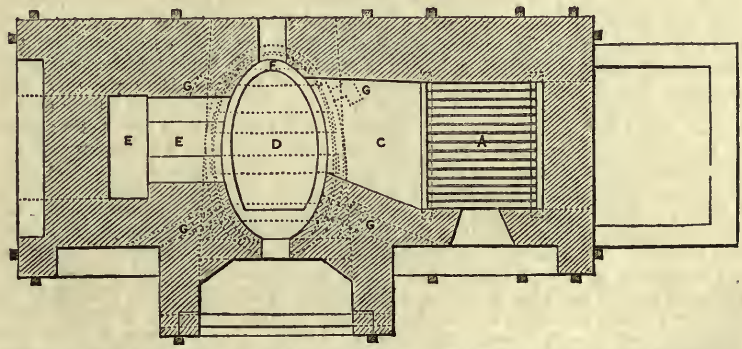
A test furnace of ordinary dimensions requires for its construction about 2,000 common bricks, 2,000 fire-bricks, and 1½ ton of fire-clay. A furnace of this kind will work off 4 pigs of lead per hour, and consume 4 cwts. of coal per ton of rich lead operated on.

1351



Figs. 1351, 1352, and 1353, represent an elevation, plan, and section of a refining furnace; A, fire-place; B, ash-pit; C, fire-bridge; D, test-ring, shown in its proper position; E, flues; F, point where blast enters; G, pig-holes.[1]

1352



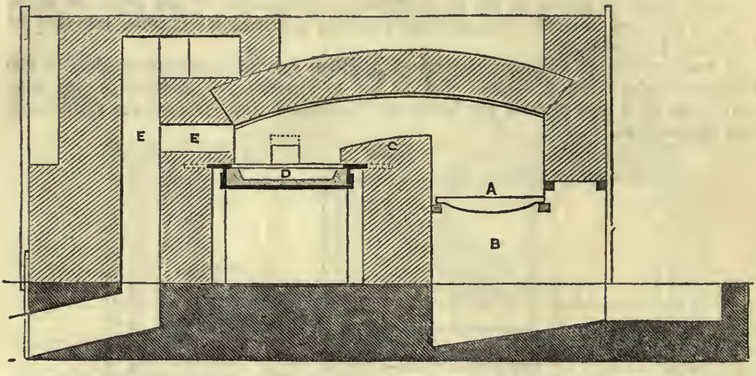
The cost of working a ton of rich lead in the neighbourhood of Newcastle, containing on an average 400 oz. of silver per ton, is as follows:—

	s.	d.
Refiner's wages	4	2·1
Coals, 4 cwts.	0	6·8
Engine wages	1	7·0
Coals, 5 cwts.	0	8·7
Pearlash	0	3·5
Bone-ash, 17·3 lbs.	3	1·0
Repairs	0	5·0
Total	10	10·1

[1] Pig-holes are used for introducing the lead in cases in which it is not laded into the test in a fused state.

Parkes' Process of Desilverising Lead by Zinc.—When lead and zinc are melted together and allowed to cool slowly, an almost complete separation occurs, the zinc, owing to its lower specific gravity and higher melting-point, cools first and may be

1353



removed in a solid crust, while the lead is still liquid underneath. Mr. Alexander Parkes of Birmingham, found that argentiferous lead might be freed from its silver by melting with it zinc; and in the process of cooling the zinc crystallises and takes out the silver; the silver may afterwards be removed from the zinc by dissolving in hydrochloric or in dilute sulphuric acid, and the zinc may be used again and again for melting with the lead. Mr. Parkes first patented his process in 1850; he improved it in 1851; and in 1852, he was granted a third patent, entitled 'Improvements in separating Silver from other Metals.' The process is as follows: There are two vessels over separate fires, one a Pattinson pot of cast iron, which will hold 7 tons of molten metal—this is for the lead—and a smaller one for melting the charge of zinc. When the 7 tons of lead to be desilverised is melted, it is skimmed, the temperature is raised to that of molten zinc, and the charge of zinc (about 1 cwt. to every ton of lead, or $1\frac{3}{4}$ lb. to every ounce of silver) which has been previously melted is laded into the lead, and the whole well stirred with a perforated rabble to insure perfect intermixture; the mass is then left to gradually cool. When the surface has hardened, it is skimmed off with a perforated ladle, and the surface of the liquid lead is skimmed off as well. The lead thus treated contains about 10 dwts. of silver per ton. The solidified zinc is placed in a retort, which is oval on bore, and placed a little on the incline over a fire for the purpose of liquation; it is heated above the melting point of lead, but decidedly below that of zinc, and so the lead that is taken up with the zinc drains off at the lower end of the retort into an iron pot placed convenient to it. The zinc, which has been thus drained of the lead, but still contains the silver, is distilled in a Belgian retort with twice its bulk of lime and its own bulk of coal; the zinc, being much more volatile than the silver, is distilled over, and the residue is very rich in silver. The partially-desilverised lead is submitted to a softening process for the separation of any remaining zinc. It is kept melted at a good red heat for a period of from 9 to 12 hours, during which time it is skimmed twice, first, after the first three hours, and again half an hour before tapping. The lead is tapped into a cast-iron receiver, and therein subjected to 'boiling;' that is, green wood is kept submerged in it, held down by a lever. Lead treated in this manner is said to contain a small quantity of silver, but no zinc.

These processes were supposed to have been improved by Flach, who patented his processes in this country in 1866. Although Flach's process has been used, it is said, with success on the Continent, it has never been permanently adopted in this country.

The difficulty with Parkes' process has been the separation of the zinc from the desilverised lead. A process for effecting this was patented by Cordurié of Toulouse in 1866. Lead to be desilverised was treated by him in the usual manner with zinc. After the removal of the crust of argentiferous zinc, superheated steam is passed into the desilverised lead, whereby the zinc retained by the lead is oxidised by the oxygen of the steam; this oxide rises to the surface in the state of powder, and is skimmed off. According to Gruner, who wrote on his process in the *Annales des Mines*, the result at Rothschild's works at Havre was most satisfactory. The desilverised zinciferous lead contained 0·75 per cent. of zinc; but after it had been subjected to the action of steam, it yielded only the most feeble traces of zinc.

A process for the desilverisation of lead by zinc has been described by E. Koch in the *Berg- und Huetten-maennische Zeitung.* In order to make the process continuous the author liquates his lead from copper in a reverberatory furnace with an inclined hearth. The liquated lead is received in a Pattinson kettle, which when it contains a charge is emptied by a siphon-tap into a lower kettle. In the second kettle the antimony is oxidised by steam, and the lead then siphoned into the lower kettles, where it is desilverised by zinc, the latter being fastened in front of the lower mouth of the siphons, so as to bring it into intimate contact with the lead. The desilverised lead is then siphoned into a still lower kettle, where the zinc is removed by steam, and then siphoned into a still lower kettle, whence it is siphoned into iron moulds. The advantages claimed for this method of plant are, a more perfect utilisation of heat, greater production of metals before the addition of zinc (*i.e.*, copper and antimony), saving in the amount of zinc, less wear of kettles, and a more suitable shape of these last.

Decopperisation of Lead by Zinc.—Mr. W. Baker of Sheffield has successfully carried out this process. When a certain portion of zinc is melted with lead containing copper, a zinc alloy with a small portion of lead is formed, and most of the copper is withdrawn from the lead with it, which floats on the surface in a pasty mass, and may be skimmed off.

In operating upon 100 tons of lead containing from 10 to 15 oz. of copper to the ton, the copper was reduced on the average to 1 oz. and 21 grs. per ton.

Mr. Baker thus describes the operation: Five tons of lead are melted, skimmed, and kept sufficiently hot to prevent the metal setting at the sides of the pot. 28 lbs. of zinc are melted with about 2 cwts. of lead in a small pot adjacent. This pot already contains about 14 lbs. of zinc, together with some lead from a previous operation. When quite liquid more lead is added from the larger pot, in order to dilute the alloy before mixing with the entire charge. The contents of the small pot, which should be not enough to prevent any alloy separating, are then added to the charge and stirred well into the melted metal. The fire is now withdrawn, and the whole allowed to cool down. In a short time a pasty alloy rises to the surface and is removed by a perforated skimmer into the small pot. This operation is continued until the lead begins to set at the sides of the pan. The charge must then be re-heated, and the alloy in the small pot liquated by heating at a regulated temperature, which will permit of the zinc alloy being removed from a quantity of zinciferous lead, which will be left with only a trace of copper. 14 lbs. more zinc are now melted with this residue in the small pot, and the operation is repeated. More certain results are obtained by thus adding the zinc in two portions. Finally, all the zinc dross and alloy are liquated in the small pot. The quantity of alloy obtained is about 1 cwt. This will contain about 25 per cent. of zinc, or 28 lbs. of the zinc employed for one operation. It may be estimated that 14 lbs. will be left in the decopperised lead, and 14 lbs. also in the liquated product remaining in the small pot ready for the next operation. The zinc remaining in the decopperised lead is oxidised in a reverberatory furnace with a slag bottom, or in a pan such as is used in the furnaces for softening hard lead. In a round pan containing from 8 to 10 tons, set in a furnace of the latter description, a charge was worked off in about 30 hours, including charging and tapping out. From 90 tons an average of 95 per cent. of softened lead was obtained. The dross was easily reduced, and yielded ordinary soft lead.

The zinc alloy containing copper and also most of the silver is best economised by melting down in a small blast-furnace, when a rich argentiferous lead may be obtained.

Natro-Metallurgy.—The various processes of refining lead employed at the present day causes, in cases where the metal is impure, considerable waste, and necessitate the reduction of an enormous quantity of oxide, to which they are, besides, inadequate for the removal of certain foreign metals. A new plan, which has recently been devised by MM. Pagen and Rous of Marseilles, France, allows the complete refining of any argentiferous lead without the formation of oxides of lead, and has, according to the *Chronique de l'Industrie*, the particular advantage of permitting the collection of all foreign metals, of which the value may be worth considering. The process is founded on the property which a bath of caustic, hydrated, melted alkali possesses in dissolving, or at least oxidising, successively, all the metals except three, by drawing them into a soluble scoria, in a state of igneous fusion. The three exceptions are lead, silver, and gold. The metals united with the lead are, one after the other, removed by melted soda, the action of the bath being maintained, first by a jet of steam, designed to restore constantly the water of the hydrate from which the metals gain oxygen, and urged according as the metals are in a less degree oxidisable, either by a blast of air, or finally, by carefully measured additions of nitrate of soda. The theory of the reaction is as follows: By simple solution in water, soda abandons all the oxides which it holds in solution or suspension, and is evaporated and dried for use, in the operation, almost without loss. The metals oxidise in the melted alkaline bath in the order of their affinity for oxygen, an order modified, however—(1) by their particular affinity for soda; (2) by the action of affinity exercised by the largest mass present. Thus, tin and the metals of platinum, although much less oxidisable than lead or copper, are attacked very rapidly; and before the latter in the soda-bath, by reason of their propensity to act as electro-negative elements. Hence, also, in an alloy very rich in lead the copper oxidises first. Another phenomenon of not less importance is that the solutions of the oxides in the soda-bath act chemically in presence of the re-agents exactly as do the metallic salts dissolved in water. It is thus in this igneous solution—all the metals are precipitated one after the other, in the inverse order of their solubility, and in the direct order they preserve each other from oxidation. In this respect even insoluble reducing agents, such as charcoal, may be employed in the bath. The principal applications in the process are its adaptation, not only to the refining of lead and the extraction of silver by the zinc process from lead and argentiferous scoriæ, but the purification of argentiferous copper and old complex alloys; the treatment of ores of platinum, gold, silver, &c., of ores of chromium, &c. Since March last the inventors have constructed a plant, and have carried on the process at Marseilles; and we learn that the hard leads of Greece (containing 2½ per cent. antimony, 1 per cent. arsenic, ½ per cent. copper, and 1 to 2 per cent. iron and sulphur), hard Spanish lead, and other forms of the metal containing large quantities of foreign substances, have been successfully treated. A company has been formed for the fusion of ores, separation of metals, and then refining by the process of natro-metallurgy.

Reducing.—The reduction to the metallic state of the litharge from the refinery, the pot-dross, and the mixed metallic oxides from the calcining furnace, is effected in a reverberatory apparatus, somewhat resembling a smelting furnace, except that its dimensions are smaller, and the sole, instead of being lowest immediately below the middle door, gradually slopes from the fire-bridge to near the flue, where there is a depression in which is inserted an iron gutter, which constantly remains open, and from which the reduced metal flows continuously into an iron pot placed by the side of the furnace for its reception, whence it is subsequently laded into moulds.

The litharge, or pot-dross, is intimately mixed with a quantity of small coal, and is charged on that part of the hearth immediately before the fire-bridge. To prevent the fused oxide from attacking the bottom of the furnace, and also to provide a sort of hollow filter for the liquid metal, the sole is covered by a layer of bituminous coal.

The heat of the furnace quickly causes the ignition of this stratum, which is rapidly reduced to the state of a spongy cinder. The reducing gases present in the furnace, aided by the coal mixed with the charge itself, cause the reduction of the oxide, which, assuming the metallic form, flows through the interstices of the cinder, and ultimately finding its way into the depression at the extremity of the hearth, flows through the iron gutter into the external cast-iron pot. The surface of the charge is frequently, during the process of elaboration, turned over with an iron rake, for the double purpose of exposing new surfaces to the action of the furnace, and also to allow the reduced lead to flow off more readily.

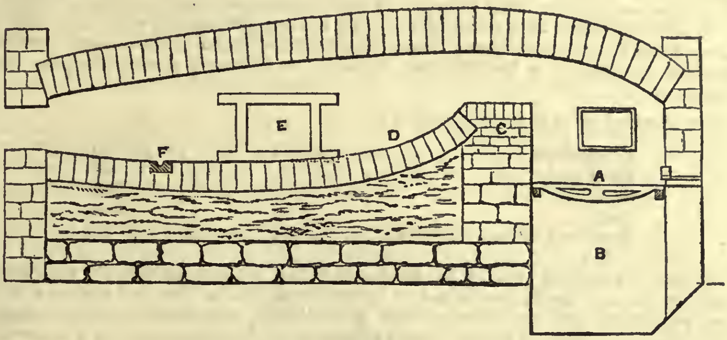
Fresh quantities of litharge, or pot-dross, with small coals, are from time to time thrown in, in proportion as that already charged disappears, and at the end of the shift, which usually extends over 12 hours, the floor of cinder is broken up, and after being mixed with the residual matters in the furnace is withdrawn. A new floor of cinders is then introduced, and the operation commenced as before. A furnace of this kind, having a sole 8 feet in length and 7 feet in width, will afford, from litharge, about 5½ tons of lead in 24 hours.

The dross from the calcining pan, when treated in a furnace of this description, should be previously reduced to a state of fine division, and intimately mixed up with small coal and soda-ash. In many cases, however, the calcined dross is treated in the smelting furnace. The hard lead obtained from this substance is again taken to the calcining furnace, for the purpose of being softened.

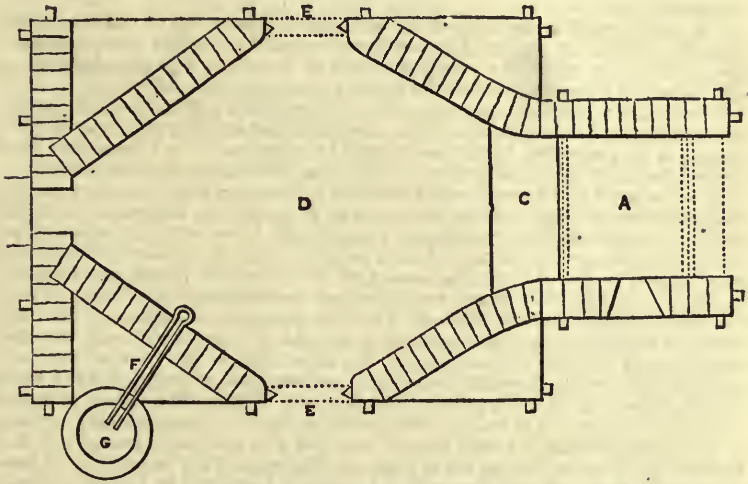
In the establishment from which the foregoing data were obtained, the cost of slack, delivered at the works, was only 2*s.* 11*d.* per ton, which is cheaper than fuel can be obtained in the majority of the lead-mills of this country. In North Wales the cost of small coal is generally about 4*s.*, and at Bristol 5*s.* 6*d.* per ton.

Figs. 1354 and 1355 represent a vertical section and plan of a reducing-furnace. A, fire-place; B, ash-pit; C, fire-bridge; D, hearth; E, working-door; F, iron spout for conducting the reduced metal into the lead-pot G, which is kept heated by means of a fire beneath.

1354



1355



The total cost of elaborating one ton of hard lead, containing 30 oz. of silver per ton, in a locality in which fuel is obtained at the low price above quoted, is nearly as follows:—

	£	s.	d.
Calcining	0	2	4·4
Crystallising	0	9	6·5
Refining	0	0	9·2
Reducing pot dross and litharge	0	1	0·8
Calcined dross	0	0	8·0

One hundred tons of hard lead treated gave:—

	Tons.
Soft lead	94·90
Black dross	3·72
Loss	1·38
Total	100·00

On comparing the expense of each operation, as given in the foregoing abstract, with the amounts stated as the cost of each separate process, they will be found to be widely different; but it must be remembered that the whole of the substances elaborated are far from being subjected to the various treatments described.

In order, therefore, to give an idea of the relative proportions which are passed through the several departments, it may be stated that in an establishment in which the ores are treated in the Castilian furnace the following were the results obtained:—

One hundred parts of raw ore yielded:—

Roasted ore	85
Hard lead	42
Soft „	36
Rich „	9
Dross and litharge re-treated	18½

It may be remarked that for the treatment of ores of good produce the reverberatory furnace and Scotch hearth are to be preferred, but for working minerals of a low percentage the blast-furnace may generally be substituted with advantage. The slag-hearth, from the amount of fuel consumed and loss experienced, is a somewhat expensive apparatus, and might in many cases be advantageously exchanged for the Castilian furnace.

It is well known that the losses which take place in this branch of metallurgy are, from the volatility of the metal operated on, unusually large. In those establishments, however, in which due attention is paid to fluxes and a proper admixture of ores, as well as the condensation of the fumes, a great economy is effected.

In some instances flues of above five miles in length have been constructed, and the most satisfactory results obtained. The attention of lead-smelters is being daily more directed to the prevention of the loss of metal by volatilisation, and those who have adopted the use of long flues have been, in all cases, quickly repaid for their outlay.

As an example of the great extent to which sublimation may take place on the scale employed in large smelting works, we may mention the lead-works belonging to Mr. Beaumont in Northumberland. Formerly the fumes or smoke arising from various smelting operations escaped from ordinary chimneys or short galleries, and large quantities of lead were thus carried off in the state of vapour, and deposited on the surrounding land, where vegetation was destroyed, and the health of both men and animals seriously affected. This led to various extensions of the horizontal or slightly-inclined galleries now in use, and the quantity of lead extracted rapidly repaid the cost of construction. The latest addition of this kind was made at Allen Mill, by Mr. Sopwith, the manager, and completed a length of 8,789 yards (nearly five miles) of stone gallery from that mill alone. This gallery is 8 feet high and 6 wide, and is in two divisions, widely separated. There are also upwards of 4 miles of gallery for the same purpose connected with other mills belonging to Mr. Beaumont in the same district, and in Durham. The value of the lead thus saved from being totally dissipated and dispersed, and obtained from what in common parlance might be called chimney-sweepings, considerably exceeds 10,000*l.* sterling annually, and forms a striking illustration of the importance of economising our waste products.

In lieu of long and extensive flues, condensers of various descriptions have from time to time been introduced, but in most instances the former have been found to be more efficient.

When, however, water can be procured for the purpose of cooling the condensers, excellent results are generally obtained.—J. A. P.

See Litharge; Red Lead; Solder; Sugar or *Acetate* of Lead; Type Metal; and White Lead.

Lead Assaying. The ores submitted to assay are galena or sulphide of lead, cerussite or carbonate of lead, anglesite or sulphate of lead, and pyromorphite or phosphate of lead. For assay purposes, the ores of lead may be divided into two classes:—

The *first class* comprehends all the ores of lead which contain neither sulphur nor arsenic, or in which they are present in small proportion only.

The *second class* comprises galena, together with all lead ores containing sulphur or arsenic.

A common wind or air furnace is best adapted for making lead assays. For this purpose the cavity for the reception of fuel should be 9 inches square, and the height of the flue-way from the fire-bars about 14 inches. For ordinary ores a furnace 8 inches square and 12 inches deep will be found sufficient; but as it is easy to regulate, by a damper, the heat of the larger apparatus, it is often found advantageous to be able to produce a high temperature. A furnace of this kind should be connected with a chimney of at least twenty feet in height, and be supplied with good coke, broken into pieces of the size of eggs.

The air furnace (see Copper, *fig.* 533), is well adapted for the assaying of lead ores. The ores should be dried in shallow, flat metal vessels, powdered and sifted through a sieve of from 40 to 60 holes to the linear inch, previous to being submitted to assay. The balance employed should carry 1,000 grs., and turn with $\frac{1}{10}$th of a grain.

The tongs (see Copper, *fig.* 536) may be used for the assay with earthen crucibles. For working with iron crucibles tongs of stronger and stouter make are desirable. The iron mould (*fig.* 534) is used for receiving the assay products, or one containing a deep conical cavity may be substituted for it. The fluxes should be employed in the dry state.

Ores of the First Class.—The assay of ores of this class is a simple operation, care being only required that a sufficient amount of carbonaceous matter be added to effect the reduction of the metal, whilst such fluxes are supplied as will afford a readily-fusible slag. When the sample has been properly powdered, 400 or 500 grains are weighed out, and well mixed with 500 or 600 grains of carbonate of soda, and from 40 to 60 grains of finely-powdered charcoal, according to the richness of the mineral operated on. This is introduced into an earthen crucible, of such a size as not to be more than one-half filled by the mixture, and on the top is placed a thin layer of the flux. The crucible is then placed in the furnace and gently heated, care being taken to so moderate the temperature, that the mixture of ore and flux, which soon begins to soften and enter into ebullition, may not swell up and flow over. If the action in the crucible becomes too strong, it must be checked by a due regulation of the heat by means of a damper. When the action has subsided, the temperature is again raised for a few minutes, and the assay completed in about half an hour. During the process of reduction, the heat should not exceed dull redness; but in order to complete the operation, and render the slag sufficiently liquid, the temperature should be raised to bright redness. When the contents have been reduced to a state of tranquil fusion, the crucible must be removed from the fire, and the assay either rapidly poured, or, after being tapped against some hard body to collect the lead in a single globule, be set to cool. When the operation has been successfully conducted, the cooled slag will present a smooth concave surface, with a more or less vitreous lustre. When cold, the crucible may be broken, and the button extracted. To remove from it the particles of adhering slag, it is hammered on an anvil, and afterwards rubbed with a hard brush. Instead of employing carbonate of soda and powdered charcoal, the ore may be fused with $1\frac{1}{2}$ times its weight of black flux, and the mixture covered by a thin layer of borax. Good results are also obtained by mixing together 400 grains of ore with an equal weight of carbonate of soda and half that quantity of crude tartar. These ingredients, after being well incorporated, are placed in a crucible, and slightly covered by a layer of borax. Each of the foregoing methods yields good results, and affords slags retaining but a small proportion of lead.

Ores of the Second Class.—This class comprehends galena, which is the most common and abundant ore of lead, and also comprises sundry metallurgic products, as well as the sulphates and arsenates of lead.

The assay of galena and other substances is variously conducted; but one of the following methods is usually employed for commercial purposes:—

Assay in an earthen crucible with metallic iron.—Mix 400 or 500 grs. of the ore with about an equal weight of carbonate of soda, and, after having placed it in the earthen crucible, of which it should occupy about one half the capacity, insert with their heads downward three or four tenpenny nails, and press the mixture firmly around them. On the top place a thin layer of borax. The whole is now introduced into the furnace, and gradually heated to redness; at the expiration of ten minutes the temperature is increased to bright redness, and the heat continued until the fused fluxes present a perfectly smooth surface. When this has taken place the pot is removed from the fire, and the nails are separately withdrawn by the use of a small pair of tongs, care being taken to well cleanse each in the fluid slag until free from adhering lead. When the nails have been thus removed, the pot is gently shaken, to collect the metal into one button, and laid aside to cool; after which it may be broken, and the button removed. Instead of first allowing the slags to cool, and then breaking the crucible, the assay may, if preferred, after the withdrawal of the nails, be poured into a mould (see Copper, *fig.* 534). Hoop iron or iron rod may be used, instead of the iron nails. The assay should be completed in from 25 to 30 minutes.

Assay in an iron pot with fluxes.—Instead of adding metallic iron to the mixture of ore and flux, it is generally better that the pot itself should be made of that metal. For this purpose a piece of ½-inch plate iron is turned up in the form of a crucible, and carefully welded at the edges. The bottom is closed by a thick iron rivet, which is securely welded to the sides, and the whole then finished on a properly-formed mandril. To make an assay in a crucible of this kind, it is first heated to dull redness, and, when sufficiently hot, 400 or 500 grs. of the powdered ore, intimately mixed with its own weight of carbonate of soda, half its weight of pearlash, and a small quantity of crude tartar, is introduced by means of a copper scoop (see COPPER, *fig.* 535). On the top of the whole is placed a thin layer of borax, whilst the crucible, which, for the ready introduction of the mixture, has been removed from the fire, is at once replaced. The heat is now raised to redness, the contents gradually becoming liquid, and giving off large quantities of gas. At the expiration of from 8 to 10 minutes the mixture will be in a state of complete fusion; the contents of the pot are now stirred with a small iron rod. Any matter adhering to its sides is scraped to the bottom of the pot, and the temperature of the furnace is increased during 3 or 4 minutes to bright redness.

The crucible is then seized by a strong pair of bent tongs, on that part of the edge which is opposite the lip, and its contents rapidly poured into a cast-iron mould (see COPPER, *fig.* 534). The sides of the pot are now carefully scraped down with a chisel-edge bar of iron, and any adhering particles of metallic lead added to the portion first obtained. When sufficiently cooled the contents of the mould are easily removed, and the button of lead cleaned and weighed. By this process pure galena yields 84 per cent. of metallic lead, free from any injurious amount of iron, and perfectly ductile and malleable. This method of assaying, with various modifications, is that adopted in almost all lead-smelting establishments, and has the advantage of affording good results with all the ores belonging to the second class.

Assay in the iron dish without fluxes.—In some of the mining districts of Wales the assay of lead ore is conducted in a manner somewhat different from that just described. Instead of fusing the ore in an iron crucible with fluxes, the fusion is effected in a flat shallow iron dish, having a hemispherical cavity of about 4½ inches in diameter, and about 1 inch in depth in the centre. 10 oz. of the ore are operated on, and the assay is made by the aid of a blacksmith's forge-fire. The ore is placed in the iron dish, provided with a sheet-iron cover, and heated for about 5 minutes, and the reduced metal poured out into a mould. The iron dish is then replaced on the fire, and the heat continued for about 5 minutes, until the regulus (slurry) is fused; the contents are then poured out into a mould, the lead detached, and added to the first portion of lead obtained; and the whole weighed. Galena will yield as much as 82 per cent. of lead by this method. In some works the assay is made in an iron crucible without fluxes, instead of the iron dish.

Estimation of silver contained in lead ores.—All varieties of lead ore contain silver, and it is consequently necessary, in order to judge of their commercial value, to ascertain the exact amount of this metal which they afford. This is effected by the process of *Cupellation*. See SILVER.

In order, therefore, to separate the silver present in buttons resulting from ordinary lead assays, it is only necessary to expose them, on a *cupel*, to such a temperature as will rapidly oxidise the lead. The oxide of lead, or litharge, produced is absorbed by the porous body on which the assay is supported, and nothing but a small button of silver ultimately remains on the test. These supports or cupels are made of bone-ash, slightly moistened with a little water, and consolidated by being pressed into a mould. The furnace employed for this purpose is described in the article SILVER, as is also the *muffle* or D-shaped retort in which the cupels are heated.

As soon as the muffle has become red hot, the cupels that have been drying in the mouth of the opening are introduced by means of proper tongs, on the bottom of the muffle, previously covered with a thin layer of bone-ash, in order to prevent its being attacked in case of any portion of litharge coming in contact with it during the progress of the subsequent operations. The open end of the muffle is now closed by means of a proper door, and the cupels are thus rapidly heated to the temperature of the muffle itself. When this has been effected the door is removed, and into each of the cupels is introduced, by the aid of slender steel tongs, a button of the lead to be assayed. The mouth of the muffle is again closed during a few minutes to facilitate the fusion of the alloy; when the oxide begins to pass off the surface of the metallic product, the assay is said to be uncovered. The lead is now quickly converted into litharge, which is absorbed by the cupel as fast as it is produced, whilst at the same time there arises a white vapour, which is gradually carried off by the door and through the openings in the sides and end. A circular stain is at the same time formed around the globule of melted metal, which gradually extends and penetrates into the substance of the cupel. When nearly the whole of the lead has thus been removed, the remaining bead of silver appears to become agitated by a rapid motion, which seems to make it revolve with great rapidity. At this stage the motion will be observed suddenly to cease, and the button becomes immoveable. This is called the *brightening* of the assay, and a button of silver now remains on the cupel.

If the cupel were now abruptly removed from the muffle, the globule of silver

would be liable to *vegetate*, by which a portion of the metal might be thrown off, and a certain amount of loss be thereby entailed. To prevent this, the cupel in which the assay has brightened should be immediately covered by another, kept red hot for that purpose. The two are now gradually withdrawn together, and, after having sufficently cooled, the upper cupel is removed, and the globule of silver detached and cleaned as follows:—

The globule is now laid hold of by a pair of fine pliers and flattened on a small steel anvil, by which the oxide of lead which may have attached itself to it becomes pulverised, and is removed by rubbing with a small hard brush. The flattened disc is then examined, in order to be sure that it is perfectly clean, and afterwards weighed in a balance capable of turning with $\frac{1}{1000}$th of a grain.

The cupellations should be conducted at the lowest possible heat at which they can be effected. The temperature best fitted for this operation is obtained when the muffle is at a red heat, and the vapours which arise from the assays curl gradually away, and are finally removed by the draught. When the muffle is heated to whiteness, and the vapours rise to the top of the arch, the heat is too great: and when, on the contrary, the fumes lie over the bottom, and the sides of the openings in the muffle begin to darken, either a little more fuel must be added or the draught increased. If an assay has been properly conducted, the button of silver obtained is round, bright, and smooth on its upper surface, and beneath crystalline, and of a dead white colour; easily removed from the cupel, and readily freed from litharge.

When the ores of lead, in addition to silver, contain gold, the button remaining on the cupel is an alloy of these metals. For the method of estimating the gold, see GOLD.

For commercial purposes the silver contained in any given ore is estimated in ounces, pennyweights, and grains troy upon the statute ton avoirdupois of 2,240 lbs. It is customary to return the silver obtained from lead ores upon the ton of lead as yielded by assay, and not upon the ton of ore. For a Table to facilitate calculation, see SILVER.

LEAD-SHOT. (*Plomb de Chasse*, Fr.; *Schrot, Flintenschrot*, Ger.) The origin of most of the imperfections in the manufacture of lead-shot is the too rapid cooling of the spherules by their being dropped too hot into the water, whereby their surfaces form a solid crust, while their interior remains fluid, and, in its subsequent concretions, shrinks, so as to produce the irregularities of the shot.

The patent shot-towers originally constructed in England obviate this evil by exposing the fused spherules after they pass through the cullender, to a large body of air during their descent into the water-tub placed on the ground. The highest erection of this kind is probably at Villach in Carinthia, being 240 Vienna, or 249 English feet high.

The quantity of arsenic added to the mass of melted lead varies according to the quality of this metal; the harder and less ductile the lead is, the more arsenic must be added. About 3 pounds of either white arsenic or orpiment is enough for one thousand parts of soft lead, and about 8 for the coarser kinds. The latter are employed preferably for shot, as they are cheaper, and answer sufficiently well. The arsenical alloy is made either by introducing some of this substance at each melting; or by making a quantity of the compound considerably stronger at once, and adding a certain portion of this to each charge of lead. If the particles of the shot appear lens-shaped, it is a proof that the proportion of arsenic has been too great; but if they are flattened upon the side, if they are hollowed in their middle, called *cupping* by the workmen, or drag with a tail behind them, the proportion of arsenic is too small.

The following is the process prescribed by the patentees, Ackerman and Martin. Melt a ton of soft lead, and sprinkle round its sides in the iron pot about two shovelfuls of wood ashes, taking care to leave the centre clear; then put into the middle about 40 pounds of arsenic to form a rich alloy with the lead. Cover the pot with an iron lid, and lute the joints quickly with loam or mortar to confine the arsenical vapours, keeping up a moderate fire to maintain the mixture fluid for three or four hours; after which skim carefully, and run the alloy into moulds to form ingots or pigs. The composition thus made is to be put in the proportion of one pig or ingot into 1,000 pounds of melted ordinary lead. When the whole is well combined, take a perforated skimmer, and let a few drops of it fall from some height into a tub of water. If they do not appear globular, some more arsenical alloy must be added.

Lead which contains a good deal of pewter or tin must be rejected, because it tends to produce elongated drops or tails.

From two to three tons are usually melted at once in the large establishments. The surface of the lead gets covered with a crust of oxide of a white spongy nature, sometimes called *cream* by the workmen, which is of use to coat over the bottom of the cullender, because without such a bed the heavy melted lead would run too rapidly through the holes for the granulating process, and would form oblong spheroids. The mounting of this filter, or lining of the cullender, is reckoned to be a nice operation by the workmen, and is regarded usually as a valuable secret.

The cullenders are hollow hemispheres of sheet-iron, about 10 inches in diameter, perforated with holes, which should be perfectly round and free from burs. These must be of an uniform size in each cullender; but of course a series of different cullenders with sorted holes for every different size of lead-shot must be prepared. The holes have nearly the following diameters for the annexed numbers of shot:—

No. 0.	$\frac{1}{50}$ of an inch.
1.	$\frac{1}{58}$,,
2.	$\frac{1}{66}$,,
3.	$\frac{1}{72}$,,
4.	$\frac{1}{80}$,,

From No. 5 to No. 9 the diameter decreases by regular gradations, the latter being only $\frac{1}{360}$th of an inch.

The operation is always carried on with three cullenders at a time, which are supported upon projecting grates of a kind of chafing-dish made of sheet-iron somewhat like a triangle. This chafing-dish should be placed immediately above the fall, while at its bottom there must be a tub half-filled with water for receiving the granulated lead. The cullenders are not in contact, but must be parted by burning charcoal in order to keep the lead constantly at the proper temperature, and to prevent its solidifying in the filter. The temperature of the lead-bath should vary with the size of the shot; for the largest, it should be such that a bit of straw plunged into it will be scarcely browned, but for all it should be nicely regulated. The height from which the particles should be let fall varies likewise with the size of the shot; as the congelation is the more rapid, the smaller they are. With a fall of 33 yards or 100 feet, from No. 4 to No. 9 may be made: but for larger sizes, 150 feet of height will be required.

Everything being arranged as above described, the workman puts the filter-stuff into the cullender, pressing it well against the sides. He next pours lead into it with an iron ladle, but not in too great quantity at a time, lest it should run through too fast. The shot thereby formed and found in the tub are not all equal.

The centre of the cullender being less hot affords larger shot than the sides, which are constantly surrounded with burning charcoal. Occasionally, also, the three cullenders employed together may have holes of different sizes, in which case the tub may contain shot of very various magnitudes. These are separated from each other by square sieves of different fineness, 10 inches broad and 16 inches long, their bottoms being of sheet-iron pierced with holes of the same diameters as those of the cullenders. These sieves are suspended by means of two bands above boxes for receiving the shot; one sieve being usually set above another in consecutive numbers, for instance, 1 and 2. The shot being put into the upper sieve, No. 0 will remain in it; No. 1 will remain in the lower sieve, and No. 2 will, with all the others, pass through it into the chest below. It is obvious that by substituting sieves of successive fineness, shot of any dimensions may be sorted.

In the preceding process the shot has been sorted to size; it must next be sorted to form, so as to separate all the spheroids which are not truly round, or are defective in any respect. For this purpose a board is made use of about 27 inches long and 16 broad, furnished partially with upright ledges; upon this tray a handful or two of the shot to be sorted being laid, it is inclined very slightly, and gently shaken in the horizontal direction, when the globular particles run down by one edge, into a chest set to receive them, while those of irregular forms remain on the sides of the tray, and are reserved to be re-melted.

After being sorted in this way, the shot requires still to be smoothed and polished bright. This object is effected by putting it into a small octagonal cask, through a door in its side, turning upon a horizontal iron axis, with rests in plummer boxes at its ends, and is made to revolve by any mechanical power. A certain quantity of plumbago or black-lead is put into the cask along with the shot.

LEAD, SALTS OF. The following are the chief artificial salts:—

Carbonate of Lead. See White Lead.

Nitrate of Lead (*Nitrate de plomb*, Fr.; *Salpetersäures bleioxyd*, Ger.), is made by saturating somewhat dilute nitric acid with oxide of lead (litharge), evaporating the neutral solution till a pellicle appears, and then exposing it in a hot chamber till it be converted into crystals, which are sometimes transparent, but generally opaque white octahedrons. Their spec. grav. is 4·068; they have a cooling, sweetish, pungent taste. They dissolve in 7 parts of cold, and in much less boiling water; they fuse at a moderate elevation of temperature, emit oxygen gas, and pass into oxide of lead. Their constituents are 67·3 oxide and 32·7 acid. Nitrate of lead is much employed in the chrome-yellow style of Calico-Printing.

There are three other compounds of nitric acid and lead oxide: viz. the bi-basic, the tri-basic, and the sex-basic; which contain respectively 2, 3, and 6 atoms of base to 1 of acid.

Oxychloride of Lead.—A white pigment patented by the late Mr. Hugh Lee Pattinson, of Newcastle, which he prepared by precipitating a solution of chloride of lead in hot water with pure lime-water, in equal measures; the mixture being made with agitation. As the operation of mixing the lime-water and the solution of chloride of lead requires to be performed in an instantaneous manner, the patentee prefers to employ for this purpose two tumbling boxes of about 16 feet cubic capacity, which are charged with the two liquids, and simultaneously upset into a cistern in which oxychloride of lead is instantaneously formed, and from which the mixture flows into other cisterns, where the oxychloride subsides. This white pigment consists of one atom of chloride of lead and one atom of oxide of lead, with or without an atom of water.

The salts of lead, beyond those already named, which enter into any of our manufactures, are few and unimportant. Watts's *Dictionary of Chemistry* should be consulted for them.

LEAD, RED. See Red Lead.

LEAD, WHITE. See White Lead.

LEADHILLITE. A sulphato-carbonate of lead found at Leadhills, in Lanarkshire, Scotland.

LEATHER (*Cuir*, Fr.; *Leder*, Ger.; *Leer*, Dutch; *Læder*, Danish; *Läder*, Swedish; *Cuojo*, Italian; *Cuero*, Spanish; *Kusha*, Russian). This substance consists of the skins of animals, chemically changed by the process called *tanning*. Throughout the civilised world, and from the most ancient times this substance has been employed by man for a variety of purposes. Barbarous and savage tribes use the skins of beasts as *skins*; civilised man renders the same substance unalterable by the external agents which tend to decompose it in its natural state, and by a variety of peculiar manipulations prepares it for almost innumerable applications.

Although the preparation of this valuable substance in a rude manner has been known from the most ancient times, it was not until the end of the last, and the beginning of the present century (1800) that it began to be manufactured upon right principles, in consequence of the researches of Macbride, Deyeux, Seguin, and Davy.

Skins may be converted into leather either with or without their hair; generally, however, the hair is removed.

The most important and costly kinds are comprised under sole leather and upper leather, to which may be added harness leather, belts used in machinery, leather hose, &c., but as far as the tanner is concerned, these are comprehended almost entirely in the kinds known as upper leather.

The active principle by which the skins of animals are prevented from putrefying, and at the same time, under some modes of preparation, rendered comparatively impervious to water, is called tannin, or tannic acid, a property found in the bark of the various species of *Quercus*, but especially plentiful in the gall-nut. When obtained pure, as it may easily be from the gall-nut, by chemical means, tannic acid appears as a slightly yellowish, almost a colourless mass, readily soluble in water; it precipitates gelatin from solution, forming what has been called *tannogelatin*. Tannic acid also precipitates albumen and starch. There can be little difficulty, after knowing the chemical combination just alluded to, in understanding the peculiar and striking change produced on animal substance in the formation of leather. The hide or skin consists principally of gelatin, for which the vegetable astringent tannin has an affinity, and the chemical union of these substances in the process of tanning produces the useful article of which we are treating.

Before entering upon the various processes by which the changes are effected on the animal fibre, it may not be uninteresting to speak of some of the principal astringents used for the purpose of producing these effects.

Bark obtained from the oak-tree is the most valuable and the most extensively used ingredient in tanning, and for a long time no other substance was used in England for the purpose. In consequence of the demand having become very much greater than the supply, and the consequent increase in the price of the article, it became necessary to investigate its properties, in order, if possible, to furnish the required quantity of tanning matter from other sources. Among other substitutes which were tried with some success in other countries may be mentioned *heath*, *myrtle leaves*, *wild laurel leaves*, *birch-tree bark*, and (according to the 'Penny Cyclopædia') in 1765 oak-sawdust was applied in England, and has since been used in Germany for this purpose.

Investigation proved that the tanning power of oak-bark consisted in a peculiar astringent property, to which the name of *tannin* has been given, and this discovery suggested that other bodies possessing this property would be suitable substitutes.

According to Sir H. Davy the following proportions of tannin in the different substances mentioned will be found:—'8½ lbs. of oak-bark are equal to 2¼ lbs. of galls, to 3 lbs. of sumach, to 7½ lbs. of bark of Leicester willow, to 11 lbs. of the bark of the Spanish chestnut, to 18 lbs. of elm-bark, and to 21 lbs. of common willow-bark.'—*Penny Cyclopædia.*

Oak-bark contains more tannin when cut in spring by four and a half times than when cut in winter; it is also more plentiful in young trees than in old ones. About 40,000 tons of oak-bark are said to be imported into this country annually, from the Netherlands, Germany, and ports in the Mediterranean. The quantity of English oak-bark used we have no means of ascertaining. It is prepared for use by grinding it to a coarse powder between cast-iron cylinders, and laid into the tan-pits alternately with the skins to be tanned. Sometimes, however, as will be hereafter noticed, an infusion of the bark in water is employed with better effect. See Oak-Bark.

Mimosa.—The bark and pods of several kinds of *Prosopis*, the astringent properties of which have rendered them valuable in tanning, are known in commerce by this name. The *Mimosæ* are a division of the leguminous order of plants, which consists of a large number of species, the Acacia being the principal. The sensitive plants belong to this division. The *Prosopis* is found in India and South America; the genus consists both of shrubs and trees.

Valonia.—The oak which produces this acorn is the *Quercus Ægilops*, or great prickly-cupped oak (*figs.* 1356, 1357). These are exported from the Morea and Levant; the husk contains an abundance of tannin.

1356

1357

Catechu, or *Terra Japonica*, is the inspissated extract of the *Acacia catechu*. At the time the sap is most perfectly formed the bark of the plant is taken off, the tree is then felled, and the outer part removed; the heart of the tree, which is brown, is cut into pieces and boiled in water; when sufficiently boiled it is placed in the sun, and, subject to various manipulations, gradually dried. It is cut into square pieces, and much resembles a mass of earth in appearance; indeed, it was once considered to be such, hence the name *Terra Japonica*.

We give Sir H. Davy's analysis; the first numbers represent Bombay, the second Bengal catechu:—

Tannin	109	97
Extractive	68	73
Mucilage	13	16
Impurities	10	14

This astringent is also obtained from the *Uncaria Gambir*.

Dividivi is a leguminous plant of the genus *Cæsalpinia* (*C. coriaria*). The legumes of this species are extremely astringent, and contain a very large quantity of tannic and gallic acid; they grow in a very peculiar manner, and become curiously curled as they arrive to perfection (*fig.* 1358). The plant is a native of America, between the tropics.

1358

Sumach is a plant belonging to the genus *Rhus*; several of the species have astringent properties; *Rhus cotinus* and *R. coriaria* are much used in tanning; the bark of the latter is said to be the only ingredient used in Turkey for the purpose of converting gelatin into leather. That used in this country is ground to a fine powder, and is extensively applied to the production of bright leather, both by tanners and curriers.

Many other vegetable products have been from time to time proposed, and to some extent adopted for the same end, but they need not be enumerated.

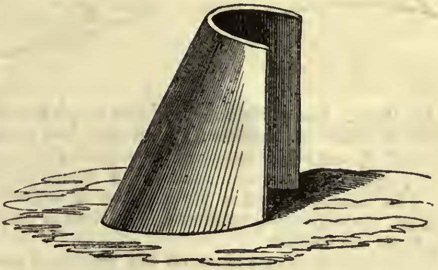
The process first attended to by the tanner is simply to soak the skin or hide in water; those from the home market may be said to be washed merely, as they remain in water only a few hours; while hides imported from foreign countries, and which have been preserved by salting or drying, *and especially the latter*, require soaking for a longer period, in order to render them supple, and beating or rubbing materially assists in bringing them to the required condition.

After removing the horns, the softened or recent hides are laid in a heap for a short time, after which they are suspended on poles in a close room called a smoke-house, heated somewhat above the common temperature by a smouldering fire. In these circumstances, a slight putrefaction supervenes, which loosens the epidermis, and renders the hair easily detachable. This method for removing the hair is by no means general in this country. The plan adopted is to place the hides in a large vat or pit, containing milk of lime, in which they must be moved frequently, to allow the lime to act equally on every part. When the menstruum has taken proper effect, the hair is easily removed, and for this purpose the hide is spread out, and a blunt tool is worked over the surface. The hair being removed, the hide is washed in water to cleanse it from the lime, which must be most thoroughly effected.

The heaviest hides are for the most part tanned for sole leather, and as the thinner parts are cut off previous to their being prepared for sale, they have received the name of *butts* or *backs*: the various processes through which these pass will be first described.

After removing the hair and washing, the hides are placed on a convex beam (*fig.* 1359), and worked with a concave tool with two handles (*fig.* 1360), in order to remove any flesh or fatty matter which may adhere to them; this being done, they are worked on the same beam, on the grain side, to drive out the grease and remove any remaining hair. The *fleshings* are pressed into cakes, and sold for making glue, as are all such portions of the hide or skin as cannot be conveniently worked. The hair is sold to plasterers, to be used in their mortar; and the tails, also for the hair, to sofa-makers and others requiring such materials.

1359

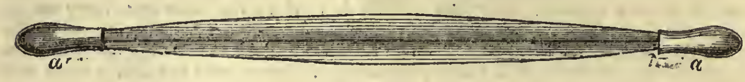


1360

Such hides as are designed for machinery purposes are next immersed in a pit containing water impregnated with sulphuric acid, the acid varying from $\frac{1}{500}$th to $\frac{1}{1000}$th of the mixture. This process is called *raising*, because it distends the pores, and makes the fibres swell, so as to become more susceptible of the action of tanning infusions. Forty-eight hours in general suffice for this operation, but more time may be safely taken. From the term *raising* it will be concluded that the substance of the hide is increased, and this is the fact; but as the gelatine is not increased, it is said that the shoemaker's hammer would condense the leather so much that it would lose any supposed advantage arising out of this increase in thickness. There is, however, a method of augmenting the substance of sole leather called *puffing*, which, when once communicated, appears to exist permanently; the process is known to a small extent only, and the material is said to be considerably injured by this mode of preparation.

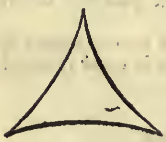
When the hides are sufficiently *raised*, they are transferred to a pit supplied with a weak infusion of bark; here they are *handled*, at first several times a day; that is, they are drawn out of the pits, or moved up and down in the *liquor*, to prevent the grain from being drawn into wrinkles. As the *ooze*, or tanning infusion, takes effect, they are put into pits containing stronger liquors, and after a month or six weeks they are placed in a pit, in which they are stratified with oak-bark, ground by a proper mill into a coarse powder. The pit is then filled with an infusion of bark. In a month or five weeks the tanning and extractive matter of the bark will have intimately combined with the animal fibre; the pit, exhausted of its virtue, must be renewed by taking out the spent bark, and repeating the dose as in the first instance. The hides, which were placed at the top of the pit at first, are now put into the bottom, to equalise the action. In about three months this also is spent, and the process being repeated two or three times more, the operation is complete. The hides are now removed from the pit, and hung up in a shed. In the progress of drying they are compressed with a steel tool, and afterwards they are subjected to the action of a brass roller. The steel tool is called a *pin*; it is of a triangular shape (*fig.* 1361), with the sides scooped out (*fig.* 1362), presenting three blunt edges. The butt is thrown across a pole, and the workman, taking the pin by the handles *a*, *a* (*fig.* 1361), presses it forcibly over the grain-side of the leather; after carefully compressing every part in this way, the *butt* is laid upon a flat bed of solid wood-work, prepared for the purpose, and the brass roller is worked backward and forward until every portion is sufficiently compressed

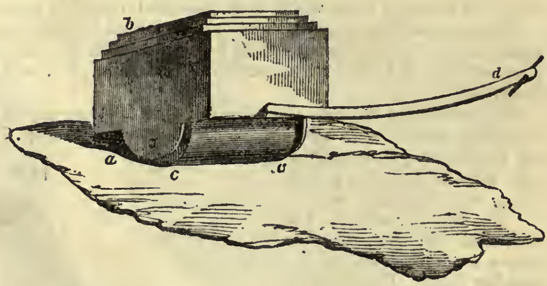
1361



1363

1362





(*fig.* 1363). The roller *a* is a cylinder varying from 9 to 12 inches in length, and from 7 to 10 inches in diameter; *b* is an open box over the roller, into which weights are placed to make the necessary pressure, ten or twelve cwts. being frequently used for the purpose; *c, c,* forms a fulcrum for lifting the roller from the bed to the leather; *d* is the handle by which the machine is worked. When the compression is completed, the only thing remaining to be done is properly to dry the leather, and then it is fit for the market.

Some manufacturers place on the bottom of the tan-pit five or six inches of spent bark, and two or three inches of fresh bark over it, then a hide, and so alternately bark and a hide, until the pit is nearly full, reserving a small space at the top for a thicker layer of bark, over which weighted boards are laid, to condense the whole down into the tanning infusion.

The operation of tanning sole leather by the above method occupies a year or more, the time depending on the nature and stoutness of the hide.

A perfect leather is recognised by its section, which should have a glistening marbled appearance, without any white streak in the middle.

Crop hides are manufactured very much like butts, that is to say, they are placed in milk of lime until the hair is sufficiently loosened, equality of action being secured by occasionally moving them in the menstruum; they are then cleared of the hair and other impurities by the *fleshing knife,* worked on the convex beam already described, they are then freed from lime by thorough washing. The next process is to plunge them into a weak ooze, from which they are transferred to other pits with stronger ooze; all the while they are frequently *handled,* that is, moved up and down in the infusion. After a month or six weeks they are subjected to a mixture of ground oak-bark and stronger ooze in other pits, to a series of which they are progressively subjected during two or three months.

The hides are next put into large vats called *layers,* in which they are smoothly stratified, with more bark and a stronger infusion. After about six weeks they are taken out of these vats, and subjected to a new charge of this material, and allowed to lay some two months; this process is repeated once or twice more till the hides are thoroughly tanned. They are then slowly dried in the shed, and folded for market. Although in general the stoutest and most compact hides are used as sole leather (notwithstanding that they have not been condensed by the tanner, as in the case of *butts*), yet many are appropriated to other purposes by the currier, and the lighter cow-hides are manufactured for the upper leather of stout shoes, water-boots, &c.

The process of tanning *skins* (as calves, seals, &c.) next claims attention. These are placed in the lime-pits until the hair can be easily removed, a process which requires about ten or twelve days; this being accomplished, they are next washed in water, so as completely to remove the lime, as far as washing can secure its removal, and then immersed in a lixivium of pigeon's dung, dog's dung, or matters of a like nature; in this state they remain about ten or twelve days, the state of the atmosphere rendering the process quicker at one time than another; here also they are frequently handled, and *worked* on both sides on the convex beam. The working, joined to the action of the peculiar lixivium, serves to separate the remaining lime, oil, and glutinous matter, and at the same time to render the skin pliant, soft, and ready to imbibe the tanning principle. It is important that great attention should be paid to the process just described, as too short a period would produce a hard and crisp leather, while a few hours more than is necessary makes the article coarse and spongy, both of which conditions should be very carefully guarded against.

The skins are next removed to a pit containing a weak solution of bark, in which they undergo nearly the same treatment as *crop hides*, but they are not commonly stratified in the layers. About three months is usually occupied in tanning calf-skins, but of course the stouter the skin the more will be the time required. When dried they are disposed of to the currier, who dresses them for the upper leathers of boots, shoes, and a variety of other purposes. It is not unusual for the lighter *cow hides* to be treated like calf-skins.

Horse-hides are also treated like calf-skins; but as the horse-hide, with the exception of the part on and near the animal's rump, produces a thin leather, it is usual, before subjecting the hide to the action of the bark, to cut out what is called the *butt*, which is tanned separately, and frequently used as an inferior sole leather. It is also to be remarked that horse-hides and *kips* (the hides of small foreign cattle) are frequently subjected to a process called *bate shaving*, in which the stout parts are reduced by a *currier's* knife previous to tanning, the object being to secure the complete infiltration of the animal fibre by the tannin in every part of the hide in the same time.

Sheepskins are usually pressed after the wool is removed, and before the tanning process is commenced, to get rid of the fatty matter contained in them, and which is not readily removed by ordinary *working*.

In all the above processes, as the animal fibres on the surface of the skin absorb most readily the tanning principles, and thereby obstruct, in a certain degree, their passage into the interior fibres, especially of thick hides, it becomes an object of importance to contrive some method of overcoming that obstacle, and promoting the penetration of the tan. The first manufacturer who appears to have employed efficacious mechanical means for favouring the chemical action was Francis G. Spilsbury, who, in April 1823, obtained a patent for the following operation:—After the hides are freed from the hairs, &c., in the usual way, they are minutely inspected as to their soundness, and if any holes be found, they are carefully sewed up, so as to be water-tight. Three frames of wood are provided of equal dimensions, fitted to each other, with the edges of the frames held together by screw bolts. A skin about to be tanned is now laid upon the frame, and stretched over its edges, then the second frame is to be placed upon it, so that the edges of the two frames may pinch the skin all round and hold it securely; another such skin is then stretched over the upper surface of the second frame, in like manner, and a third frame being set upon this, confines the second skin. The three frames are then pinched tightly together by a series of screw bolts, passing through ears set round their outer edges, which fix the skin in a proper manner for being operated upon by the tanning liquor.

A space has been thus formed between the two skins, into which, when the frames are set upright, the infusion is introduced by means of a pipe from the cistern above, while the air is permitted to escape by a stopcock below. This cock must of course be shut whenever the bag is filled, but the one above is left open to maintain a communication with the liquor cistern, and to allow the hydrostatic pressure to force the liquor through the cutaneous pores by a slow infiltration, and thus to bring the tannin into contact with all the fibres indiscriminately. The action of this pressure is evinced by a constant perspiration on the outer surfaces of the skins.

When the tanning is completed, the upper stopcock is closed, and the under is opened to run off the liquor. The frames are now removed, the bolts are unscrewed, and the pinched edges of the skins pared off; after which they are to be dried and finished in the usual manner.

A modification of this ingenious and effectual process was made the subject of a patent, by William Drake, of Bedminster, tanner, in October 1831. The hides, after the usual preparatory processes, are immersed in a weak tan liquor, and by frequent handling or turning over, receive an incipient tanning before being submitted to the infiltration plan. Two hides, as nearly of the same size and shape as possible, are placed grain to grain, when their corresponding edges are sewed firmly together all round by shoemaker's waxed thread, so as to form a bag sufficiently tight to hold tan liquor. This bag must then be suspended by means of loops sewed to its shoulder-end, upon pegs, in such a manner that it may hang within a wooden-barred rack, and be confined laterally into a book form. About an inch of the bag is left unsewed at the upper end, for the purpose of introducing a funnel through which the cold tan liquor is poured into the bag till it be full. After a certain interval, which varies with the quality of the hides, the outer surface becomes moist, and drops begin to form at the bottom of the bag. These are received in a proper vessel, and when they accumulate sufficiently may be poured back into the funnel; the bag being thus, as well as by a fresh supply from above, kept constantly distended.

When the hides are observed to feel hard and firm, while every part of them feels equally damp, the air of the tanning apartment, having been always well ventilated, is now to be heated by proper means to a temperature gradually increasing from 70° to 150° of Fahrenheit's scale. This heat is to be maintained till the hides become firmer and harder in all parts. When they begin to assume a black appearance in some parts, and when the tan liquor undergoes little diminution, the hides may be considered to be tanned, and the bag may be emptied by cutting a few stitches at its bottom. The outer edges being pared off, the hides are to be finished in the usual way. During their suspension within the racks, the hides should be shifted a little sideways, to prevent the formation of furrows by the bars, and to facilitate the equable action of the liquor.

By this process the patentee says, that a hide may be tanned as completely in ten days as it could be in ten months by the usual method.

Messrs. Knowlys and Duesbury obtained a patent in August 1826 for accelerating the impregnation of skins with tannin, by suspending them in a close vessel, from which the air is to be extracted by an air-pump, and then the tanning infusion is to be admitted. In this way, it is supposed to penetrate the hide so effectually as to tan it uniformly in a short time.

Danish leather is made by tanning lamb and kid skins with willow bark, whence it derives an agreeable smell. It is chiefly worked up into gloves.

Of the tawing or dressing of skins for gloves, and white sheep leather.

The operations of this art are: 1, washing the skins; 2, properly treating them with lime; 3, taking off the fleece; 4, treatment in the leather steep.

A shed erected upon the side of a stream, with a cistern of water for washing the skins; wooden horses for cleaning them with the back of the fleshing knife; pincers for removing the fibres of damaged wool; a plunger for depressing the skins in the pits; a lime pit; a pole with a bag tied to the end of it; a two-handled fleshing knife; a rolling pin, from 15 to 18 inches long, thickened in the middle;—such are some of the utensils of a tawing establishment. There must be provided also a table for applying the oil to the skins; a fulling mill, worked by a water-wheel or other power; a dressing peg; a press for squeezing out the fatty filth; a stove; planks mounted upon legs, for stretching the skins, &c.

Fresh skins must be worked immediately after being washed, and then dried, otherwise they ferment, and contract either indelible spots, or get tender in certain points, so as to open up and tear under the tools. When received in the dry state they should be steeped in water for two days, and then treated as fresh skins. They are next strongly rubbed on the convex horse-beam with a round-edged knife, in order to make them pliant. The rough parts are removed by the fleshing knife. One workman can in this way prepare 200 skins in a day.

The flesh side of each being rubbed with a cold cream of lime, the skins are piled together with the woolly side of each pair outermost, and the flesh sides in contact. They are left in this state for a few days, till it is found that the wool may be easily removed by *plucking*.

They are next washed in running water, to separate the greater part of the lime, stripped of the wool by small spring tweezers, and then fleeced smooth by means of the rolling pin, or sometimes by rubbing with a whetstone. Unless they be fleeced soon after the treatment with lime, they do not well admit of this operation subsequently, as they are apt to get hard.

They are now steeped in the milk-of-lime pit, in order to swell, soften, and cleanse them; afterwards in a weak pit of old lime-water, from which they are taken out and drained. This steeping and draining upon inclined tables, are repeated frequently during the space of three weeks. Only the skins of young animals, or those of inferior value are tawed. Sometimes the wool is left on, as for housings, &c.

The skins, after having been well softened in the steeps, are rubbed on the outside with a whetstone set in a wooden case with two handles, in order to smoothe them completely by removing any remaining filaments of wool. Lamb-skins are rubbed with the pin in the direction of their breadth, to give them suppleness; but sheep-skins are fulled with water alone. They are now ready for the *branning*, which is done by mixing 40 lbs. of bran with 20 gallons of water, and keeping them in this fermentable mixture for three weeks—with the addition, if possible, of some old bran-water. Here they must be frequently turned over, and carefully watched, as it is a delicate operation. In the course of two days in summer, and eight in winter, the skins are said to be *raised*, when they sink in the water. On coming out of the bran they are ready for the white stuff; which is a bath composed of alum and sea-salt. Twelve, fourteen, and sometimes eighteen pounds of alum for 100 skins, form the basis of the bath; to which two and a half pounds of salt are added in winter, and three in summer. These ingredients are introduced into a copper with twelve gallons of water. The salt aids in the whitening action. When the solution is about to boil, three gallons of it are passed through the cullender into a basin; in this 26 skins are worked one after another, and, after draining, they are put together into the bath, and left in it for ten minutes to imbibe the salts. They are now ready to receive the paste. For 100 skins, from 13 to 15 pounds of wheat-flour are used, along with the yolks of 50 eggs. After having warmed the alum-bath through which the skins have been passed, the flour is dusted into it, with careful stirring. The paste is well kneaded by the gradual addition of the solution, and passed through the cullender, whereby it becomes as clear as honey. To this the yolks being added, the whole is incorporated with much manual labour. The skins are worked one after another in this paste; and afterwards the whole together are left immersed in it for a day. They are now stretched and dried upon poles, in a proper apartment, during from 8 to 15 days, according to the season.

The effects of the paste are to whiten the skins, to soften them, and to protect them from the hardening influence of the atmosphere, which would naturally render them brittle. They would not bear working upon the *softening iron*, but for the emulsion which has been introduced into their substance. With this view they are dipped in a tub of clear water during five or six minutes, and then spread and worked upon the board. They are increased by this means in length, in the proportion of 5 to 3. No hard points must be left in them. The whiteness is also better brought out by this operation, which is performed upon the flesh side. The softening tool is an iron plate, about 1 foot broad, rounded over above, mounted upon an upright beam, 30 inches high, which is fixed to the end of a strong horizontal plank, 3½ feet long and 1 broad. This plank is heavily loaded, to make it immoveable upon the floor. Sometimes the skins are next spread over an undressed clean skin upon the horse, and worked well with the two-handled knife, for the purpose of removing the first and second epidermis, called the *fleur* and *arrière-fleur* by the French *mégissiers*. They are then dried while stretched by hooks and strings. When dry they are worked on the *stretching-iron*, or they are occasionally polished with pumice-stone. A delicate yellow tint is given by a composition made of two parts of whitening and one of ochre, applied in a moistened state, and well worked in upon the grain side. After being polished with pumice, they are smoothed with a hot iron, as the laundresses do linen, whereby they acquire a degree of lustre, and are ready to be delivered to the *glover*.

For *housings*, the best sheep-skins are selected, and such as are covered with the longest and most beautiful fleece. They are steeped in water, in order to be cleaned and softened; after which they are thinned inside by the fleshing knife. They are now steeped in an old bran-pit for 3 or 4 days, when they are taken out and washed. They are next subjected to the white or alum-bath, the wool being carefully folded within; about 18 lbs. of alum being used for 100 skins. The paste is made as for the fleeced skins, but it is merely spread upon their flesh side, and left upon them for 18 hours, so as to stiffen. They are then hung up to dry. They are next moistened by sprinkling cold water upon them, folded up, piled in a heap, and covered with boards weighted with heavy stones; in which state they remain for two days. They are next opened with a round iron upon the horse, and subjected to the stretching iron, being worked broadwise. They are dried with the fleece outermost, in the sun if possible, and are finished upon the *stretcher*.

Calf- and lamb-skins with their hair and wool are worked nearly in the same manner; only the thicker the skin, the stronger the alum-bath ought to be. One pound of alum and one of salt are required for a single calf-skin. It is left four days in this bath, after which it is worked upon the *stretcher*, and then fulled. When half dry, the skins are opened upon the horse. In eight days of ordinary weather, they may be completely dressed. Lamb-skins are sometimes steeped during eight days in a bath prepared with unbolted rye-flour and cold water, in which they are daily moved about two or three times. They are then dried, stretched upon the iron, and switched upon the fleecy side.

Chamois, or *Shamoy leather*.—The skins are first washed, limed, fleeced, and branned as above described. They are next *efflowered*, that is, deprived of their epidermis by a concave knife, blunt in its middle part, upon the convex horse-beam. The cutting part serves to remove all excrescences, and to equalise the thickness, while the blunt part softens and smooths. The skins of goats, does, and chamois are always treated in this way. They are next subjected to the fermenting bran-steep for one or two days, in ordinary weather; but in hot weather for a much shorter time, sometimes only moving them in the sour bran-liquor for a few minutes. They are lastly wrung at the peg, and subjected to the fulling mill.

When the skins have been sufficiently swelled and suppled by the branning, they may receive the first oil as follows: a dozen skins being stretched upon the table, the fingers are dipped in the oil, and shaken over the skins in different places, so as to impart enough of it to imbue the whole surface slightly, by friction with the palms of the hands. It is to the outside or *grain* that the oil is applied. The skins are folded four together, so as to form balls of the size of a hog's bladder, and thrown into the trough of the fulling mill, to the number of twelve dozen at once. Here they remain exposed to the beater for two, three, or four hours, according to their nature and the state of the weather. They are taken out, aired, oiled, and again fulled. The airing and fulling are repeated several times, with more or less frequent oilings. Any cheap animal oil is employed.

After these operations, the skins require to be subjected to a fermenting process, to dilate their pores, and to facilitate their combination with the oil. This is performed in a chamber only 6 feet high and 10 or 12 feet square. Poles are suspended horizontally a few inches from the ceiling, with hooks fixed in them to which the skins are attached. A somewhat elevated temperature is maintained, and by a stove if need be. This operation requires great skill and experience.

The remainder of the epidermis is next removed by a blunt concave knife and the horse; whereby the surface is not cut, but rather forcibly scraped.

The skins are now scoured to carry off the redundant oil; which is effected by a potash-lye, at 2° Baumé, heated no hotter than the hand can bear. In this they are stirred briskly, steeped for an hour, and lastly wrung at the peg. The soapy liquor thus expelled is used for inferior purposes. The clean skins after being dried are finished first on the *stretcher-iron*, and then on the *horse* or stretching frame.

Leather of Hungary.—This is manufactured by impregnating strong hides with alum, common salt, and suet; by a rapid process which is usually completed in the space of two months. The workshop is divided into two parts: 1. A shed on the side of a stream, furnished with wooden horses, fleshing knives, and other small tools. In one corner is a furnace with a boiler for dissolving the alum, a vat for immersing the hides in the solution, and several subsidiary tubs. 2. A chamber, 6 feet high, by 15 feet square, capable of being made very tight, for preserving the heat. In one corner is a copper boiler, of sufficient size to contain 170 lbs. of tallow. In the middle of the stove is a square stone slab, upon which an iron grate is placed about a yard square. This is covered with charcoal. At each side of the stove are large tables, which occupy its whole length, and on which the leather is spread to receive the grease. The upper part below the ceiling is filled with poles for hanging the leather upon to be heated. The door is made to shut perfectly close.

The first operations are analogous to those of tanning and tawing; the skins being washed, cut in halves, shaved, and steeped for 24 hours in the river. They are then cleaned with 5 or 6 lbs. of alum, and 3½ lbs. of salt, for a piece of hide which weighs from 70 to 80 lbs. The common salt softens the effect of the alum, attracts the moisture of the air, and preserves the suppleness of the skin. When the alum and salt are dissolved, hot water is poured upon the hides placed in a vat, and they are trampled upon by a workman walking repeatedly from one end of the vat to the other. They are then transferred into a similar vat containing some hot water, and similarly trampled upon. They are next steeped for eight days in alum-water. The same round of operations is repeated a second time.

The skins are now dried either in the air, or in a stove-room; but before being quite dry, they are doubled together, well stretched to take out the wrinkles, and piled up. When dry, they are again trampled to open the pores as well as to render the skin pliant, after which they are whitened by exposure to the sun.

Tallow of inferior quality is employed for greasing the leather. With this view the hides are hung upon the poles in the close stove-room, then laid upon the table, and besmeared with the tallow melted till it begins to crackle. This piece is laid on another table, is there covered with a second, similarly greased, and so forth. Three pounds of fat are commonly employed for one piece of leather.

When the thirty strips, or fifteen hides passed through the grease in one operation are completed, two workmen take the first piece in their hands, and stretch it over the burning charcoal on the grate for a minute, with the flesh-side to the fire. The rest are passed over the flame in like manner. After *flaming*, the pieces are successively laid on an inclined table exposed to the fire, where they are covered with a cloth. They are finally hung upon poles in the air to dry; and if the weather be warm, they are suspended only during the night, so as to favour the hardening of the grease. Instead of the alum-bath, M. Curaudau has employed with advantage a steep of dilute sulphuric acid.

The Russians have long been possessed of a method of making a peculiar leather, called by them *Jucten*, dyed red with the aromatic saunders wood. This article has been much sought after, on account of not being subject to mould in damp situations, being proof against insects, and even repelling them from the vicinity by its odour. The skins are freed from the hair or fleece, by steeping in an ash-lye too weak to act upon the animal fibres. They are then rinsed, fulled for a longer or shorter time according to their nature, and fermented in a proper steep, after having been washed in hot water. They are taken out at the end of a week, but they may be steeped a second time if deemed necessary, to open their pores. They are now cleaned by working them at the horse on both the flesh and grain sides.

A paste is next composed, for 200 skins, of 38 lbs. of rye-flour, which is set to ferment with leaven. This dough is worked up with a sufficient quantity of water to form a bath for the skins, in which they are soaked for 48 hours; they are then transferred into small tubs, where they remain during fifteen days, after which they are washed at the river. These operations serve to prepare the skins for absorbing the astringent juices with uniformity. A decoction of willow-bark (*Salix cinerea* and *Salix caprea*) being made, the skins are immersed in the boiler whenever the temperature of the liquor is sufficiently lowered not to injure the animal fibres, and handled and pressed for half an hour. This manipulation is repeated twice daily during the period of a week. The tanning infusion is then renewed, and applied to the same skins for another week; after which, being exposed to the air to dry, they are ready for being dyed, and then curried with the empyreumatic oil of the bark of the birch tree. To this substance the Russia leather owes its peculiarities. Many modes have been prescribed for preparing it; but the following is the one practised in Russia.

The whitish membranous epidermis of the birch, stripped of all woody parts, is introduced into an iron boiler, which, when stuffed full, is covered tight with a vaulted iron lid, having a pipe rising from its centre. A second boiler into which this pipe passes without reaching its bottom, is set over the first, and is luted to it at the edges, after the two are bolted together. They are then inverted, so that the upper one contains the birch-bark. The under half of this apparatus is sunk in the earth, the surface of the upper boiler is coated over with a clay lute, then surrounded with a fire of wood, and exposed to a red heat, till the distillation be completed. This operation, though rude in appearance, and wasteful of wood, answers its purpose perfectly well. The iron cylinder apparatus used in Britain for distilling wood-vinegar would, however, be much more convenient and productive. When the above bodies are unluted, there is found in the upper one a very light powder of charcoal, and in the under one, which served as a receiver, there is an oily, brown, empyreumatic fluid, of a very strong smell, which is mixed with the tar, and which floats over a small quantity of crude vinegar. The former matter is the oil employed to impregnate the skins, by working it into the flesh side with the currier's tools. It is difficult to make this oil penetrate with uniformity; and the Russians do not always succeed in this process, for they turn out many skins in a spotted state. This oil is at present obtained in France by distilling the birch-bark in copper stills, and condensing the products by means of a pipe plunged in cold water. About 60 per cent. of the weight of the bark is extracted.

The skins imbibe this oil most equally before they are fully dry. Care must be taken not to apply too much of it, for fear of its passing through and staining the grain side of the leather. Chevreul has investigated the chemical nature of this odoriferous substance, and finding it to be a peculiar compound, has called it *betuline.*

In the Franklin Institute for February 1843, Mr. Gideon Lee has published some judicious observations on the process of tanning. He believes that much of the original gelatine of the hides is never combined with the tannin, but is wasted; for he thinks that 100 lbs. of perfectly dry hide, when cleaned from extraneous matter, should, on chemical principles, afford at least 180 lbs. of leather. The usual preparation of the hide for tanning he believes to be a wasteful process. In the liming and bating, or the unhairing and the cleansing, the general plan is first to steep the hides in milk of lime for one, two, or three weeks, according to the weather and texture of the skin, until the hair and epidermis be so loosened as to be readily removed by rubbing down, by means of a knife, upon a beam or block. Another mode is to suspend the hides in a close chamber, heated slightly by a smouldering fire, till the epidermis gets loosened by incipient putrefaction. A third process, called sweating, used in Germany, consists in laying the hides in a pack or pile, covered with tan, to promote fermentative heat, and to loosen the epidermis and hairs. These plans, especially the two latter, are apt to injure the quality of the hides.

The *bate* consists in steeping the haired hides in a solution of pigeons' dung, containing, Mr. Lee says, muriate of ammonia, muriate of soda, &c.; but most probably phosphates of ammonia and lime, with urate of ammonia, and very fermentable animal matter. The dry hides are often subjected first of all to the operation of the fulling-stocks, which opens the pores, but at the same time prepares them for the action of the liming and bate; as also for the introduction of the tanning matter. When the fulling is too violent, the leather is apt to be too limber and thin. Mr. Lee conceives that the liming is injurious, by carrying off more or less of the gelatine and albumen of the skin. High-limed leather is loose, weighs light, and wears out quickly. The subsequent fermentation in the bating aggravates that evil. Another process has therefore been adopted in New York, Maine, New Hampshire, and some parts of Philadelphia, called, but incorrectly, *cool sweating*, which consists in suspending the hides in a subterranean vault, at a temperature of 50° F., kept perfectly damp, by the trickling of cold spring-water from points in the roof. The hides being first soaked, are suspended in this vault from 6 to 12 days, when the hair is well loosened, by the mere softening effect of moisture, without fermentation.—H.M.

LEATHER, MOROCCO. (*Maroquin*, Fr.; *Saffian*, Ger.) Morocco leather of the finer quality is made from goat-skins tanned with sumach; inferior morocco leather (roan) from sheep-skins. The goat-skins as imported are covered with hair; to remove which they are soaked in water for a certain time, and they are then subjected to the operation called breaking, which consists in scraping them clean and smooth on the flesh side, and they are next steeped in lime-pits (milk of lime) for several days, during which period they are *drawn out*, with a hook, from time to time, laid on the side of the pit to drain, and replunged alternately, adding occasionally a little lime, whereby they are eventually deprived of their hair. When this has become sufficiently loose, the skins are taken out one by one, laid on convex beams, the work-benches, which stand in an inclined position, resting on a stool at their upper end, at a height convenient for the workman's breast, who scrapes off the hair with a concave steel blade or knife, having a handle at each end. When unhaired, the skins are once more soaked in milk of lime for a few days, and then scraped on the flesh side to render it very even. For removing the lime which obstructs their pores, and would impede the tanning process, as well as to open these pores, the skins are steeped in a warm semi-putrid alkaline liquor, made with pigeons' and hens' dung diffused in water. Probably some very weak acid, such as fermented bran-water, would answer as well, and not be so offensive to the workmen. (In Germany the skins are first washed in a barrel by a revolving axle and discs.) They are again scraped, and then sewed into bags, the grain outermost, like bladders, leaving a small orifice, into which the neck of a funnel is inserted, and through which is poured a certain quantity of a strong infusion of the sumach; and they are now rendered tight round the orifices, after being filled out with air, like a blown bladder. A parcel of these inflated skins are thrown into a very large tub, containing a weaker infusion of sumach, where they are rolled about in the midst of the liquor, to cause the infusion within to act upon their whole surface, as well as to expose their outsides uniformly to the tanning action of the bath. After a while these bladder-skins are taken out of the bath, and piled over each other upon a wooden rack, whereby they undergo such pressure as to force the enclosed infusion to penetrate through their pores, and to bring the tannin of the sumach into intimate contact, and to form a chemical combination with the skin fibres. The tanning is completed by a repetition of the process of introducing some infusion or decoction into them, blowing them up, and floating them with agitation in the bath. In this way goat-skins may be well tanned in the course of one day.

The bags are next undone by removing the sewing, the tanned skins are scraped as before on the curriers' bench, and hung up in the drying loft or shed; they are said now to be 'in the crust.' They are again moistened and smoothed with a rubbing tool before being subjected to the dyeing operations, in which two skins are applied face to face to confine the dye to one of their surfaces only, for the sake of economising the dyeing materials, which may be of several different colours. The dyed skins are grained by being strongly rubbed with a ball of box wood, finely grooved on its surface.

Preparatory to being dyed, each skin is sewed together edgewise, with the grain on the outside, and it is then mordanted either with a solution of tin, or with alum-water. The colour is given by cochineal, of which from 10 to 12 ounces are required for a dozen of skins. The cochineal being boiled in water along with a little tartar or alum for a few minutes, forms a red liquor, which is filtered through a linen cloth, and put into a clean cask. The skins are immersed in this bath, and agitated in it for about half an hour; they are taken out and beaten, and then subjected to a second immersion in the cochineal bath. After being thus dyed, they are rinsed and tanned with Sicilian sumach, at the rate of two pounds for a skin of moderate size. The process is performed in a large tub made of white wood, in the liquor of which the skins are floated like so many bladders, and moved about by manual labour during four hours. They are then taken out, drained, and again subjected to the tanning liquor; the whole process requiring a space of twenty-four hours. The skins are now unstitched, rinsed, fulled with beetles, drained, rubbed hard with a copper blade, and lastly hung up to dry.

Some manufacturers brighten the colour by applying to the surface of the skins, in a damp state, a solution of carmine in ammonia with a sponge; others apply a decoction of saffron to enliven the scarlet tint. At Paris, the morocco leather is tanned by agitation with a decoction of sumach in large casks made to revolve upon a horizontal axis, like a barrel churn. White galls are sometimes substituted for sumach; a pound being used for a skin. The skins must be finally cleaned with the utmost care.

The black dye is given by applying with the brush a solution of red acetate of iron to the grain side. Blue is communicated by the common cold indigo vat; violet, with a light blue followed by cochineal red; green, by Saxon blue followed by a yellow dye, usually made with the chopped roots of the barberry. This plant serves also for yellows. To dye olive, the skins are first passed through a weak solution of green vitriol, and then through the decoction of barberry root, containing a little Saxon blue. Puce colour is communicated by logwood with a little alum; which may be modified by the addition of a little Brazil wood. In all these cases, whenever the skins are dyed, they should be rinsed, wrung, or rather drained, stretched upon a table, then besmeared on the grain side with a film of linseed oil applied by means of a sponge, in order to promote their glossiness when curried, and to prevent them becoming horny by too rapid drying.

The last process in preparing morocco leather is the currying, which brings out the lustre, and restores the original suppleness. This operation is practised in different manners, according to the purpose the skins are to serve. For pocket-books, portfolios, and case-making in general, they must be thinned as much as possible upon the flesh side, moistened slightly, then stretched upon the table, to smooth them; dried again, moistened, and lastly passed two or three times through the cylinder press in different directions, to produce the crossing of the grain. The skins intended for the shoemaker, the saddler, the bookbinder, &c., require more pliancy, and must be differently curried. After being thinned, they are glazed with a polisher while still moist, and a grain is formed upon the flesh side with the roughened lead plate or grainer of the curriers, called in French *pommelle*; they are glazed anew to remove the roughness produced by the pommel, and finally grained on the flesh side with a surface of cork applied under a pommel of white wood.

Tawing of Skins. (*Mégisserie*, Fr.; *Weissgerberei*, Ger.) The kid-, sheep-, and lamb-skins, are cleaned as has been already described. In some factories they receive the tanning power of the submuriate of alumina (from a solution of alum and common salt) in a large barrel-churn apparatus, in which they are subjected to violent agitation, and thereby take the *aluming* in the course of a few minutes. In other cases, where the yolks of eggs are added to the above solution, the mixture, with the skins, is put into a large tub, and the whole trampled strongly by the naked feet of the operator, till the emulsion of the egg be forced into the pores of the skin. The tawed skins, when dry, are 'staked,' that is stretched, scraped, and smoothed by friction against the blunt edge of a semi-circular knife, fixed to the top of a short beam of wood set upright. The workman holding the extremities of the skin with both hands, pulls it in all directions forcibly, but skilfully, against the smoothing 'stake.'

In an entertaining article on tanning in the 11th vol. of the 'Penny Magazine,' at page 215, the following description is given of one of the great tawing establishments of London:—

'In the production of "imitation" kid leather, the skin of lambs is employed; and for this purpose lamb-skins are imported from the shores of the Mediterranean. They are imported with the wool yet on them; and as this wool is valuable, the leather manufacturer removes this before the operations on the pelt commence. The wool is of a quality that would be greatly injured by the contact of lime, and therefore a kind of natural fermentation is brought about as a means of loosening the wool from the pelt.' The following is a description of one of the buildings: 'On the ground floor, a flight of stone steps leads down to a range of subterranean vaults or close rooms, into which the lamb-skins are introduced in a wet state, after having been steeped in water, 'broken' on the flesh side, and drained. The temperature of these rooms is nearly the same all the year round, a result obtained by having them excluded as much as possible from the variations of the external atmosphere; and the result is, that the skins undergo a kind of putrefactive or fermenting process, by which the wool becomes loosened from the pelt. During this chemical change ammonia is evolved in great abundance; the odour is strong and disagreeable; a lighted candle, if introduced, would be instantly extinguished, and injurious effects would be perceived by a person remaining long in one of the rooms. Each room is about ten feet square, and is provided with nails and bars whereon to hang the lamb-skins.

The doors from all the rooms open into one common passage or vault, and are kept close, except when the skins are inspected. It is a point of much nicety to determine when the fermentation has proceeded to such an extent as to loosen the wool from the pelt; for if it be allowed to proceed beyond that stage, the pelt itself would become injured.

When the fermentation is completed, generally in about five days, the skins are removed to a beam, and there 'slimed,' that is, scraped on the flesh side, to remove a slimy substance which exudes from the pores. The wool is then taken off, cleaned, and sold to the hatters, for making the bodies of common hats. The stripped pelts are steeped in lime-water for about a week, to kill the grease; and are next 'fleshed on the beam.' After being placed in a 'drench,' or a solution of sour bran for some days to remove the lime and open the pores, the skins are alumed, and subjected to nearly the same processes as the true kid-skins. These Mediterranean lamb-skins do not in general measure more than about 20 inches by 12; and each one furnishes leather for two pairs of small gloves. These kinds of leather generally leave the leather-dresser in a white state; but undergo a process of dyeing, softening, 'stroking,' &c., before being cut up into gloves.

The tanning of one average-sized skin requires about 1¼ lb. of good Sicilian sumach; but for leather which is to receive a bright scarlet dye, from one half to three quarters of a pound of gall-nuts are employed in preference. Inferior goat-skins are tanned with a willow-bark infusion, in pits, in which they are turned repeatedly, and laid out to drain, as in tanning sole leather. The finest skins for the brightest scarlet are cured with salt, to prevent their receiving damage in the transport, and are dyed before being tanned. This method is practised in Germany and France.

Leather of deer- and sheep-skins is prepared with oil, for the purpose of making breeches, &c., and for wash-leather, used in cleaning plate. After they are completely washed, limed, and beamed, as above described, they have their 'grain' surface removed, to give them greater softness and pliability. This removal of the grain is called 'frizing,' and it is done either with the round edge of a blunt knife, or with pumice-stone. After being freed from the lime by steeping in fermented bran-water, they are pressed as dry as may be, and are then impregnated with cod-oil, by beating with stocks in the trough of a kind of fulling mill. Previously to the application of the oil, they are usually beat for some time alone to open their substance. The oiled skins are stretched, hung up for some time in the air, then fulled with oil as before—a process which is 8 or 9 times repeated. The oil is slowly and evenly poured upon the skins in the trough during the action of the beaters. One hundred skins usually take up in this way from two to three gallons of oil. The fulled oil skins are thrown into large tubs, and left for some time to ferment, and thereby to combine more intimately with the oil. They are lastly subjected to a weak potash-lye-bath, to strip them of the loosely adhering oil. They are then hung up in the air to dry, and dressed for the market.—H.M.

LEATHER, RUSSIAN, *as tanned at Kazan.* The hides to be tanned may be either fresh from the animal or dry, no matter which; they are first laid to soak for three days and nights in a solution of potash, to which some quicklime is added. The potash used is made of the tree called in Russ *ilim* (the common elm), which sort is said to be preferable to any other, if not essential; it is not purified, so that it is of a brown colour and of an earthy appearance: about 12 poods of this (the pood is 36 lbs. English), and 2 poods of lime, serve for 100 skins. As they have no way of ascertaining the degree of causticity of the alkali but by its effect upon the tongue, when they find it weak they let the skins lie longer in the solution.

When the skins are taken out of this solution they are carried to the river, and left under water for a day and night.

Next a vedro of dog's dung is boiled in as much water as is enough to soak 50 skins, (the vedro is equal to 2·696 English imperial gallons) but in the winter time, when the dung is frozen, twice that quantity is found necessary. The skins are put into this solution, not while it is boiling hot, but when at the heat which the hand can bear; in this they lie one day and one night.

The skins are then sewed up so as to leave no hole; in short, so as to be water-tight; about one third of what the skin will contain is then filled up with the leaves and small twigs chopped together of the plant called in Russ Toloknanka (*Arbutus uva-ursi*, sometimes called bearberry), which is brought from the environs of Solikamskaga, and the skin is then filled up with water.

The skins thus filled are laid one on the other in a large trough, and heavy stones upon them, so as by their weight to press the infusion through the pores of the skin in about 4 hours; yet, as it was said at the same time, that the skins are filled up with the same water which had been pressed out 10 times successively, and that the whole operation takes but one day and one night, this leaves but 2½ hours for each time.

The skins are then taken to the river and washed, and are ready for the dyeing. The whitest skins are laid aside for the red and yellow leather.

To soften the skins after dyeing, they are harassed by a knife, the point of which is curved upwards.—H. M.

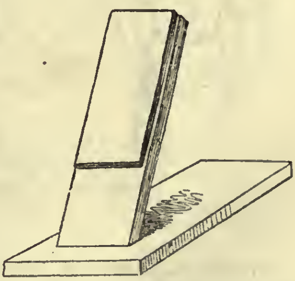
LEATHER, CURRYING OF. The currier's shop has no resemblance to the premises of the tanner, the tools and manipulations being quite different.

Within the last twenty or thirty years, many tanners have added the currying business to their establishments, and many curriers have likewise commenced tanning; but in each case, an extension of premises is necessary, and the two departments are still separate, The advantages derivable from this arrangement are two-fold:—first, a saving of time is effected, for as the tanned leather is sold by weight, it is required to be well dried before being disposed of to the currier, an operation which is not needed where the tanner carries on the currying also; and secondly, by the currier's art, the skins can be reduced to a comparatively uniform thickness previous to their being tanned, thus saving *time* and *bark* (used for tanning), and insuring a more equal distribution of tannin through the substance of the skin. In the following description, the business of currying will be considered as practised at the present time.

The currier's shop or premises, to be convenient, should be spacious. A frequent, though not universal method, is to have the ground-floor appropriated to such operations as require the use of a large quantity of water. The place or apartment thus used, is called the *scouring-house*, and is commonly furnished with a number of *vats* or *casks open at one end*, in which the leather is placed for the purpose of soaking, and undergoing such treatment as will be hereafter described. In this apartment also is placed a large, flat, slate stone, called a *scouring stone*, or, more consistently, the stone on which the leather is scoured. This stone, which has its face perfectly flat and smooth, and which should measure 8 or 9 feet in length, by 4½ broad, forms a table, supported generally by masonry, but sometimes by a strong frame of wood, so constructed that the water, which is freely used in scouring, may drain off on the opposite side from that on which the workman is engaged; an inclination of about 3 or 4 inches on the width of the table, is sufficient for this purpose. Another piece of furniture very frequently found *in*, or *on the same floor with* the scouring-house, is a block of sandstone, in the form of a parallelopipedon, between 2 and 3 feet long, and 9 or 10 inches broad, the upper face of which is kept as near as possible a perfect plane; this stone is fixed at a convenient height on a strong trussel, and is called the *rub-stone*, because here the workman *rubs* or sharpens his knives and other tools. In some large establishments where the premises and water are heated by steam, the scouring-house will be found with a service of pipe leading to the various vats, and the boiler for generating the steam may be conveniently placed in or near this part of the building.

The floor above the scouring-house, in the arrangement here laid down, is what is specially designated *the shop*. The furniture in this department consists of a *beam* (*fig.* 1364), on which the leather is *shaved*. It consists of a heavy block of wood, on which the workman stands, and into one end of which a stiff piece of wood is firmly mortised, at an angle of about 85°; this upright (so called) is about a foot wide, the height being greater or less, according to the height of the workman, each of whom has his beam adjusted to meet his convenience. On the front of the *upright* a piece of deal is firmly screwed, to which is glued a face or plate of *lignum vitæ*, worked to perfect smoothness to agree with the edge of the knife used in the operation of shaving. It is of the greatest importance to the workman, to keep his *skin* from injury, that this knife and beam should be kept in good order. A *table* or *tables*, generally of mahogany, large planks of which are used for the purpose to avoid joints, may be said to form a necessary part of the furniture of this department. These tables are firmly fixed, to resist the pressure of the workman when using various tools; and as light is of the greatest consequence in the operations performed on them, they are usually placed so as to have windows in front of them. A high *trussel* is frequently used, across which the leather is thrown, after undergoing any of the processes, while the currier subjects other pieces to the same operation.

1364



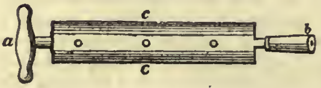
Another part of the premises is termed the *drying-loft*. In good buildings the drying-loft is surrounded with *weather-boards*, constructed to be opened or closed as may be required. The use of this part being the drying of the leather, the ceiling is furnished with a number of rails or long pieces of wood, with hooks or nails on which to hang the leather for drying; and where steam is used for this purpose, the floor is traversed with pipes for heating the *loft*. Here also is a table, similar to that previously described; it should not be less than 7 or 8 feet long by 4½ broad, if possible, without joint, and with a smooth face.

There are other subordinate departments, each furnished with a *table* similar to those described.

Of the tools used in currying, the *knife* stands first in importance (*fig.* 1365). Here *a* and *b* are two handles, *a* is held in the left hand, and forms a powerful lever when the edge *c* is applied to the leather. The blade of the currier's knife is peculiarly *tempered*; it is composed of a plate of fine steel, strongly riveted between two plates of iron. This instrument is taken to the *rub-stone*, and ground to a perfectly sharp edge by successively rubbing forward and backward; care being taken to keep the edge *true*, that is, *straight*. When this has been satisfactorily accomplished, it is still further rubbed on a fine Scotch or Welsh stone, called a *clearing-stone*, until the scratches of the *rub-stone* disappear.

In this operation a fine thread or *wire* forms on the edges, for the knife has two edges, *c*, *c*, which must be carefully got rid of; after which it is wiped dry, and the edges greased with tallow or oil. The workman then takes a strong steel, and placing himself on his knees, he fixes the knife with the straight handle *b* against any firm body, and the cross handle *a* between his knees; then holding the steel in both hands, he carefully rubs it forward and backward the whole length of the edge. During this operation the knife is gradually raised by means of the handle *a*, until it is nearly perpendicular; by this means the edge is turned completely over. If the knife is not well tempered, the edge thus obtained will be irregular or broken; in either of which cases, it is of no use whatever.

1365



1366

1367

1368

1369

To keep the instrument just described in proper order requires great skill on the part of the currier. The edge is so delicate and liable to injury that it cannot be used more than a minute or two without losing its keenness. To restore this a very carefully prepared small steel is used, *fig.* 1366; the point of the steel is first run along the groove which is formed by turning the edge over, and the steel is then made to pass outside the edge (*fig.* 1367). It is remarkable that a skilful hand can thus restore the efficiency of the knife, and keep it in work for hours without going for a new edge to the *rub-stone*. The other tools will be described as their uses are mentioned.

The first thing done by the currier is the soaking of the leather received from the tanner in water; the skin requires a thorough wetting, but not to saturation. In some cases the thicker parts are partially soaked before the immersion of the whole, and when, from the nature of the skin, this cannot be done, water is applied to the stout parts after the dipping; it is requisite that the whole should be as nearly as possible equally wet. In some instances the wetted leather is beaten, and sometimes a coarse graining-board (hereafter to be described) is used, to make it more supple previous to shaving it. The skin is then laid over the beam (*fig.* 1368), and the rough fleshy portion is shaved off. This operation is generally called *skiving*. In all the operations at the *beam* the leather is kept in its place by pressure of the knees or body of the workman from behind. In *skiving* the right-hand handle of the knife somewhat precedes the left, but in *shaving*, properly so called, the left-hand precedes the right, *fig.* 1369. In *skiving* the knife is driven obliquely a few inches at a time; in *shaving* it is driven with great force, not unfrequently from the top to the bottom of the beam; great skill is requisite in the performance of these operations, to guide the knife and to keep its edge. The carpenter's plane can be most completely regulated by the projection of the plane iron from the wood, but the currier's knife admits of no such arrangement, and the unskilful currier is constantly liable to injure the leather by cutting through it, as well as by failing to produce a regular substance. The kind of skin, and the use for which it is designed, will regulate the work at the beam. In some cases, as in the calf-skin, it is skived and then shaved, or, as it is called, *flattened* at right angles to the skiving—in other kinds, as the cow-hide prepared for the upper leather of heavy shoes, after skiving it is *shaved across* (*i. e.* nearly at right angles to the skiving), and *flattened* by being again shaved in the same direction as the skiving. In some manufactories there are certain kinds of leather which are subjected to the operation called by curriers *stoning* before *flattening*: this is done by forcibly driving the stock-stone (*fig.* 1370) over the *grain* side of the leather, thereby stretching it, and rendering the grain smooth. The *flattening* process is considerably facilitated by this stoning; and if the skin has been allowed slightly to harden by exposure to air, and the edge of the knife is fine, as it should be, the workman has but to strike the flat part of the knife over the leather after the shaving is performed, to produce a beautiful face to the flesh side of the skin. It will not be difficult to understand that a good hand is easily distinguished from an inferior one in this part of the business. With such nicety will a skilful workman set the edge of his knife, that although there seems nothing to guide him, he can take shaving after shaving from the hide extending from the top to the bottom of the beam, thus rendering the leather extremely even in its substance.

1370

1371

After the process of shaving is completed, the leather is placed in water, where it remains until it is convenient to carry on the operation next required. It is to be observed that in the condition in which leather is shaved, it cannot long be kept without becoming heated; when, however, it is put into water, it is safe from injury, and may be kept a very long time, provided the water be occasionally changed for a fresh, sweet supply; stale water is regarded as injurious for the skin to remain in.

Scouring is next proceeded with; the skin is taken out of the water, and laid on the scouring-stone. In respectable manufactories, it is usual first to *scour on the flesh*; this is done by passing a *slicker* smartly over the flesh side, by which the *grain* of the leather is brought into close contact with the scouring-stone, and, being in a wet condition, the air is easily excluded, so that the leather *sticks* to the stone. A plentiful supply of water is now applied, and a large brush, with stiff hairs, is rubbed over the flesh, or upper side. Portions of the surface, in a pulpy condition, come off with the scrubbing, and the skin presents a soft, whitened and pulpy appearance; the pores are rendered capable of containing more moisture, and, altogether, the leather is much benefited. The *slicker* is a plate of iron or steel, or for particular purposes, of brass or copper; it is about five inches long, and like the *stock-stone*, is fixed in a stock, or handle (*fig.* 1371). It is sharpened at the *rub-stone*, by grinding the plate perpendicularly, and then on either side, thus producing two edges (or, rather, *right angles*). The edges thus produced are not of an order to cut the leather, but rather to *scrape* it. The *slicker* is not intended to remove irregularities in the leather; but its uses are various, and it may be considered a very important tool, as will hereafter appear.

In the process of *tanning*, the grain side of the hide or skin becomes covered with a whitish body, derived from the bark called *bloom*; this is more or less difficult to remove according to the hardness or softness of the water used in tanning, and the peculiar treatment of the tanner. It is, however, the currier's business to remove it, which he effects thus:—In the case of leather whose grain is *tender*, as *cordovan*, which is manufactured from horse-hides, the grain being kept uppermost, the leather is spread on the scouring-stone, and being plentifully supplied with water, is stretched by using the slicker, or a fine pebble, ground to the shape of the stock-stone, the *bloom* is thus loosened, and at the same time, by making it adhere to the scouring-stone, the next operation is readily carried on, which consists in smartly brushing the grain with a stiff-haired brush, and at the same time keeping a quantity of water on the surface, the slicker is again used to remove the water and loosened *bloom*, and the scouring is complete. In the scouring of calf-skins, and cow- or ox-hides, the stock-stone is used to fix the leather, and a piece of pumice-stone, the face of which has been ground to smoothness, and afterwards cut in grooves, is then forcibly rubbed over the grain, in order to remove the *bloom*. In this, as in other operations on the scouring-stone, *water* is a necessary ingredient. The *bloom* being sufficiently loosened by the pumice-stone, the *brush* is used to scrub up the remaining dirt, which is then removed by the stock-stone or slicker. In harness leather, which is stout, and requires to be stretched as much as possible, the pumice-stone is seldom used, the stock-stone and scouring-brush being lustily applied until the bloom is sufficiently removed. Ordinary manufacturers within the present (nineteenth) century have considered the operations of the *scouring-house* complete at this point. The modern currier takes a different view, and not unfrequently detains his *scoured* property for days, and sometimes for weeks, in the *scouring-house*.

If the leather is imperfectly tanned, or it is required to be made of a bright colour, there are other processes to be passed through. In these cases sumach (an evergreen shrub of the natural order *Anacardiaceæ*, genus *Rhus*, and from the bark of which all the leather made in Turkey is said to be tanned) is infused in boiling water, and when cooled to a tepid state the leather is placed in it. After staying a sufficient time it is taken to the scouring-stone; if *cordovan*, it is slicked as dry as can be well accomplished on the *flesh* side; other leather is for the most part slicked in a similar way on the grain side. Saddle leather, which is required to be of a bright colour, is still further placed in warm water slightly acidulated with sulphuric or oxalic acid, or both; here for a time it is kept in motion, then taken to the scouring-stone, it is washed with peculiar chemical lotions, according to the taste or knowledge of the workman; then again it is dipped in tepid sumach infusion, then slicked with a copper or brass slicker (iron is liable to stain leather thus prepared), and a thin coat of oil being applied to either side, it is removed to the *drying-loft*. Until within a very few years much time and trouble were taken to produce *very bright* leather for the saddler; but of late brown-coloured leather has been adopted to a considerable extent, as it is less liable to become soiled. Nearly all leather is placed a short time in the *loft* before further manipulations are carried on, in order to harden it slightly by drying.

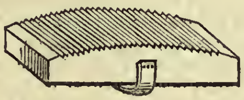
In the drying-loft, or its immediate vicinity, the leather receives the *dubbing* (*daubing*, probably) or *stuffing*. The substance so called is composed of tallow, brought to a soft plastic condition by being melted and mixed with *cod-liver oil*; occasionally *sod* (an oil made in preparing sheep-skins) is, in very small quantities, added to the mixture. This is laid upon the leather either with a soft-haired brush or a mop made generally of rags.

The leather is prepared for stuffing by wetting slightly such parts as have become too dry. It is then taken to the table previously described, which, being slightly oiled, the process is carried on by placing the skin on the table in the manner most convenient for stretching it and making the surface smooth. In those kinds that have a rough wrinkled grain the flesh side is placed next the table, and the *stock-stone* is used very smartly to stretch and smooth the grain. A kind of *clamp* or *hold-fast*, composed of two cheeks fastened with a screw, is sometimes used to prevent the leather from moving during this operation, but in general these are not required; the slicker is then applied to remove the marks left by the *stock-stone*, and a thin stuffing being spread over the grain it is turned over, slicked on the flesh lightly, a coat of *stuffing* is spread over it, and it is hung up to dry. In those kinds which have to be blacked (or stained) on the *grain*, a little *cod-oil* only is spread on the grain, and the slicker is applied on the flesh side most laboriously previous to *stuffing*. Much skill is required to give the requisite quantity of *stuff* (dubbing) to the leather without excess, excess being injurious, and the quantity required is further regulated by the freshness or otherwise of the leather, the tan-yard from which it comes, and the treatment it has received in the scouring-house.

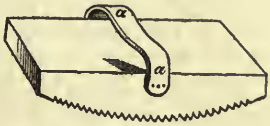
When dry, the skins or hides are folded together, to remain until required. It is certain the leather improves by remaining some weeks in this condition. It should be observed that, in drying, the leather absorbs a large quantity of the oleaginous matter with which it is charged, and the unabsorbed portion forms a thick coating of hardened greasy matter on the flesh side.

Leather which has to be blackened on the flesh (*wax-leather*), from this point, receives different treatment from *grain*-leather. *Wax*-leather is taken to the *shop-table* and softened with a *graining-board*. The skin is laid on the table and doubled, grain to grain, the *graining-board* (*fig.* 1373), which is confined to the hand by a leather strap (*a a*), is driven forward and drawn back alternately until a grain is raised on the

1372



1373



leather, and it has attained the required suppleness. Observe, the graining-board is slightly rounded on the lower surface, and traversed by parallel grooves from side to side, which are coarser or finer, as occasion requires. The grease is next removed from the flesh by the slicker. and afterwards a sharp slicker is passed over the grain to remove grease or other accumulations from it. The next process is called *whitening*. The leather is laid over the *beam*, and a *knife* with an extremely fine edge is used to take a thin shaving from the flesh side; this is a point at which a currier's skill is tested. The knife used is one that has been very much worn, the quality of which has been tested to the utmost; and so extremely *true* is the edge expected, that not the slightest mark (*scratch*) is allowed to appear on the surface of the leather. Only a good workman can satisfactorily accomplish this. The slightest gravel in the flesh of the skin may break the edge of the knife in pieces, and it is not easy to rectify so serious a misfortune; besides, a poor workman may turn up the edge by *steeling*, an operation which ought to mend the mischief instead of provoking it.

A fine *graining-board* is next used to soften the leather; the stiffer parts being *boarded* both on the grain and flesh sides, and the operation being carried on in two or three directions, to insure both softness and regularity of grain. *Boarding* is performed by doubling the leather and driving the double part forward and drawing it backward by the graining-board.

The leather is now prepared for the *waxer*, and passes, consequently, into his hands. Waxing, in large establishments, is a branch considered separate from the general business, and is usually in the hands of a person who confines himself to this occupation alone. The skin is laid on the table, and the *colour* rubbed into the flesh side with a brush. It is necessary to give the brush a kind of circular motion to insure the required blackness in the leather. The *colour* is made by stirring a quantity of the best lampblack into *cod-liver-oil*; sometimes a little *dubbing* is added, and in order to make it work smoothly so as not to clog the brush, some stale *tan-water* from the vats in the scouring-house is *beaten up* with the mixture until it combines therewith. The preparation of the *colour* is an important affair, and requires a considerable amount of time and labour to render it such as the *waxer* desires.

A *slick-stone*, or *glass*, is next used; this tool is about the size and shape of the slicker, but instead of being ground like it, the edges are very carefully removed, so that while, from end to end, it preserves nearly a right line, it is circular *across* the edge. The *stone* (a fine pebble) is little used now, plate-glass being substituted for it. The use of the tool just described is to smooth the flesh after the operation by the colouring brush, thereby getting rid of any marks made on the surface.

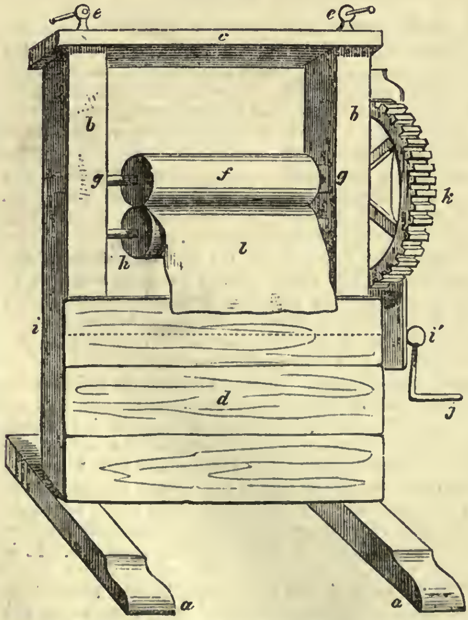
The next step in waxing is what is called *sizing*. Size is prepared by boiling glue in water; the melted glue is diluted with water to the extent required, and in some cases it is softened by mixing *cod-liver oil* with it in cooling. When cold, it is beaten up with various ingredients, according to the taste or experience of the waxer; the waxer then well rubs the size into the coloured side of the leather, and with a sponge, or, more generally, the fleshy part of his hand, smooths it off. When dry, the *slick-stone*, or *glass*, is again applied, thus producing a polish on the size; and a very thin coat of oil completes the work. In different manufactories different methods are pursued, but the above is convenient and satisfactory in almost all circumstances. It is now ready for the shoemaker.

Leather intended to be blacked on the grain is left folded up when dry after stuffing. Some years ago it was the custom to stain these kinds of leather while wet in the scouring-house, by spreading stale urine over it, and then applying a solution of *copperas* (sulphate of iron). That method is now exploded. The dry skins or pieces of leather are laid on the shop-board: a brush is used to saturate the *grain* with urine, or, as is now more common, a *solution of soda in water*, and a peculiar preparation of *iron in solution* is afterwards laid over it, which blackens the surface. It may be observed that in wax-leather a body of black is laid on, and rubbed into the flesh; in grain-leather the black is a stain. After the blackening, it is necessary to rub a small quantity of oil or *dubbing* over the blackened surface, then turning the oiled grain toward the table, a sharp slicker is used on the flesh side; the leather sticks to the table by means of the oil, and the slicker is driven so smartly over it, that it is *stretched* on the table at the same time that the grease is removed. It is quite an important point to take *all the stretch* out of the leather in this operation, after which it is turned over; the table is covered with a very thin coat of hard tallow, a roll of tallow being rubbed over the table, for the purpose of keeping the leather fastened to it. A *dull* slicker is used on the grain to remove remaining marks and wrinkles, or to smooth any coarse appearance on the grain; a sharp slicker removes all the grease, and a thin coat of weak size, made of glue dissolved in water, is spread over it, and the process, usually called *seasoning*, is completed. The next object is carefully to dry the *seasoned* leather, and in this state it may be stored without injury.

The next step is very similar to that described in the case of *wax-leather*, and called whitening:—it is then softened by means of a fine graining-board, or a board of the same shape and size covered with cork, the grain side is placed next the table, and the flesh doubled against the flesh, and thus driven forward and backward until the required degree of suppleness is obtained. The loose particles of flesh are brushed off, and a slicker carefully passed over the grain removes all *marks* of the last operation. If a sufficiency of *stuff* has not been applied in the drying-loft, the deficiency is remedied by a coat of *tallow-dubbing* now spread over the grain, and allowed to remain some hours. As the leather absorbs the oily matter, a hardened coat of grease has to be removed by the aid of the slicker. The leather is then *sized*, and a very thin coat of oil spread over the size, completes the operation.

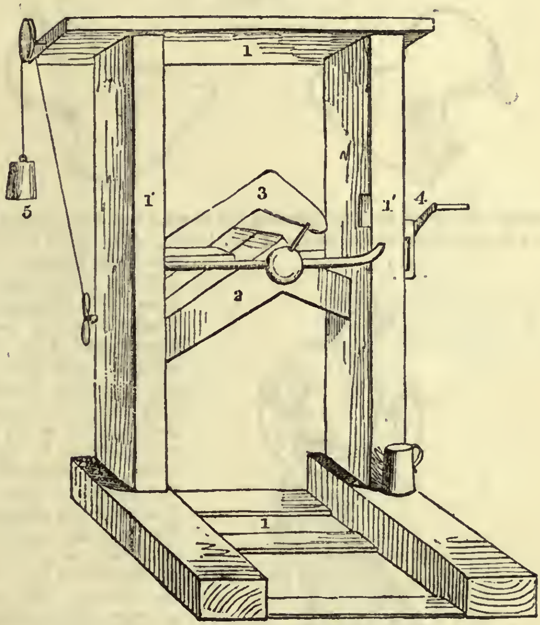
In the preparation of various kinds of leather, or of leather for particular purposes, the currier has particular appliances. *Harness-leather* is considerably dryer than other kinds before stuffing, and is subjected to immense labour by the stock-stone and slicker, to procure a smooth grain. It is blackened when dry like other *grain*-leather, but instead of the oiling and other processes described, the hardest tallow procurable is rubbed into it, *stoned* with a fine pebble, slicked, and tallow again rubbed into it by the hand. When dry after this operation, the grease is slicked from the flesh side, and a repetition of the tallowing, stoning, and rubbing finishes the work.

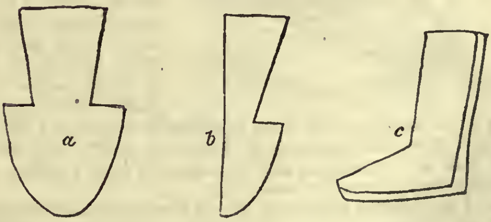
1374



Saddle-leather, which is cut into comparatively small pieces, after hardening in the drying-loft, is passed through a very different process from any described previously. The skin of the hog is much used for certain parts of hackney saddles, and the bristles, when removed by the tanner, leave indentations, or even holes in the tanned skin. Probably it was deemed desirable to obtain some imitation for the parts of the saddle where the hog-skin was not suitable. The skin of the dog-fish (*Scyllium*, Cuv.), to some extent supplied the imitation, having hard tubercles on its surface. At first the skin was laid on the leather, and lustily pressed into it by rubbing it with a pebble or plate of glass; at length a press was invented, and, more recently, various methods have been proposed to produce the best effect. We have here (*fig.* 1374) a representation of one of these presses, which may stand as a type of all others *a a* are the feet into which the uprights are inserted; *b b* are the two upright sides tied at the top by *c*, a similar cross-piece ties them a little above the feet; *d* is a leaf fastened with hinges, which closes upon *c* when the press is not in use; *e e* are screws which press on the iron plate, in which the axes of the roller *f* are inserted; these plates imbedded in the uprights *b b* have considerable play, so as to allow the rollers *f h* more or less pressure as the case may require. The dotted line *i i'*, represents an iron bar or cylinder, supplied with a small cog-wheel at *i'*, and a *crank handle j*; this is turned round by the hand, and the small cog-wheel acts on a larger one, *k*, which is attached to the axis of the roller *f*: *f* is a solid roller of hard wood, such as *lignum vitæ*; upon this cylinder is strongly glued the *fish-skin*, previously alluded to; *h* is a cylindrical solid piece of wood, covered with stout flannel; *l* is a piece of leather on which the leather to be pressed is placed; when all is adjusted, the piece to be pressed is placed on *l*, the handle is moved slowly round, and the whole is carried between the rollers; the leather thus receives the imprint of the *fish-skin*, and at the same time becomes extremely solid. After drying, this is fit for the saddler.

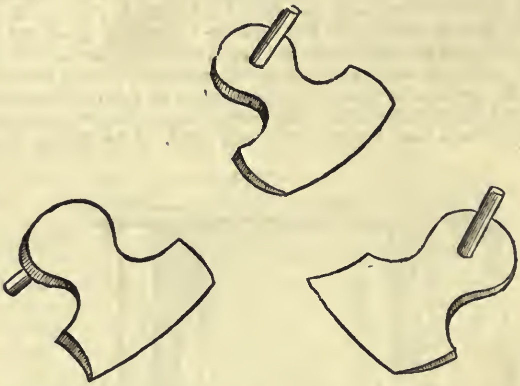
1375





Of late years the currier has undertaken an office which was previously the business of the bootmaker; namely, the *blocking* of boot fronts. This is performed by the instrument represented by *fig.* 1375. The leather is first dressed, as previously described, up to the point of being ready for *whitening*. The fronts are then cut (*fig.* 1375 *a*), and when folded or doubled appear as *fig.* 1375 *b.* 1′ 1′, 1 1, is a strong framework; 2, represents a pair of cheeks, strongly fastened in the frame, and regulated as to *distance* by a screw; these cheeks are lined with zinc; 3 is a strong plate of metal, the angle at 3 corresponding exactly with the angle of the cheeks; the ends of this plate are fixed in moveable plates passing down the columns 1′ 1′; 4 is a handle by which the instrument is worked, and which, by cog-wheels acting on the moveable plates, brings 3 downwards. The *front*, *a*, is laid, after a thorough soaking in water, over the cheeks 2, the handle being turned, 3 comes down upon the front, and

1376



forces it through the small opening between the cheeks, and when brought out below the cheeks, it has the appearance given in *fig.* 1375 *c.* The plate 3 having carried the front between the cheeks, is removed (*below*), and the weight 5 assists in bringing the perpendicular moveable plates to their place, when 3 is again put in position; and thus the operation is rapidly carried on. After this, the *fronts* are regularly placed on a *block*, being forced into position by an instrument called the *flounder* (*fig.* 1376), and *tacked* to their place; after this, they are slightly oiled and dried. Some ingenious methods have been adopted for softening the fronts, so as not to disturb the *blocking.* They are whitened on a very sloping *beam* (*fig.* 1377), which enables the workman to hold them better than he could on the common beam. They are again *blocked* by the *waxer*, and when these processes are carefully performed, much trouble is saved to the bootmaker. Of course, in a manufactory many appliances are found which are not here mentioned; the general idea, however, may be easily gathered from this description. The work is dirty and very laborious, requiring great skill and experience, and consequently good workmen have generally commanded better wages than other mechanics.

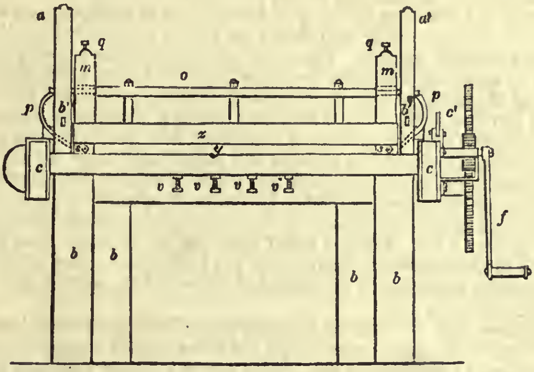
1377

Hides intended for covering coaches are shaved as thin as shoe hides, and blacked on the grain.—H. M.

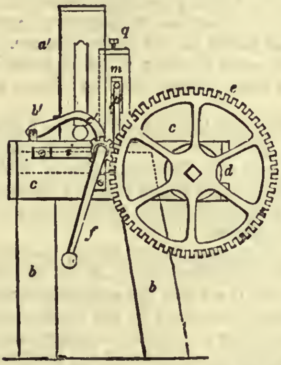
LEATHER SPLITTING. This operation is employed sometimes upon certain sorts of leather for glovers, for bookbinders, sheath-makers, and always to give a uniform thickness to the leather destined for the cotton and wool card-makers.

Figs. 1378, 1379, 1380, 1381 represent a well-contrived machine for that purpose; of which *fig.* 1378 shows the front view, *fig.* 1379 a view from the left side, *fig.* 1380 a vertical section across the machine, and *fig.* 1381 a ground plan. *a* is a strong table, furnished with four legs *b*, which to the right and left hand bears two horizontal pieces *c*. Each of these pieces is cut out in front, so as to form in its substance a half-round fork, that receives a cylinder *d*, carrying on its end a toothed spur-wheel *e*. Motion is com-

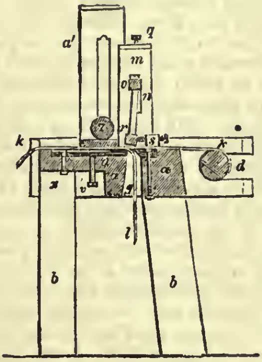
1378



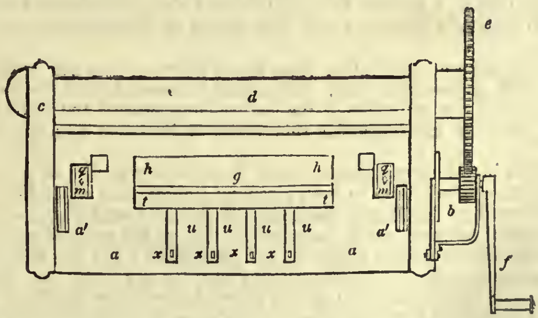
1379



1380



1381



municated to the wheel by means of the handle *f*, upon whose axis the pinion *i* is fixed, working into the wheel *d*, made fast to the end of the cylinder round which the leather is rolled. The leather is fixed at one of its ends or edges to the cylinder, either with a wedge pressed into a groove, or by a moveable segment of the cylinder itself.

The table, *a*, is cut out lengthwise with a slot, that is widened below, as shown in *fig.* 1380.

The knife *h* (*figs.* 1380 and 1381) is fixed flat upon the table with screw bolts, whose heads are countersunk into the table, and secured with taps beneath (*fig.* 1380), the edge of the knife being placed horizontally over the opening, and parallel with it.

In *fig.* 1380 the leather, *k*, is shown advancing against the knife, getting split, and has a portion coiled round the cylinder, which is made to revolve in proportion as the leather is cleft. The upper portion of the leather is rolled upon the cylinder *d*, while the under half, *l*, falls through the oblong opening upon the ground.

In regulating the thickness of the split leather, the two supports, *m*, act; they are made fast to the table *a* (one on each side of the knife), and are mortised into the table by two tenons secured beneath. These supports are furnished near their tops with keyed slots, by means of which the horizontal iron rod *o* (*figs.* 1378, 1380) is secured, and outside of the uprights they press upon the springs *p p*, which tend to raise the rod, *o*, in its two end slots; but the adjusting screws *q*, which pass down through the tops of the supports into the mortise *n* (*fig.* 1380), and press upon the upper half of the divided tenon, counteract the springs, and accordingly keep the rod *o* exactly at any desired height or level. The iron rod *o* carries another iron bar, *r*, beneath it, parallel and also rectangular, *fig.* 1380. This lower bar, which is rounded at its under face, lies upon and presses the leather by the action of two screws, which pass through two upright pieces *s* (*figs.* 1378 and 1380) made fast to the table; thus the iron bar *r* may be made to press forwards the edge of the knife, and it may be adjusted in its degree of pressure, according to the desired thickness of the leaf of split leather that passes through under it.

Fig. 1380 shows that the slant or obliquity of the knife is directed downwards, over one of the edges of the oblong opening *g*; the other edge of this opening is provided with an iron plate *t* (*figs.* 1378, 1380), which serves to guide the blade in cutting the leather to the proper depth. For this purpose the plate is made adjustible by means of the four springs *u* (*fig.* 1381) let into the table, which press it downwards. Four screws, *v*, pass down through the table, each belonging to its respective spring *u*, and by means of these screws the plate *t* may be raised in any desired degree. Each of the screws *u* has besides a small rectangular notch through which a screw bolt *x* passes, by which the spring is made fast to the table. Thus also the plate *t* may be made to approach to or recede from the knife.

y, in *figs.* 1378 and 1380, is a flat board, laid upon the leather a little behind the edge of the plate *t*; this board is pressed by the cylinder *z*, that lies upon it, and whose tenons rest in mortises cut out in the two supports *a'*. The cylinder *z* is held in its position by a wedge or pin, *b* (*figs.* 1378 and 1380), which passes through the supports. When the leather has been split, these pins are removed, and the cylinder rises then by means of two counter-weights, not shown in the figures.

The operation of the machine is as follows:—The edge or end of the leather being secured to the cylinder *d*, the leather itself having the direction upon the table shown in *fig.* 1380, and the bar *r* its proper position over the knife, the edge begins to enter in this position into the leather, while the cylinder *d* is moved by the handle or winch, and the piece gets split betwixt the blade and the roller *d*. When the other end of the leather, *k*, advances to the knife, there is, consequently, one half of the leather split; the skin is to be then rolled off the cylinder *d*; it is turned; the already split half, or the end of the leather, *k*, is made fast into the wood of the cylinder, and the other half is next split; while the knife now acts from below, in an opposite direction to what it did at first.

That the unrolling of the leather from the cylinder, *d*, may not be obstructed by the pinion *i*, the stop-wedge *e* (*figs.* 1378, 1379) is removed from the teeth. In the process of splitting, the grain side of the leather is uppermost, and is therefore cut of an uniform thickness, but the under side varies in thickness with the inequality of the skin.

Several other ingenious contrivances have been introduced for this purpose, illustrated descriptions of which have been given by Hebert, who states that a splitting-machine, long used by the Messrs. Bevington, of Bermondsey, had been made to split sheep-skins into three equal parts, one of which, that on the grain side, might be used as leather; the middle portion converted into parchment; and the slice on the flesh side, being unequal in thickness, and therefore unfit for any better use, being used for glue-making. In this machine the skin is drawn between two revolving rollers, and presented, as it emerges from their grasp, to the edge of a long and very sharp knife, which is kept continually moving a little backwards and forwards with great velocity. As a skin of unequal thickness could not be grasped in the proper manner between two perfectly true and rigid rollers, the upper roller, instead of being solid, is composed of a number of circular discs or rings of metal, about half an inch thick, slipped on to an axis rather smaller than the holes in their centres, but compelled to revolve with it by means of what may be termed a planetary axis, which is a rod passing loosely through holes in the whole series of discs between their centre and their circumference, and so connected with the axis by its ends as to be carried round with it. By this contrivance the upper roller is enabled to adapt its surface to that of the skin, which is everywhere pressed with an equal force, due to the weight of the discs of which the upper roller is composed. It is stated in the 'Penny Magazine' 'that this machine will split a sheep-skin of the ordinary size in about two minutes, during which time the knife makes from two to three thousand vibratory motions to and fro.' This machine is said to be the invention of Lieutenant Parr. Another contrivance is known as Duxbury's Patent Skin-Splitting Machine, in which the knife consists of a series of plates of steel, so attached to the periphery of a wheel or disc, seventeen feet in diameter, as to form a gigantic cutting instrument, resembling a crown or trepan saw, the compound blade projecting horizontally from the rim of the wheel parallel to its axis. The skin to be split passes round the circumference of a horizontal drum, the axis of which is at right angles with that of the great disc, and lies very nearly in the same plane with its face, and which instead of being perfectly cylindrical has its sides so hollowed as to present a concavity perfectly tallying with the curvature of the periphery of the disc. As therefore the drum revolves it brings the skin, which is confined closely to its concave surface by a contrivance somewhat resembling the upper roller in the machine above described, in contact with the edge of the revolving knife, which cuts by a continuous onward movement, instead of a sawing action backwards and forwards. The extreme nicety required to fix the concavity of the feeding roller to the edge of the circular knife, and to keep the knife or cutter itself perfectly true in shape, appear to be the chief objections to this ingenious contrivance.—*Penny Cyclopædia, Suppl.*, '*Leather.*'

Exports of leather of British produce and manufacture in 1872:—

		Total value
Tanned, unwrought	139,019 cwts.	£1,220,981
Wrought, boots and shoes	579,130 dozen pairs	1,695,248
Other articles unenumerated	1,937,604 lbs.	376,441

Imports of Leather in 1872.

		Total value
Leather, unwrought: hides not tanned, tawed, curried, or in any way dressed	808,930 cwts.	£3,063,920
Hides, wet	627,930 „	1,915,342
„ tanned, not otherwise dressed	23,574,061 lbs.	1,179,716
„ tanned, curried, but not enamelled	3,135,162 „	479,680
„ varnished, japanned, or enamelled	479,658 „	123,098

Imports of leather manufactured, &c., in 1872:—

		Value
Boots and shoes	46,139 dozen pairs	£151,218
Gloves	1,052,717 „	1,403,622
Unenumerated	— „	139,209

LEATHER-CLOTH. Under the name of *American Leather-cloth*, an enamelled oil-cloth has been introduced. Much of it possessed great elasticity, and resembled the vegetable leather described in the next article. The trade has, however, rapidly declined, as will be seen by the following table of *imports* of this material:—

	yards	value
1854	631,304	£38,210
1855	565,395	42,405
1856	507,326	38,069
1858	174,573	13,094
1860	151,969	11,398
1861	127,051	9,528

The recent importations of leather-cloth are not obtainable.

LEATHER, VEGETABLE. Under this name a new material, composed of india-rubber spread upon linen, has been introduced. Of this the 'Mechanics' Magazine' writes:—'Having seen some specimens of these leathers, as well as various articles of utility manufactured therewith, we have been induced to pay the extensive works of Messrs. Spill and Co., the eminent Government contractors, on Stepney Green, a visit, in order to cull sufficient to place upon record the present position of artificial as a substitute for real leather. The face and general character of the vegetable leather resembles the natural product so closely, that it is only by actual examination that the difference can be determined. This is more particularly the case in that description which is made for bookbinding, the covering of library tables, and like purposes.

Amongst other advantages it possesses over leather proper, may be mentioned, that however thin the imitation is, it will not tear without considerable force is exercised; that it resists all damp, and that moisture may be left upon it for any period without injury, consequently, it does not sodden or cockle, is always dry, and its polish is rather increased than diminished by friction. Add to these facts, that any attempt to scratch or raise its surface with the nail, or by contact with any ordinary substance, will not abrade it, and enough will have been said to justify its entering the list against an article of daily use, which has of late years been deemed far from sufficient for the demand, and has consequently risen in price to the manifest loss and injury of every class of the community. We believe that the largest entire piece of real leather that can be cut from a bullock's hide, is not more than 7 feet by 5 feet, and this includes the stomach and other inferior parts. Vegetable leather, on the contrary, is now produced 50 yards in length and 1½ yard wide, every portion being of equal and of any required thickness, and the smallest portion is convertible. We were agreeably disappointed, however, to find that instead of vegetable leather being a discovery requiring the aid of ourselves and contemporaries, it was, although so young, an active agent in the fabrication of numerous articles of daily requirement, and that it had already become the subject of large, indeed we may say enormous, contracts. Caoutchouc and naphtha are used in its manufacture; but by a process known to the senior of the firm, who is himself an accomplished chemist, all odour is removed from the naphtha, and the smell of vegetable leather is rendered thereby less in strength, if anything, than that of leather. The principal objects to which it is at present applied, although it is obvious it will take a wider range of usefulness than leather itself, are carriage and horse aprons, antigropola, soldiers' belts, buckets which pack flat, harness of every description, bookbinding, &c. For, the latter, its toughness, washable quality and resistance to stains, render it remarkably fitted. Its thickness, which may be carried to any extent, is obtained by additional backings of linen, &c., cemented with the caoutchouc, and its strength is something marvellous, while in the all-important commercial view, it is but one-third the price of leather. Many of the articles we were shown possessed the appearance of much elegance and finish; but it was curious to observe, that although most of them could be made without a stitch, and within the factory itself, a deference to the feelings of the workmen in the several trades has been shown by the firm, and the material is given out as ordinary leather, to undergo the process of the needle, which it submits to with a greater facility than its original prototype.'

LEAVEN. Under BREAD, the employment of yeast is fully explained. A few particulars relative to the French leaven may not, however, be out of place.

In Paris, where bread-making has been brought to a high degree of perfection, the fermentation is produced chiefly by the gluten of the dough, yeast being used merely to facilitate the action. A lump of dough remaining from the last batch of bread, and consisting of 8 lbs. flour and 4 lbs. of water, is left to itself for ten hours: in this state it is called *fresh leaven* (*levain de chef*). By kneading this with another quantity of 8 lbs. flour and 4 lbs. water, the *once revived leaven* (*levain de première*) is obtained. After another interval of eight hours, 16 lbs. of flour and 8 lbs. water are added, forming the *twice revived leaven* (*levain de seconde*); and after three hours more 100 lbs. flour and 52 lbs. water, containing ¼ to ½ lb. beer-yeast are added, forming the finished leaven (*levain de tout point*). The 200 lbs. leaven thus obtained are mixed after two hours with 132 lbs. flour and 68 lbs. water containing ½ lb. of yeast in suspension, and 2 lbs. common salt dissolved. This quantity of dough serves for five or six bakings. For the first baking half the dough (200 lbs.) is made into loaves of the required size and form, which are exposed for a while in shallow baskets to a temperature of 25° C. (77° F.), and then transferred to the oven. The bread thus obtained has a sourish taste and dark colour. The remaining half of the dough is again mixed with 132 lbs. of flour, 70 lbs. water, ½ lb. yeast, and the requisite quantity of salt, the half of this quantity of dough is then formed into loaves, left to ferment, and baked. The same operation is repeated three times, one-half of the dough being each time mixed with 130 lbs. flour and 1½ lb. yeast, and the proper quantity of water and salt. The last stage yields the finest and whitest bread. See Watts's 'Dictionary of Chemistry.'

LECANORIC ACID. An acid obtained from a South American variety of the *Roccella tinctoria*.

LECYTHIDACEÆ. The Brazil-nut order, remarkable for the edible seeds of many of its members. The *Lecythis ollaria* is found in the forests of Brazil and Cumâna. The fruit is about the size of a child's head; and it contains numerous edible seeds. The natives, who eat the seeds, and use the case for various purposes, call the fruit 'the monkey pots.' The *L. Zapucajo* is a native of Guiana: its fruit is about the size of the above; it contains numerous seeds, larger than almonds, and of an agreeable taste. These are the 'sapucaya' nuts of the fruiterers' shops. The Brazil-nuts are the produce of the juvia tree (*Bertholletia excelsa*). See Brazil Nuts.

LEDUM PALUSTRE. This plant is employed in Russia to tan the skins of goats, calves, and sheep, into a reddish leather of an agreeable smell; as also in the preparation of the oil of birch, for making what is commonly called Russia leather.

LEER. An arched building, forming an annealing furnace, in which glass is tempered or annealed.

LEGUMINE. A name applied to vegetable casein, in allusion to its occurrence in the seeds of many of the *Leguminosæ*, or Pea and Bean family.

LEMNIAN EARTH. A yellowish-grey earth, obtained from Lemnos by the Greeks. It is very similar to fuller's earth.

LEMONS. The fruit of the *Citrus limonum*. Both the juice and the peel of the fruit are employed medicinally, and in the preparation of lemonade, See Citric Acid, and Oils, Essential.

LEMON GRASS. The *Andropogon citratum* (De Can.). This, and certain allied species, yield fragrant essential oils imported from India under the name of lemon grass and citronelle oils.

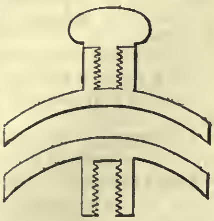
LENS. (*Lentille*, Fr.; *Linsenglas*, Ger.) Lenses are transparent bodies, usually made of glass, which by their curvature either concentrate or disperse the rays of light. Lenses are of the following kinds:—*Double convex*: having the same or a different degree of convexity on either side. *Plano-convex*, having one plane and one convex surface. *Concavo-convex*, having one concave and one convex side, commonly called *meniscus* lenses. *Plano-concave*, having one plane surface and one concave one; and the *double concave* lens.

The first three, which are thicker in the middle than at the edge, are *converging lenses*, because they occasion the rays of light to converge in passing through them. The others, which are thicker at the edges than in the middle, and therefore cause the pencils of light refracted through them to diverge, are called *diverging* lenses.

For the most complete examination of the laws regulating the construction of lenses, and the action of these on the rays of light, we must refer the reader to Sir John Herschel's admirable treatise on *Light* in the *Encyclopædia Metropolitana*. In this work we have only to deal with the mode of manufacturing the ordinary varieties. The spherical surfaces are produced by grinding them in counterpart tools, or discs of metal, prepared to the same curvature as the lenses. For the formation of the grinding tools, a concave and a convex template are first made to the radius of the curvature of the required lens. The templates of large radius are sometimes cut out of crown glass. More usually the templates are made out of sheet brass, the templates of long radii are cut with a strong radius bar and cutter, and those of only a few inches radius are cut in the turning-lathe. The brass concave and convex gauges are cut at separate operations, as it is necessary to adjust the radius to compensate for the thickness of the cutter, and the brass templates are not usually corrected by grinding, as practically it is found more convenient to fit the tools themselves together. The templates, having been made of the required radius, are used for the preparation of the grinding and polishing tools, which for concave lenses consist of a concave rough grinding-tool of cast iron, called a *shell*.

A pair of brass tools is, however, the most important part of the apparatus. One of these is concave and the other convex, made exactly to the curvature of the templates, and to fit each other as accurately as possible. The concave tool is used as the grinder for correcting the curvature of the lenses after they have been roughly figured in the concave shell, and the convex tool is employed for producing and maintaining the true form of the concave grinding-tool itself, and also that of the polisher. These polishers are adjusted with great accuracy. The concave tool is placed upon the convex, and they are first rubbed together dry, so that by the brightened parts the inequalities may be distinguished; they are then ground true, first by means of emery and water, and then with dry emery.

1382



The annexed figure (1382) represents those tools, which are fitted with screws at the back, so that they can be fixed upon pillars in connection with the machinery for giving motion to them.

By grinding with sundry niceties of motion, which are required to produce the best effect, such as the production of motion which shall resemble as nearly as possible the kind of stroke which would be given by the hand, these tools are eventually brought to true spherical figures which fit each other exactly.

The glasses for lenses, being selected of suitable quality, are brought to a circular form by means of flat pliers called *shanks*. The pressure of the pliers applied near the edges of the glass causes it to crumble away in small fragments, and this process, which is called *shanking* or nibbling, is continued until the glasses are made circular, and of a little larger diameter than the finished size of the lenses.

A cement is made by mixing wood-ashes with melted pitch. Some nicety is required in the adjustment of the proportion, since the cement must not be too adhesive, nor must it be too hard or too brittle; generally about 4 lbs. of wood-ashes to 14 lbs. of pitch are employed. This when melted is poured on one side of the glasses to be ground, in small quantities at a time, until a sufficient quantity adheres to the back of the lens to form a handle. The glass is rough ground by rubbing it within the spherical shell. The glass is rubbed with large circular strokes, and the *shell* is usually placed within a shallow tray to catch the loose emery or polishing powder which may be employed. When one side is rough ground in this way, the glass is warmed to detach it from the handle, which is transferred to the other side and the operation repeated. When both sides are thus rudely formed, the lenses are cemented upon a runner. The best object-glasses for telescopes are ground and polished singly, while as many as four dozen of common spectacle glasses are ground and polished together. When many are thus fixed on one runner, the number must be such as will admit of their being arranged symmetrically around a central lens, as 7, 13, or 21; or sometimes 4, form the nucleus, and then the numbers run 14, 30. Lenses of ordinary quality are usually ground true and polished 7 at a time. This runner with its lenses attached is shown in *fig.* 1383.

1383

The cement at the back of the lenses is first flattened with a heated iron. The cast-iron runner is heated just sufficiently to melt the cement, and carefully placed upon the cemented backs of the lenses. As soon as the cement is sufficiently softened to adhere firmly to the runner, it is coated with a wet sponge, as the cement must only be so far fused as to fill up the spaces nearly, but not quite, level with the surface of the lenses. The block of lenses is now mounted upon a post, and ground with the concave brass tool, *fig.* 1382, motion being given to it either by the hand or by machinery similar to the sweeping motion already named. As the grinding proceeds, the fineness of the emery-powder employed is increased, until in the last operation it is sufficiently fine to produce a finely-polished surface. This grinding being completed successfully, the lenses have to be polished. The polisher is made by warming a cast-iron shell, and coating it uniformly about one quarter of an inch thick with melted cement. A piece of thick woollen cloth is cut to the size of the polisher and secured to it, and pressed into form by working the brass tool within it. When this is properly adjusted it is covered with very finely-divided putty-powder, sprinkled with a little water, and the powder worked into the pores of the cloth with the brass convex tool. Repeated supplies of putty-powder are put on the polisher until it is made quite level, and it is worked smooth with the tool. Many hours are expended in the proper preparation of a polisher. When completed it is fixed upon the block of lenses still fixed to the post, and worked with wide and narrow elliptical strokes. Where a very large number of glasses are ground or polished at the same time, this peculiar motion is imitated by the excentric movement of a lever attached to the revolving shaft. In the processes of grinding and polishing, other materials beside emery and putty-powder are sometimes employed, such as *raddle*, an earthy oxide of iron, the finer kinds of which are much employed in the large lens manufactory at Sheffield.

The best account of these processes and of the instruments used is by the late Andrew Ross, in the fifty-third volume of the *Transactions of the Society of Arts*. In *Holtzapffel's Mechanical Manipulation* there is also some practical information. See PHOTOGRAPHY.

LENTILS. The seeds of *Ervum lens*, a leguminous plant, from which the flour called *Ervalenta*, or *Revalenta*, is prepared.

LEPIDINE. $C^{10}H^{9}N$ ($\mathbf{C^{5}H^{9}N}$). A volatile base, homologous with chinoline, found in coal-naphtha and in the fluid produced by distilling cinchonine with potash.

LEPIDOCROCITE. A scaly or fibrous variety of Göthite, or hydrous peroxide of iron. See IRON.

LEPIDOLITE, or *Lithia Mica*. A beautiful purple mineral, which occurs in fine masses on Mount Hradisko, near Rosna, in Moravia. It is remarkable for the large quantity of lithia which it contains, and also for its containing the newly-discovered metal rubidium. See SPECTRUM ANALYSIS.

LEPIDOMELANE. An iron-potash mica, of black colour.

LETTSOMITE. A beautiful blue velvety mineral, from the Banat, first described by Dr. J. Percy. It is a hydrous sulphate of copper, of rare occurrence.

LETTUCE. The *Lactuca sativa*, cultivated as a salad. 'Lettuce opium' is prepared from this species, and from *L. virosa*, a more highly narcotic species.

LEUCANILINE. If a solution of *rosaniline* is left in contact with metallic zinc, or treated with sulphide of ammonium, it is rapidly decomposed. The rosaniline disappears, and is transformed into a remarkable base, which has received the name of *leucaniline*, and which may be obtained in completely colourless needles scarcely soluble in water, very soluble in alcohol. Its formula is:—

$$C^{20}H^{21}N^{3}\ (\mathbf{C^{10}H^{21}N^{3}}).$$

The salts of leucaniline are also colourless, easily crystallisable, and very soluble in water, from which they may be precipitated by the addition of an excess of acid.

There exists an extremely remarkable relation between the composition of leucaniline and that of rosaniline:—

Rosaniline	$C^{20}H^{19}N^{3}$ ($\mathbf{C^{10}H^{19}N^{3}}$).
Leucaniline	$C^{20}H^{21}N^{3}$ ($\mathbf{C^{10}H^{21}N^{3}}$).

Leucaniline differs therefore from rosaniline simply by containing two atoms more of hydrogen.

The two bases bear to each other the relation which exists between blue and white indigo:—

Blue indigo	$C^{16}H^{10}N^{2}O^{2}$ ($\mathbf{C^{8}H^{10}N^{2}O}$).
White indigo	$C^{16}H^{12}N^{2}O^{2}$ ($\mathbf{C^{8}H^{12}N^{2}O}$).

Leucaniline, as might have been expected from this interesting relation, may be reconverted into the red colouring matter by oxidising agents. On gently heating the colourless solution of hydrochlorate of leucaniline with peroxide of barium, perchlorides of iron or platinum or chromate of potassium, the liquid at once re-assumes the splendid colour of the rosaniline salts. (*Hofmann.*)

LEUCITE. A mineral found in volcanic rocks, containing usually 56·10 of silica, 23·10 of alumina, and 21·15 of potash. The finest and most beautiful crystals are found in the older lavas of Vesuvius and Rocca Monfina, and in the neighbourhood of Rome. It is sometimes called the *white garnet*, from the similarity of its crystallisation to that of the common garnet. Kirwan calls it the *white garnet of Vesuvius*. It was always supposed that leucite crystallised in the cubic system until Vom Rath showed, in 1872, that the crystals belonged to the tetragonal system.

LEUCOLINE. A synonym of LEUKOL.

LEUCOPYRITE. An arsenide of iron, resembling Lölingite.

LEUKOL. See CHINOLINE.

LEVEL (*a mining term*). An adit gallery or horizontal working in a mine.

LEVIGATION is the mechanical process whereby hard substances are reduced to a very fine powder.

LEVULOSE. A kind of sugar which turns the plane of polarisation of a ray of light towards the left hand.

LEWIS is the name of one kind of shears used in cropping woollen cloth.

LIAS. Under this term are comprehended the strata which intervene between the Trias, or New Red Series, and the Inferior Oolite. In the aggregate they are of considerable thickness, and occupy a large area in this country, stretching in a north-easterly direction from the sea west of Lyme Regis, in Dorsetshire, to Redcar, on the coast of Yorkshire. The strata which compose the Liassic series consist, in the lower part, of compact argillaceous limestone, alternating with or forming *layers* in clay, to a provincial pronunciation of which word the name *lias* probably owes its origin. This limestone forms the base of a thick deposit of blue clays and marls, which are overlaid by a series of sands and sandstone, called Marlstone; these in their turn are separated from another mass of sands, which form the uppermost member of the group, by a stratum of clay, known as the Upper Lias Clay.

By the term lias, however, is ordinarily only understood the calcareous and argillaceous division, which constitutes the lower section of the entire formation.

In an economical point of view, it is of considerable value from its furnishing a useful and durable stone, both for building and paving; for the latter purpose it is particularly suited, not only from the large dimensions of the flags it affords, but on account of its occurrence in thin layers, which, in many cases, when required for rough purposes only, are used in the state in which they are taken from the quarry, without undergoing subsequent dressing. The lime furnished by the blue lias limestone is also well known, and in great request, some of the beds possessing the valuable property of forming hydraulic mortars and cements, for manufacturing which it is collected from the shore and the sea-cliffs at Charmouth, and largely quarried at Lyme Regis and the neighbourhood. See HYDRAULIC CEMENTS.

The clayey members of the lias furnish a poor and cold agricultural soil, which is chiefly devoted to pasture, but the land upon the marlstone is, on the contrary, of a very rich and fertile description, and constitutes a district, where it prevails, that is marked by the luxuriance of its crops and the excellence of the cider it produces. In the upper part, it contains beds of ferruginous, brown, calcareous sandstone, which is used for building purposes in the neighbourhoods where it occurs. The sandstone is always more or less of a ferruginous character, but in some instances the ferruginous ingredient prevails to such a degree, as to constitute a valuable ore of iron, as in the neighbourhood of Blenheim, to which attention has been directed by Mr. Edward Hull, of the Geological Survey.

Like the marlstone, the calcareous sands of the uppermost portion of the liassic series also furnish a rich agricultural soil. Until recently, these sands were considered to form the base of the inferior oolite series, but the researches of Dr. Wright render it highly probable that they should, with more propriety, be classed with the underlying lias, rather than with the oolitic strata.[1]

The stone found at Cotham and other places in the neighbourhood of Bristol, and which has in consequence received the name of *Cotham marble*, and has also been called *ruin*, or *landscape marble*, from the curious delineations displayed upon polished sections of it, resembling trees, landscapes, &c., is a limestone from the lower part of the lias.—H. W. B.

LIBAVIUS, FUMING LIQUOR OF, is the bichloride of tin, prepared by dissolving that metal with the aid of heat in *aqua regia*, or by passing chlorine gas through a solution of muriate of tin till no more gas be absorbed, evaporating the solution, and setting it aside to crystallise. The anhydrous bichloride is best prepared by mixing four parts of corrosive sublimate with one part of tin, previously amalgamated with just so much mercury as to render it pulverisable; and by distilling this mixture with a gentle heat, a colourless fluid, the dry bichloride of tin, or the proper fuming liquor of Libavius, comes over. When it is mixed with one-third of its weight of water it becomes solid. The first bichloride of tin is used in calico-printing. See CALICO-PRINTING.

LIBETHENITE. A hydrous phosphate of copper, named from one of its localities —Libethen, near Neusohl, in Hungary.

LICHEN. A certain set of plants, composed chiefly of cellular tissue devoid of spiral vessels, with the stems and leaves undistinguishable, are termed Thallogens. These are of two kinds, the first admitting of two divisions:—

1. *Aquatic* thallogens, or such as are nourished through their whole surface by water, are ALGÆ. *Aërial* thallogens nourished through their whole surface by air are LICHENS.

2. Thallogens nourished through their *thallus* (spawn or mycelium) by juices derived from the matrix are FUNGI.

Lichens are numerous, as *Ground liverwort*, *Cup moss*, and *Tree lungwort*, used in Siberia as a substitute for hops in brewing; *Gyrophora*, employed by the hunters in the arctic regions as an article of food, under the name of *tripe de roche*; *Reindeer moss*, and *Iceland moss*, much used in this country as a remedy for coughs; the *Common yellow wall lichen*, and some others.

The *Tinctorial lichens* are also numerous. They furnish four principal colours, brown, yellow, purple, and blue.

Gyrophora pustulata and *Sticta pulmonaria* yield brown colours. The latter, with mordants of tin and cream of tartar, produces on silk a durable carmelite colour. (*Guibourt.*)

Parmelia parietina and *Evernia vulpina* produce yellows; the yellow principle of the former being called *chrysophanic acid*, that of the latter *vulpinic acid*.

[1] The evidence brought forward by Dr. Wright in favour of the liassic origin of these sands is purely of a palæontological nature; physically, the most natural arrangement is to connect them rather with the inferior oolite than with the lias.—H. W. B.

Rocoella, Lecanora, Variolaria, &c., yield purple and blue colours. In this country archil and cudbear, purple colours, are prepared from it. In Holland, a blue colour, litmus.

Dr. Stenhouse, to whom we are much indebted for many important inquiries connected with the applications of chemistry, has given the following table of the lichens:—

Lichens		Colorific Principles		Colouring Principles		Authority
Commercial Names	Locality	Names	Formulæ	Names	Formulæ	
S. American orchella weed	Lima, &c.	Alpha orsellic acid	$C^{32}H^{15}O^{13}+HO$	Orceine	$C^{18}H^{10}NO$	Stenhouse
Cape orchella weed	C. of Good Hope	Beta orsellic acid	$C^{34}H^{18}O^{14}+HO$	„	„	Stenhouse
Angola orchella weed	Africa	Erythric acid	$C^{20}H^{10}O^{9}+HO$	„	„	Stenhouse
Perelle moss (*Lecanora parella*)	Switzerland	Lecanoric acid	$C^{18}H^{8}O^{8}$	„	„	Shunck
Tartareous moss (*Lecanora tartarea*)	Norway	Gyrophoric acid	$C^{36}H^{18}O^{15}$	„	„	Stenhouse
Pustulatous moss (*Gyrophora pustulata*)	Norway	„	„	„	„	Stenhouse
Ragged hoary lichen (*Evernia prunastri*)	Scotland	Evernic acid	$C^{34}H^{15}O^{13}+HO$	..	..	Stenhonse
Usnea (*Florida, plicata*, and *nirta*)	Germany	Usnic acid	$C^{38}H^{7}O^{14}$	..	..	Rochleder and Heldt
Reindeer moss (*Cladonia rangiferina*)	..	„	„	..	..	„
Ramalina (*Fastigiata calicaris*)	..	„	„	..	..	„

See Archil; French Purple; Litmus; Orchella Weed.

LICKNER'S BLUE. The silicate of cobalt and potash.

LIEBIGITE. A hydrous carbonate of uranium and lime, named after the late Baron Liebig.

LIEVRITE. A silicate of iron, known as *Ilvaite* and *Jenite*.

LIGHT. (*Lumière*, Fr.; *Licht*, Ger.) The operation of light as an agent in the arts or manufactures has scarcely yet received attention. Sufficient evidence has, however, been collected to show that it is of the utmost importance in producing many of the remarkable changes in bodies which are desired in some cases as the result, but which in others are to be, if possible, avoided.

There is a very general misconception as to the power or principle to which certain phenomena, the result of exposure to sunshine, are to be referred. In general *light* is regarded as the principle in action, whereas frequently it has nothing whatever to do with the change. A few words therefore in explanation are necessary. The solar ray, commonly spoken of as *light*, contains, in addition to its *luminous power, calorific power, chemical power*, and, in all probability, *electrical power*. (See Actinism.) These phenomena can be separated one from the other, and individually studied. All the photographic phenomena are dependent upon the chemical (actinic) power. Many of the peculiar changes which are effected in organic bodies are evidently due to *light*, and the phenomena which depend entirely on heat are well known.

Herschel has directed attention to some of the most striking phenomena of *light*, especially its action upon vegetable colours. As these have direct reference to the permanence of dyes, they are deserving of great attention. The following quotation from Sir John Herschel's paper 'On the Chemical Action of the Rays of the Solar Spectrum, &c.,' will explain his views and give the character of the phenomena which he has studied. He writes:—

'The evidence we have obtained by the foregoing experiments of the existence of chemical actions of very different and, to a certain extent, opposite characters at the opposite extremities (or rather, as we ought to express it, in the opposite regions) of the spectrum, will naturally give rise to many interesting speculations and conclusions, of which those I am about to state will probably not be regarded as among the least so. We all know that colours of vegetable origin are usually considered to be destroyed and whitened by the continual action of light. The process, however, is too slow to be made the subject of any satisfactory series of experiments, and, in consequence, this subject, so interesting to the painter, the dyer, and the general artist, has been allowed to remain uninvestigated. As soon, however, as these evidences of a counterbalance of mutually opposing actions, in the elements of which the solar light consists, offered themselves to view, it occurred to me, as a reasonable subject of inquiry, whether this slow destruction of vegetable tints might not be due to the feeble amount of residual action outstanding after imperfect mutual compensation, in the ordinary way in which such colours are presented to light, *i.e.* to mixed rays. It appeared therefore to merit inquiry, whether such colours, subjected to the uncompensated action of the elementary rays of the spectrum, might not undergo changes differing both in kind and in degree which mixed light produces on them, and might not, moreover, by such changes indicate chemical properties in the rays themselves hitherto unknown.

'One of the most intense and beautiful of the vegetable blues is that yielded by the blue petals of the dark velvety varieties of the common heartsease (*Viola tricolor*). It is best extracted by alcohol. The alcoholic tincture so obtained, after a few days keeping in a stoppered phial, loses its fine blue colour, and changes to a pallid brownish red, like that of port wine discoloured by age.

'When spread on paper it hardly tinges it at first, and might be supposed to have lost all colouring virtue, but that a few drops of very dilute sulphuric acid sprinkled over it, indicate by the beautiful and intense rose colour developed where they fall, the continued existence of the colouring principle. As the paper so moistened with the tincture dries, however, the original blue colour begins to appear, and when quite dry is full and rich. The tincture by long keeping loses this quality, and does not seem capable of being restored. But the paper preserves its colour well, and is even rather remarkable among vegetable colours for its permanence in the dark or in common daylight.

'A paper so tinged of a very fine and full blue colour, was exposed to the solar spectrum concentrated, as usual (October 11, 1839), by a prism and lens; a water-prism, however, was used in the experiment, to command as large an area of sunbeam as possible. The sun was poor and desultory; nevertheless, in half an hour there was an evident commencement of whitening from the fiducial yellow ray to the mean red. In two hours and a half, the sunshine continuing very much interrupted by clouds, the effect was marked by a considerable white patch extending from the extreme red to the end of the violet ray, but not traceable beyond that limit. Its commencement and termination were, however, very feeble, graduating off insensibly; but at the maximum, which occurred a little below the fiducial point (corresponding nearly with the orange rays of the luminous spectrum), the blue colour was completely discharged. Beyond the violet there was no indication of increase of colour, or of any other action. I do not find that this paper is discoloured by mere radiant heat unaccompanied with light.'

The late Dr. George Wilson of Edinburgh made some exceedingly interesting experiments *on the influence of sun light over the action of dry gases on organic colours.* The results arrived at were communicated to the British Association, and an abstract of the communication is published in their Transactions. The experiments were on chlorine, sulphurous acid, sulphuretted hydrogen, carbonic acid, and a mixture of sulphurous and carbonic acid, oxygen, hydrogen and nitrogen on organic colouring matters. 'I had ascertained,' says Dr. George Wilson, 'the action of the gases mentioned already on vegetable colouring matters, so arranged, that both colouring matter and gas should be as dry as possible, the aim of the inquiry being to elucidate the theory of bleaching, by accounting for the action of dry chlorine upon dry colours. In the course of this inquiry, I ascertained that in darkness dry chlorine may be kept for three years in contact with colours without bleaching them, although when moist it destroys their tints in a few seconds (see Bleaching); and I thought it desirable to ascertain whether dry chlorine was equally powerless as a bleacher when assisted by sunlight. The general result of the inquiry was, that a few weeks sufficed for the bleaching of a body by chlorine in sunlight, where months, I may even say years, would not avail in darkness.' The form of the experiment was as follows:—Four tubes were connected together so as to form a continuous canal, through which a current of gas could be sent. Each tube contained a small glass rod, on which seven pieces of differently-coloured papers were spiked. It is not necessary here to state the colours employed, suffice it to say, that all the tubes thus contained seven different coloured papers, of different origins, and easily distinguishable by the eye. They were arranged in the same order in each tube, and were prepared as nearly as possible of the same shade. These papers were carefully deprived of every trace of moisture by a current of very dry air. The tubes were then filled with the gas, also dried, on which the experiment was to be made. One tube of each series was kept in darkness, two others were exposed in a western aspect behind glass, and the other was turned to the south in the open air.

The results were as follow:—In the dark chlorine tube the colours were very little altered, and would probably have been altered less had not the tube been frequently exposed to light for the sake of examination. In the western tube, the original grey and green wallflower papers became of a bright crimson, the blue litmus bright red, and the brown rhubarb yellow. The whole of the chlorine had apparently entered into combination with the colouring matters, for the yellow tint of the gas had totally disappeared. In the southern tube the colour of the chlorine could still be seen, the reddening action was less decided, and the bleaching action was more powerfully evinced. The general result was that the action of sunlight is less uniform than might have been expected in increasing the bleaching power of chlorine, or while some tints rapidly disappeared under its action assisted by light, other colours remained, in apparently the very same circumstances, unaffected.

Sulphurous acid, if thoroughly dried, may be kept for months in contact with dry colours without altering them; under the influence of sunlight it however recovers to some extent its bleaching power.

Sulphuretted hydrogen acts as a weak acid, and readily as a bleacher when moist, and becomes inactive in both respects if made dry and kept in darkness. With the assistance of sunlight it recovers in no inconsiderable degree its bleaching power.

Oxygen is a well-known bleaching agent, but when dry its action upon colouring matter in the dark is extremely slow. In sunlight, however, it recovers its bleaching power.

Carbonic acid, when dry in darkness, loses all power on colouring matter, but a faint bleaching action is exerted by it under exposure to sunlight.

Hydrogen is without any action when dry upon colours, but it acquires a slight decolorising power when exposed to sunshine.

'The general result,' concludes Dr. George Wilson, 'of this inquiry, so far as it has yet proceeded, is, that the bleaching gases, viz. chlorine, sulphurous acid, sulphuretted hydrogen, and oxygen, lose nearly all their bleaching power, if dry and in darkness, but all recover it, and chlorine in a most marked degree, by exposure to sunlight.'

All these experiments appear to show that the action of the solar rays on vegetable colours is dependent upon the power possessed by one set of rays to aid in the oxidation or chemical changes of the organic compound constituting the colouring matter. The whole matter requires careful investigation.

It is a proved fact, that colouring matters, either from the mineral or the vegetable kingdoms, are much brighter when they are precipitated from their solutions in bright sunshine, than if precipitated on a cloudy day or in the dark. It must not be supposed that all the changes observed are due to chemical action; there can be no doubt but many are purely physical phenomena, that is, the result of molecular change, without any chemical disturbance.

LIGHT CARBURETTED HYDROGEN. Marsh-gas or fire-damp.

LIGHT, ELECTRIC. See ELECTRIC LIGHT.

LIGHTHOUSE. The importance of lights of great power and of a distinguishable character around our coasts is admitted by all. One of the noblest efforts of humanity is certainly the construction of those guides to the mariners upon rocks which exist in the tracks of ships, or upon dangerous shores and the mouths of harbours. This is not the place to enter largely upon any special description of the lights which are adopted around our shores; a brief account only will be given of some of the more remarkable principles which have been introduced of late years by the Trinity Board.

The early lighthouses appear to have been illuminated by coal or wood fires contained in 'chauffers.' The Isle of Man light was of this kind until 1816. The first decided improvement was made by Argand, in 1784, who invented a lamp with a circular wick, the flame being supplied by an external and internal current of air. To make these lamps more effective for lighthouse illumination, and to prevent the ray of light escaping on all sides, a reflector was added in 1780 by M. Lenoir; this threw the light forward in parallel rays towards such points of the horizon as would be useful to the mariner. Good reflectors increase the luminous effect of a lamp about 400 times; this is the 'catoptric' system of lighting. When reflectors are used, there is a certain quantity of light lost, and the 'dioptric' or *refracting* system, invented by the late M. Augustin Fresnel in 1822 is designed to obviate this effect to some extent: the 'catadioptric' system is a still further improvement, and acts both by refraction and reflection. Lights of the first order have an interior radius or focal distance of 36·22 inches, and are lighted by a lamp of four concentric wicks, consuming 570 gallons of oil per annum. Recently (1874) mineral oil has been used with much advantage and economy in the lighthouses of America.

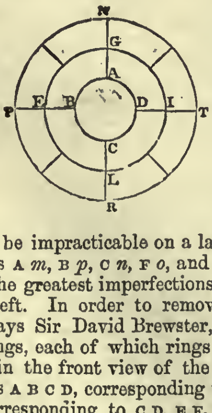
The following notices may be of interest:—The Eddystone Lighthouse, 9½ miles from the Rame Head, on the coast of Cornwall, was erected of timber by Winstanley in 1696–98, and was washed away in 1703. It was rebuilt by Rudyard in 1706, and destroyed by fire in 1755. The present edifice was erected by Smeaton 1757–59. Tallow candles were used in the first instance for the lights; but in 1807 argand lamps, with paraboloidal reflectors of silvered copper were substituted.

The Skerryvore Rocks, about 12 miles south-west of Tyree on the coast of Argyleshire, lying in the track of the shipping of Liverpool and of the Clyde had long been regarded with dread by the mariners frequenting these seas. The extreme difficulty of the position, exposed to the unbroken force of the Atlantic Ocean, had alone deterred the Commissioners of Northern Lights from the attempt to place a light upon this dangerous spot; but in 1834 they caused the reef to be surveyed, and in 1838 Mr. Alan Stevenson, their engineer, inheriting his father's energy and scientific skill, commenced his operations upon a site from which 'nothing could be seen for miles around but white foaming breakers, and nothing could be heard but the howling of the winds and the lashing of the waves.' His design was an adaptation of Smeaton's tower of the Eddystone to the peculiar situation, a circumstance with which he had to contend. He established a circular base 42 feet in diameter, rising in a solid mass of gneiss or granite, but diminishing in diameter to the height of 26 feet, and presenting an even concave surface all round to the action of the waves. Immediately above this level the walls are 9·58 feet thick, diminishing in thickness as the tower rises to its highest elevation, where the walls are reduced to 2 feet in thickness, and the diameter to 16 feet. The tower is built of granite from the islands of Tyree and Mull, and its height from the base is 138 feet 8 inches. In the intervals left by the thickness of the walls are the stairs, a space for the necessary supply of stores, and a not uncomfortable habitation for three attendants. The rest of the establishment, stores, &c., are kept at the depôt in the island of Tyree. The light of the Skerryvore is revolving, and is produced by the revolution of eight annular lenses around a central lamp, and belongs to the first order of dioptric lights in the system of Fresnel, and may be seen from a vessel's deck at a distance of 18 miles.

Some of the lenticular arrangements must now claim attention. The appearance of light called short eclipses has hitherto been obtained by the following arrangement:—An apparatus for a fixed light being provided, composed of a central cylinder and two zones of catadioptric rings forming a cupola and lower part, a certain number of lenses are arranged at equal distances from each other, placed upon an exterior moveable frame making its revolution around the apparatus in a given period. These lenses, composed of vertical prisms, are of the same altitude as the cylinder, and the radius of their curves is in opposite directions to those of the cylinder, in such a manner that at their passage they converge into a parallel pencil of light, all the divergent rays emitted horizontally from the cylinder producing a brilliant effect, like that obtained by the use of annular lenses at the revolving lighthouses. Large lenses, or any large masses of glass, are liable to striæ, which by dispersing, occasion a loss of much light.

1384

1385



'In order to improve a solid lens formed of one piece of glass whose section is A, *m*, *p*, B, F, E, D, C, A (*fig.* 1384), Buffon proposed to cut out all the glass left white in the figure, namely, the portions between *m p* and *n o*, and between *n o* and the left-hand surface of D E. A lens thus constructed would be incomparably superior to a solid one, but such a process we conceive to be impracticable on a large scale, from the extreme difficulty of polishing the surfaces A *m*, B *p*, C *n*, F *o*, and the left-hand surface of D E; and even if it were practical, the greatest imperfections of the glass might happen to occur in the parts which are left. In order to remove these imperfections and to construct lenses of any size,' says Sir David Brewster, 'I proposed in 1811 to build them up of separate zones or rings, each of which rings was again to be composed of separate segments, as shown in the front view of the lens in *fig.* 1385. This lens is composed of one central lens A B C D, corresponding with its section D E in *fig.* 1384; of a middle ring G E L I, corresponding to C D, E F, and consisting of 4 segments; and another ring N P R T, corresponding to A C, F B, and consisting of 8 segments. The preceding construction obviously puts it in our power to execute those lenses, to which I have given the name of *polyzonal lenses*, of pure flint glass free from veins; but it possesses another great advantage, namely, that of enabling us to correct very nearly the spherical aberration by making the foci of each zone coincide.'

This description will enable the reader to understand the system which has been adopted by Fresnel, and carried out by the French Government and by our own Commissioners of Lights.

In the fixed dioptric light of Fresnel, the flame is placed in the centre of the apparatus, and within a cylindric reflector of glass, of a vertical refracting power, the breadth and height of a strip of light emitted by it being dependent upon the size of the flame and the height of the reflector itself; above and below is placed a series of reflecting prismatic rings or zones for collecting the upper and lower divergent rays, which, falling upon the inner side of the zone are refracted, pass through the second side where they suffer total reflection, and, passing out on the outer side of the zone, are again refracted. The effect of these zones is to lengthen the vertical strip of light, the size of which is dependent upon the breadth of the flame and the height of the apparatus.

In Fresnel's revolving lighthouse, a large flame is placed in the centre of a revolving frame which carries a number of lenses on a large scale and of various curvatures for the avoidance of spherical aberration. With the view of collecting the divergent rays above the flame, an arrangement of lenses and silvered mirrors is placed immediately over it. By this compound arrangement the simply revolving character of the apparatus is destroyed, as, in addition to the revolving flash, a vertical and fixed light is at all times seen, added to which a great loss of light must be sustained by the loss of metallic reflectors. In 1851, Messrs. Wilkins and Letourneau introduced a catadioptric apparatus of great utility, which was thus described by them:—

The first improvement had special reference to the light, and produced a considerable increase in its power, whilst the simplicity of the optical arrangements was also regarded. It consisted, first, in completely dispensing with the moveable central cylindrical lenses; secondly, it replaced these by a single revolving cylinder composed of four annular lenses and four lenses of a fixed light introduced between them; but the number of each varying according to the succession of flashes to be produced in the period of revolution.

The second improvement consisted in a new method of arranging the revolving parts, experience having shown that the arrangements in use were very faulty. A short time is sufficient for the action of the friction-rollers, revolving on two parallel planes, to produce, by a succession of cuttings, a sufficiently deep groove to destroy the regularity of the rotatory movement. To obviate this great inconvenience the friction-rollers were so placed and fitted, on an iron axis with regulating screws and traversing between two bevelled surfaces, and when an indentation was made in one place they could be adjusted to another part of the plates which is not so worn.

The third improvement produced the result of an increase of the power of the flashes in revolving lighthouse apparatus to double what had been obtained hitherto. By means of lenses of vertical prisms placed in the prolongation of the central annular lenses, the divergent rays emerging from the catadioptric zone were brought into a straight line, and a coincidence of the three lenses obtained.

The whole of the prisms, lenses, and zones are mounted with strength and simplicity, accurately ground and polished to the correct curves according to their respective positions, so as to properly develope this beautiful system of Fresnel. The glass of which they are composed should be of the clearest crystal colour, and free from that green hue which so materially reduces the power of the light, and is considered objectionable for apparatus of this kind. The lamp by which the apparatus is to be lighted consists of a concentric burner with four circular wicks attached to a lamp of simple construction, the oil being forced up to the burner by atmospheric pressure only, so that there are no delicate pumps or machinery to become deranged.

Stevenson's Revolving Lighthouse.—This apparatus consists of two parts. The principal part is a right octagonal hollow prism composed of eight large lenses, which throw out a powerful beam of light whenever the axis of a single lens comes in the line between the observer and the focus. This occurs once in a minute, as the frame which bears the lens revolves in eight minutes on the rollers placed beneath. The subsidiary parts consist of eight pyramidal lenses inclined at an angle of 30° to the horizon, and forming together a hollow truncated cone, which rests above the flame like a cap. Above these smaller lenses (which can only be seen by looking from below) are placed eight plane mirrors, whose surfaces being inclined to the horizon at 50° in the direction opposite to that of the pyramidal lenses, finally cause all the light made parallel by the refraction of these lenses to leave the mirror in a horizontal direction. The only object of this part is to turn to useful account, by prolonging the duration of the flash, that part of the light which would otherwise escape into the atmosphere above the main lenses. This is effected by giving to the upper lenses a slight horizontal divergence from the vertical plane of the principal lenses. Below are five tires of totally reflecting prisms, which intercept the light that passes below the great lenses, and by means of two reflections and an intermediate refraction project them in the shape of a flat ring to the horizon.

Stevenson's fixed dioptric apparatus of the first order (same as that at the Isle of May, with various improvements). The principal part consists of a cylindric belt of glass which surrounds the flame in the centre, and by its action refracts the light in a *vertical* direction upward and downward, so as to be parallel with the focal plane of the system. In this way it throws out a flat ring of light equally intense in every direction. To near observers, this action presents a narrow vertical band of light, depending for its breadth on the extent of the horizontal angle embraced by the eye. This arrangement therefore fulfils all the conditions of a fixed light, and surpasses in effect any arrangement of parabolic reflectors. In order to save the light which would be lost in passing above and below the cylindrical belt, curved mirrors with their common focus in the lamp were formerly used; but by the present engineer, the adaptation of *catadioptric* zones to this part of the apparatus was, after much labour, successfully carried out. These zones are triangular, and act by *total* reflection, the inner face *refracting*, the second *totally reflecting*, and the third or outer face, a second time *refracting*, so as to cause the light to emerge *horizontally*. The apparatus has received many smaller changes by the introduction of a new mode of grouping the various parts of the framework, by which the passage of the light is less obscured in every azimuth.

Mechanical lamps of four wicks are used in these lighthouses; in these the oil is kept continually overflowing by means of pumps which raise it from the cistern below; thus the rapid carbonisation of the wicks, which would be caused by the great heat, is avoided. The flames of the lamp reach their best effect in three hours after lighting, *i.e.* after the whole of the oil in the cistern, by passing and repassing over the wicks repeatedly, has reached its maximum temperature. After this the lamp often burns fourteen hours without sensible diminution of the light, and then rapidly falls. The height varies from sixteen to twenty times that of the argand flame of an inch in diameter; and the quantity of oil consumed by it is greater nearly in the same proportion.

In *Stevenson's ordinary parabolic reflector*, rendered *holophotal* (where the entire light is parallelised) by a portion of a catadioptric annular lens, the back part of the parabolic conoid is cut off, and a portion of a spherical mirror substituted, so as to send the rays again through the flame; while his *holophotal catadioptric annular lens apparatus* is a combination of a hemispherical mirror and a lens having totally-reflecting zones; the peculiarity of this arrangement is, that the catadioptric zones, instead of transmitting the light in parallel horizontal plates, as in Fresnel's apparatus, produces, as it were, an extension of the lenticular or quaquaversal action of the central lens by assembling the light around its axis in the form of concentric hollow cylinders.

Mr. Chance, of Birmingham, constructed a lighthouse which may be regarded as Fresnel's revolving light rendered holophotal. This arrangement was divided into three compartments, the upper and lower of which were composed respectively of thirteen and six catadioptric zones which produce the vertical strip of light extending the whole length of the apparatus, and is similar to Fresnel's dioptric light. The central or catoptric compartment consisted of eight lenses of three feet focal length, each of which was the centre of a series of eleven concentric prismatic rings, designed to produce the same refractive effect as a solid lens of equal size. These compound lenses were mounted upon a revolving frame and transmitted horizontal flashes of light as they successively rotated. The motion was communicated to the frame by a clock movement, and performs one revolution in four minutes; consequently, as there are eight lenses, a flash of light is transmitted every thirty seconds to the horizon.

LIGN ALOES. This wood is supposed to be the produce of *Aquilaria Agallocha*, one of the Lace-bark order.

LIGNEOUS MATTER is vegetable fibre. See FIBRE, VEGETABLE.

LIGNITE. Under BROWN COAL, and COAL, the characteristics of lignite have already received attention, therefore little further need be said. The term lignite should be confined to fossil wood, or, still more correctly to wood which has undergone one of the changes leading *towards* the production of coal. If wood is buried in moist earth there is the production of carbonic acid from the elements of the wood, and the wood is changed into either lignite or brown coal. Lignite and coal differ chemically from each other. Lignite yields by dry distillation acetic acid and acetate of ammonia, whereas coal produces only an ammoniacal liquor. (*Kremers.*) Woody fibre gives rise to acetic acid; therefore, lignite must still contain undecomposed woody fibre. The following table gives the composition of several well-known lignites:—

	Carbon	Hydrogen	Oxygen and Nitrogen	Earthy matter	Chemist
From Uttweiler . . .	77·9	2·6	19·5	1·0	Karsten
„ Hungary . . .	67·3	4·3	...	0·8	Nendtwich
„ the Rhône . . .	72·2	4·9	20·1	1·8	Regnault
„ Meissner . . .	68·6	5·9	19·0	2·3	Gräger
„ Bovey Heathfield .	67·9	5·8	24·8	...	Vaux

The products of the destructive distillation of lignite, by B. Niederstadt is well deserving attention.—The lignites examined came from the Rhenish-Hessian basin. 1. Lignite from Meissner, of a red-brown colour and woody texture; specific gravity 1·12. 2. Lignite from Rheinhardswalde, grey or black, containing abundance of resin; specific gravity 1·13. 3. Brilliant lignite of Meissner, black, fracture fibrous, lustre vitreous; specific gravity 1·32. 4. Lignite of Hirschberg, brownish-black, in tree-like masses; specific gravity 1·35. The following is their elementary composition:—

	1	2	3	4
Carbon	51·238	58·782	69·995	60·302
Hydrogen	4·169	4·042	3·192	4·859
Oxygen	32·326	20·803	17·591	20·169
Nitrogen	0·175	0·150	0·123	0·121
Ash	0·795	5·940	5·470	3·167
Moisture	10·297	10·283	3·629	11·391

On distillation these lignites yielded solid, liquid, and gaseous products; at a dark-red heat, a brown tarry matter passing over along with combustible gases. To separate the watery portion from the tar, common salt was added to the mixture, heated to 40°. The quantity of tar, when freed from water, amounted to 4 to 5 per cent., and the watery products 48 to 55 per cent., containing acetic acid and ammonia. The oily matters distilled over at 95° to 220°, leaving a black pitchy residue. The distillate, on agitation with concentrated soda-lye, yields phenol. On fractional distillation, the portions passing over up to 150° contain pyrrol and picoline, which boils at 135°, and is distinguished from aniline by not giving a violet colouration with chloride of lime. The part passing over about 220° solidified on cooling, yielding a crystalline mass soluble in alcohol and ether. It melts at 49° to 51°, and is a paraffin formed of hydrocarbons C^nH^{2n}. It amounts to 1 per cent. of the lignite employed. The gaseous mixture, from the Meissner lignite, consisted of:—Hydrogen, 14·26; carbonic oxide, 40·12; marsh-gas, 10·29; nitrogen, 4·09; carbonic acid, 2·10; ethylene and superior hydrocarbons, 2·13. There appears, consequently, little prospect of using the gases from lignite for lighting purposes.

In Prussia, Austria, and many other parts of the Continent, lignite forms a very important product, being largely employed for domestic and for manufacturing purposes. In this country, with the single exception of the Bovey Heathfield formation, which is used in the adjoining pottery, lignite is not employed. See Coal.

LIGNUM-VITÆ, or *Guaiacum* (*Guaiacum officinale* and *G. sanctum*), a very hard and heavy wood. The fibrous structure of this wood is very remarkable; the fibres cross each other sometimes as obliquely as at an angle of 30° with the axis, as if one group of the annual layers wound to the right, the next to the left, and so on, with any exactitude. The wood can hardly be split, it is therefore divided by the saw. Lignum-vitæ is much used in machinery for rollers, presses, mills, &c., and for pestles and mortars, sheers for ship's blocks, skittle balls, and a great variety of other works requiring hardness and strength.

The gum guaiacum of the apothecary is extracted from this wood.

LILAC DYE. See Calico-Printing; Dyeing; and Aniline.

LIMA WOOD. See Brazil Wood.

LIME, THE. The *Citrus Limetta,* yielding the lime-juice so much esteemed for flavouring sherbet, punch, &c.

LIME. *Quicklime,* an *Oxide of Calcium.* This useful substance is prepared by burning calcareous stones in kilns or furnaces.

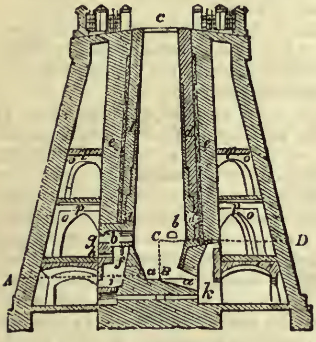
Limestone used to be calcined in a very rude kiln, formed by inclosing a circular space of 10 or 15 feet diameter, by rude stone walls 4 or 5 feet high, and filling the cylindrical cavity with alternate layers of turf or coal and limestone broken into moderate pieces. A bed of brushwood was usually placed at the bottom, to facilitate the kindling of the kiln. Whenever the combustion was fairly commenced, the top, piled into a conical form, was covered in with sods, to render the calcination slow and regular. This method being found relatively inconvenient and ineffectual, was succeeded by a permanent kiln built of stones or brickwork, in the shape of a truncated cone with the narrow end undermost, and closed at bottom by an iron grate. Into this kiln, the fuel and limestone were introduced at the top in alternate layers, beginning of course with the former; and the charge was either allowed to burn out, when the layer was altogether removed at a door near the bottom, or the kiln was successively fed with fresh materials, in alternate beds, as the former supply sunk down by the calcination, while the thoroughly-burnt lime at the bottom was successively raked out by a side door immediately above the grate. The interior of the lime kiln has been changed of late years from the conical to the elliptical form, and probably the best is that of an egg placed with its narrow end undermost, and truncated both above and below; the ground plot or bottom of the kiln being compressed so as to give an elliptical section, with an *eye* or draft-hole towards each end of that ellipse. A kiln thus arched in above gives a reverberatory heat to the upper materials, and also favours their falling freely down in proportion as the finished lime is raked out below; advantages which the conical form does not afford. The size of the draft-holes for extracting the quicklime, should be proportionate to the size of the kiln, in order to admit a sufficient current of air to ascend with the smoke and flame, which is found to facilitate the extrication of the carbonic acid. The kilns are called *perpetual,* because the operation is carried on continuously as long as the building lasts; and *draw-kilns,* from the mode of discharging them by raking out the lime into carts placed against the draft-holes. Three bushels of calcined limestone, or lime-shells, are produced on an average for every bushel of coals consumed. Such kilns should be built up against the face of a cliff, so that easy access may be gained to the mouth for charging, by making a sloping cart-road to the top of the bank.

Figs. 1386, 1387, 1388, 1389, represent the *lime-kiln* of Rüdersdorf near Berlin, upon the continuous plan, excellently constructed for economising fuel. It is triple, and yields a threefold product. *Fig.* 1388 is a view of it as seen from above; *fig.* 1389, the elevation and general appearance of one side; *fig.* 1386, a vertical section, and *fig.* 1387, the ground plan in the line A B C D of *fig.* 1386. The inner shaft *fig.* 1386, has the form of two truncated cones, with their larger circular ends applied to each other; it has the greatest width at the level of the fire-door *b*, where it is 8 feet in diameter; it is narrower below, at the discharge door, and at the top orifice, where it is about 6 feet in diameter. The interior wall *d*, of the upper shaft is built with hewn stones to the height of 38 feet, and below that for 25 feet, with fire-bricks *d′ d′*, laid stepwise. This inner wall is surrounded with a mantle *e*, of limestone, but between the two there is a small vacant space of a few inches filled with ashes, in order to allow of the expansion of the interior with heat taking place without shattering the mass of the building.

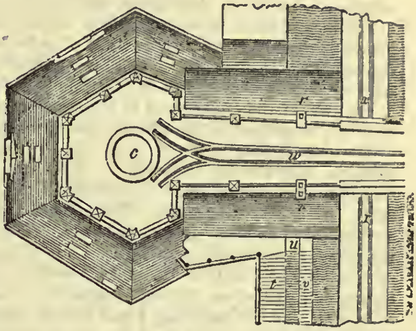
The fire-grate, *b*, consists of fire-tiles, which at the middle, where the single pieces press together, lie upon an arched support *f*. The fire-door is also arched, and is secured by fire-tiles. *g* is the iron door in front of that orifice. The tiles which form the grate have 3 or 4 slits of an inch wide for admitting the air, which enters through the canal *h*. The under part of the shaft from the fire to the hearth is 7 feet, and the outer enclosing wall is constructed of limestone, the lining being of fire-bricks. Here are the ash-pit *i*, the discharge outlet *a*, and the canal *k*, in front of the outlet. Each ash-pit is shut with an iron door, which is opened only when the space *i* becomes filled with ashes. These indeed are allowed to remain till they get cool enough to be removed without inconvenience.

The discharge outlets are also furnished with iron doors, which are opened only for taking out the lime, and are carefully luted with loam during the burning. The outer walls *l m n* of the kiln, are not essentially necessary, but convenient, because they afford room for the lime to lie in the lower floor, and the fuel in the second. The several stories are formed of groined arches *o*, and platforms *p*, covered over with limestone slabs. In the third and fourth stories the workmen lodge at night. See *fig.* 1389. Some enter their apartments by the upper door *q*, others by the lower door *s*. *r* is one of the chimneys for the several fireplaces of the workmen; *t*, *u*, *v* are stairs.

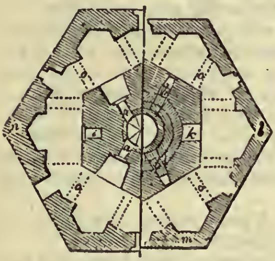
1386



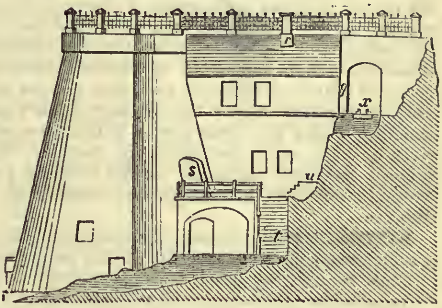
1388



1387



1389



As the limestone is introduced at top, the mouth of the kiln is surrounded with a strong iron balustrade to prevent the danger of the people tumbling in. The platform (*fig.* 1388) is laid with rails *w*, for the waggons of limestone, drawn by horses, to run upon. *x* is another railway, leading to another kiln. Such kilns are named after the number of their fire-doors, single, twofold, threefold, fourfold, &c.; from three to five being the most usual. The outer form of the kiln also is determined by the number of the furnaces, being a truncated pyramid of equal sides, and in the middle of each alternate side there is a fireplace, and a discharge outlet. A cubic foot of limestone requires for burning, one and five-twelfths of a cubic foot of wood, and one and a half of turf.

When the kiln is to be set in action, it is filled with rough limestone, to the height C D, or to the level of the firing; a wood fire is kindled in *a*, and kept up till the lime is calcined. Upon this mass of quicklime a fresh quantity of limestone is introduced, not thrown in at the mouth, but let down in buckets, till the kiln is quite full; while over the top a cone of limestones is piled up, about 4 feet high. A turf-fire is now kindled in the furnaces *b*. Whenever the upper stones are well calcined, the lime under the fire-level is taken out, the superior column falls in, a new cone is piled up, and the process goes on thus without interruption, and without the necessity of once putting a fire into *a*; for in the space C B, the lime must be always well calcined. The discharge of lime takes place every 12 hours, and it amounts at each time in a threefold kiln, to from 20 to 24 Prussian *tonnes* of 6 imperial bushels each; or to 130 bushels imperial upon the average. It is found by experience that fresh-broken limestone, which contains a little moisture, calcines more readily than what has been dried by exposure for some time to the air: in consequence of the vapour of water promoting the escape of the carbonic acid gas; a fact well exemplified in distilling essential oils, as oil of turpentine and naphtha, which come over with the steam of water at upwards of 100° Fahr. below their natural term of ebullition. Six bushels of Rüdersdorf quicklime weigh from 280 to 306 pounds. See KILNS.

Anhydrous lime, or, as it is commonly called, '*quicklime*,' is an amorphous solid, varying much in coherence, according to the kind of rock from which it is obtained; its specific gravity varies from 2·3 to 3. Lime is one of the most infusible bodies which we possess; it resists the highest heats of our furnaces.

When exposed to air, quicklime rapidly absorbs water and crumbles into a powder, commonly known as *slaked lime*, which is a *hydrate of lime*.

Hydrate of lime, when exposed to the air, absorbs carbonic acid, and after long exposure it is converted into a mixture of carbonate of lime and hydrate of lime in single equivalents. Hydrate of lime is but slightly soluble in water, 729 to 733 parts of that fluid dissolving only 1 part of the lime at ordinary temperatures.

Hydrate of lime is applied to numerous purposes in the arts and manufactures. It is chiefly employed in the preparation of mortar for building purposes. See MORTAR.

The pure limes, prepared from the carbonates of lime, form an imperfect mortar suitable only for dry situations. In damp buildings or in wet situations they never *set* (as the process of hardening is technically termed), but always remain in a pulpy state. General Pasley says, 'The unfitness of pure lime for the purposes of hydraulic architecture has been proved by several striking circumstances that have come under my personal observation, of which I shall only mention a few. First, a great portion of the boundary-wall of Rochester Castle having been completely undermined, nearly throughout its whole thickness, which was considerable, whilst the upper part of the same wall was left standing, I had always ascribed this remarkable breach to violence, considering it as having been the act of persons intending to destroy the wall for the sake of the stone; but on examining it more accurately after I had begun to study the subject of limes and cements, I observed that the whole of the breached part was washed by the Medway at high water, and that all the mortar of a small portion of the back part of the foot of the wall still left standing was quite soft, but that towards the ordinary high water level it became a little harder, and above that level it was perfectly sound. I observed the same process at the outer wall of Cockham Wood Fort, on the left bank of the Medway, below Chatham, of which the upper part was standing, whilst the lower part of it had been gradually ruined by the action of the river at high water destroying the mortar.' The peculiar conditions necessary to insure a good and useful mortar for building purposes, and the peculiarities of the hydraulic mortars or cements are treated of under HYDRAULIC CEMENTS and MORTAR.

LIMESTONE. (*Calcaire*, Fr.; *Kalkstein*, Ger.) A great variety of rocks contain a sufficient quantity of carbonate of lime to be called limestones.

Chalk is an earthy massive opaque variety, usually soft and without lustre, and may be regarded as a tolerably pure carbonate of lime. Carbonate of lime dissolves in 1,000 parts of water charged with carbonic acid. (*Bischof.*) Fresenius states that it dissolves in 8,834 parts of boiling water and in 10,601 parts of water at ordinary temperatures.

Carbonate of lime is found in nature more or less pure; it occurs crystallised, as in calcspar and aragonite; and also occurs as granular limestone; and in compact masses, as in common limestone, chalk, &c.

Stalactitic carbonate of lime, frequently called concretionary limestone, is formed by the infiltration of water through rocks containing lime, which is dissolved out, and as it slowly percolates the rocks into cavernous openings, the water parts with its carbonate of lime, which is deposited in zones more or less undulated, which have a fibrous structure from the crystalline character of the concretionary lime. The long fibrous pieces called stalactites show those fibres very beautifully. The stratiform masses called stalagmites exhibit a similar structure, varied only by the conditions under which they are formed. A very remarkable stalagmitic limestone found in Egypt is known as oriental alabaster.

True *Alabaster* is a sulphate of lime, but the stalagmitic carbonate is not unfrequently called by this name. See ALABASTER.

Incrusting concretionary limestones differ but little from the above. They are deposits from calcareous springs which are common in some parts of Derbyshire, Yorkshire, and other places. It is a common practice to place vegetable substances in those springs; they then become incrusted with carbonate of lime, and are sold as petrifactions, which they are not. In volcanic districts many very remarkable springs of this character exist. One of the most remarkable is at the baths of San Filippo, in Tuscany, where the water flows in almost a boiling state; carbonate of lime here appears to be held in solution by sulphuretted hydrogen, which flies off when the water issues to-day. Dr. Vegny has taken advantage of this property of the spring to obtain basso-rilievo figures of great whiteness and solidity by occasioning the lime to deposit in sulphur moulds.

Agaric mineral, *Spongy limestone*, *Rock milk*, is found at the bottom of and about lakes whose waters are impregnated with lime. The *calcareous tufa* of Derbyshire is of this character; it may be studied in every stage of formation.

Travertino, which served to construct most of the monuments in ancient Rome, appears to have been formed by the deposits of the Anio and the Solfatara of Tivoli. The temples of Pæstum, which are of extreme antiquity, have been built with a *travertino*, formed by the waters which still flow in this territory.

Compact limestone has a compact texture, usually an even surface of fracture, and dull shades of colour.

Granular limestone includes common statuary and architectural marble, and has a texture something like loaf-sugar. Under those two heads are grouped a great number of varieties.

Oolite or *roe-stone* consists of spherical grains of various sizes, from a millet seed to a pea, or even an egg.

Coarse-grained limestone. Coarse lias has been referred to this head.

Marly limestone. Lake- and fresh-water limestone formation; texture fine-grained, more or less dense; apt to crumble down in the air; colour white or pale yellow; fracture rough-grained, somewhat conchoidal; rather tenacious. Texture occasionally cavernous, with cylindrical winding cavities. This true limestone must not be confounded with lime marl, which is composed of calcareous matter and clay.

Siliceous limestone. A combination of silica and carbonate of lime, varying very much in the proportions, and sometimes passing from *cherty limestone* into *chert*. It scratches steel, and leaves a siliceous residuum after the action of muriatic acid.

Stinkstone or *Swinestone.* A carbonate of lime combined with sulphur and organic matter. It emits the smell of sulphuretted hydrogen by a blow or by friction. It occurs at Assynt, in Sutherlandshire, in Derbyshire, and some parts of Ireland.

Bituminous limestone. Limestone containing various hydrocarbon compounds, diffusing by the action of fire a bituminous odour, and becoming white when burnt.

Limestones of whatsoever kind may be referred to deposition effected by chemical change. The immense lapse of time required to form the great limestone ranges of this country can scarcely be estimated.

Oolitic limestone includes Bath stone, Portland stone, and Caen stone.

Pisolite is a variety of oolite, in which the concretions become as large as peas.

Nummulitic limestone, *Clymenia*, *Crinoidal*, or *Encrinital* limestones, &c., are so called from the fossils which the rock contains.

Shell-limestone or *Muschelkalk* has its name in the same way from its composition.

Cipolino is a granular limestone containing mica.

Majolica, a white and compact limestone.

Scaglia, a red limestone in the Alps.

See ALABASTER; CHALK; HYDRAULIC CEMENT; and MARBLE.

LIMESTONE, MAGNESIAN (*Dolomie*, Fr.; *Bitterkalk*, *Talkspath*, Ger.), is a mineral which crystallises in the rhombohedral system. Spec. grav. 2·88; scratches calc-spar; does not fall spontaneously into powder when calcined, as common limestone does. It consists of 1 equivalent of carbonate of lime = 50, associated with 1 of carbonate of magnesia = 42.

Massive magnesian limestone is yellowish-brown, cream-yellow, and yellowish-grey; brittle. It dissolves slowly and with feeble effervescence in dilute muriatic acid; whence it is called *Calcaire lent dolomie*, by the French mineralogists. Specific gravity, 2·6 to 2·7.

Near Sunderland it is found in flexible slabs. The principal range of hills composing this geological formation in England, extends from Sunderland on the north-east coast to Nottingham, and its beds are described as being about 300 feet thick on the east of the coal-field in Derbyshire, which is near its southern extremity.—H. W. B. See DOLOMITE.

LIME TREE (*Tilia Europæa*). The well-known linden tree, common to all Europe. The wood is very light-coloured, fine and close in the grain, and when properly seasoned, not liable to warp. It is much used in the manufacture of pianofortes and harps. It is made into cutting boards for curriers, shoemakers, &c., as it does not turn the knife in any direction of the grain, nor injure the edge.

Lime-tree wood is especially useful for carving, from its even texture and freedom from knots. The beautiful works of Gibbons at Hampton Court, at Windsor, and at Chatsworth, are executed in lime-tree wood, as are also the works of Rogers.

LIMNITE. A name applied to certain varieties of hydrous peroxide of iron, having the composition—$Fe^2O^3.3HO$ ($\mathbf{Fe^2O^3.3H^2O}$). Some kinds of bog iron-ore and stalactitic brown iron-ore may come under this denomination. The name is derived from λιμνή (*limnē*), a marsh.

LIMOGES ENAMELS. See ENAMELS.

LIMONITE. A hydrous peroxide of iron of the composition—$2Fe^2O.^3 3HO$ ($2Fe^2O^3.3H^2O$). It includes most of the bog iron-ores and the so-called brown hæmatites. The name is derived from λειμῶν (*leimōn*), a meadow. See IRON.

LINARITE. A hydrous sulphate of copper and lead, occurring in beautiful dark blue crystals at Leadhills in Lanarkshire, and at several localities in Cumberland. It takes its name from Linares in Spain.

LINDEN TREE. See LIME TREE.

LINEN. History does not state at what period of the world's existence the manufacture of cloth from flaxen material was first introduced; but from many evidences found in Egyptian mausoleums the process of weaving must have been known and practised even before the great shipbuilder laid the first planks of his famous Ark. Throughout the pages of Sacred Writ the allusions to 'fine linen,' 'broidered linen,' and the fancy styles of the fabric as they were brought out wefted with gold threads and coloured yarns, show that in those days the clothing of princes, priests, and people was largely composed of the different qualities of such material. In ancient Greece the embroidering of linen robes was delighted in as a popular pastime by the ladies of high degree, and the Romans of old were no less fond of the manufacture. But all their fancy goods were not furnished by the needle alone. Homer alludes to his famous heroine weaving pictures in the loom, and other productions similar in pattern to the damask of modern days were worked by the shuttle in ancient Greece.

The use of linen was pretty general in the higher circles of society in the British isles at a very remote period; but all the finer varieties of the fabric were imported from the continent of Europe. Woollen goods formed the principal material for inner as well as outside clothing of the people on both sides the Tweed in the fifth century; but even then linen was considered an essential requisite for special purposes, and particularly for wrapping the bodies of the dead. Weaving was cultivated by the more skilful peasants for a long period afterwards; but it does not appear that any high order of work had been produced until the reign of Henry III., when a number of Flemings brought over by that monarch settled in Sussex and introduced a very superior make of linen. We have only slight allusions in after history respecting the progress of the trade either in England, Scotland, or Ireland. The yarns, at least those of the upper counts used in Sussex and Lancashire were imported from Holland, Flanders and Ireland. A high authority—Leland—in alluding to the Liverpool trade says: 'Irysh merchantes doe cum muche heyre withe linnen yarne, the whiche Manchester men doe bye.' King William tried to give greater impulse to the trade in England, but somehow the pride of the people in manufacturing districts to uphold woollen, 'the noble and national fabric,' stood in the way; and while royal patronage did immense good in Scotland and Ireland, it had little effect in England. Sam Homespun's calculations relative to the value of a single acre's produce of flax when spun and woven were made in 1742, and given at length in the leading magazine of that day; but marvellous as they were, so far as referred to the profits which might be made in the linen manufacture, the subject was not taken up in the spirit intended by that writer. Shortly afterwards the discoveries of Hargreaves, Arkwright, and others, and the enterprise created thereby in the cotton trade opened up new avenues in the manufacturing world of England; farmers there gradually decreased the area of flax culture; and, except in few localities, linen weaving no longer occupied any large space in the republic of labour.

In the meantime very great progress had been maintained in the manufacture of linen in Scotland and Ireland. Bounties and other artificial stimulants were freely administered by the State; a Board of Trustees for Scotland sat in Edinburgh, and local influence was largely used to give effect to the movement for improving the manufacture. The Bounty Act became law in 1742, and in the course of that year 4,431,500 yards of linen were stamped by the inspectors appointed for that purpose. Twelve years afterwards, and when the bounty system was given up, the turn out of goods had increased to 8,914,400 yards; in 1800, 24,236,630 yards were produced and stamped by the inspectors; and in 1822 there was a total of 36,268,530 yards of linen made in Scotland. The introduction of flax spinning by mechanical power and of weaving linen on the steam-loom principle, made a remarkable change in the Scotch trade. Dundee had long been the great centre of the flaxen manufactures, and of late years it has taken the lead in the Jute trade. Twenty-five years ago the imports of Jute into Dundee were 12,500 cwts.; in 1863, 46,900 cwts. were landed there; and of the total import of 2,583,842 cwts. for the six months ending June 30, 1874, a large proportion went to Dundee. The capital employed in that town and neighbourhood in the flax and Jute trades cannot at present be under five and a half millions sterling.

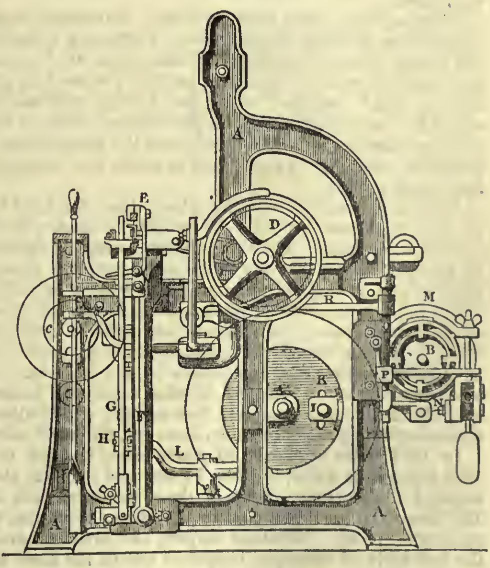
Ireland's linen trade was its great sheet anchor in times the records of which have been lost in the mist of ages. Long before the reign of William the Conqueror Irish linen occupied a large space among the wares exposed for sale at the great fairs of England. The looms used in the make of goods were, however, of very primitive construction; and, until the semi-regal reign of Wentworth, Earl of Strafford, no effort had been made to improve those machines. In course of a tour through Ulster that viceroy saw that much was required to place the Irish trade on something like equality with their French and Dutch competitors. He had already, by importing superior flax seed and giving it at cost price to the farmers succeeded in creating, as it were, a higher class of fibre, and at considerable cost he brought over from Holland some hundreds of looms, all of which he distributed among the more ambitious class of weavers.

The trade at that time may be said to have been a local one, as the total annual value of linen exports did not exceed an average of 10,000*l.*, and that aggregate had not increased in any great degree when the first batch of Huguenot exiles landed in Ireland. How much the Prince of Orange contributed towards the establishment of a new system of flaxen manufacture has still to be acknowledged by the people of that country. He was the warm friend of the Gallic fugitives, and his kindly feeling towards those victims of persecution led to the most important results in all departments of the Irish trade. We have alluded to the value of exports in 1690. In 1706 the quantity of linen sent from Ireland was 530,900 yards, valued at 10*d.* a yard. In 1726 there were 4,368,396 yards exported; and in 1766 the account had ran up to 17,892,000 yards, while the average value had arisen to 15*d.* a yard. Forty years afterwards, Ireland exported 43,534,000 yards of linen, and in 1836 the export was 60,000,000 yards.

Up to this time, and for a great many years afterwards, all the linen produced in Ireland had been woven by hand. Considerable impulse was given to the trade by the introduction, a few years before, of flax-spinning by steam-power. Still, although flaxen goods were largely produced in Kirkcaldy and Dundee on the power-loom principle, no attempt had been made to bring out the new weaving-machine in Ireland. We here give two figures of the loom as constructed some years ago for the working of heavy linen.

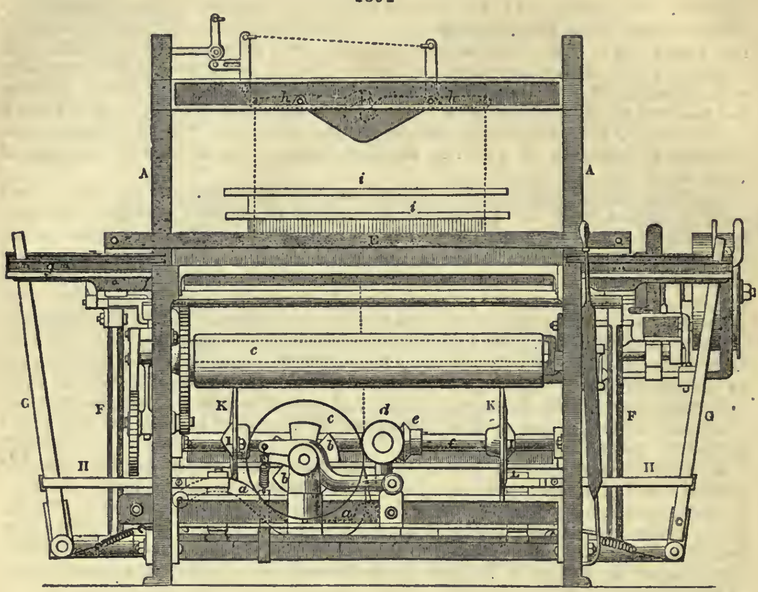
Flax Weaving Loom for Heavy Fabrics.—A A A, *figs.* 1390, 1391, frame of loom; B, beam on which the yarn for warp is wound; C, cloth-receiving beam; D, driving pulleys and fly-wheel; E, hand rail for supporting the reed; F, swords of supports of going part; G, picking sticks for driving the shuttle; H, leather straps for connecting the picking sticks with their actuating levers L; M, N, jaws of a clamp to cause the retaining friction on the collars of the beam B, by which friction the quantity of weft is regulated; O, end of lever, bearing the weight by which the jaws are brought together; P, lever, keyed at one end to the upright shaft Q, and connected with the other to the fulcrum of the weighted lever O; R, lever, one end of which is also keyed to the upright shaft Q, and the other is provided with a wood sole, and is pressed by a strong spring against the yarn wound upon the beam B. It will be seen that, as the yarn is taken off the beam B, and its diameter consequently reduced, the lever P moves the fulcrum of the weighted lever O, and thus regulates the pressure upon the clamps M and N, causing an equal tension upon the yarn from the full to the empty beam; *a*, treddles, actuated by the cams *b*, driven by the wheels *c*, *d*, *e*, from the

1390



picking shaft *f*; *g g*, shuttle-boxes at each end of the going part; *h h*, arrangement of levers to conduct equally each end of the gears *i i*. This loom has also, in addi-

1391



tion to the ordinary stopping arrangement connected with the shuttle, one also for relaxing the reed in case the shuttle should be arrested in its course across the warp, whereby the danger, ordinarily incurred by that accident, of breaking many threads in the warp is avoided; it will also be seen that the bands called picking bands are superseded by the ends of the picking levers striking the shuttle direct; thus, by these improvements, drills are currently woven in this loom at the rate of 120 to 130 picks per minute.

About a dozen years since extensive trials were made to adapt the power-loom to the weaving of light linen fabrics. Previously it had been found that while coarse and strong flax fabrics, such as those made at Dundee, Arbroath, &c., in Scotland, and the drills made at Barnsley, could be produced by power as well and more cheaply than by hand, yet that the lighter fabrics, such as shirtings, cambrics, lawns, &c., would not bear the strain of the power-loom, or, at all events, that to make them of as good appearance as by the hand-loom the manufacturer required to employ a dearer article of yarn, and so found that he could not compete with his neighbours who had hand-loom weavers.

Irish manufacturers were for a long time very hard to convince that, except for the production of sets, say from 8^{00} to 12^{00}, the steam-driven loom was not likely to be worked successfully. But at length the increasing demand for linen, and the difficulty of procuring hands to work on the ordinary loom, forced capitalists to adopt the new mode of production, and rapidly did the system extend when it was found not only to equal, but far exceed that which had been expected from it. Hand-loom weaving, in coarse, heavy linens, was a labour that required more than average strength, and yet, when it was maintained for fourteen hours a day, the operator did not earn as much as a factory worker can now realise by his ten hours' labour. Many linen weavers, as demand for hands increased in other sections of industry, forsook the loom, and the only alternative manufacturers had was the substitution of the iron machine and the steam-engine for the old wooden loom and the hand-weaver.

In 1857 there were only 30 power-looms at work on linen weaving in Ireland, in 1860 there were 4,000, in 1866, 10,000, and in 1872, about 15,500 power-looms were engaged in the trade. Some of these machines work up to 16^{00}. In one factory an 18^{00} linen has been produced by the steam loom, but such high sets can hardly be made with profit. Damasks, diapers, and cambric handkerchiefs, are brought out in the best style, of course, up to certain sets on the same principle, but the upper class of work can only be rightly done by hand. In fact, the practical limit to steam production of linens has been found to be the weaving of a 16^00-web; any fabric above that 'set' cannot well be brought out by 'power,' so as to compete with the hand-loom work.

The improvements recently effected in the make of the steam loom have nearly all been favourable to the operatives. Stronger and better fitted-up machines are now seen in factories; for instance, a loom which a dozen years ago, and constructed for a certain class of work, weighed 15 to 16 cwts., would now be brought out so much heavier as to weigh 17 to 18 cwts. One effect of the improvement in gearing is to give the workpeople greater facility of production; they get through their labour with more ease, and the quality of cloth is decidedly better. In the last case, however, we must add that the superior class of yarns now thrown off the spindles has had much to do with the order of fabric made in 1874, compared with that brought out in 1863. And while thus alluding to the improvements in machinery, we must not forget to add that the better mode of ventilation in mills, the care taken as to sanitary regulations and the regularity of labour, have been producing a very gratifying change on the physical aspect of the people connected with public works. Contrasted with the appearance of the hand-loom or factory weaver of half a century since, that of his successor in the present day shows a marvellous advance in social position as well as in bodily stamina.

LINNÆITE. A sulphide of cobalt, named after the Swedish naturalist, Linné (Linnæus). See COBALT.

LINSEED. (*Graine de lin*, Fr.; *Leinsame*, Ger.) . The seed of the flax, *Linum usitatissimum*, which is indigenous to our islands, and is cultivated extensively in this and other countries for its seed, and for *flax*. Linseed contains in its dry state, 11·265 of oil; 0·146 of wax; 2·4808 of a soft resin; 0·550 of a colouring resinous matter; 0·926 of a yellowish substance analogous to tannin; 6·154 of gum; 15·12 of vegetable mucilage; 1·48 of starch; 2·932 of gluten; 2·782 of albumine; 10·884 of saccharine extractive; 44·382 of envelopes, including some vegetable mucilage. It contains also free acetic acid; some acetate, sulphate, and muriate of potash, phosphate and sulphate of lime; phosphate of magnesia; and silica.

LINSEED OIL is obtained from linseed by first bruising the seeds, grinding them, and subjecting them to violent pressure, either by means of wedges, or of the hydraulic or screw press. Cold drawn linseed oil is obtained cold, and is paler coloured, less odorous, and has less taste than that which is obtained when heat is applied.

It is usual to employ a steam heat of about 200° Fahr. By cold expression the seeds yield about 20 per cent., while by the aid of heat nearly 27 per cent. of oil can be obtained. The ultimate composition of linseed oil is carbon 76·014, hydrogen 11·351, and oxygen 12·635; its proximate constituents being oleic and margaric acids, and glycerine. Linseed oil is much used as a vehicle for colours by the painter. If linseed oil is exposed in a thin coat to the air it absorbs oxygen and becomes tenacious. and in many respects like caoutchouc: upon this property mainly depends its use in the arts. To secure this more readily a drying process is adopted, which must be described.

When linseed oil is carefully agitated with acetate of lead (tribasic acetate of lead), and the mixture allowed to clear by settling, a copious white cloudy precipitate forms, containing oxide of lead, whilst the raw oil is converted into a drying oil of a pale straw colour, forming an excellent varnish, which, when applied in thin layers, dries perfectly in twenty-four hours. It contains from four to five per cent. of oxide of lead in solution. The following proportions appear to be the most advantageous for its preparation:—

In a bottle containing 4½ pints of rain water, 18 ounces of neutral acetate of lead are placed, and when the solution is complete, 18 ounces of litharge in a very fine powder are added; the whole is then allowed to stand in a moderately warm place, frequently agitating it to assist the solution of the litharge. This solution may be considered as complete when no more small scales are apparent. The deposit of a shining white colour (sexbasic acetate of lead) may be separated by filtration. This conversion of the neutral acetate of lead into vinegar of lead, by means of litharge and water, is effected in about a quarter of an hour, if the mixture be heated to ebullition. When heat is not applied, the process will usually take three or four days. The solution of vinegar of lead, or tribasic acetate of lead, thus formed, is sufficient for the preparation of 22 lbs. of drying oil. For this purpose, the solution is diluted with an equal volume of rain-water, and to it is gradually added, with constant agitation, 22 lbs. of oil, with which 18 ounces of litharge have previously been mixed.

When the points of contact between the lead solution and the oil have been frequently renewed by agitation of the mixture three or four times a day, and the mixture allowed to settle in a warm place, the limpid straw-coloured oil rises to the surface, leaving a copious whitish deposit. The watery solution rendered clear by filtration, contains intact all the acetate of lead first employed, and may be used in the next operation, after the addition to it as before of 18 ounces of litharge.

By filtration through paper or cotton the oil may be obtained as limpid as water, and by exposure to the light of the sun it may also be bleached.

Should a drying oil be required absolutely free from lead, it may be obtained by the addition of dilute sulphuric acid to the above, when, on being allowed to stand, a deposit of sulphate of lead will take place, and the clear oil may be obtained free from all trace of lead.

Linseed oil was at one time much used in the preparation of a liniment, which, as it is one of the very best possible applications to a burnt surface, cannot be too generally known. *If equal parts of limewater and linseed oil* are agitated together, they form a thick liniment, which may be applied to the burn with a brush or feather. It relieves at once from pain, and forming a pellicle, protects the abraded parts from the air. The *Linimentum calcis* of the Pharmacopœia is equal parts of limewater and olive oil; this is a more elegant, but a less effective preparation. *See* OIL.

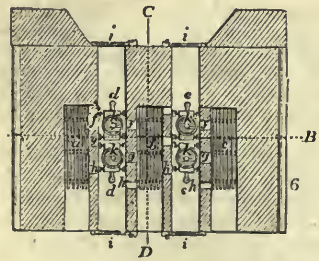
LINT *for Surgery*, was formerly prepared by scraping up linen by the hand; the preparation of it, however, has been made the subject of a patent by Mr. Thomas Ross, which consists in the employment of peculiarly constructed scrapers for abrading the surface of the linen cloth, and producing a pile or nap upon it. The scrapers are worked by a rotary motion.

Instead of rotary scrapers, a reciprocating pendulous movement is sometimes applied to a single scraper. Chisel-formed blades are claimed by the patentee as scrapers for raising the pile, by working with the bevel edges forwards, so as to scrape and not to cut the fabric. He has in the rotary form a ledge or bed concentric with the axis of the scraper, which he also claims; both of which seem to be serviceable. Several kinds of lint-making machines are now employed, but as they all partake more or less the above principles they do not require description.

LIQUATION (Eng. and Fr.; *Saigerung*, Ger.) is the process of sweating out, by a regulated heat, from an alloy a more easily fusible metal from the interstices of a metal which is more difficult of fusion. Lead and antimony are the metals most commonly subjected to liquation: lead for the purpose of removing by its superior affinity the silver present in any complex alloy; antimony as an easy means of separating it from its combinations in the ores.

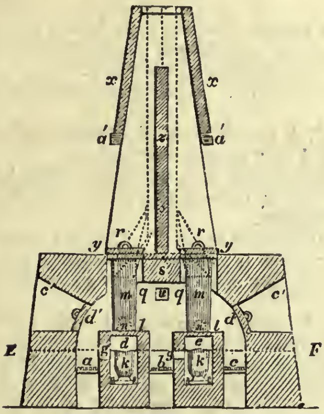
Figs. 1392, 1393, 1394, represent the celebrated antimonial liquation furnaces of Malbosc, in the department of Ardèche, in France. *Fig.* 1392 is a ground plan taken at the level of the draught holes *g g*, *fig.* 1393, and of the dotted line E F; *fig.* 1393 is a vertical section through the dotted line A B, of *fig.* 1392; and *fig* 1394 is a vertical section through the dotted line C D of *fig.* 1392. In the three figures, the same letters denote like objects. *a*, *b*, *c*, are three grates upon the same level above the floor of the works, 4½ feet long, by 10½ inches broad; between which are two rectangular galleries, *d e*, which pass transversely through the whole furnace, and lie at a level of 12 inches above the ground. They are separated by two walls from the three fire-places. The walls have three openings, *f g h*, alternately placed for the flames to play through. The ends of these galleries are shut in with iron doors *i i*, containing peep-holes. In each gallery are two conical cast-iron crucibles *k k*, into which the *eliquating* sulphuret of antimony drops. Their height is from 12 to 14 inches; the width of the mouth is 10 inches, that of the bottom is 6, and the thickness four-tenths of an inch. They are coated over with fire-clay, to prevent the sulphuret from acting upon them; and they stand upon cast-iron pedestals with projecting ears, to facilitate their removal from the gallery or platform. Both of these galleries are lined with tiles of fire-clay *l l*, which also serve as supports to the vertical liquation tubes *m m*, made of the same clay. The tiles are somewhat curved towards the middle, for the purpose of receiving the lower ends of these tubes, and have a small hole at *n*, through which the liquid sulphuret flows down into the crucible.

1392

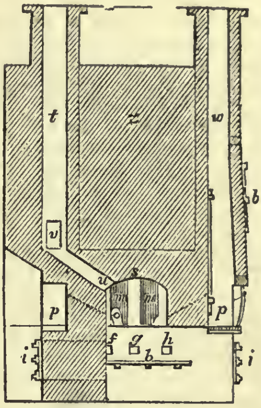


The liquation tubes are conical, the internal diameter at top being 10 inches, at bottom 8; the length fully 40 inches, and the thickness six-tenths of an inch. They have at their lower ends notches or slits, *o*, *fig.* 1394, from 3 to 5 inches long, which look outwards, to make them accessible from the front and back part of the furnaces through small conical openings *p p*, in the walls. These are closed during the operation with clay stoppers, and are opened only when the gangue, rubbish, and cinders are to be raked out. The liquation-tubes pass across the arch of the furnace, *q q*, the space of the arch being wider than the tubes; they are shut in at top with fire-covers *r r*. *s s*, the

1393



1394



middle part of the arch, immediately under the middle grate, is barrel-shaped, so that both arches are abutted together. The flames, after playing round about the sides of the liquation-tubes, pass off through three openings and flues into the chimney *t*, about 13 feet high; *u*, being the one opening, and *v*, the two others, which are provided with register-plates. In front of the furnace is a smoke-flue, *w*, to carry off the sulphurous vapours exhaled during the clearing-out of the rubbish and slag; another, *x*, begins over *y y*, at the top of the tubes; a wall, *z*, separates the smoke-flue into halves, so that the workmen upon the one side may not be incommoded by the fumes of the other. This wall connects at the same time the front flue, *w*, with the chimney *t*. *a a'* and *b' b'* are iron and wooden bearer beams and rods for strengthening the smoke-flue. *c' c'* are arches upon both sides of the furnace, which become narrower from without inwards, and are closed with well-fitted plates *d' d'*. They serve in particular circumstances to allow the interior to be inspected, and to see if either of the liquation-furnaces be out of order. Each tube is charged with 500 lbs. of antimonial ore, previously warmed; in a short time the sulphuret of antimony begins to flow off. When the liquation ceases, the cinders are raked out by the side openings, and the tubes are charged afresh. The luted iron crucibles are allowed to become three-fourths full, are then drawn out from the galleries, left to cool, and emptied, The ingot weighs about 85 lbs. The average duration of the tube is 3 weeks. This plan is proved to be an exceedingly economical one.

LIQUEURS, LIQUORISTE. Names given by the French, and adopted into our language, to denote certain aromatic alcoholic cordials, and to the manufacturer of them.

Some liqueurs are prepared by infusing the woods, fruits, or flowers, in either water or alcohol, and adding thereto sugar and colouring matter. Others are distilled from the flavouring agents.

Many of the liqueurs are of very compound character, as the following recipes will show:—

Martinique Noyeau.—Put into a stone jar,

Preserved guavas and their syrup, or the jelly of that fruit	½ lb.
Oil of sweet almonds	1 oz.
Sweet almonds, beaten fine	1 lb.
Bitter " "	1
Preserved ginger and its syrup	2
Cinnamon and cloves (bruised) of each	½
Nutmeg and Pimento " "	½
Jamaica ginger "	½
Candied lemon and citron, of each	1
White sugar-candy (powdered)	14
Proof spirit of wine	5 quarts.

Beat the oil with a little brandy, and mix it with the almonds, when beaten to a paste with orange-flower water. Stop up the jar securely, and let it remain in a warm room, or in the sun, shaking it often, for a fortnight. Keep it in the jar for twelve or fifteen months; then strain it, and filter repeatedly until it is as clear as spring water. Rinse phials or half-pint bottles, with any white wine, drain them and fill. Cork and seal well. In six months it will be fit for use, if required, but will improve greatly by age.—*Robinson.*

Tears of the Widow of Malabar.—To ten pounds of spirit (pale brandy), add 4 pounds of white sugar, and 4 pints of water, adding 4 drachms of powdered cinnamon, 48 grains of cloves, and the same quantity of mace; colour with caramel.

The Sighs of Love.—Spirit, water, and sugar as above. Perfume with otto of roses, and slightly colour with cochineal.

Absinthe.—Take of the tops of wormwood, 4 pounds, root of angelica, calamus aromaticus, aniseed, leaves of dittany, of each, 1 oz.; alcohol, four gallons.

Macerate these substances during eight days, add a little water, and distil by a gentle fire until two gallons are obtained. This is reduced to a proof spirit, and a few drops of the oil of aniseed added. See ABSINTHE.

These forms exemplify the character of all kinds of liqueurs. They are coloured *yellow* by the colouring matter of carthamus; *fawn* is produced by caramel; *red*, by cochineal; *violet*, by litmus, or archil; *blue*, by the sulphate of indigo; *green*, by mixing the blue and the yellow together.

Ratafia is the generic name, in France, of *liqueurs* compounded with alcohol, sugar, and the odoriferous or flavouring principles of vegetables. Bruised cherries with their stones are infused in spirit of wine to make the ratafia of Grenoble *de Teyssère.* The liquor being boiled and filtered, is flavoured, when cold, with spirit of *noyeau*, made by distilling water off the bruised bitter kernels of apricots, and mixing it with alcohol. Syrup of bay laurel and galango are also added.

LIQUIDAMBAR. A balsam obtained from the *Liquidambar styraciflua*, a native of North America.

LIQUID STORAX. The produce of the *Liquidambar orientale.*

LIQUORICE (*Glycyrrhiza glabra;* from γλυκὺς, sweet, and ῥίζα, a root. The root only is employed; these roots are thick, long, and running deep in the ground.

Besides the use of liquoric roots in medicine, they are also employed in brewing, and are pretty extensively grown for these purposes in some parts of England. Liquorice requires a rich, deep, dry, sandy soil, which, previous to forming a new plantation, should be trenched to the depth of about 3 feet and a liberal amount of manure regularly mixed with the earth in trenching. The plants which are procured by slipping them from those in old plantations are, either in February or March, dibbled in rows 3 feet apart, and from 18 inches to 2 feet in the row. They require three summers' growth before being fit for use, when the roots are obtained by retrenching the whole, and they are then stored in sand for their preservation until required.—*Peter Lawson.*

Large quantities of extract of liquorice-root are imported into this country under the name of *Spanish* or *Italian juice*, according as it comes from one peninsula or the other. Whilst the Spanish juice is yielded by *G. glabra*, it is said that the Italian liquorice is prepared from *G. echinata.* Liquorice juice contains an uncrystallisable sugar called *Glycyrrhizin* or *Liquorice Sugar.*

LIROCONITE. A hydrous arsenate of copper, occurring in sky-blue crystals. It was formerly found in some of the Cornish copper-mines.

LITHARGE (Eng. and Fr.; *Glätte*, Ger.) is the fused yellow protoxide of lead, which on cooling passes into a mass consisting of small six-sided plates, of a reddish yellow colour and semi-transparent. It generally contains more or less red lead, whence the variations of its colour, and carbonic acid, especially when it has been exposed to the air for some time. For its mode of preparation, see LEAD, and SILVER.

LITHIA is a simple earthy or alkaline substance, discovered in the minerals called petalite and triphane. It is white, very caustic, reddens litmus and red cabbage, and saturates acid with great facility. When exposed to the air it attracts humidity and carbonic acid. It is more soluble in water than baryta, and has such a strong affinity for it as to be obtained only in the state of a hydrate. It forms neutral salts with all the acids. It is most remarkable for its power of acting upon or corroding platinum. This earth is now used medicinally.

The following interesting account of a new source of lithium is from the address of Sir Charles Lyell at the Bath meeting of the British Association. After stating that Professor Roscoe of Manchester had detected the chloride of lithium in the Bath waters, Sir Charles Lyell proceeds:—

'While I was pursuing my inquiries respecting the Bath waters, I learned casually that a hot spring had been discovered at a great depth in a copper mine, near Redruth in Cornwall, having about as high a temperature as that of the Bath waters, and of which, strange to say, no account has yet been published. It seems that, in the year 1839, a level was driven from an old shaft, so as to intersect a rich copper lode at a depth of 1,350 feet from the surface. This lode or metalliferous fissure occurred in what was formerly called the United Mines, and which have since been named the Clifford Amalgamated Mines. Through the contents of the lode a powerful spring of hot water was observed to rise, which has continued to flow with undiminished strength ever since. At my request Mr. Horton Davey, of Redruth, had the kindness to send up to London many gallons of this water, which have been analysed by Professor William Allen Miller, F.R.S., who finds that the quantity of solid matter is so great as to exceed by more than four times the proportion of that yielded by the Bath waters. Its composition is also in many respects very different; for it contains but little sulphate of lime, and is almost free from the salts of magnesium. It is rich in the chlorides of calcium and sodium, and it contains one of the new metals, *Cæsium*, never before detected in any mineral spring in England; but its peculiar characteristic is the extraordinary abundance of lithium, of which a mere trace had been found by Professor Roscoe in the Bath waters; whereas, in this Cornish hot spring, this metal constitutes no less than a twenty-sixth part of the whole of the solid contents, which, as before stated, are so voluminous. When Professor Miller exposed some of these contents to the test of spectrum analysis, he gave me an opportunity of seeing the beautiful bright crimson line which the lithium produces in the spectrum.

'Lithium was first made known in 1817 by Arfvedsen, who extracted it from petalite; and it was believed to be extremely rare, until Bunsen and Kirchhoff, in 1860, by means of the spectrum analysis, showed that it was a most widely-diffused substance, existing in minute quantities in almost all mineral waters and in the sea, as well as in milk, human blood, and the ashes of some plants. It has already been used in medicine, and we may therefore hope that now that it is obtainable in large quantities, and at a much cheaper rate than before the Huel Clifford hot spring was analysed, it may become of high value. According to a rough estimate, which has been sent to me by Mr. Davey, the Huel Clifford spring yields no less thon 250 gallons per minute, which is almost equal to the discharge of the King's Bath, or chief spring of this city. As to the gases emitted, they are the same as those of the Bath water, namely, carbonic acid, oxygen, and nitrogen.'

Mr. Warington Smyth, who had already visited the Huel Clifford lode in 1855, re-examined it shortly before this meeting, chiefly with the view of replying to several queries which Sir Charles Lyell put to him; and, in spite of the stifling heat, ascertained the geological structure of the lode, and the exact temperature of the water. This last he found to be 122° Fahr. at the depth of 1,350 feet; but he scarcely doubts that the thermometer would stand two or three degrees higher at a distance of 200 feet to the eastward, where the water is known to gush up more freely. The Huel Clifford lode is a fissure varying in width from 6 to 12 feet, one wall consisting of elvan or porphyritic granite, and the other of killas or clay-slate. Along the line of the rent, which runs east and west, there has been a slight throw or shift of the rocks. The vein-stuff is chiefly formed of cellular pyrites of copper and iron, the porous nature of which allows the hot water to percolate freely through it. It seems, however, that in the continuation upwards of the same fissure, little or no metalliferous ore was deposited, but, in its place, quartz and other impermeable substances, which obstructed the course of the hot spring so as to prevent its flowing out on the surface of the country.

Huel Clifford Amalgamated Mine, having ceased to pay the adventurers, was stopped working in 1872. It is now (1874) full of water, and in all probability it will never again be opened.

A similar hot spring has been discovered in Huel Seton Mine near Camborne, Cornwall. The waters issue, at the rate of 50 gallons per minute, from the eastern fore-breast of the 160-fathom level, at a temperature of 92° Fahr. This water has been analysed with the greatest care by Mr. John Arthur Phillips, and found to contain a larger quantity of lithium than the Huel Clifford spring. Mr. J. A. Phillips communicated the results of his examination to the Royal Society; from which communication the following analysis is extracted:—

	Grains per gallon
Calcium carbonate	7·03
Ferrous carbonate	0·33
Manganous carbonate	trace
Calcium sulphate	2·11
Cupric chloride	minute trace
Calcium chloride	475·54
Carried forward	485·06

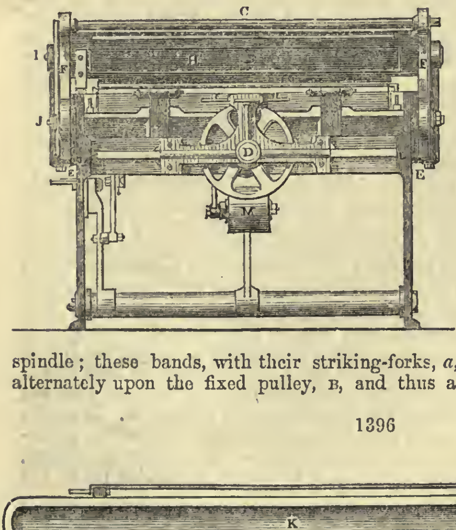
	Grains per gallon
Brought forward	485·06
Magnesium chloride	11·80
Aluminum chloride	63·09
Potassium chloride	6·30
Sodium chloride	407·47
Lithium chloride	33·74
Potassium bromide	trace
Potassium silicate	5·03
Nitric acid	trace
Ammonia	trace
Total	1012·49

LITHIUM is the metallic basis of lithia; the latter substance consists of 100 of metal and 123 of oxygen. Lithium is the lightest known solid, its specific gravity being 0·59. Its atomic weight (7) is lower than that of any other element, excepting hydrogen. Lithium is not of any use in the arts. See LITHIA.

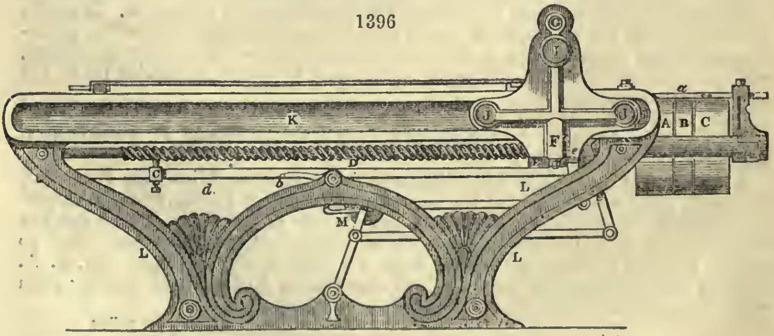
LITHOFRACTEUR. See EXPLOSIVE AGENTS.

LITHOGRAPHIC PRESS. The lithographic press in common use has long been regarded as a very inadequate machine. The amount of manual power required to work it, and the slow speed at which, under the most favourable circumstances, copies can be produced, disables lithography in its competition with letter-press. A career of brilliant success has attended the efforts of scientific men towards speed and success in this latter branch of the art; and the present printing-machines surpass the hand-press somewhat in the same ratio as does our express-speed the jog-trot of our forefathers. The engravings annexed, *figs.* 1395, 1396, will serve to illustrate Messrs. Napier and Sons' improvements upon the lithographic press. The machine is arranged to be driven by steam-power; has belts, 'crossed' and 'open,' supposed to be in connection with the engine, and to rank upon the pulleys, A, B, C. The crank-pulley, B, is fixed on the screw-spindle, D, and the other two work loose, or 'dead,' on the same spindle; these bands, with their striking-forks, *a*, are arranged so as to be brought alternately upon the fixed pulley, B, and thus a reversing-motion is given to the

1395



1396



screw. The nut in which the screw works is fixed to a cross-piece, E, which braces the side-frames, F F, together at bottom, while the bar, G, performs the same office at top; the scraper-box, H, is sustained between these frames at bearings, I, and is so fitted as to work freely. To support the frames and scraper-box independent of the screw and maintain them in position, allowing freedom of action, the rollers, J J, are provided, which run in the planed recesses, K, along the top of the main standards, L.

The machine is shown with its tympan down, ready for starting; this is effected by pressing lightly upon the lever, *b*, which raises a catch, and allows the weight, M, to descend in the direction of its present inclination, and act upon the connections with the striking-forks, so as to bring one of the bands upon the fast pulley, B, and make the scraper and its frames move forward. The return is caused by the frame, F, coming in contact with a stop, C, which, yielding, acts upon the striking-forks by its bar, *d*, upon which it may be adjusted to give the travel required. On the return being accomplished, the machine stops itself by a striking action against stop *e*, the catch, *b*, falling in to prevent the weight descending to its full throw, and thus retaining the two bands upon the two dead pulleys, A, C, while the machine is prepared for another impression.

The action of the scraper is peculiar and novel: it is balanced so that its tendency is to remain slightly raised, but in its forward movement, and at the point desired, it is made to descend by a stop fixed upon the top of the main standard, L, into a position vertical, or nearly so, in which position it is retained by its own onward progress against strong abutments projecting from the frames, F; on the return it resumes its raised position, and passes back without impediment. The scraper may be adjusted to give the pressure desired, or the table on which the stone is placed regulated by screws.

The advantages embodied in this machine will be at once recognised by those interested. The pulling down of the scraper, and the labour and inconvenience attendant upon that operation, are entirely superseded by the simple and effectual valve-like movement just explained, which forms the groundwork of this combination, although it will alike apply to the press-work by hand, and is the most striking novelty in the machine.

LITHOGRAPHY. Though this subject belongs rather to the arts of taste and design than to productive manufactures, its chemical principles fall within the province of this Dictionary.

The term *lithography* is derived from λίθος, *a stone*, and γραφή, *writing*, and designates the art of throwing off impressions upon paper of figures and writing previously traced upon stone. The processes of this art are founded—

1. Upon the adhesion to a grained or smoothly-polished limestone of an encaustic fat which forms the lines or traces.

2. Upon the power acquired by the parts penetrated by this encaustic of attracting to themselves, and becoming covered with, a printer's ink having linseed-oil for its basis.

3. Upon the interposition of a film of water, which prevents the adhesion of the ink in all the parts of the surface of the stone not impregnated with the encaustic.

4. Lastly, upon a pressure applied to the stone, such as to transfer to paper the greater part of the ink which covers the greasy tracings or drawings of the encaustic.

The lithographic stones of the best quality are still procured from the quarry of Solenhofen, a village at no great distance from Munich, where this mode of printing had its birth. They resemble in their aspect the yellowish-white lias of Bath, but their geological place is much higher than the lias. Abundant quarries of these fine-grained limestones occur in the county of Pappenheim, along the banks of the Danube, presenting slabs of every required degree of thickness, parted by regular seams, and ready for removal with very little violence. The good quality of a lithographic stone is generally denoted by the following characters: its hue is of a yellowish-grey, and uniform throughout; it is free from veins, fibres, and spots; a steel point makes an impression on it with difficulty; and the splinters broken off from it by the hammer display a conchoidal fracture.

The Munich stones are retailed on the spot in slabs or layers of equal thickness; they are quarried with the aid of a saw, so as to sacrifice as little as possible of the irregular edges of the rectangular tables or plates. One of the broad faces is then dressed, and coarsely smoothed. The thickness of these stones is nearly proportional to their other dimensions; and varies from $1\frac{2}{3}$ inch to 3 inches.

In each lithographic establishment the stones receive their finishing, dressing, and polishing; which are performed like the grinding and polishing of mirror-plate. The work is done by hand, by rubbing circularly a moveable slab over another in a horizontal position, with fine-sifted sand and water interposed between the two. The style of *work* that the stone is intended to produce determines the kind of polish that it should get. For crayon-drawing the stone should be merely grained more or less *fine* according to the fancy of the draughtsman. The higher the finish of the surface the softer are the drawings; but the printing process becomes sooner *pasty*, and a smaller number of impressions can be taken. *Works in ink* require the stone to be more softened down, and finally polished with pumice and a little water. The stones thus prepared are packed for use with white paper interposed between their faces.

Zinc plates are sometimes used in lieu of stones; they are prepared by graining the surface with fine sand, rubbed over by means of a small piece of the metal. Zinc takes a finer surface than stone, and yields more delicate impressions; but great care is necessary in keeping it dry, so that it does not corrode; this is almost the only objection to its more general use, for it is far more convenient to handle and move about than heavy stones.

Lithographic Crayons.—Fine lithographic prints cannot be obtained unless the crayons possess every requisite quality. The ingredients composing them ought to be of such a nature as to adhere strongly to the stone, both after the drawing has undergone the preparation of the acid, and during the press-work. They should be hard enough to admit of a fine point, and trace delicate lines without risk of breaking. The following composition has been successfully employed for crayons by MM. Bernard and Delarue, at Paris:—

	Parts
Pure wax (first quality)	4
Dry white tallow soap	2
White tallow	2
Gum lac	2
Lamp-black, enough to give a dark tint	1
Occasionally copal varish	1

The wax should be melted over a gentle fire, and the lac, broken to bits, is then added by degrees, stirring all the while with a spatula: the soap is next introduced in fine shavings; and when the mixture of these substances is very intimately accomplished, the copal varnish, incorporated with the lamp-black, is poured in. The heat and agitation are continued until the paste has acquired a suitable consistence; which may be recognised by taking out a little of it, letting it cool on a plate, and trying its quality with a penknife. This composition, on being cut, should afford brittle slices. The boiling may be quickened by setting the rising vapours on fire, which increases the temperature, and renders the exhalations less offensive. When ready it is to be poured into a brass mould, made of two semi-cylinders joined together by clasps or rings, forming between them a cylindric tube of the crayon size. The mould should be previously rubbed with a greasy cloth.

The soap and tallow are to be put into a small goblet and covered up. When the whole is thoroughly fused by heat, and no clots remain, the black is gradually sprinkled in with careful stirring.

Lithographic ink is prepared nearly on the same principle:—

	Parts
Wax	16
Tallow	6
Hard tallow soap	6
Shell-lac	12
Mastic in tears	8
Venice turpentine	1
Lamp-black	4

The mastic and lac, previously ground together, are to be carefully heated in the turpentine; the wax and tallow must be added after they are taken off the fire, and when their solution is effected, the soap-shavings are to be thrown in. Lastly, the lamp-black is to be well intermixed. Whenever the union is accomplished by heat, the operation is finished; the liquor is left to cool a little, then poured out on tables, and, when cold, cut into square rods.

Lithographic ink of good quality ought to be susceptible of forming an emulsion so attenuated that it may appear to be dissolved when rubbed upon a hard body in distilled or river water. It should flow in the pen, but not spread on the stone; capable of forming delicate traces, and very black, to show its delineations. The most essential quality of the ink is to sink well into the stone, so as to reproduce the most delicate outlines of the drawing, and to afford numerous impressions. It must, therefore, be able to resist the acid with which the stone is moistened in the preparation, without letting any of its greasy matter escape.

M. de Lasteyrie states that, after having tried a great many combinations, he gives the preference to the following:—

	Parts
Tallow soap, dried	30
Mastic in tears	30
White soda of commerce	30
Shell-lac	150
Lamp-black	12

The soap is first put into the goblet, and melted over the fire; the lac being added, it fuses immediately; the soda is then introduced, and next the mastic, stirring all the while with a spatula. A brisk fire is applied till all these materials are melted completely, when the whole is poured out into the mould.

The inks now prescribed may be employed, either with the pen and the hair-pencil, for writings, black-lead drawings, *aqua tinta*, mixed drawings, those which represent engraving on wood (woodcuts), &c. When the ink is to be used it is to be rubbed down with water, in the manner of China ink, till the shade be of the requisite depth. The temperature of the place ought to be from 84° to 90° Fahr., or the saucer in which the ink-stick is rubbed should be set in a heated plate. No more ink should be dissolved than is to be used at the time, for it rarely keeps in the liquid state for 24 hours; and it should be covered or corked up.

Autographic Paper.—Autography, or the operation by which a writing or a drawing is transferred from paper to stone, presents not merely a means of abridging labour, but also that of *re*verting the writings or drawings into the direction in which they were traced, whilst, if executed directly upon the stone, the impression given by it is *in*verted. Hence, a writing upon stone must be inverted from right to left to obtain direct impressions. But the art of writing thus is tedious and difficult to acquire; while, by means of the autographic paper and the transfer, proofs are obtained in the same direction with the writing and drawing.

Autographic Ink.—It must be fatter and softer than that applied directly to the stone, so that, though dry upon the paper, it may still preserve sufficient viscidity to adhere to the stone by mere pressure.

To compose this ink we take—

	Parts
White soap	100
White wax, of the best quality	100
Mutton-suet	30
Shell-lac	50
Mastic	50
Lamp-black	30 or 35

These materials are to be melted as above described for the lithographic ink.

Lithographic Ink and Paper.—The following recipes have been much commended:—

Virgin or white wax	8 parts
White soap	2 ,,
Shell-lac	2 ,,
Lamp-black	3 table-spoonfuls.

Preparation.—The wax and soap are to be melted together, and before they become so hot as to take fire, the lamp-black is to be well stirred in with a spatula, and then the mixture should be allowed to burn for 30 seconds; the flame being extinguished, the lac is added by degrees, carefully stirring all the time; the vessel is to be put upon the fire once more in order to complete the combination, and till the materials are either kindled or nearly so. After the flame is extinguished, the ink must be suffered to cool a little, and then put into the moulds.

With the ink-crayons thus made, lines may be drawn as fine as with the point of the graver, and as full as can be desired, without risk of its spreading in the carriage. Its traces will remain unchanged on paper for years before being transferred.

Some may think it strange that there is no suet in the above composition, but it has been found that ink containing it is only good when used soon after it is made, and when immediately transferred to the stone, while traces drawn on paper with the suet ink become defective after 4 or 5 days.

Lithographic Paper.—Lay on the paper 3 successive coats of sheep's-foot jelly, 1 layer of white starch, 1 layer of gamboge.

The first layer is applied with a sponge dipped in the solution of the hot jelly, very equally over the whole surface, but thin; and if the leaf be stretched upon a cord, the gelatine will be more uniform. The next two coats are to be laid on until each is dry. The layer of starch is then to be applied with a sponge, and it will also be very thin and equal. The coat of gamboge is lastly to be applied in the same way. When the paper is dry it must be smoothed by passing it through the lithographic press; and the more polished it is, the better does it take on the ink in fine lines.

Transfer.—When the paper is moistened, the transfer of the ink from the gamboge is perfect and infallible. The starch separates from the gelatine, and if, after taking the paper off the stone, we place it on a white slab of stone, and pour hot water over it, it will resume its primitive state.

The coat of gamboge ought to be laid on the same day it is dissolved, as by keeping it becomes of an oily nature; in this state it does not obstruct the transfer, but it gives a gloss to the paper which renders the drawing or tracing more difficult, especially to persons little accustomed to lithography.

The starch paste can be employed only when cold, the day after it is made, and after having the skin removed from its surface.

A leaf of such lithographic paper may be made in two minutes.

In transferring a writing, an ink drawing, or a lithographic crayon, even the impression of a copper-plate, to the stone, it is necessary, (1) that the impressions be made upon a thin and slender body, like common paper; (2) that they may be detached and fixed totally on the stone by means of pressure; but as the ink of a drawing sinks to a certain depth in paper, and adheres rather strongly, it would be difficult to detach all its parts, were there not previously put between the paper and the traces a body capable of being separated from the paper, and of losing its adhesion to it by means of the water with which it is damped. In order to produce this effect, the paper gets a certain preparation, which consists in coating it over with a kind of paste ready to receive every delineation without suffering it to penetrate into the paper. There are different modes of communicating this property to paper.

Besides the above, the following may be tried. Take an unsized paper, rather strong, and cover it with a varnish composed of—Starch, 120 parts; gum arabic, 40 parts; alum, 20 parts.

A paste of moderate consistence must be made with the starch and some water, with the aid of heat, into which the gum and alum are to be thrown, each previously dissolved in separate vessels. When the whole is well mixed, it is to be applied, still hot, on the leaves of paper, with a flat smooth brush. A tint of yellow colour may be given to the varnish with a decoction of the berries of Avignon, commonly called French berries by our dyers. The paper is to be dried, and smoothed by passing under the scraper of the lithographic press.

Steel pens are employed for writing and drawing with ink on the lithographic stones; in many establishments a sable brush is more frequently used.

Engraving on stone, for maps, geometrical drawings of every kind, patent inventions, machinery, &c., is performed with a diamond point as clearly and distinctly as if executed on copper or steel plates; to print these engraved stones, the ink should be laid on with a dabber, not a roller. Another method is by preparing the surface of the stone with a thin covering, or etching ground, of gum and black, upon which the design is traced or engraved with an etching point; it then appears in *white* lines upon a black surface. In this state the stone is taken to the printer, who applies ink to the engraved part, and washing off the gum, the drawing appears in *black* lines upon the white surface of the stone, and after being submitted to the process of fixing, described below, is ready for printing.

Lithotint, a process of drawing upon stone was adopted, first, by Mr. J. D. Harding, a few years back, and since by one or two other artists; several works were at the time executed by this method, which consists in *painting* the subject with a camel's-hair pencil, dipped in a preparation of liquid lithographic chalk, using the latter as if it were an ordinary colour, or Indian ink, sepia, &c. The results of this process were, however, so uncertain in printing, that it has been almost, if not entirely, abandoned.

The process of printing a subject executed in lithography is as follows:—The drawing is first executed by the artist on the stone in as perfect and finished a manner as if done on paper or cardboard: the stone is then washed over with nitric acid, diluted with gum, which neutralises the alkali, or soap, contained in the chalk, fixes the drawing, and cleanses the stone at the same time: this is technically called *etching*. The acid is then washed off with cold water, and any particles of the crayon or other substances which may have adhered to the surface are removed by the application of a sponge dipped in spirits of turpentine: the stone is now ready for printing: it is slightly wetted, charged with printing-ink by means of a roller, the sheet of paper, which is to receive the impression, is laid on it in a damp state, and the whole is passed through the press.

Chromolithography, or printing in colours from stones (χρῶμα, colour), is a comparatively recent introduction; but has been brought to such perfection, that works of art of the highest pictorial excellence are sometimes so closely imitated, as to deceive very competent judges. A portrait of Shakspeare, for example, executed in chromolithography by Mr. Vincent Brooks, of London, from an old oil painting, is so marvellous a copy of the original as almost to defy detection. Chromolithography, as a beautiful medium of illustration, is now in very general use: the process may be thus described, A drawing of the subject, in outline, on transfer tracing-paper, is made in the ordinary way: when transferred to a stone, this drawing is called the *keystone*, and it serves as a guide to all the others, for it must be transferred to as many different stones as there are colours in the subject; as many as thirty stones have been used in the production of one coloured print. The first stone required, generally for flat, local tints, is covered with lithographic ink where the parts should be of solid colour: the different gradations are produced by rubbing the stone with *rubbing-stuff*, or tint-ink, made of soap, shell-lac, &c. &c., and with a painted lithographic chalk where necessary; the stone is then washed over with nitric acid, and goes through the entire process described above. A roller charged with lithographic printing-ink is then passed over it to ascertain if the drawing comes as desired; and the ink is immediately afterwards washed off with turpentine: if satisfactory, this stone is ready for printing, and is worked off in the requisite colour; the next stone undergoes the same process for another colour, and so with the rest, till the work is complete: it will of course, be understood, that before any single impression is finished, it will have to pass through as many separate printings as there are drawings on stones. The colours used in printing are ground up with burnt linseed-oil, termed *varnish.*

LITHOMARGE. An iron ochre; essentially a silicate of alumina, with 6 to 7 per cent. of oxide of iron, in many respects resembling China clay or kaolin. It is found abundantly in co. Antrim. See IRON.

LITMUS (*Tournesol*, Fr.; *Lackmus*, Ger.) is prepared in Holland from the species of lichen called *Lecanora tartarea*, and *Roccella tinctoria*. The ground lichens are first treated with urine containing a little potash, and allowed to ferment for several weeks, whereby they produce a purple-red; the coloured liquor, treated with quicklime and some more urine, is set again to ferment during two or three weeks, then it is mixed with chalk or gypsum into a paste, which is formed into small cubical pieces by being pressed into brass moulds, and dried in the shade. Litmus has a violet-blue colour, is easy to pulverise, is partially soluble in water and dilute alcohol, leaving a residuum consisting of carbonate of lime, of clay, silica, gypsum, and oxide of iron combined with the dye. The colour of litmus is not altered by alkalis, but is reddened by acids; and is therefore used in chemistry as a delicate test of acidity, either in the state of solution or of unsized paper stained with it.

Litmus is used in Holland to give a peculiar tint to certain kinds of Dutch cheese.

The preparation of litmus has been described by Ferber, Moreloz, and others.

Litmus is imported from Holland, in the form of small, rectangular, light, and friable cakes of an indigo blue colour. Examined by the microscope, we find sporules and portions of the epidermis and mesothallus of some species of lichen, moss, leaves, sand, &c. The odour of the cakes is that of indigo and violets. The violet odour is acquired while the mixture is undergoing fermentation, and is common to all the tinctorial lichens. It has led some writers into the error of supposing that the litmus-makers use Florentine orris in the manufacture of litmus. The indigo colour depends on the presence of indigo in the litmus cakes. See LICHEN.

LITMUS-PAPER. Paper coloured with an infusion of litmus, used as a test for the presence of acids.

Faraday, in his 'Chemical Manipulation,' recommended an infusion of one ounce of litmus, and half a pint of hot water. Bibulous paper is saturated with this. Prof. Graham preferred good letter-paper to the unsized paper. In order to obtain very delicate test-paper, the alkali in the litmus must be *almost* neutralised by a minute portion of acid.

LITTORAL, *a geological term.* Belonging to the sea-shore.

LIVI-DIBI. Another name for Divi-divi. See LEATHER.

LIXIVIATION (*Lessivage*, Fr.; *Auslaugen*, Ger.) signifies the abstraction by water of the soluble alkaline or saline matters present in any earthy admixture; as from that of quicklime and potashes to make potash-lye, from that of effloresced alum schist to make aluminous liquors, &c.

LLAMA. A genus of animals belonging to the class *Mammalia*, order *Ungulata*, family *Bovidæ*, and tribe *Camelina.* They are the camels of South America, to which country they are confined. In the wild state the llamas keep together in herds of from one to two hundred. There are two distinct species found wild in South America, inhabiting the Peruvian Alps, the Pampas, and the mountains of Chili. These animals are used as beasts of burthen; cords and sacks, as well as stuffs for ponchos, &c., are fabricated from their wool; and their bones are converted into instruments for weaving the same. The Alpaca, which is a variety of the llama, has given its name to a cloth manufactured from its hair; and this has become so valuable, that attempts have been made to naturalise the animal in Europe. The success, however, which has attended these attempts has not been great. The following note from the 'Penny Cyclopædia,' article 'Llama,' is important:—

'In reference to the wool, we may here state that a herd of thirty-six, including the kinds called llamas, alpacas, and vicunas or vigonias, were sent from Lima (Peru) and Concepcion (Chili) to Buenos Ayres by journeys of two or three leagues. To those who may be inclined to import these animals, it may be necessary to state that they were fed during the journey with potatoes, maize, and hay. As soon, however, as the potatoes were exhausted, constipation came on so obstinately, that medical relief was required. They were shipped as a present from Godoy, the Prince of Peace, to the Empress Josephine, but only eleven arrived at Cadiz in 1808, just as Godoy fell into disgrace. Here two died, and the rest were near being thrown into the sea by the infuriated rabble, in their detestation of the late minister and minion. The poor llamas were however saved from the tender mercies of the populace by the governor of Cadiz, and were consigned to Don Francisco de Theran of Andalusia, who had a fine menagerie at San Lucar de Barrameda. When the French occupied the province, Marshal Soult protected them; and M. Bury St. Vincent, who was with the army, studied their habits, and executed drawings of them, which were lost at the battle of Vittoria. M. Bury paid great attention to their wool, and some from each kind was sent to the Academy of Sciences at Paris. From the report of the French naturalist and the philosophical Spaniard, it would appear that the fleece of the alpa-vigonia (produced by a cross between a vigonia and an alpaca) has much greater length than any other variety, and is six times heavier.'

The following is from James's 'History of the Worsted Manufacture in England,' p. 652:—

To commence with the earliest mention of the alpaca, we must recur to so early a period as the year 1525, when Pizarro and his ferocious companions invaded Peru. It is related by the Spanish historians, that they found there four varieties of sheep: two, the guanaco and the vicuna, in a wild state, ranging the mountainous tracts of South America; and the others, the llama, and the pacos, or alpaca, domesticated. The former of these domestic animals, partaking somewhat of the nature and size of the Arabian camel, was in like manner employed as a beast of burthen. Though in many features similar to the llama, the alpaca had several clear marks of distinction, and among others was less, and the fleece much longer and softer in fibre. In the sixteenth century, and even from the remotest times, the Peruvians being comparatively (to the other tribes of the great continent of America) a civilised people, and well acquainted with the arts of spinning and weaving, fabricated from alpaca-wool textures of much delicacy and beauty, which were highly prized as articles of dress. And that the use of them had prevailed for centuries is demonstrated by the opening of several very ancient tombs of the Peruvians, in which the dead had been enwrapped in stuffs made from the fleece of the alpaca.

In general, the alpaca ranges about four feet in height, the size of a full-grown deer, and, like it, is of graceful appearance. Its fleece is superior to the sheep in length and softness, averaging six inches (the length of the staple of the alpaca fleece is on an average much less than formerly, probably from being shorn oftener), and sometimes it has been procured even of an extraordinary length; a specimen shown at the Great Exhibition, by Messrs. Walter Milligan and Son, reaching to forty-two inches in length. The fleeces, when annually shorn, range from five to six pounds. Contrary to experience in other descriptions of wool, the fibre of the alpaca fleece acquires strength without coarseness; besides, each filament appears straight, well-formed, and free from crispness, and the quality is more uniform throughout the fleece. There is also a transparency, a glittering brightness upon the surface, giving it the glossiness of silk, which is enhanced on its passing through the dye-vat. It is also distinguished by softness and elasticity, essential properties in the manufacture of fine goods, being exempt from spiral, curly, and shaggy defects; and it spins, when treated properly according to the present improved method, easily, and yields an even, strong, and true thread. With all these remarkable qualities, it was long before the value of alpaca wool was known or appreciated in this country.

Recurring to the application of the alpaca fleece to manufacturing purposes in England, it was long delayed, though so early as the year 1807, the British troops returning from the attack of Buenos Ayres brought with them a few bags of this wool, which were submitted for inspection in London; but, observes Walton, in his work on alpaca, 'owing to the difficulty of spinning it, or the prejudice of our manufacturers, it did not then come into notice,' and for more than twenty years the attempt does not seem to have been renewed; thus depriving, for that period, the country of the advantage derived from this notable manufacture.

According to the best authorities, the first person in England who introduced a marketable fabric made from this material was Mr. Benjamin Outram, a scientific manufacturer of Greetland, near Halifax, who, about the year 1830, surmounted, with much difficulty, the obstacles encountered in spinning the wool, and eventually produced an article which sold at high prices for ladies' carriage-shawls and cloakings; but their value arose more from being rare and curious articles than from intrinsic worth.

These were, it is well established, quite destitute of the peculiar gloss and beauty which distinguish the alpaca lustres and fabrics of later times, and after a short period the manufacture was abandoned.

About the same time as Mr. Outram was weaving goods from alpaca, the wool attracted the notice of the Bradford spinners. Messrs. Wood and Walker spun it to some extent for camlet warps used in the Norwich trade. Owing to the cheapness of alpaea wool during the first years of its consumption in England, it was occasionally employed instead of English hog wool for preparing lasting and camblet warps, being spun to about No. 48.

The earliest manufacture of the alpaca-wool into goods at Bradford appears to have occurred under these circumstances. In the commencement of 1832 some gentlemen, connected with the trade to the west coast of South America, were on a visit at the house of J. Garnett, Esq., of Clithero, and, on their alluding to the difficulty of meeting with suitable returns for goods forwarded to that part of the world, he suggested to them the transmission of alpaca-wool, and offered, if they would send him a few pounds weight to ascertain its value for manufacturing purposes. In a few months he received some samples of alpaca-wool, which, on October 2, 1832, he forwarded to Messrs. Horsfall of Bradford, with a request that they would test its value. Accordingly, they fabricated from this wool a piece resembling heavy camblet, which they showed to the Leeds merchants; but the piece, not developing any peculiar qualities of alpaca, did not please, so that Messrs. Horsfall were not encouraged to proceed further with experiments. However, in the same year Messrs. Hoyam, Hall, and Co., spirited merchants of Liverpool, perceiving the value of the alpaca-wool, directed their agents in Peru to purchase and ship over all the parcels of alpaca-wool they could meet with; some of which, being sent to the Bradford district, was spun and manufactured by several parties there. The pieces chiefly fabricated from alpaca in the neighbourhood of Bradford were figures made with worsted warp and alpaca weft, the figures being raised and lustrous, like union damasks. These goods were in vogue only for a limited time, for neither the figured nor plain ones seem to have suited the public taste.

Until the introduction of cotton warps into the worsted trade it may safely be averred that the alpaca manufacture had not been developed, and would never have made much progress without being combined with cotton or silk warp. To Sir Titus Salt, of Bradford, must undoubtedly be awarded the high praise of finally overcoming the difficulties of preparing and spinning the alpaca-wool so as to produce an even and true thread; and, by combining it with cotton warps, which had then (1836) been imported into the trade at Bradford, improved the manufacture so as to make it one of the staple industries of the kingdom. He has, by an admirable adaptation of machinery, been enabled to work up the material with the ease of ordinary wool, and thus present beautiful alpaca-stuffs at a reasonable rate. Every previous attempt had been made, as far as can be ascertained, with worsted warps, with which the alpaca did not easily assort.

About the year 1836 the alpaca trade had become established, and has since risen to much importance. After this period the manufacture rapidly extended. The great mercantile house of A. and S. Henry took very large quantities of alpaca-stuffs, which began to be made in an endless variety of goods suited both for male and female dress, including scarfs, handkerchiefs, and cravats, plain and figured goods, both with silk and cotton warp, for ladies' dresses, dyed alpaca checks of beautiful texture, and a variety of grograms, codringtons, silk-striped, checked, and figured alpacas and alpaca linings. The demand for these various alpaca fabrics during the period between 1841 and 1846 remained uniform and steady.

At the commencement of the manufacture of alpaca goods with cotton warps (silk was not used) the weft was spun from fine qualities of the wool into low numbers, and the pieces were made much richer and heavier than has been the case more recently, the demand having altered in favour of lighter and less costly cloth.

Most of the alpaca-wool brought into the United Kingdom is unshipped at Liverpool, but a small portion is also carried to London. At these two ports, it may be asserted, the whole imported into this country is landed. It arrives in small bales, called ballots, weighing about 70 lbs., and is generally in an impure state, with different qualities mixed. Like the fleece of the sheep, that of the alpaca is composed of different qualities, so that the portion growing on the hind-quarters is of an inferior description. The wool is sorted into about eight different qualities, each fitted for a particular class of goods. Owing to the dirty state of the fleeces, and the peculiar nature of the dusty particles arising during the progress of sorting, the operation is an unhealthy one, unless great care be taken by ventilation to counteract this baneful effect. After being sorted, it is at Saltaire washed and combed by machinery. Until of late years it was combed wholly by hand, and the combs used for this purpose were of a deeper pitch than those usually adopted for preparing sheep's wool, that is, those combs had a larger number of teeth than ordinary. The next process is to draw the sliver, which is perfected by an improved gill-machine, especially adapted for this material. And here, in combing and preparing the alpaca-wool, so as to make a clean, even, and glossy thread, lay the grand difficulty in the way of applying the alpaca-fibre to the worsted manufacture, and which was so successfully surmounted by Sir Titus Salt.

The main articles now manufactured from alpaca-wool consists of alpaca lustres, which are dyed, and alpaca mixtures, which are undyed; and both are made of cotton or silk warp. These plain goods may, from their extensive and steady use, be termed stock-articles. Large quantities of fancy alpacas are made, but they are rapidly varying, and are distinguished by innumerable names. The material is at present much shorter in staple than formerly, owing to the alpaca being shorn oftener, so that it is now commonly from 5 to 8 inches in length. Nearly all the alpaca-wool consumed in England is worked up in the Bradford district.

Dating from the year 1834, when the importation of alpaca-wool sprung up as a permanent branch of commerce, the demand in this country has, on the whole, been a growing one. Mr. Walton, in his work on the alpaca, exhibits the quantities imported until the year 1843, when, the tariff law having come into operation, the returns began to be more correctly framed, and the alpaca-wool was then classed by itself.

Our imports were in 1843, 1,458,032 lbs.; in 1853, 2,148,267 lbs. These large quantities were yet increased in 1863, when we imported from Peru, 2,772,836 lbs.; from New Granada, 622,889 lbs.; and 6,857 lbs. from other parts; and the *Imports* of llama, alpaca, and vicuna during the three years ending 1872 were as follows:—

	1870		1871		1872	
	lbs.	Value	lbs.	Value	lbs.	Value
From Germany	..	..	..	..	184,144	£34,450
„ Peru	3,324,454	£388,969	3,083,328	£402,590	3,522,314	460,532
„ Chili	563,782	65,996	565,855	80,861	124,219	20,417
„ Other countries	300	14	2,067	282	48,062	6,433
Total	3,888,536	454,979	3,651,250	483,733	3,878,739	521,839

In the interval, the price had, with the demand, progressively increased: the price in 1834 only amounted to about 8½*d.* per pound; next year it reached nearly 10*d.*; the year after, 1*s.*; in 1838, to upwards of 1*s.* 3½*d.*; and in 1839 to 1*s.* 4*d.*

During the last ten years the prices have fluctuated considerably. In 1844, 1*s.* 8*d.* per pound was quoted as the price of the white fleece, and 2*s.* for the black one. In the year 1855, according to the price-currents, the average rates were thus quoted:—

	s.	*d.*		*s.*	*d.*
Alpaca, best white	2	6	to	2	8
„ brown and black	2	6	„	2	8
Vicuna, best dark coloured	3	0	„	3	6
Llama	0	10½	„	1	3

But these quotations are somewhat higher for alpaca-wool than the prices now realised, which of late years have ranged from 2*s.* to 2*s.* 2*d.* per pound.

Alpaca Fat was shown in the Exhibition of 1862, and was stated to be remarkable in its power of resisting rancidity. It was thought this would make it valuable to the arts, especially in perfumery.

LOAD. A burthen or freight. As the various quantities of material contained in a load cannot but be useful, the following Table is borrowed from Mr. P. L. Simmonds's 'Trade Products,' &c.:—

Corn	5 qrs. or 40 bushels.
Straw	36 trusses, or 11 cwts. 64 lbs.
Old hay	18 cwts.
New hay	19 cwts. 32 lbs.
Bricks	500.
Tiles	1,000.
Lead ore (in Derbyshire)	9 dishes or nearly 3 cwts.
Bulrushes	63 bundles.

Mortar . . 27 feet.		Timber :—	square feet
Coffee, in bags . . .	12 cwts.	2 inch plank . . .	300
Rice	10 „	2½ „ . . .	240
Timber :—	square feet	3 „ . . .	200
1 inch plank . . .	600	3½ „ . . .	170
1½ „	400	4 „ . . .	150

LOADSTONE, *Magnetic Iron-stone.* (*Fer oxydulé*, Fr.; *Magneteisenstein*, Ger.) An iron ore, consisting of the protoxide and peroxide of iron in a state of combination.

It was first discovered in Magnesia, and from that province has been derived the name MAGNET applied to this ore of iron. The term loadstone, however, is given to those specimens which are powerfully magnetic only. See IRON.

LOAM. (*Terre limoneuse*, Fr.; *Lehm*, Ger.) A native clay, mixed with quartz-sand and iron-ochre, and occasionally with some carbonate of lime.

'More commonly we find sand and clay, or clay and marl, intermixed in the same mass. When the sand and clay are each in considerable quantities, the mixture is called "loam."'—*Lyell.*

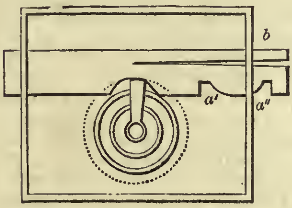
LOCKS. Although locks are distinctly a manufacture, yet they were not embraced in the early editions of this work; the chief cause of this being the desire on the part of Dr. Ure to limit the articles of the Dictionary to such manufactures as were not comprehended within his meaning of the term Handicraft.

The lock manufacture is essentially one of handicraft; and seeing that these volumes could not possibly enter into any detailed description of this and numerous other trades, as watch-making and the like, it has been determined that a brief notice of the several kinds of locks alone shall find a place in its pages.

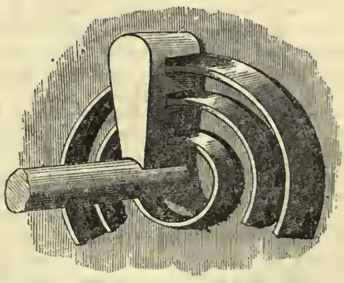
The lock manufacture of this country is confined almost exclusively to Wolverhampton and the neighbouring village of Willenhall. There are very few large manufactories, almost all kinds of locks being made by small masters, employing from half-a-dozen to a dozen men.

In nearly every kind of lock a bolt shoots out from the box or lock, usually of an oblong shape, and catches in some kind of staple or box fixed to receive it. In some a staple enters the lock, and the bolt passes through the staple within the lock. The lock of a room-door is of the first character; the lock of a writing-desk, or ordinary box, is of the second kind. The key is merely a bent piece of iron, which, on entering the lock, can move freely, and push forward the bolt. To the bolts of superior locks springs are attached, and the force required to turn the key in a lock is the force necessary to overcome the resistance of the springs. The following two figures, 1397, 1398, represent the character of a lock with wards or wheels, which are introduced to give safety. *Fig.* 1397 is an ordinary back-spring lock, representing the bolt half-shot; a' a'' are notches on the under side of the bolt, connected by a curved portion; b is the back-spring, which is of course compressed as the curved portion of the bolt

1397



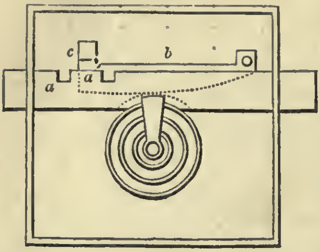
1398



passes through the aperture prepared for it in the rim of the lock; when the bolt is withdrawn, the notch a' rests in the rim; when the bolt is shot, the notch a'' rests in the same manner. The action of the key and wards is shown in *fig.* 1398. The curved pieces of metal are the wards; and there are two clefts in the bit of the key to enable it to move without interruption.

The tumbler-lock is shown in its most simple form in *fig.* 1399. Here the bolt has two slots, *a a*, in the upper part; and behind the bolt is a kind of latch, *b*, which carries a projecting piece of metal; *c*, this is the tumbler, which moves freely on a pivot at the other end. When the bolt is fully shot the projecting piece of metal falls into one notch, and when withdrawn it falls into the other. It will be evident here that the action of the key is to raise the tumbler, so that the bolt has free motion: this action will be intelligible by tracing the action of the key on the dotted lines. These tumbler-locks are greatly varied in character; but in principle they are as above described.

1399



Numerous well-known locks have been patented, the most remarkable being Chubb's lock, which has been fully described by the inventors in a paper read before the Institution of Civil Engineers; and also in an excellent treatise on locks to be found in Mr. Weale's series of useful manuals. This lock is essentially a tumbler-lock, it being fitted up with no less than six tumblers; and the key has to raise, by a series of steps, these before the bolt is free to move. It will be obvious, that unless the key is exactly fitted to move these, there is no chance of moving the bolt. In this paper already alluded to Mr. Chubb says:—

'The number of changes which may be effected on the keys of a three-inch drawer-lock is $1 \times 2 \times 3 \times 4 \times 5 \times 6 = 720$, the number of different combinations which may be made on the six steps of unequal lengths without altering the length of either step. The height of the shortest step is however capable of being reduced, 20 times; and each time of being reduced, the 720 combinations may be repeated; therefore $720 \times 20 = 14{,}400$ changes.' By effecting changes of this character, therefore, almost any number of combinations can be produced. The Bramah lock has been long celebrated, and most deservedly so. Notwithstanding the fact that this lock was picked by Mr. Hobbs after having the lock in his possession for sixteen days, it appears to us that it most fully justifies the boast made by Mr. Bramah in his 'Dissertation on the Construction of Locks.' 'Being confident,' he says, 'that I have contrived a security which no instrument but its proper key can reach, and which may be so applied as not only to defy the art and ingenuity of the most skilful workman, but to render the utmost force ineffectual, and thereby to secure what is most valued as well from dishonest servants as from the midnight ruffian, I think myself at liberty to declare (what nothing but the discovery of an infallible remedy would justify my disclosing) that all dependence on the inviolable security of locks, even of those which are constructed on the best principle of any in general use, is fallacious.' He then proceeds to demonstrate the imperfections of ordinary locks, and to describe his own.

'The body of a Bramah lock may be considered as formed of two concentric brass barrels, the outer one fixed, and the inner rotating within it. The inner barrel has a projecting stud, which, while the barrel is rotating, comes in contact with the bolt in such a way as to shoot or lock it; and thus the stud serves the same purpose as the bit of an ordinary key, rendering the construction of a bit to the Bramah key unnecessary. If the barrel can be made to rotate to the right or left, the bolt can be locked or unlocked, and the problem is, therefore, how to insure the rotation of the barrel. The key, which has a pipe or hollow shaft, is inserted in the keyhole upon the pin, and is then turned round; but there must be a nice adjustment of the mechanism of the barrel before this turning round of the key and the barrel can be insured. The barrel has an external groove at right angles to the axis, penetrating to a certain depth; and it has also several internal longitudinal grooves from end to end. In these internal grooves thin pieces of steel are able to slide, in a direction parallel with the axis of the barrel. A thin plate of steel, called the locking plate, is screwed in two portions to the outer barrel, concentric with the inner barrel; and at the same time occupying the external circular groove of the inner barrel; this plate has notches, fitted in number and size to receive the edges of the slides which work in the internal longitudinal grooves of the barrel. If this were all, the barrel could not revolve, because the slides are catching in the grooves of the locking plate; but each slide has also a groove, corresponding in depth to the extent of this entanglement; and if this groove be brought to the plane of the locking plate, the barrel can be turned, so far as respects the individual slide. All the slides must, however, be so adjusted, that their grooves shall come to the same plane; but, as the notch is cut at different points in the lengths of the several slides, the slides have to be pushed in to different distances in the barrel, in order that this juxtaposition of notches may be insured. This is effected by the key, which has notches or clefts at the end of the pipe equal in number to the slides, and made to fit the ends of the slides when the key is inserted; the key presses each slide, and pushes it so far as the depth of its cleft will permit; and all these depths are such that all the slides are pushed to the exact position where their notches all lie in the same plane; this is the plane of the locking plate, and the barrel can be then turned.'—*Tomlinson on the Construction of Locks.* In this work the details of construction are given with great clearness.

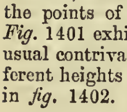
The American bank locks, especially that of Messrs. Day and Newall, have excited much attention. Their English patent describes it thus:—

'The object of the present improvements is the constructing of locks in such manner that the interior arrangements, or the combination of the internal moveable parts, may be changed at pleasure according to the form given to, or change made in, the key, without the necessity of arranging the moveable parts of the lock by hand, or removing the lock or any part thereof from the door. In locks constructed on this plan the key may be altered at pleasure; and the act of locking, or throwing out the bolt of the lock, produces the particular arrangements of the internal parts, which correspond to that of the key for the time being. While the same is locked, this form is retained until the lock is unlocked or the bolt withdrawn, upon which the internal moveable parts return to their original position, with reference to each other; but these parts cannot be made to assume or be brought back to their original position, except by a key of the precise form and dimensions as the key by which they were made to assume such arrangement in the act of locking. The key is changeable at pleasure, and the lock receives a special form in the act of locking according to the key employed, and retains that form until in the act of unlocking by the same key it resumes its original or unlocked state. The lock is again changeable at pleasure, simply by altering the arrangement of the moveable bits of the key; and the key may be changed to any one of the forms within the number of permutations of which the parts are susceptible.'—April 15, 1851.

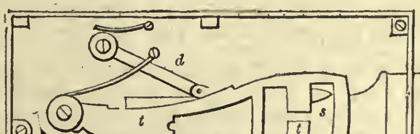
Mr. Hobbs who has been carrying out the manufacture of American locks in this country has introduced an inexpensive lock, which he calls a *protector lock.* The following description is borrowed from Mr. Charles Tomlinson's 'Treatise on the Construction of Locks':—

'When the American locks became known in England, Mr. Hobbs undertook the superintendence of their manufacture, and their introduction into the commercial world. Such a lock as that just described must necessarily be a complex piece of mechanism; it is intended for use in the doors of receptacles containing property of great value; and the aim has been to baffle all the methods at present known of picking locks, by a combination of mechanism necessarily elaborate. Such a lock must of necessity be costly; but in order to supply the demand for a small lock at moderate price, Mr. Hobbs has introduced what he calls a *protector lock.* This is a modification of the ordinary six-tumbler lock. It bears an affinity to the lock of Messrs. Day and Newall, inasmuch as it is an attempt to introduce the same principle of security against picking, while avoiding the complexity of the changeable lock. The distinction which Mr. Hobbs has made between secure and insecure locks will be understood from the following proposition: viz. 'that whenever the parts of a lock which come in contact with the key are so affected by any pressure applied to the bolt, or to that portion of the lock by which the bolt is withdrawn, as to indicate the points of resistance to the withdrawal of the bolt, such a lock can be picked.' *Fig.* 1401 exhibits the internal mechanism of this new patent lock. It contains the usual contrivances of tumblers and springs, with a key cut into steps to suit the different heights to which the tumblers must be raised. The key is shown separately in *fig.* 1402. But there is a small additional piece of mechanism, in which the

1400



1401



1402

tumbler stump shown at *s* in *figs.* 1400 and 1401 is attached; which piece is intended to work under or behind the bolt of the lock. In *fig.* 1401, *b* is the bolt; *t t* is the front or foremost of the range of six tumblers, each of which has the usual slot and notches. In other tumbler-locks the stump or stud which moves along these slots is riveted to the bolt, in such manner that, if any pressure be applied in an attempt to withdraw the bolt, the stump becomes pressed against the edges of the tumblers, and bites or binds against them. How far their biting facilitates the picking of a lock will be shown further on; but it will suffice here to say, that the moveable action given to the stump in the Hobbs lock transfers the pressure to another quarter. The stump *s* is riveted to a peculiarly-shaped piece of metal *h p* (*fig.* 1400), the hole in the centre of which fits upon a centre or pin in a recess formed at the back of the bolt; the piece moves easily on its centre, but is prevented from so doing spontaneously by a small binding spring. The mode in which this small moveable piece takes part in the action of the lock is as follows: when the proper key is applied in the usual way, the tumblers are all raised to the proper heights for allowing the stump to pass horizontally through the grating; but should there be an attempt made, either by a false key or by any other instrument, to withdraw the bolt before the tumblers are properly raised, the stump becomes an obstacle. Meeting with an obstruction to its passage, the stump turns the piece to which it is attached on its centre, and moves the arm of the piece *p* so that it shall come into contact with a stud riveted into the case of the lock; and in this position there is a firm resistance against the withdrawal of the bolt. The tumblers are at the same moment released from the pressure of the stump. There is a dog or lever *d*, which catches into the top of the bolt, and thereby serves as an additional security against its being forced back. At *k* is the drill-pin on which the pipe of the key works; and *r* is a metal piece on which the tumblers rest when the key is not operating upon them.

Another lock, patented by Mr. Hobbs in 1852, has for its object the absolute closing of the key-hole during the process of locking. The key does not work or turn on its own centre, but occupies a small cell or chamber in a revolving cylinder, which is turned by a fixed handle. The bit of the moveable key is entirely separable from the shaft or stem, into which it is screwed, and may be detached by turning round a small milled headed thumb-screw. The key is placed in the key-hole in the usual way, but it cannot turn; its circular movement round the stem as an axis is prevented by the internal mechanism of the lock; it is left in the key-hole, and the stem is detached from it by unscrewing. By turning the handle, the key-bit, which is left in the chamber of the cylinder, is brought into contact with the works of the lock, so as to shoot and withdraw the bolt. This revolution may take place whether the bit of the moveable key occupy its little cell in the plate or not; only with this difference—that if the bit be *not* in the lock, the plate revolves without acting upon any of the tumblers; but if the bit be in its place, it raises the tumblers in the proper way for shooting or withdrawing the bolt. It will be understood that there is only one key-hole, namely, that through which the divisible key is inserted; the other handle or fixed key working through a hole in the cover of the lock only just large enough to receive it, and not being removable from the lock. As soon as the plate turns round so far as to enable the key-bit to act upon the tumblers, the key-hole becomes entirely closed by the plate itself, so that the actual locking is effected at the very time when all access to the interior through the key-hole is cut off. When the bolt has been shot, the plate comes round to its original position, it uncovers the key-hole, and exhibits the key-bit occupying the little cell into which it had been dropped; the stem is then to be screwed into the bit, and the latter withdrawn. It is one consequence of this arrangement, that the key has to be screwed and unscrewed when used; but through this arrangement the key-hole becomes a sealed book to one who has not the right key. Nothing can be moved, provided the bit and stem of the key be both left in; but by leaving in the lock the former without the latter, the plate can rotate, the tumblers can be lifted, and the bolt can be shot.

LOCUST TREE. A North American tree, the *Robinia pseudacacia.* 'It grows most abundantly in the southern States; but it is pretty generally diffused through the whole country. It sometimes exceeds four feet in diameter and seventy feet in height. The locust is one of the very few trees planted by the Americans.' This wood is much used for ships' tree-nails, and is employed for stakes and pales.

The wood of the *Hymenæa Courbaril* is also known as locust wood.

LODE (*a mining term*). A mineral lode, or a mineral vein, is the name given to a fissure in the crust of the earth which has been filled in with metalliferous matter. The miner gives the same name *lode* to a fissure filled with quartz, carbonate of lime, &c., but then he says the lode is not 'mineralised,' confining the word 'mineral' to metalliferous matter.

The term *vein* has frequently led to the idea that it expresses the condition of something analogous to the blood-vessels of the animal body, to which a lode has not in the remotest degree any resemblance. During some primary convulsions, the crust of the earth has been cracked, these fissures having, of course, some special relation to the direction of the force which produced them. These cracks have during ages of submergence been filled in, according to some law of polarity, with mineral matter, the character of the lode having generally some special relation to its direction. See MINING.

LOGWOOD (*Bois de Campêche, Bois bleu*, Fr.; *Blauholz*, Ger.) is the wood of the *Hæmatoxylon Campechianum*, a native tree of Central America, grown in Jamaica since 1715. It was first introduced into England in the reign of Elizabeth, but as it afforded to the unskilful dyers of her time a fugitive colour, it was not only prohibited from being used, under severe penalties, but was ordered to be burned wherever found, by a law passed in the 23rd year of her reign. The same prejudice existed, and the same law was enacted against indigo. At length, after a century of absurd prohibition, these two most valuable tinctorial matters, by which all our hats, and the greater part of our woollen cloths, are dyed, were allowed to be used. The logwood tree grows from 40 to 50 feet high, the stems are cut into logs of about 3 feet long, the bark and white sap (alburnum) of which are chipped off, the heart or red part only being sent to England. Chevreul gave the constituents of logwood as *volatile oil, hæmatin, resinous matter, tannin, glutinous matter, acetic acid*, sundry salts of *lime*, with *alumina, silica, manganese, and iron.* The decoction of logwood is of a deep dull red, which is rendered paler and of a brighter colour by acids. Alkalis give it a purplish or violet colour. Acetate of lead causes a blue, alum a violet precipitate; the salts of iron make it a dark violet blue, gelatine forming a reddish precipitate with it. The colouring principle of logwood is a crystallisable substance known as *hæmatoxylin*, which contains $C^{16}H^{7}O^{6}$ ($\mathbf{C^{16}H^{14}O^{6}}$).

Old wood, with black bark and with little of the white alburnum, is preferred. Logwood is denser than water, specific gravity, 1·057, very hard, of a fine compact grain, and almost indestructible by the atmospheric elements; it has a sweet and astringent taste, and a peculiar but inoffensive smell, and will take a fine polish.

When chipped logwood is for some time exposed to the air, it loses a portion of its dyeing power. Its decoction absorbs the oxygen of the atmosphere, and then acquires the property of precipitating with gelatine, which it had not before. The dry extract of logwood, made from an old decoction, affords only a fugitive colour.

For its applications in dyeing, see BLACK DYE; CALICO PRINTING; DYEING; HAT DYEING, &c.

Imports of Logwood.

LÖLINGITE. An arsenide of iron, resembling mispickel. It is occasionally auriferous, and has been worked for gold at Reichenstein in Silesia. See PYRITES.

LOOKING GLASS. See MIRRORS.

LOOM (*Métier à tisser*, Fr.; *Weberstuhl*, Ger.) is the ancient and well-known machine for weaving cloth by the decussation of a series of parallel threads, which run lengthwise, called the warp or chain, with other threads thrown transversely with the shuttle, called the woof or weft. See JACQUARD LOOM and WEAVING.

LOVAGE. The *Levisticum officinale*, an umbelliferous plant, with aromatic fruit.

LUBRICANTS. Oleaginous or fatty bodies employed for the purpose of reducing the friction between two parts of a machine or carriage.

LUBRICATING OIL. This name has recently been specially given to an oil or grease prepared from the mineral naphthas. It ought to have a specific gravity varying from 0·920 to 0·950, and to possess but a very slight odour. Although it contain paraffin, yet it ought not to deposit any when cooled to 2° Cent. See NAPHTHA.

LUBRICATION. The lubrication of the wheel and axle of railway carriages is effected by a kind of soap: a combination of cocoa-nut oil or palm oil, or ordinary fats, with soda being the 'grease' with which the boxes are filled. The heat produced by the friction melts the grease, and it flows out upon the parts in motion through an opening in the bottom of the box. Heavy machinery, such as pumping-engines, require tenacious bodies as their lubricants, while the finer parts must be carefully oiled with oils as free as possible from any of the fatty acids. Spinning machinery, for example, must be lubricated with the finest oils, or, as it is found to be still better, with those peculiar hydro-carbon compounds, as paraffin, glycerine, and the like. The following is a simple and efficacious plan of lubricating the joints and bearings of machinery by capillary attraction, the invention of Edward Woolsey, Esq.:—

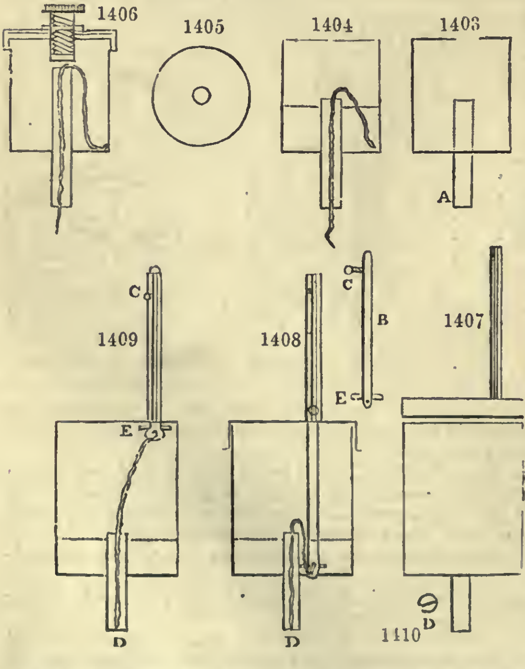
Fig. 1403 represents a tin cup, which has a small tin tube A, which passes through the bottom. It may have a tin cover to keep out the dust.

Fig. 1404 is a plan of the same.

Fig. 1405 is a section of the same. Oil is poured into the cup, the one end of a worsted or cotton thread is dipped into the oil, and the other end passed through the tube. The capillary attraction causes the oil to ascend and pass over the orifice of the tube, whence it gradually descends, and drops slower or quicker according to the length of the thread or its thickness, until every particle of oil is drawn over by this capillary siphon. The tube is intended to be put into the bearings of shafts, &c., and is made of any size that may be wished. If oil, or other liquids, is desired to be dropped upon a grindstone or other surface, this cup can have a handle to it, or be hung from the ceiling.

Fig. 1406. It is frequently required to stop the capillary action when the machinery is not going; and this has been effected by means of a tightening screw, which passes through a screw boss in the cover of the cup, and presses against the internal orifice of the tube, preventing the oil from passing.

Fig. 1407. As when these screw cups are used upon beams of engines and moving bearings, the screw is apt to be tightened by the motion; and also, as the action of the screw is uncertain, from the workman neglecting to screw it down sufficiently, it answers best to take out the capillary thread when the lubrication is not required; and to effect this easily, a tin top is fixed to the cup, with a round pipe soldered to it; this pipe has a slit in it, like a pencil-case, and allows a bolt B to slide easily. In *fig.* 1408 the bolt is down; in *fig.* 1409 the bolt, which is a piece of brass wire, is drawn up, and thus the flowing of the oil is checked. In *fig.* 1409 it will be observed, that the bolt is kept in its place by its head C, resting in a lateral slit in the pipe, and it cannot be drawn out on account of the pin E. One end of the thread is fastened to the eye-hole at the bottom of the bolt, and the other end is tied to a small wire which crosses the lower orifice of the tube at D, and which is shown in plan, *fig.* 1410.



The saving by this plan, instead of pouring oil into the bearings, is 2 gallons out of 3, while the bearings are better oiled.

The saving in labour is considerable where there are many joints to keep oiled three or four times a day; and the workman does not, with this apparatus, run the risk of being caught by the machinery. To tie on the cotton or worsted thread, pass a long thread through the eye-hole, E, of the bolt, and then draw the two ends through the tube by a fine wire with a hook to it, one end on one side of the cross-wire D, and the other end on the other side. Then put the cover on, and the bolt in the position shown in *fig.* 1409; when, by drawing the two ends of the thread, and tying them across the wire D, you have the exact length required. When you wish to see the quantity of oil remaining in the lubricator, the bolt must be dropped, as in *fig.* 1408, and you can then lift the cover a little way off, without breaking the thread, and replenish with oil. The figures in the woodcut are one-third of the full size.

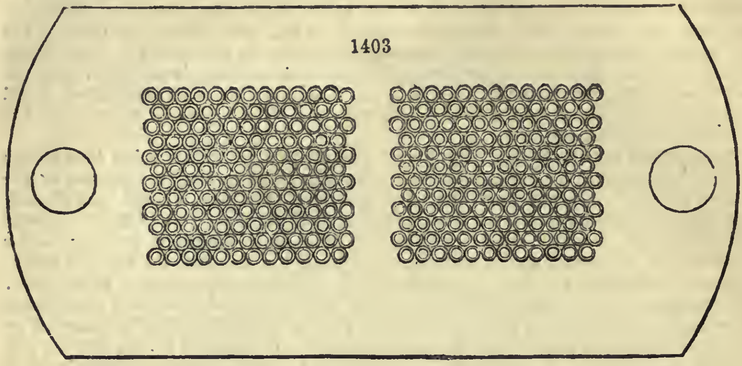
LUCIFER MATCHES. The importance of this manufacture has been shown by Mr. Tomlinson in a communication made by that gentleman to the 'Journal of the Society of Arts.' 'It has been estimated,' he says, 'that the English and French manufacturers of phosphorus are now producing at the rate of 300,000 lbs. of common phosphorus per annum, nearly the whole of which is consumed in making lucifer matches. In compounding the emulsion for tipping the matches, the German manufacturers make three pounds of phosphorus suffice for five or six millions of matches. If we suppose only one-half of the French and English annual product of phosphorus to be employed in making matches, this will give us 250,000,000,000 of matches as the annual product consequent on the consumption of one-half of the French and English phosphorus. We need not suppose this to be an exaggerated statement when we consider the daily product of some of our match manufactories. I lately had occasion to describe the processes of a London factory, which produces 2,500,000 matches daily. For this purpose, fourteen 3-inch planks are cut up; each plank produces 30 blocks; each block, of the dimensions of 11 inches long, $4\frac{1}{2}$ inches wide and 3 inches thick, produces 100 slices; each slice 31 splints; each splint 2 matches: thus we have—$14 \times 30 \times 100 \times 31 \times 2 = 2,604,000$ matches as the day's work of a single factory in London. At Messrs. Dixon's factory, near Manchester, from 6,000,000 to 9,000,000 of matches are produced daily.'

The lucifer matches formerly employed for procuring a light were the wooden sulphur matches, coated with a paste containing phosphorus, which, when dry, would ignite by friction. To prepare the paste, phosphorus was melted with a certain quantity of water at 120°, the requisite proportion of nitrate, with a small proportion of chlorate of potash, was dissolved in this water, a small quantity of binoxide of manganese or red lead added, and the liquid thickened with gum; the whole was well triturated together in a mortar till the globules of phosphorus ceased to be visible to the eye, and the mass was coloured with Prussian blue or with minium. The points of the matches were dipped into this paste, and then cautiously dried in a stove. The use of the gum was to serve as a varnish to protect the phosphorus from oxidation by the air.

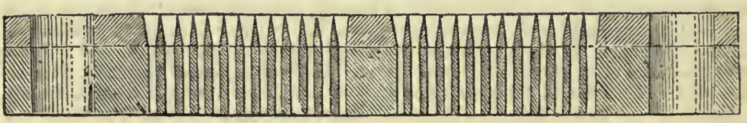
For the rapid manufacture of the wooden splints for lucifer matches, a patent was obtained by Mr. Reuben Partridge, in March 1842. He employed a perforated metallic plate, having a steel face, strengthened by a bell-metal back; see *figs.* 1411, 1412. The size of the perforations must depend on that of the desired splints; but they must be as close together as possible, that there may be a very small blank space between them, otherwise the plate would afford too great a resistance to the passage of the wood. By this construction, the whole area of the block of wood may be compressed laterally into the countersunk openings, and forced through the holes, which are slightly countersunk to favour the entrance and separation of the wooden fibres. *Fig.* 1411 represents the face of one of these plates; and *fig.* 1412 is a rectangular section through the plate. A convenient size of plate is 3 inches broad, 6 inches long, and 1 inch thick. The mode of pressing is by fixing the back of the plate against a firm resisting block or bearing, having an aperture equal to the area of the perforations in the plate, and then placing the end of the piece or pieces of wood in the direction of the grain against the face of the plate within the area of the perforated portion. A plunger or lever, or other suitable mechanical agent, being then applied to the back or reverse end of the piece of wood, it may be forced through the perforations in the plate, being first split as it advances by the cutting edges of the holes, and afterwards compressed and driven through the perforations in the plate, coming out on the opposite side or back of the plate in the form of a multitude of distinct splints, agreeably to the shapes and dimensions of the perforations.

The first stage in the manufacture of lucifers is the cutting the wood, which is done, according to the extent of the manufactory, either by hand or by machinery. This, as well as the subsequent process of counting and placing the matches in frames, is in itself necessarily free from any inconvenience or evil consequences; nor does it appear that the third stage, which consists of melting the sulphur and dipping the heads of the matches in it, produces any inconvenience. The fourth, fifth, sixth, and seventh stages comprise the grinding, mullering, and mixing of the explosive compound; the process of dipping the matches in it, the counting and boxing. The dipping, counting,

1403



1404



and packing appear to be, according to Mr. Geist, the only departments in which the workpeople are in any way affected with peculiar complaints; we would even limit the appearance of the jaw-disease to those engaged in dipping—at least, all that we have examined on the subject were unanimous as to the fact that dippers only were attacked. There is a certain degree of secrecy observed relative to the proportions of the composition; and the mixture of the materials is generally performed by the proprietor of the manufactory, or by a confidential workman. Chlorate of potash is considered an essential ingredient in England; but in the manufactories at Nürnberg it has not been employed for a number of years, as its explosive properties much endangered the safety of the buildings and the limbs of the workmen.

The composition used in Nürnberg consists of one-third of phosphorus, of gum-arabic (which is eschewed by English manufacturers on account of its hygrometric property), of water, and of colouring-matter, for which either minium or Prussian blue is employed. If ignition be required without a flame, the quantity of phosphorus is diminished, or nitrate of lead is added. The mixing is conducted in a water-bath; and during this process, and as long as the phosphorus is being ground or 'mullered,' copious fumes are evolved. The dipping is performed in the following manner:—The melted composition is spread upon a board covered with cloth or leather, and the workman dips the two ends of the matches alternately that are fixed in the frame; and as this is done with great rapidity, the disengagement of fumes is very considerable, and the more liable to be injurious, as they are evolved in a very concentrated form close to the face of the workman. This department is generally left to a single workman; and the average number that he can dip in an hour, supposing each frame to hold 3,000 matches, would be 1,000,000.

As the matches have been dipped, they require to be dried. This is generally done in the room in which the former process is carried on; and as a temperature of from 80° to 90° Fahr. is necessary, the greatest quantity of fumes is evolved at this stage. When the matches are dried, the frames are removed from the drying-room, and the lucifers are now ready to be counted out into boxes. As this is done with great rapidity they frequently take fire, and, although instantly extinguished in the sawdust or the water which is at hand, the occurrence gives rise to an additional and frequent evolution of fumes.

The composition of lucifer matches varies greatly, as it regards the proportions of the materials employed. In principle they are, however, as we have described them above; everything depending on the ignition of the phosphorus, and the perfection of a lucifer match is in tipping the match with a composition which will ignite quietly upon attrition against any rough surface, but which is not liable to ignition by such pressure as it may be subjected to under the ordinary condition of keeping in closed boxes.

According to Dr. R. Böttger, in *Annalen der Chemie und Pharmacie*, vol. xlvii. p. 334, the best composition for lucifer matches is—

	Parts		Parts
Phosphorus	4	Red ochre, or red lead	5
Nitre	10	Smalt	2
Fine glue	6		

Convert the glue, with a little water, by a gentle heat into a smooth jelly, put it into a slightly-warm porcelain mortar to liquefy; rub the phosphorus down through this gelatine at a temperature of about 140° or 150° Fahr.; add the nitre, then the red powder, and lastly the smalt, till the whole forms a uniform paste. To make writing-paper matches, which burn with a bright flame, and diffuse an agreeable odour, moisten each side of the paper with tincture of benzoin, dry it, cut it into slips, and smear one of their ends with a little of the above paste by means of a hair-pencil. On rubbing the said end, after it is dry, against a rough surface the paper will take fire, without the intervention of sulphur.

To form lucifer wood-matches that act without sulphur, melt in a flat-bottomed tin pan as much white wax as will stand $\frac{1}{10}$th of an inch deep; take a bundle of wooden matches free from resin, rub their ends against a red-hot iron plate till the wood be slightly charred; dip them now in the melted wax for a moment, shake them well on taking them out, and finally dip them separately in the above viscid paste. When dry, they will kindle readily by friction.

The phosphorus may be introduced into the composition of lucifer matches in the form of a solution in bisulphide of carbon. It has been suggested by C. Puscher to employ a sulphide of phosphorus in the place of pure phosphorus.

A '*Safety Lucifer Match*,' as it is called, has been manufactured at Jönköping in Sweden and by Böttger in Germany. A patent was obtained in this country, by Messrs. Bryant and May, for this match. Its peculiarity consists in the division of the combustible ingredients of the lucifer between the match and the friction-paper. In the ordinary lucifer the phosphorus, sulphur, and chlorate of potash or nitre, are all together on the match, which ignites when rubbed against any rough substance. In the Swedish matches these materials are so divided that the phosphorus is placed on the sand-paper, whilst the sulphur and a minimum amount of chlorate or nitrate of potash is placed on the match. In virtue of this arrangement it is only when the phosphorised sand-paper and the sulphurised match come in contact with each other that the ignition occurs. Neither match nor sand-paper, singly takes fire by moderate friction against a rough surface. The phosphorus used in the sand-paper for these safety matches is the amorphous variety described below.

The preparation of lucifer matches has been attended with much human suffering. Every person engaged in a factory of this kind is more or less exposed to the fumes of phosphorus, and this exposure produces a disease which has thus been described by Mr. Harrison in the 'Quarterly Journal of Medical Science':—'This disease,' he says, 'is of so insidious a nature that it is at first supposed to be common toothache, and a most serious disease of the jaw is produced before the patient is fully aware of his condition. The disease gradually creeps on, until the sufferer becomes a miserable and loathsome object, spending the best period of his life in the wards of a public hospital. Many patients have died of the disease; many, unable to open their jaws, have lingered with carious and necrosed bones; others have suffered dreadful mutilations from surgical operations, considering themselves happy to escape with the loss of the greater portion of the lower jaw.'

By the introduction of an amorphous phosphorus discovered by M. Schrötter, which is in nearly all respects unlike the ordinary phosphorus, except in combustibility, but which answers exceedingly well for the manufacture of lucifer matches, this disease is prevented, the manufactory is rendered more healthy, and the boxes of matches themselves less dangerous.

Lucifer matches are now manufactured without sulphur. Letchford employs paraffin or paraffin-oil for saturating the wood: these ignite rapidly, and burn regularly with little or no smell. Notice and approbation are due to the persevering efforts which have been made to produce friction matches, containing neither ordinary nor amorphous phosphorus. Wiederhold has proved that lucifer matches of good quality may be made with chlorate of potash and hyposulphite of lead: a result which may prove most valuable, should experience show it to be attainable on the industrial scale. Other matches free from phosphorus have been made with the following mixtures, which are given by Jettel: chlorate of potash 4 parts, sulphur 1, and bichromate of potash, 0·4; or, chlorate of potash 7, sulphur 1, bichromate of potash 2, and nitrate of lead 2; or, chlorate of potash 8 parts, bichromate of potash 0·5, and sulphide of antimony 8. Wiederhold's mixture, mentioned above, may be made of chlorate of potash 7·8 parts, hyposulphite of lead 2·6, and gum-arabic, 1.

LUMACHELLA, or *Fire Marble.* This is a dark-brown shelly marble, having brilliant fiery or *chatoyant* reflections from within. See MARBLE.

LUNAR CAUSTIC. A name for nitrate of silver, when fused and run into cylindrical moulds.

LUPININE is a substance of a gummy appearance, so named by M. Cussola, because it was obtained from Lupines.

LUPULINE. The peculiar bitter aromatic principle of the hop, *Humulus Lupulus.* See BEER.

LUSTRING, sometimes spelled and pronounced *Lutestring*; a peculiar shining silk.

LUTE (from *Lutum,* clay; *Lut,* Fr.; *Kitte, Beschläge,* Ger.) is a pasty or loamy matter employed to close the joints of chemical apparatus, or to coat their surfaces, and protect them from the direct action of flame. Lutes differ according to the nature of the vapours which they are destined to confine, and the degree of heat which they are to be exposed to.

1. *Lute of linseed-meal,* made into a soft plastic dough with water, and immediately applied pretty thick to junctions of glass, or stoneware, makes them perfectly tight, hardens speedily, resists acids and ammoniacal vapours, as also a moderate degree of heat. It becomes stronger when the meal is kneaded with milk, lime-water, or solution of glue, and is the best lute for fluo-silicic acid.

2. Lute of thick gum-water, kneaded with clay, and iron filings, serves well for permanent junctions, as it becomes extremely solid.

3. By softening in water a piece of thick brown paper, kneading it first with rye-flour paste, and then with some potter's clay, till it acquire the proper consistence, a lute is formed which does not readily crack or scale off.

4. Lute, consisting of a strong solution of glue kneaded into a dough with new slaked lime, is a powerful cement, and, with the addition of white-of-egg, forms the *lute d'âne*—a composition adapted to mend broken vessels of porcelain and stoneware.

5. Skim-milk cheese, boiled for some time in water, and then triturated into paste with fresh-slaked lime, forms also a good lute.

6. Calcined gypsum (plaster-of-Paris), diffused through milk, solution of glue, starch, or gum-water, is a valuable lute in many cases.

7. A lute made with linseed, melted caoutchouc, and pipe-clay, incorporated into a smooth dough, may be kept long soft when covered in a cellar, and serves admirably to confine acid-vapours. As it does not harden, it may therefore be applied and taken off as often as we please.

8. Caoutchouc itself, after being melted in a spoon, may be advantageously used for securing joints against chlorine and acid vapours, in emergencies when nothing else would be effectual; or we may use 1 part of caoutchouc dissolved in 2 parts of hot linseed-oil, and worked up with pipe-clay (3 parts) into a plastic mass. It bears the heat at which sulphuric acid boils.

9. The best lute for joining crucibles inverted into each other is a dough made with a mixture of fresh fire-clay and ground fire-bricks, worked with water. That cement, if made with a solution of borax, answers still better upon some occasions, as it becomes a compact vitreous mass in the fire.

LUTEOLINE is the colouring-principle of the weld (*Reseda luteola*), a slender plant, growing to the height of about three feet, and cultivated for the use of dyers. When ripe it is cut and dried.

Chevreul was the first to separate the *luteoline.* It is extracted from the weld by boiling-water, and when this solution is concentrated and allowed to cool, the luteoline separates; it is then collected, dried, and submitted to sublimation, when it is condensed in yellow needles.

It is valued for its durability, and is used as a yellow dye, on cottons principally, and also on silks, but is little used at present. It was formerly used by paper-hanging manufacturers, to form a yellow pigment, but has been entirely superseded for that purpose by *quercitron bark* and *Persian berries.* It unites with acids and alkalis, the former making the colour paler, and the latter heightening the colour. The compound which it forms with potash is of a golden colour, becoming greenish when exposed to the air, by absorption of oxygen, and at length becomes red.

It forms yellow compounds with alum, protochloride of tin, and acetate of lead; with the salts of iron it produces a blackish-grey precipitate; and with sulphate of copper a greenish-brown precipitate.

It is readily soluble in alcohol and ether, but sparingly so in water.—H. K. B.

LUTIDINE, $C^{14}H^9N$ (C^7H^9N). A volatile nitryle base, discovered by Anderson in bone-oil. It has also been found in shale-naphtha, coal-naphtha, and in crude chinoline.

LYCOPODIUM CLAVATUM. The spores of the lycopodium, or club-moss, ripen in September. They are employed, on account of their great combustibility, in theatres, to imitate the sudden flash of lightning, by throwing a quantity of them from a powder-puff, or bellows, across the flame of a candle. They are sometimes known as 'vegetable sulphur.'

LYDIAN STONE, *Touchstone*, or *Basanite*. A flinty variety of jasper, used on account of its hardness, fine texture, and velvet-black colour, for trying the purity of the precious metals. The amount of alloy is indicated by the colour left on the stone after the metal has been rubbed across it.

LYELLITE. A basic sulphate of copper, occurring as a blue incrustation on killas, from certain Cornish mines. It is named after Sir Charles Lyell. According to Tschermak, it is a mixture of langite and gypsum.

LYNX. An animal producing a favourite fur of a greyish-white with dark spots. Most of the lynx-fur is imported from North America, and is obtained from the Canadian lynx (*Felis Canadensis*).

M

MACARONI is a dough of fine wheat-flour, made into a tubular or pipe form, of the thickness of goose-quills, which was first prepared in Italy, and introduced into commerce under the name of Italian or Genoese paste. The wheat for this purpose must be ground into a coarse flour, called *gruau semoule*, by the French, by means of a pair of light mill-stones, placed at a somewhat greater distance than usual. This *semoule* is the substance employed for making the dough. See VERMICILLI.

MACE is a somewhat thick, tough, unctuous membrane, reticulated, and of a yellowish-brown or orange colour. It forms the envelope of the shell of the fruit of the *Myristica moschata*, the nutmeg. It is dried in the sun, after being dipped in brine; sometimes it is sprinkled over with a little brine, before packing, to prevent the risk of moulding. Mace has a more agreeable flavour than nutmeg, with a warm and pungent taste. It contains two kinds of oil: the one of which is unctuous, bland, and of the consistence of butter; the other is volatile, aromatic, and thinner. Mace is used as a condiment in cookery, and the aromatic oil occasionally in medicine. See NUTMEG.

MACHINES FOR THE CUTTING OF COAL IN MINES. The severe character of the labour of the coal-miner, and the dangers connected with his employment have led to several mechanical appliances, by which the task of 'hewing coal' might be lessened, and the dangers attendant on the work diminished. No one has given more attention to the subject than Mr. William Firth of Leeds, to whom we are indebted for one of the very first machines which have been successfully employed in the cutting of coal in mines. To this gentleman we owe the following notice of the progress made within the past century in this direction:—

'In 1761 Michael Menzies of Newcastle obtained a patent for cutting coal in mines, and that is the earliest evidence which we have of any attempt having been made to produce a mechanical coal-cutter; and his plans having regard to the *time* at which they were produced, were remarkable for their ingenuity.

'Menzies' specification is also remarkable in other respects, as showing that it was his intention to make use of the 'fire-engine' as his motor; which engine had, about two years previously, through the improvements of Watt and of Smeaton, attained only to so much perfection as to become a doubtful rival to the 'water miln' or 'wind miln,' and the 'horse gin.'

'By the power of one or other of these agents, he proposed to give motion to a heavy iron pick, made to reciprocate by means of spears and chains, carried down the pit, and with wheels and horizontal spears, on rollers, extended to the working places, and there to "shear" the coal exactly as it is now performed. In the same patent, Menzies included a "saw" to cut the coal; and although nothing came from his labours, he displayed so much mechanical knowledge, as to have deserved success; and his failure was evidently due to the absence of an eligible power, and not to his deficiencies as a mechanic.

'During the hundred years that followed these events more than a hundred other patents were applied for, and granted; but amongst them all, there was not one machine that approached nearer to success than the invention of Michael Menzies.

'This fact is not referred to in disparagement of the patentees, for there were many curious devices, ingeniously arranged; but the matter is referred to to show that the object excited much continuous interest, and that amongst so many miscarriages, our mechanics were still hopeful.

'Amongst these devices may be enumerated the "saw," "catapult," "battering ram," "plough," "rotary wheel," "endless chain," "planing machine," and many others by which the coal was to be either crushed, cut, or shared out.

'There had been no suitable power made known for driving the machines; and it was to that cause, without doubt, that so many failures and disappointments were attributable. The steam-engine, even when it attained to its most perfect form, is not in itself sufficient for the purpose, because steam cannot be produced near to the place where the work has to be done, nor can it be carried long distances in an effective condition, by reason of its rapid condensation. Moreover, an escape of exhaust-steam could not be permitted in the coal-mine, because of its tendency to soften and bring down the roof, the difficulty of maintaining which is already the most serious and troublesome part of coal-mining operations.

'Hydraulic power might, in certain cases, be, and has been recently, tried, but its unfavourable conditions exceed its advantages for the purpose of cutting coal in mines, and may be put aside from present considerations.

'But in compressed air, in so far as the moving power is concerned, every requirement is found; and from the date of the experiments made at West Ardsley in Yorkshire, in 1862, the question was undoubtedly settled.

'The elastic property of air under compression, is an old and well-known power; but until these experiments had been completed, its value was but imperfectly understood, and its future beneficial influence on coal-mining was unappreciated.

'The engine for compressing the air, by which a coal-cutting machine is worked, is generally placed on the surface, near to the top of the shaft; a receiver is fixed in close proximity thereto, and the air is taken from the compresser to the receiver, which is 30 feet in length and 4 feet in diameter.

'The density is generally of about three atmospheres.

'Iron pipes of sufficient area are laid on from the receiver to the bottom of the shaft, and there, being split into smaller sizes, is led in every needed direction through the roads and passages of the mine, exactly as the gas and water services are laid on in any town.

'At the entrance into the working places, screw joints or stop-cocks are fixed to the iron air-pipe, at which point an india-rubber nose, 50 or 60 yards in length (as the length of the "benk" may require) is screwed on; the other end of the nose is attached to the cutting machine, and when all is in readiness, the tap at the receiver is turned on, and the air rushes down, and throughout the whole service of pipes.

'The air does not require to be forced from the receiver, for by its own elasticity it is carried forward at a velocity corresponding to its own density.

'Apparently it loses, if the arrangements are good, but little of its power by distance, except the frictional retardation; and machines are working underground, at nearly two miles distance from the air-engine, without any serious loss of force.'

Firth's Coal-Cutting Machine.—A machine which may be simply described as a pick placed horizontally, and worked by a crank motion, has for some five or six years (1874) been steadily at work in the West Ardsley collieries. The colliers, who at first objected to 'following the machine,' instead of working with their old implements, have at length yielded to the evident advantages of the 'coal-cutter,' and in many of our largest collieries these machines are now fairly introduced.

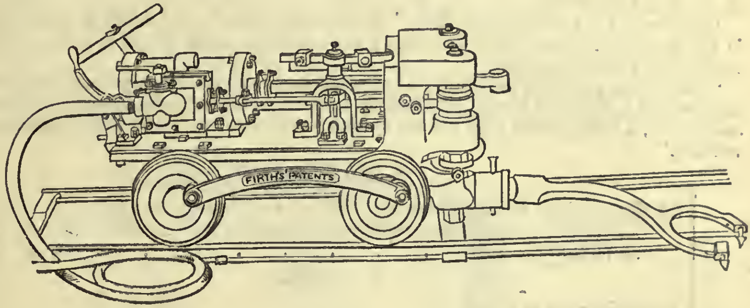
We must now turn to the consideration of this machine for cutting the coal, as invented by Mr. William Firth. *Fig.* 1413 shows its form and construction; the weight is about 15 cwts. for an ordinary sized machine, its length 4 feet, its height 2 feet 2 inches, and a gauge 1 foot 6 inches to 2 feet; it is very portable, and easily transferred from one 'benk' to another.

The front and hind wheels of the machine are coupled together in a similar manner to the coupled locomotive engines. The 'pick' or cutter is double-headed, whereby the penetrating power is considerably increased.

The groove is now cut to a depth of 3 feet to 3 feet 6 inches at one course, whereas by the old form of a single blade, the machine had to pass twice over the face of the coal to accomplish the same depth. The points are loose and cottered into the boss, so that when one is blunt or broken, it can be replaced in a few minutes. It dispenses with the necessity of sending the heavy tools out of the pit to be sharpened, and is an immense improvement on the old pick.

When all is in readiness for work, the air is admitted to the machine, and the reciprocating action commences. The piston works at a speed of sixty to ninety strokes per minute, varying according to the density of the compressed air, the hardness of the strata to be cut, or the expertness of the attendant.

1413



As to the quantity of *work*. In 'long-wall,' a machine can, under favourable circumstances, cut 20 yards in an hour, to a depth of 3 feet; but we consider 10 yards per hour very good work, or say 60 yards in a shift.

This is about equal to the day's work of twelve average men, and the persons employed to work the machine are one man, one youth, and one boy, who remove and lay down the road and clear away the *débris*.

The machines are built so strong that they rarely get out of working condition. Some of those now working at West Ardsley (and other places), have been in constant use for three or four years.

At that colliery there are about eight machines in use. One of the seams is so hard and difficult to manage, that it could not be done 'by hand,' and the proprietors had to abandon it, but *now*, by the employment of these machines, it is worked with perfect ease. It is a thin cannel seam, with layers of iron-stone, and the machines now 'hole' for about 1,200 tons per week.

The groove made by the machine is only 2 or 3 inches wide at the face, and 1½ at the back, whereas by hand, it is 12 to 18 inches on the face, and 2 to 3 inches at the back, thus:—

In thick seams worked by hand, the holeing is often done to a depth of 4 feet 6 inches to 5 feet, and the getter is quite within the hole he has made, and where the coal does not stick well up to the roof, or where there is a natural parting, there is great difficulty and danger from falls of coal. In cutting coal by the ordinary method, the angle is such that when the upper portion of coal falls off from the roof, that it must pitch forward into the 'road,' but by the machine cutting a perfectly horizontal groove. The coal, having lost its support, simply settles upon its own bed; and has no tendnecy to fall forward.

The following statement was made by the inventor at the meeting of the British Association at Bradford:—

'The cost of applying coal-cutting machinery is an important part of the question, but it frequently happens that at old established collieries there may be surplus power, which can be utilised; but supposing that everything has to be provided new, then the following may be taken as an approximate estimate of the necessary outlay:—

	£
2 Boilers at 500*l*. each	1,000
1 Steam-engine	1,250
10 Machines at 150*l*. each	1,500
Pipes, Receivers, Fixings, and sundry other outgoings	1,250
	say 5,000

'This outlay would provide all necessary power and plant for the regular working of eight machines, with two in reserve; and estimating that each machine will cut 60 yards per day, the product in a 4-foot seam would be 85 tons per day, or per week say 500 tons per machine, and 8 by 500 is 4,000 tons.

'Now at this rate of expenditure and work done, an allowance of 2*d*. per ton would in three years liquidate the entire outlay.

'But there is no reason why the machines should be restricted to a single shift daily; indeed, it is far more economical to work double shifts, there is no additional outlay of capital, and so far as depends upon the machinery, the output might be easily increased to 8,000 tons per week. . . . . . .

'We now come to the relative costs of cutting the coal, by hand and by *machine*, and the following figures may be taken as representing a somewhat favourable state of things for the latter.

'The seam is the "Middleton Main" or "Silkstone Bed." The depth of the mine is 160 yards, and the coal four feet thick; there are two bands of shale, with a thin layer of coal between them.

'The bottom portion is not always wholly merchantable, but when it is so, it yields one ton and a third of a ton per running yard. For the purpose, however, of this comparison, I take 60 tons only per day (which would come out of 45 yards of machine working.'

The Cost by Hand.

All cut on the end.

	£	s.	d.	£	s.	d.

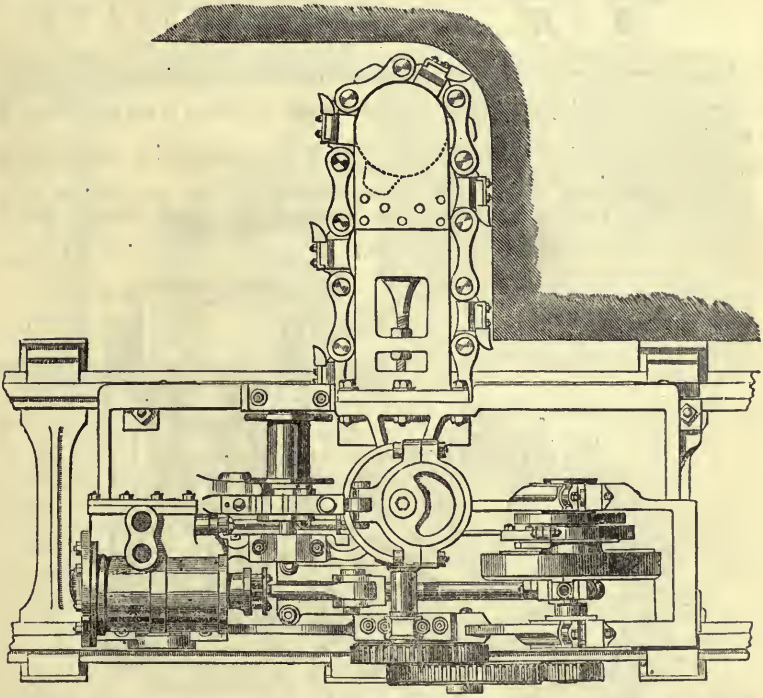
It is necessary now to bring under notice some of the other coal-cutting machines which have been introduced of late years.

Baird's, or the Gartsherrie Machine.—One of the machines which has claimed the largest share of attention is the 'Gartsherrie coal-cutter' of the Messrs. Baird. This appears to be a modified form of a machine which was patented many years since by Mr. Gleadhill.

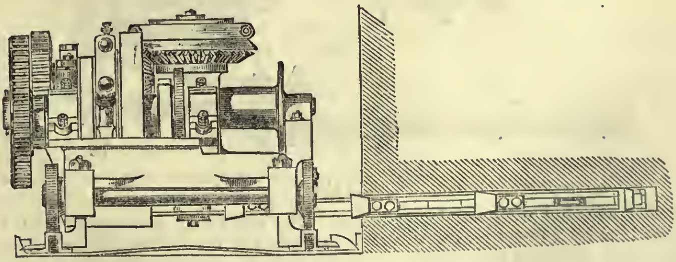
The cutting in these machines is done by an endless chain with cutters attached, driven round a jib or arm, which extends underneath the coal. The machine is actuated by air compressed on pit bank to 35 or 40 lbs. per square inch, and conveyed therefrom in cast-iron pipes. The machine at work draws or "feeds" itself along the coal face, with the jib projecting underneath the coal 2 ft. 9 in. or 3 ft. as required. The present work done (1874) is 300 to 350 ft., cut 2 ft. 9 in. deep, in a shift of eight to ten hours, and as the seam worked is 2 ft. 10 in. thick, this yields 75 to 90 tons. This rate includes all stoppages, and, of course, if it were possible to drive along without interruption, the figures would be very much higher. The speed also is capable of considerable increase by extra pressure of air, and when it is stated that even in the hard Gartsherrie coal the machine has frequently been timed at about 6 ft. in four minutes, an idea may be formed of what it would do in soft English coal with a good pressure above. The machine at work is attended by three men. The working parts of the machine are carried upon a strong cast-iron soleplate 6 ft. long by 2 ft. 6 in. broad, set upon four wheels. On the soleplate is bolted the cylinder, 8½ in. in diameter, with a 12-in. stroke. The crank shaft is fixed in bearings cast on soleplate. On this shaft is the fly-wheel and excentric, which is reversible. On one end of the shaft, overhanging the soleplate, is attached a spur-wheel, which by means of another shaft and bevel-gearing, is connected to an upright shaft, on under end of which is the chain-wheel, communicating motion to the cutting chain. The whole of these wheels are of Bessemer steel, and, so far as proved, appear to give the greatest satisfaction in wear. The cutters, nine in number, and 2¾ in. broad on face, are secured to the chain by means of two bolts passing through cutter and link. The jib, which distends the chain, is bolted to side of soleplate, and consists of two parts, the stock and point, adjustable by means of a nut and screw working against a bridge in stock. The chain is made of wrought steel, and the cutters of the best tool-steel. The machine draws or "feeds" itself by means of a drum and a $\frac{5}{16}$ in. chain passed round a pulley fixed to a prop 100 ft. in advance. The drum shaft is actuated through a toothed wheel worked by a racket motion from an excentric cast or bevel-wheel of upright shaft. The roadway on which the machine travels is of cast malleable iron. The rails are keyed down to sleepers, and are kept in condition by means of snugs cast on sleepers, which fit into oblong holes in end of rails. Each machine is fitted with 21 ft. or seven pairs of such rails 3 ft. long. The machines are of two designs. No. 1, being 2 ft. 4 in. high, requires about 3 ft. of head room between pavement and roof. No. 2 is 1 ft. 8 in. high, including roadway, and so is capable of working the thinnest seam. The gearing can be altered to speed required by the nature of the coal or other material cut. They have been adapted to undercut clay band iron-stone lying

1414



on hard sandy fire-clay. At work the machine is attended by three men, one driving, one lifting roadway behind machine, and the other laying roadway in front, &c.

1415

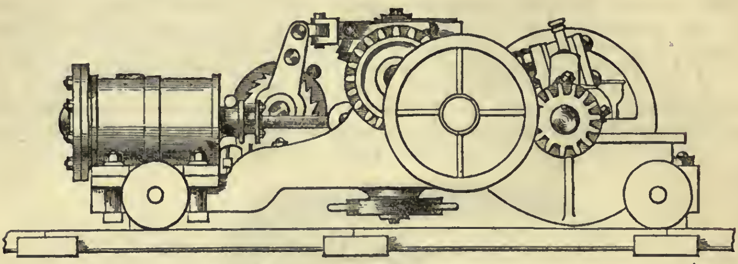


The cutters are sharpened at each shift, the cutting chain being brought to bank daily for this purpose, and the cutters removed, sharpened, and dressed to a gauge.

This description will be rendered quite intelligible by reference to the drawings.

Fig. 1414 shows the Gartsherrie machine in plan. *Fig.* 1415 gives an end elevation of the machine. In both cases the way in which the cutting work into the coal is effected is clearly shown. In *fig.* 1416 a side elevation is given, from which it will be

1416

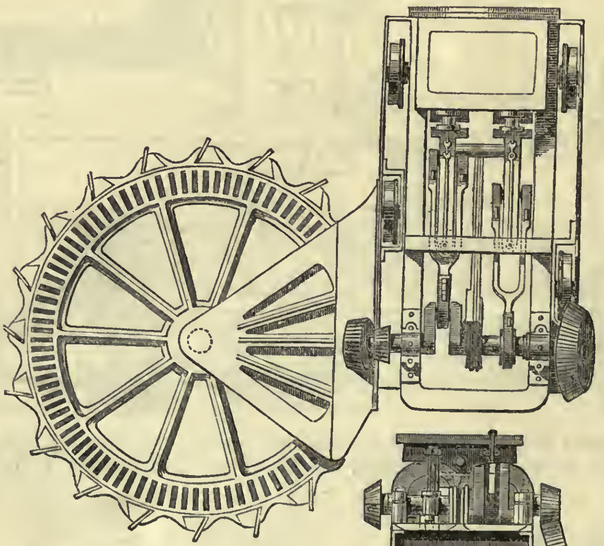


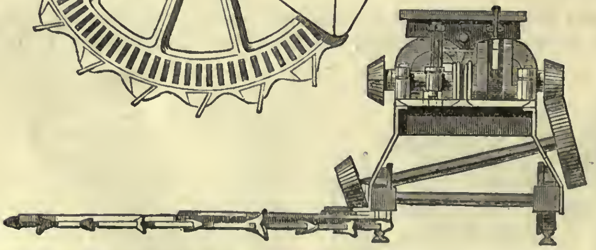
easy for anyone having but a slight acquaintance with machinery to see how motion is given to the cutters.

Gillott and Copley's Machine, which is shown in the accompanying woodcuts, was patented in 1868. *Fig.* 1417 gives the machine in plan.

The machine, with the exception of the cylinders and one spur-wheel, is made entirely of steel and wrought iron, thus combining the greatest strength in the

1417



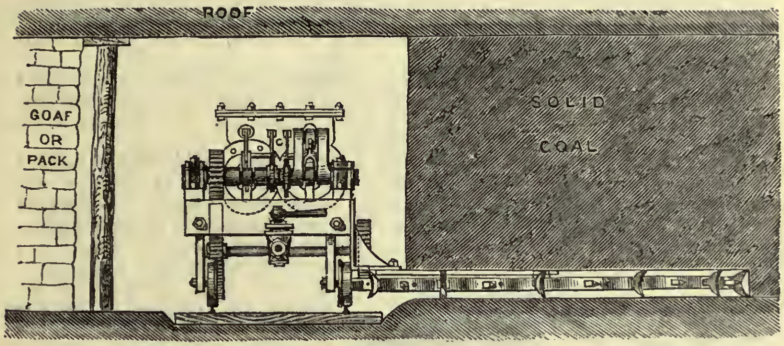


1418

smallest space, and with the least weight. The top frame is of angle-iron, 4 feet 9 inches long by 2 feet 4 inches wide, and on this are fixed two cylinders, 7½ inches in diameter, with a 9-inch stroke, working on to a crank-shaft, which, by a very simple arrangement, drives the pinion which gears into the slots of the cutter-wheel. This wheel, which is of cast steel, is carried by a bracket projecting horizontally from the side of the machine. It makes about six revolutions per minute, and on its outer edge are fixed twenty steel picks or cutters, these giving 120 strokes per minute; it is 3 feet 10 inches in diameter, and makes a clean cut of 3 feet 4 inches deep by 3 inches thick, and from this space it entirely sweeps out the whole of the coal as it revolves. The machine is propelled by a wire rope having one end secured at the extremity of the face, and passing round a drum driven by the air-cylinders, or by hand-gearing attached to the side of the machine. The whole is covered in with a moveable sheet-iron casing to protect it from anything falling from the roof. One man only is required to be in attendance on the machine, and another should follow to sprag the coal as it is cut.

With a pressure of 27 lbs. of compressed air per square inch the machine has holed, in a hard tough fire-clay seating, 25½ yards in 40 minutes, and 24 yards 1 foot of strong solid coal in 55 minutes, with only 20 lbs. pressure. A fair average rate of work with 27 lbs. pressure may be stated at thirty yards per hour, 3 feet 2 inches to 3 feet 4 inches under and 3 inches thick, either in a seating or moderately hard coal. The average rate of holeing by manual labour in the seam where it is now working is

1419



about 7 yards for a day's work—equivalent to about nine men working a whole day to do what the machine does better in two hours. The men have only to wedge or shoot the coal down and clear it away, while the machine is taken to another bank to do its work there. In *figs.* 1418 and 1419 the machine is shown in sectional elevations.

Winstanley's Machine,—The coal cutting machine of Messrs. Winstanley and Barker is not essentially different from the machines already described. It consists of a small frame running upon four wheels adapted to the colliery gauge, and carrying two oscillating cylinders driven by compressed air or steam. On the crank-shaft and underneath the frame is a pinion which gears into a very coarse-pitched toothed wheel, the ends of the teeth being armed with cutters. This cutting wheel can be turned under the carriage when not required, and when placed in position is brought to bear against the coal by turning a handle into which it cuts, until the arm carrying the wheel is at right angles to the carriage. The machine is slowly dragged forward by means of a chain attached to a crab and worked by a boy. As the machine advances, the miner in attendance drives wooden wedges into the cut to support the coal, and when the machine is out of the way the wedges are withdrawn and the coal falls. The machine itself only weighs 15 cwts., and will cut at the rate of 30 yards per hour with a pressure of only 25 lbs. per square inch, making a 'holing' in the coal 3 feet deep and only 2¾ inches high. The height of the machine is only 22 inches. It has the disadvantage of being only able to cut on one side of the carriage, but of course it can be constructed to cut on the right- or left-hand side as may be desired by the purchaser.

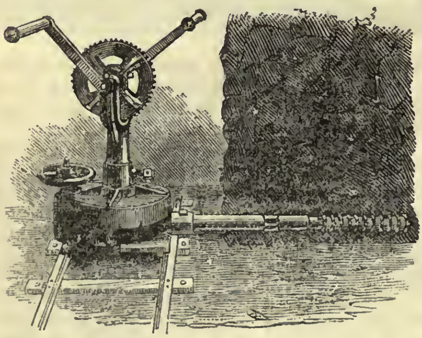
Hurd and Simpson's 39-inch self-acting, right and left-hand, variable height coal-cutter was specially constructed for the Glass Houghton Coal Company to undercut in the blue stone band lying between two portions of the coal-seam. This machine is worked on a somewhat similar principle to that of Winstanley and Barker; that is to say, the coal is undercut by means of a *circular saw* working at the end of a moveable lever, but with this important difference, that in Hurd and Simpson's machine the cutter is placed in front, and can thus cut the coal right ahead of the machine or on either side of it. The cutting wheel is slightly excentric, and the machine hauls itself along by means of a chain anchored ahead of it; for as the cutter revolves, being an excentric, the teeth on one portion of the periphery would revolve without touching the coal, but at this time the self-acting hauling gear comes into play, the machine advances, and the cutters get a fresh feed on the coal. This coal-cutter is 30 inches high over all, and cuts to a depth of 3 feet 3 inches.

Brown's Monitor Coal-Cutter has excited some attention in America. The machine consists of a five horse-power steam-engine driven by steam carried into the mine by a steam-pipe, terminating, however, in a few feet of rubber-hose, which permit of full freedom of motion to the machine. The intention of the proprietors is to employ compressed air in place of steam eventually. The cutting arrangement is an iron rim of four feet in diameter, which has on its periphery moveable steel teeth, placed at points about 12 inches apart. These teeth may be taken out and ground whenever they become dull. This rim lies on small wheels which support it and allow a free motion, and has cogs on its under surface which gear into cogs on a shaft turned by the engine. By this means the power is applied near the circumference of the wheel, instead of at the centre as in the ordinary circular saw. The principal reason for this arrangement is to get a deeper cut at the coal. The cutter can be put to a depth of $3\frac{1}{3}$ feet, or $\frac{7}{8}$ths of its whole diameter, whereas the ordinary circular saw can hardly cut to one-half of its diameter. The machine runs on a moveable track, and is fed by means of a screw working in cogs. The track is put down along the side of the coal at the proper distance from it, and when a cut has been made the whole length, the machine is put on tracks and wheeled to the next 'room,' where the track is laid as before, and so on through the mine. The duty of the machine is calculated to be at about a yard in five minutes.

The estimate of its economy given by the proprietors is that it saves about 35 cents per ton over the cost of putting out coal by hand labour, which in a mine turning out, say 200 tons a day, amounts to a saving of 70 dollars per day. The first cost of the machine is very moderate, being only about 800 dollars.

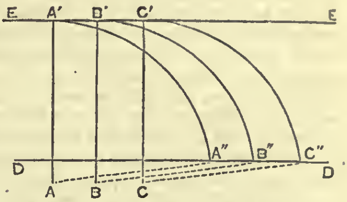
Jones's Hand Coal-Cutter.—This machine is practically a combination of inclined circular-saws mounted upon a revolving rod, so that the groove cut by each saw runs into the groove cut by the next, thus thoroughly under-cutting a seam. The saws are set on the rod obliquely, and provision is made for retaining them at a proper distance from each other, and in the most suitable position on the rod, the end of which has a screw-thread cut upon it, by means of which it is fastened into the spindle and bearings. Another form of cutting apparatus may be formed from a flat bar of steel, with saw teeth along both of its outer edges, and so twisted that the toothed edges are formed into spirals (*fig.* 1420). By this arrangement, which resembles that of Macdermott's rock-perforator, the cutter readily clears itself from the slack which it cuts away. See Rock-Perforator. A revolving cutter of this kind may be worked in two ways. It may be caused to sweep in the arc of a circle into and out of the coal, so as to cut out a groove in it, the spindle of the cutter being for that purpose carried by a frame turning upon an axis, such axis being also traversed forward from time to time in a line parallel with the face of the coal operated upon. Alternatively the frame carrying the spindle of the cutter may simply be caused to move forward continuously in a line parallel with the face of the coal, in which latter case a groove will be produced of a depth equal to the length of the cutter. But if the cutter is caused to sweep round in the arc of a circle, a groove of any desired depth can be cut, irrespective of the length of the cutter itself.

1420



Revolving cutters, such as above described, can be driven either by hand-power or by compressed air. In the former case, and when the machine is to be used only for holing or undercutting, the following is proposed as the preferable arrangement. The spindle of the cutter is mounted on bearings in a frame which can turn upon a stud on the bed-plate of the machine. On the under side of this bed-plate are sledge runners to run on rails laid upon the floor of the mine. On the frame which carries the cutter spindle is a toothed arc, into which gears a pinion carried in bearings from the bed-plate. The pinion can be turned by a hand wheel on its spindle, and thus the cutter can be caused to sweep round to and fro in the arc of a circle. Upon the cutter spindle is fixed a bevel pinion gearing into a horizontal bevel wheel, which is concentric with the stud upon which the frame carrying the cutter is mounted. The horizontal bevel is mounted upon a vertical shaft, upon which is a fly-wheel, and at its upper end a pinion which gears with a bevel wheel, which latter can be driven by a crank handle, and thus a quick revolving motion can be given to the cutter, whilst that, at the same time, may be freely swept round to and fro in the arc of a circle. Means are provided for the exclusion of dirt from the machinery, and for holding the apparatus securely while the cutter is in motion. An adjustment may be made for cutting grooves, either vertically or horizontally in the upper part of the seam, and in such case the spindle of the cutter is driven by a rotary engine set in motion by compressed air.

1421



The mode of action of Mr. Jones's apparatus will be more clearly understood on reference to the diagram (*Fig.* 1421). The fixed end of the cutter is supposed to be successively at A, B, and C, the seam of coal lying between the lines D D and E E. First the cutter, starting from the position A A′, travels round to the position A A″, clearing the triangular space A A′ A″. Then the fixed end is transferred from A to B, when a quarter revolution changes its direction from B B′ to B B″, clearing the space B B′ B″, and on removal to the fixed point C, the similar space C C′ C″ is cleared.

Bidder's Machine for breaking down Coal.—Mr. S. P. Bidder, jun., had, in conjunction with Mr. John Jones, devised a machine which had been submitted to actual trial on a working scale at the Harecastle Colliery, where the results were so satisfactory as to induce the proprietors to make arrangements for its immediate adoption. The machine consisted of a small hydraulic press of 12 tons power, to which was attached a pair of tension-bars, bent in the form of a connecting rod or hinge-strap. These were placed one over the other in the bore-hole, and between them, at the extreme end, there were a clearance-box and two metal pressing-blocks, between which was forced, by the action of the hydraulic press, a split wedge 15 inches long, causing a lateral expansion of 3 inches. The ram was then withdrawn, and a second wedge was inserted between the two parts of the first wedge, and was forced up until sufficient expansion was obtained to break the coal. The operation could be repeated several times if found necessary. The whole apparatus would weigh about 50 lbs. The hydraulic press was in future to be made of steel, and the ram would be cored out. In practical working, each gang of colliers would be provided with the tension-bars and three wedges, while the presses would be under the charge of the men who at present occupied the position of firemen, so that no new class of labour would be introduced, while the risk of firing would be got rid of. Trials had been made both in the 7-feet and the 9-feet seams at Harecastle; and in the latter, with three wedges, about 12 tons of coal had been brought down in only three or four pieces. It was found that the press could be applied, and the blocks brought down, in less time than was consumed by firing a hole and waiting for the smoke clearing.

Explosions in mines were known to arise, very frequently, from the employment of gunpowder for blasting. In the interests of humanity alone, an efficient substitute had long been desired by practical men; and this, it was believed, had been accomplished by Bidder's machine, which had also the advantage of preventing the waste of coal incurred by the present system.

The following remarks, made by Mr. W. Menelaus of Dowlais, on the use of coal-cutting machines in the collieries of South Wales, are so much to the point that they are extracted from the 'Journal of the Institution of Mechanical Engineers.' These remarks have reference more especially to the coal-cutting machine of Mr. Robert Winstanley.

Mr. Menelaus said that, having paid considerable attention to the subject of coal-cutting by machinery, and watched carefully the several plans that had been tried, he had not yet found any machine that could compete with colliers' labour under the exceptional circumstances attending the working of the thick veins of coal in South Wales. The holing of the coal constituted there only one-tenth of the entire labour in the collieries; and the margin for saving upon this portion of the work was therefore so small, that he had given up as hopeless the introduction of coal-cutting machines in that district. The colliers at present worked only one turn of about 8 hours per day of 24 hours; and the coal was all brought down by natural pressure during the interval while the men were all absent, the bulk of the coal being obtained with very little holing. If three turns were worked per day he was not sure that the holing might not be advantageously done by a machine, even in the thick soft veins of the South Wales collieries; and in such a case, he should be very glad to adopt machines for the purpose. In thin veins of hard coal he considered the introduction of coal-cutting machines would be attended with very great advantages, and he hoped they would be generally adopted, and thought every possible endeavour should be made to establish their use. The machine now described appeared to him to be one of the best that had been brought forward for coal-cutting; and he thought the principle of its construction and action was more likely to prove the right one than that of machines designed to work a pick in a similar manner to hand-labour. One of the earliest coal-cutting-machines that he remembered had been made on the same principle as a circular saw, but in that case the cutting-wheel had been literally a circular saw with fixed teeth, and had consequently proved a failure in actual working. The use of moveable teeth in the cutting-wheel of the present machine was an important practical improvement, and this machine appeared to him to have been worked out in a very ingenious way, and seemed one of the most likely to succeed that he had yet met with. Whether the air was worked expansively in the cylinders was a question that should not be overlooked in regard to the economy of any coal-cutting machine; and if the expansion could be obtained without complicating the construction of the machine, it was by all means desirable to have the benefit of it. If, however, it involved the introduction of cams or excentrics and ordinary valve-gear, he thought it would be better to waste a portion of the power than to introduce these complications, as he considered the utmost simplicity of construction was an object of such essential importance for the success of a coal-cutting machine; and in working with compressed air it must be borne in mind that the power was cheaply produced at the mouth of the pit, and readily conveyed to the machine. The construction of the machine now described seemed to possess the advantage of simplicity, and he thought this machine was very likely to prove one of the best yet introduced; it had also another advantage in being able to hole its own way into the coal at starting, without requiring any preliminary holing to be done by hand before it could be got to work. He agreed in considering that the discharge of exhaust-air from a coal-cutting machine was hardly capable of producing an appreciable effect upon the ventilation of a colliery, as the quantity of fresh air so discharged was insignificant in comparison with the total quantity passing through the mine.

MACLE is the name given to certain spots in minerals, of a deeper hue than the main substance, and differing from it. Clay-slate may be macled with Iron Pyrites; —or it may be that the macle spots are some peculiar form of the same mineral matter supposed to proceed from some disturbance of the particles in the act of crystallisation.

Macles are twin crystals which are united, or which interpenetrate.

MADDER (*Garance*, Fr.; *Krapp*, *Färberröthe*, Ger.), a substance very extensively used in dyeing, is the root of the *Rubia tinctorum*, Linn. It is employed for the production of a variety of colours, such as red, pink, purple, black, and chocolate.

The *Erythrodanum* or *Ereuthrodanum* of the Greeks, of which Pliny says that it was named *Rubia* in Latin, and that its roots were used for dyeing wool and leather red, was probably identical with the *Rubia tinctorum*, since the description of its appearance and uses given by ancient authors can hardly apply to any other plant. It was cultivated in Galilee, Caria, and near Ravenna in Italy, where it was planted either among the olive-trees or in fields destined for that purpose. Another species of Rubia, viz. the *R. manjista*, grows in the mountainous regions of Hindostan, and the roots of this and an allied plant, the *Oldenlandia umbellata*, called by the natives *Chaya*, have been in use in that country since the most remote period, for the purpose of producing the red and chocolate figures seen in the chintz calicoes of the East Indies. (See CALICO-PRINTING.) The peculiar process by which the colour called Turkey red is imparted to cotton was probably invented originally in India, but the dyeing material generally employed in this process was not madder, but the chaya-root. From India the art of dyeing this colour seems to have been carried to Persia, Armenia, Syria, and Greece; where it was practised for many centuries before it became known in the western part of Europe. In those countries, however, the root of the *Rubia peregrina*, called in the Levant *Alizari*, was the material to which dyers had recourse for this purpose, and large quantities of it are at the present day imported into Europe from Smyrna, under the name of *Turkey roots*. In the middle ages, according to Beckmann, madder went by the name of *Varantia* or *Verantia*. The cultivation of madder was introduced into the province of Zeeland, in Holland, in the reign of the Emperor Charles V., who encouraged it by particular privileges conferred on the inhabitants for the purpose. According to Macquer, however, it was to the Flemish refugees that the Dutch were first indebted for their knowledge of the method of preparing the plant. It is still grown very extensively in that part of Holland, and large quantities are annually exported thence into other countries. Until very recently indeed, the dyers of this country derived almost the whole of their supply of madder from Holland; and it was the discovery that Dutch madder was incapable of producing some of the finer colours more recently introduced, that first led to its being to some extent supplanted by madder grown in other countries.

In the district of Avignon, in France, the cultivation of the plant commenced about the year 1666, under Colbert, but it was chiefly by the efforts of the Secretary of State, Bertin, towards the close of the last century, that it became firmly established there. The French dyers and printers are supplied with madder from Avignon and Alsace, and large quantities are also exported from France into England and other countries. Madder is also grown for the use of dyers in Silesia, Naples, and Spain. It was formerly more extensively cultivated in England than it is now, when it can be imported at a less expense than it can be raised. The *Rubia peregrina* grows wild in the south of England, but it is not applied to any useful purpose.

The *Rubia tinctorum* is one of the least conspicuous and ornamental of our cultivated plants. In external appearance it bears great resemblance to the ordinary bed-straws or Galiums, with which it is also botanically allied. Some species of galium seem also to contain a red colouring matter, and one of them, the *G. verum*, is used in the Hebrides for dyeing. The *R. tinctorum* belongs to the class Tetrandria, order Monogynia, of the Linnæan, and the order Rubiaceæ, of the Natural system. It is a perennial plant, but has an herbaceous stem, which dies down every year. The main part of the root, which extends perpendicularly downwards to a considerable depth, is cylindrical, fleshy, tolerably smooth, and of a pale carrot colour. On cutting it across transversely, it is found to consist externally of a thin cortical layer, or epidermis, to which succeeds a thick, spongy mass of cellular tissue, filled with a yellow juice, and in the centre runs a thin tough string of woody fibre, of a rather paler yellow colour than the enveloping cellular tissue, which may easily be peeled off. The root when freshly cut has a yellow colour, but speedily acquires a reddish tinge on exposure to the air. Many side roots issue from the upper part or head of the parent root, and they extend just beneath the surface of the ground to a considerable distance. It in consequence propagates itself very rapidly, for these numerous side roots send forth many shoots, which, if carefully separated in the spring, soon after they are above ground, become so many plants. From the roots spring forth numerous square-jointed stalks, which creep along the ground to the length of from 5 to 8 feet. Round each joint are placed in a whorl from 4 to 6 lance-shaped leaves, about 3 inches in length, and almost an inch wide at the broadest part. The upper surface of the leaves is smooth, but their margin and keel, as well as the four angles of the stem, are armed with reflexed prickles, so as to cause the plant to adhere to any rough object with which it comes in contact. The flowers, which are yellow, are arranged in compound panicles, which rise in pairs opposite to each other from the axils of the leaves. The calyx is very small. The corolla is small, campanulate, and 5-cleft. The flower contains 4 stamens, and 1 style. The fruit or berry is at first red, but afterwards becomes black. It consists of two lobes, each of which contains a seed.

The *Rubia tinctorum* thrives best in a warm climate, and if grown in the north of Europe a warm sheltered situation should be chosen. A deep, dry soil, containing an abundance of humus, is best adapted for its cultivation. A rich loam, in which there is a large proportion of sand and but little clay, is preferable to the stiffer soils. As the plant requires to be left in the ground several years, it is not one which can be adapted to any system of rotation of crops, and its cultivation must be carried on independently. Land which has lain for a considerable time in grass is preferred to any other for the purpose. At all events, it is well not to allow it to follow on root crops. The finest qualities of madder grow in calcareous soils. In the district called *Palud*, which produces the best quality of French madder, the soil contains about 90 per cent. of carbonate of lime, and is moreover capable of yielding several successive crops of the plant; whereas the land which grows the second quality called *rosée* is richer, but less calcareous, and can only be made to grow madder alternately with other crops. The land must be well dug up with the spade about the beginning of autumn, and before winter. The manure used must be well rotten, and mixed with earth in a compost some time before it is used. Good stable-dung, which has heated to a certain degree and been turned over two or three times before it is mixed with earth, is the best. The dung should be put in layers with the earth, and if the whole can be well-watered with urine or the drainings of the yard, and then mixed up by the spade, the compost will be much superior to fresh dung alone. The manure having been dug or ploughed in, the land is left over winter, and in spring it is turned over again, in order to destroy all weeds, and make the soil uniform to the depth of 2 feet at least. After having been harrowed flat it is ready for planting. Madder is generally grown from suckers or shoots, rarely from seeds. The shoots are prepared by cutting in the previous autumn, from the secondary roots of old plants, pieces at least 5 inches long and of the thickness of a quill, each length containing several joints for the development of buds, and preserving them through the winter in a dry place by covering them over with litter or leaves. Before planting, the land is in some districts laid in beds, about 3 feet wide, with deep intervals dug out with the spade, and the layers are set, by means of a dibble or narrow trowel, in rows, each bed containing two rows about 16 inches apart, and the layers being at a distance of 4 to 6 inches from each other. In other districts, furrows about 3 or 4 inches deep, and 1½ or 2 feet apart, are made, and in these furrows the suckers are placed at a distance of 1 foot from one another, and the furrows are then filled up with soil by means of a rake. Should the weather be dry, the plants must be watered. A watering with diluted urine after sunset greatly assists their taking root. After 3 or 4 weeks they appear above the ground. When they have grown to the length of a finger they must be well weeded and earthed up with the hoe, and this process must be repeated 4 or 6 weeks later, taking care that the roots be well covered with earth, which very much promotes their growth. The stems and leaves should not be cut off, but allowed to die down as winter approaches. Where the winter cold is very great, the roots should in the course of November be covered up with earth to the depth of 2 or 3 inches, and an additional covering of litter is also advisable as a protection from the frost. Water must on no account be allowed to stand in the furrows between the rows during the winter. In spring the covering is removed, and the plant then sends up fresh stalks and leaves as in the first year. The same attention must be paid to weeding and earthing-up during the second as the first year. A second winter and a third summer must elapse before the root is sufficiently mature to be taken up. The object of allowing the roots to remain for such a length of time in the ground seems to be to give time for the interior or woody part of the root to increase; for this part, though it is no richer in colouring matter than the outer or fleshy part of the root, yields a product of finer quality. In France, however, it is usual to gather the crop in 18 months after planting, that is, in the autumn of the second year.

In Germany the roots are sometimes even taken up at the end of the first year, and it is to the product thus obtained that the special name of *Röthe* is applied, the term *Krapp* being restricted to that which has been in the ground the usual length of time. The root is the only part of the plant generally used. The East Indian product called *Munjeet* seems, however, to consist entirely of the stalks of the madder plant. It is much inferior in quality to ordinary madder, and is comparatively poor in colouring-matter.

The time usually selected for taking up the roots is October or November. In doing so care must be taken to break and injure them as little as possible. The quantity of fresh roots obtained in France from one arpent of ground (of 48,000 square feet) varies from 4,000 to 6,000 lbs. In England an acre of ground will yield from 10 to 20 cwts., and in the south of Germany the produce of 1 morgen of land (equal to about 4,075 square yards) amounts to 50 cwts. of dry roots. In warm climates the roots, as soon, as they are taken out of the ground, are simply dried in the sun, and after having been separated from the earth, &c., are broken into pieces, and then brought to market. This kind of madder is called in the East *Alizari*, and in England *Madder-roots*. It consists of short twisted pieces, a little thicker than a quill, reddish-brown, and rather rough externally. A transverse section of one of these pieces exhibits in the centre several concentric layers of pale yellowish-red woody fibre, surrounded by a thin reddish-brown layer of cellular tissue, the original volume of which has been much reduced by drying. Madder is also imported in this state from France, Naples, and Bombay.

In France and Holland the cultivator generally dries his roots, after shaking out the earth as much as possible, partially in stoves. He then takes them to the threshing-floor, and threshes them with the flail, partly for the purpose of separating the small radicles and epidermis of the root, and partly in order to divide the latter into pieces about 7 or 8 centimètres in length. They are then sieved or winnowed, in order to remove what has been detached by threshing. The particles which are separated in this process are ground by themselves, and constitute an inferior kind of madder called *Mull*. The remainder is then handed over to the madder manufacturer, who proceeds to dry it completely in stoves heated to about 100° Fahr. by means of furnaces so constructed as to allow an occasional current of fresh air to pass through. It is afterwards taken to a large sieve with different compartments, moved by machinery. The compartment with the narrowest meshes serves to separate the portions of epidermis, earthy particles, and other refuse matter which had been left adhering to the roots after the threshing. The compartments with wider meshes are for the purpose of separating the smaller roots from the larger ones, the latter being considered the best. In France this operation is called *robage*. The roots are then subjected to the process of grinding, by means of vertical millstones, and afterwards passed through sieves of different sizes, until they are reduced to a state of fine powder. When the larger and better roots are ground by themselves, the madder is called in France *garance robée fine*, or *garance surfine*, and it is marked with the letters S F. The smaller roots yield an inferior madder, which is called *garance non robée*, or *mifine*, and is marked M F. When the different kinds of roots are not separated from one another, but all ground together, the product is called *garance petite robée*, *moins robée*, or *fine*, and is marked F F. By far the greater portion of the madder consumed in France consists of this quality, since it is found to be perfectly well adapted for all the purposes to which madder is usually applied. The letter O is applied to the lowest quality of madder or mull, which is obtained by grinding the epidermis and other portions of the root which are detached after the first stoving, and during the process called *robage*. The qualities C F and C F O consist of mixtures of M F and O. There is also another quality, which receives the designation S F F, and which is obtained by grinding separately the internal ligneous part of the root, previously deprived of the outer or cortical portion. This quality is employed for dyeing fine colours on wool and silk, as well as for the preparation of madder-lakes. Other marks, such as S F F F, E X S F F F, &c., are also occasionally employed by French manufacturers and dealers, to distinguish particular qualities. In Holland the product obtained by grinding together the whole roots, after the separation of the mull, is called *onber*, whilst the term *crop* is applied to the internal part of the root ground separately.

The Levant madder, usually called Turkey roots, is considered to be the finest quality imported into this country. It comes to us from Smyrna, and consists of the whole roots broken into small pieces, and packed in bales. It is ground as it is, without any attempt being made to separate the different portions of the root; and has then the appearance of a coarse, dark reddish-brown powder. It is employed chiefly for the purpose of dyeing the finer purples on calico. Next to this comes the madder of Avignon, of which two varieties are distinguished in commerce, viz. *Paluds* and *rosée*. The first, which is the finest, owes its name to the district in which it is grown, consisting of a small tract of reclaimed marsh land in the neighbourhood of Avignon. Avignon madder is considered to be the best adapted for dyeing pink. It has the appearance, as imported into this country, of a fine pale yellowish-brown or reddish-brown powder. The paler colour, as compared with that of ground *roots*, is owing to the partial separation of the external or cellular portion of the root during the process of grinding, as practised in France. The madders of Alsace, Holland, and Naples, are richer in colouring-matter than the two preceding kinds, but they yield less permanent dyes, and are therefore only employed for colours which require little treatment with soap and other purifying agents after dyeing. Of late years, indeed, the employment of *garancine*, a preparation of madder, in the place of these lower descriptions, has become very general.

All kinds of madder have a peculiar, indescribable smell, and a taste between bitter and sweet. Their colour varies extremely, being sometimes yellow, sometimes orange, red, reddish-brown, or brown. They are all more or less hygroscopic, so that even when closely packed in casks in a state of powder, they slowly attract moisture, increase in weight, and at length lose their pulverulent condition, and form a firm, coherent mass. This change takes place to a greater extent with Alsace and Dutch madders than with those of Avignon. Madder which has undergone this change is called by the French *garance grappée*. It is probable that some process of fermentation goes on at the same time, for madder that is kept in casks in a dry place, and as much out of contact with the air as possible, is found constantly to improve in quality for a certain length of time, after which it again deteriorates. Some kinds of madder, especially those of Alsace and Holland, when mixed with water and left to stand for a short time, give a thick coagulum or jelly, which does not take place to the same degree with Avignon madder. The madder of Avignon contains so much carbonate of lime as to effervesce with acids. The herbaceous parts of the plant, when given as fodder to cattle. are found to communicate a red colour to their bones, a circumstance which was first observed about a hundred years ago, and has been employed by physiologists to determine the manner and rate of growth of bone.

There exists no certain means of accurately ascertaining the intrinsic value of any sample of madder, except that of dyeing a certain quantity of mordanted calico with a weighed quantity of the sample, and comparing the depth and solidity of the colours with those produced by the same weight of another sample of known quality, and even this method may lead to uncertain results, if practised on too small a scale. The Paluds, which is the most esteemed of the Avignon madders, has a dark red hue, whereas the other kinds have naturally a yellow, reddish-yellow, or brownish-yellow colour. Nevertheless, means have been devised of communicating to the latter the desired reddish tinge, which, therefore, no longer serves as a test. A method formerly employed to ascertain the comparative value of a number of samples of madder consisted in placing a small quantity of each sample on a slate, pressing the heaps flat with some hard body, and then taking them to a cellar or other damp place. After 10 or 12 hours they were examined, and that which had acquired the deepest colour, and increased the most in volume was considered the best. This method led, however, to so many frauds on the part of the dealer, for the purpose of producing the desired effect, that it is no longer resorted to. Madder is sometimes adulterated with sand, clay, brick-dust, ochre, sawdust, bran, oak-bark, logwood and other dye-woods, sumac and quercitron bark. Some of these additions are difficult to detect. Such as contain tannin may be discovered by the usual tests, since madder contains naturally no tannin. If the material used for adulteration be of mineral nature, its presence may be discovered by incinerating a weighed quantity of the sample. If the quantity of ash which is left exceeds 10 per cent. of the material employed, adulteration may be suspected. The ash obtained by incinerating pure madder consists of the carbonates, sulphates, and phosphates of potash and soda, chloride of potassium, carbonate and phosphate of lime, phosphate of magnesia, oxide of iron and silica. If a considerable amount of any other mineral constituents is found, it is certainly due to adulteration.

There is probably no subject connected with the art of dyeing which has given rise to so much discussion as the composition of madder, and the chemical nature of the colouring matters to which it owes its valuable properties. The subject has engaged the attention of a number of chemists, whose labours, extending over a lengthened period, have thrown considerable light on it. Nevertheless, the conclusions at which they have severally arrived do not perfectly agree with one another, nor with the views entertained by the most intelligent of those practically engaged in madder dyeing. The older investigators supposed that madder contained two colouring matters, one of which was tawny, and the other red. Robiquet was the first chemist who asserted that it contained two distinct red colouring matters, both of which contributed to the production of the dyes for which madder is employed; and his views, though they were at the time of their promulgation strongly objected to by some of the most eminent French dyers and calico-printers, still offer probably the best means of explaining some of the phenomena occurring during the process of madder dyeing. The two red colouring matters discovered by Robiquet were named by him *Alizarine* and *Purpurine*, and these names they still retain. Several crystallised yellow colouring matters have been discovered by other chemists; but the only one which exists ready-formed in the madder of commerce is the *Rubiacine* of Schunck, and this substance may also be taken as the type of the whole class, the members of which possess very similar properties. Among the other organic substances obtained by different chemists from madder, two resinous colouring matters, sugar, a bitter principle, a peculiar extractive matter, pectin, a fermentative nitrogenous substance, and malic, citric, and oxalic acids, may be mentioned.

When madder is extracted with boiling water, a dark brown muddy liquid, having a taste between bitter and sweet, is obtained. On adding a small quantity of an acid to this liquid, a dark brown precipitate is produced, while the supernatant liquid becomes clear, and now appears of a bright yellow colour. The precipitate consists of alizarine, purpurine, rubiacine, the two resinous colouring matters, pectic acid, oxidised extractive matter, and a peculiar nitrogenous substance. The liquid filtered from this precipitate contains the bitter principle and the extractive matter of madder, as well as sugar and salts of potash, lime, and magnesia. No starch, gum, or tannin can be detected in the watery extract. After the madder has been completely exhausted with boiling water, it appears of a dull red colour. It still contains a quantity of colouring matter, which cannot, however, be extracted with hot water, or even alkalis, since it exists in a state of combination with lime and other bases, forming compounds which are insoluble in those menstrua. If, however, the residue be treated with boiling dilute muriatic acid, the latter dissolves a quantity of lime, magnesia, alumina, and peroxide of iron, as well as some phosphate and oxalate of lime, which may be discovered in the filtered liquid; and if the remainder, after being well washed, be treated with caustic alkali, a dark red liquid is obtained, which gives with acids a dark reddish-brown precipitate consisting of alizarine, purpurine, rubiacine, resin, and pectic acid. That portion of the madder left after treatment with hot water, acids, and alkalis, consists almost entirely of woody fibre.

A short description of some of the substances just mentioned will not be out of place here, as it may assist in rendering the process of dyeing with madder more intelligible.

The most important of these substances is *alizarine*, since it forms the basis of all the finer and more permanent dyes produced by madder. The *matière colorante rouge* of Persoz and the *madder-red* of Runge also consist essentially of alizarine, mixed with some impurities. Robiquet first obtained it in the form of a crystalline sublimate, by extracting madder with cold water, allowing the liquid to gelatinise, treating the jelly with alcohol, evaporating the alcoholic liquid to dryness, and heating the residue; and since the application of heat seemed to be an essential part of his process, it was for a long time doubted whether alizarine was contained as such in madder, and was not a product of decomposition of some other body. It was proved, however, by the experiments of Schunck that it does in reality pre-exist in the ordinary madder of commerce, though not in the fresh root when just taken out of the ground. It has the following properties:—It crystallises in long, transparent, lustrous, yellowish-red needles. These needles when heated to 212° F. lose their water of crystallisation, and become opaque. At about 420° F. alizarine begins to sublime, and if carefully heated may be almost entirely volatilised, only a little charcoal being left behind. The sublimate obtained by collecting the vapours consists of long, brilliant, transparent, orange-coloured crystals, which are pure anhydrous alizarine. If madder, or any preparation or extract of madder, be heated to the same temperature, a sublimate of alizarine is also obtained, but the crystals are then generally contaminated with drops of empyreumatic oil, produced by the decomposition of other constituents of the root. This oily matter may, according to Robiquet, be removed by washing the crystals with a little cold alcohol. Alizarine is almost insoluble in cold water. It is only slightly soluble in boiling water, and is deposited, on the solution cooling, in yellow crystalline flocks. When the water contains large quantities of acid or salts in solution, it dissolves very little alizarine, even on boiling. The colour of the solution is yellowish when it is quite free from alkalis or alkaline earths. Alizarine dissolves much more readily in alcohol and ether than in water; the solutions have a deep yellow colour. Alizarine is decomposed by chlorine, and converted into a colourless product. It is also decomposed by boiling nitric acid, the product being a colourless, crystallised acid, *phthalic acid*, the same that is formed by the action of nitric acid on naphthaline. Alizarine dissolves in concentrated sulphuric acid, yielding a yellow solution, which may be heated to the boiling point without changing colour and without any decomposition of the alizarine, which is precipitated unchanged on the addition of water. Alizarine dissolves in caustic alkalis with a splendid purple or violet colour, which remains unchanged on exposure of the solutions to the air. The ammoniacal solution, however, loses its ammonia entirely on being left to stand in an open vessel, and deposits its alizarine in the form of shining prismatic crystals, or of a crystalline crust. The alkaline solutions give with solutions of lime and baryta salts precipitates of a beautiful purple colour, with alumina salts a red, with iron salts a purple precipitate, and with most of the salts of metallic oxides precipitates of various shades of purple. The affinity of alizarine for alumina is so great, that if the compound of the two bodies be treated with boiling caustic potash-lye, it merely changes its colour from red to purple without being decomposed. Alizarine is not more soluble in boiling alum-liquor than in boiling water. The chemical formula of anhydrous alizarine is, according to the researches of Messrs. Graebe and Liebermann, $C^{14}H^{4}O^{4}$ ($\mathbf{C^{14}H^{8}O^{4}}$).

If alizarine in a finely divided or, what is still better, in a freshly precipitated state, be suspended in distilled water, and a piece of calico printed with alumina and iron mordants of different strengths be plunged into it, the latter, on gradually heating the bath, become dyed. The process is necessarily a slow one, because alizarine is only slightly soluble in boiling water, and as the mordants can only combine with that portion actually in solution, a constant ebullition of the liquid must be kept up, in order to cause fresh portions of colouring matter to dissolve in the place of that portion taken up by the mordants. A very small proportional quantity of alizarine is required in order to dye very dark colours, but it is absolutely necessary that the bath should contain no trace of either acid or base, since the former would combine with the mordants, and the latter with the alizarine. When the process is complete the alumina mordant will be found to have acquired various shades of red, while the iron mordant will appear either black or of different shades of purple, according to the strength of the mordant employed. These colours are as brilliant and as permanent as those obtained from madder by means of a long and complicated process. Nevertheless, the red is generally found to have more of a purplish hue, and the black to be less intense than when madder or its preparations are employed. On the other hand, if one of the finer madder colours which are produced on calico, such as pink or lilac, be examined, the colours are found to contain, in combination with the mordants, almost pure alizarine. Hence it may be inferred, that alizarine alone is required for the production of these colours, and that the simple combination of this colouring matter with the mordants is the principal end which is to be attained by the dyer in producing them.

Alizarine has been obtained artificially by Messrs. Graebe and Liebermann, as a derivative of anthracene or paranaphthaline, which is one of the products obtained in the distillation of coal-tar. Artificial alizarine is now extensively manufactured and used for a substitute for madder. By the action of bromine upon alizarine, Mr. Perkin has recently obtained a derivative called *bromalizarine*, which may also be used in dyeing. For the manufacture of artificial alizarine, see ALIZARINE; ANTHRACENE.

Purpurine, the other red colouring matter of madder, with which the *matière colorante rose* of Gaultier de Claubry and Persoz, and the *madder-purple* of Runge, are substantially identical, can hardly be distinguished by its appearance from alizarine, which it also resembles in most of its properties. It crystallises in small orange-coloured or red needles. When carefully heated it is almost entirely volatilised, yielding a sublimate of shining orange-coloured scales and needles. It is slightly soluble in boiling water, giving a pink solution. It is more soluble in alcohol than in water, the solution having a deep yellow colour. It dissolves in concentrated sulphuric acid, and is not decomposed on heating the solution, even to the boiling point. It is decomposed by boiling nitric acid, and yields, like alizarine, phthalic acid. It is distinguished from alizarine, by its solubility in alum-liquor. When treated with a boiling solution of alum in water, it dissolves entirely, yielding a peculiar opalescent solution, which appears of a bright pink colour by transmitted light, and yellowish by reflected light. The solution deposits nothing on cooling, but on adding to it an excess of muriatic or sulphuric acid, it becomes colourless, and the purpurine falls down in yellow flocks. On this property depends the method of separating it from alizarine. The compounds of purpurine with bases are mostly purple. It dissolves in alkalis with a bright purplish-red or cherry-red colour. If the solution in caustic potash or soda be exposed to the air, its colour changes gradually to reddish-yellow, and the purpurine contained in it is decomposed. a characteristic which also serves to distinguish purpurine from alizarine, the alkaline solutions of which are not changed by the action of oxygen. The composition of purpurine approaches very near to that of alizarine. but its chemical formula is unknown. It communicates to calico, which has been printed with various mordants, colours similar to those imparted by alizarine, but the red is more fiery, and the black more intense than when alizarine is employed. On the other hand, the purple dyed by means of purpurine has a disagreeable reddish tinge, and presents an unpleasant contrast with the beautiful purple from alizarine. The name of this colouring matter is therefore very inappropriate, and is calculated to mislead. The colours dyed with purpurine are less stable than those dyed with alizarine, they are less able to resist the action of soap and other agents than the latter. Hence, very little purpurine is found in combination with the mordants, in such madder colours as have undergone a course of treatment with alkalis and acids, after having been dyed; indeed, the principal object of this treatment appears to be the removal of this and other substances, so as to leave compounds of alizarine only on the fabric. Purpurine seems to abound more in the lower, stronger qualities of madder than in the finer. To this cause, Robiquet chiefly ascribed the superiority of the latter in dyeing fast colours, and no better way of accounting for it has hitherto been suggested. Purpurine forms the basis of the red pigment called madder-lake.

Rubiacine is the name which has been applied to a yellow crystallised colouring matter contained in madder. It coincides in most of its properties with the *madder-orange* of Runge. It crystallises in greenish-yellow lustrous scales and needles. When heated it is entirely volatilised, yielding a crystalline sublimate. It is only slightly soluble in boiling water, but more soluble in boiling alcohol, from which it crystallises on cooling. It dissolves in concentrated sulphuric acid, and is not decomposed on boiling the solution. It also dissolves in boiling nitric acid without being decomposed. It dissolves in caustic alkalis with a purple colour. Its compounds with earths and metallic oxides are mostly red. When treated with a boiling solution of pernitrate or perchloride of iron it dissolves entirely, yielding a brownish-red solution, which deposits nothing on cooling, but gives, on the addition of an excess of muriatic acid, a yellow flocculent precipitate, consisting of a peculiar acid, called *rubiacic acid*.

Two amorphous resinous colouring matters, forming brownish-red compounds with bases, have also been obtained from madder. Both are very little soluble in boiling water. One of them is a dark brown, brittle, resin-like substance, very easily soluble in alcohol, which melts at a temperature a little above 212° F. The other is a reddish-brown powder, less soluble in alcohol than the preceding. These two colouring matters, together with rubiacine, constitute probably the *tawny* or *dun colouring matter* of the older chemists. They do not contribute to the intensity of the colours dyed with madder, and exert a very prejudicial effect on the beauty of the dyes. If printed calico be dyed with a mixture of alizarine, and any one of these three colouring matters, the colours are found to be both weaker and less beautiful than when alizarine is employed alone. The red acquires an orange tinge, and the purple a reddish hue, whilst the black is less intense, and the parts of the calico which should remain white are found to have a yellowish colour. Hence it is of importance to the dyer that their effect should be counteracted as much as possible, by preventing them either from dissolving in the dye-bath or from attaching themselves to the fabric.

The other constituents of madder possess no interest in themselves, but may become of importance in consequence of the effects which they produce during the process of dyeing. The pectine, in the state in which it exists in the root, is probably an indifferent substance, but in consequence of the ease and rapidity with which it passes into pectic acid, it may in dyeing act very prejudicially by combining with the mordants and preventing them taking up colouring matter. The extractive matter of madder, when in an unaltered state, produces no injurious effects directly; but by the action of oxygen, especially at an elevated temperature, it acquires a brown colour and then contributes, together with the rubiacine and the resinous colouring matter, in deteriorating the colours and sullying the white parts of the fabric. The extractive matter, when in a state of purity, has the appearance of a yellow syrup like honey, which is easily soluble in water and alcohol. When pure it is not precipitated from its watery solution by an earthy or metallic salt, but if the solution be evaporated in contact with the air, it gradually becomes brown, and then gives an abundant brown precipitate with sugar of lead. When its watery solution is mixed with muriatic or sulphuric acid and boiled, it becomes green and deposits a dark green powder. Hence this extractive matter has, for the sake of distinction, been called *Chlorogenine*, and *Rubichloric Acid*. The bitter principle of madder will be referred to presently. The *Xanthine* of Kuhlmann, and the *madder-yellow* of Runge are mixtures of the extractive matter and the bitter principle. The sugar contained in madder is probably grape-sugar. It has not hitherto been obtained in a crystallised state, but it yields by fermentation alcohol and carbonic acid, like ordinary sugar. The woody fibre which is left after madder has been treated with various solvents until nothing more is extracted, always retain a slight reddish or brownish tinge from the presence of some colouring matter which cannot be completely removed, and seems to adhere to it in the same way as it does to the cotton fibre of unmordanted calico.

There is a question connected with the chemical history of madder which must not be passed over in silence, since it is one which possesses great interest, and may at some future time become of great importance, viz. the question as to the state in which the colouring matters originally exist in the root. It has long been known, that when ground madder is kept tightly packed in casks for some time, it constantly improves in quality for several years, after which it again deteriorates; and it was always supposed that this effect was due to some process of slow fermentation going on in the interior of the mass, an opinion which seemed to be justified by the evident increase in weight and volume, and the agglomeration of the particles which took place at the same time. Nevertheless, the earlier chemical examinations of madder threw no light whatever on this part of the subject, since the red colouring matters were found to be very stable compounds, not easily decomposed except by the action of very potent agents, so that when once formed it seemed improbable that they would be at at all affected by any mere process of fermentation. Hence some chemists were led to the conclusion that the improvement which takes place in the quality of madder on keeping is caused by an actual formation of fresh colouring matter. A very simple experiment may indeed suffice to prove that the whole of the colouring matter does not exist ready formed, even in the article as used by the dyer. If ordinary madder be extracted with cold water, the extract after being filtered has generally an acid reaction, and cannot contain any of the colouring matters, since these are almost insoluble in cold water, especially when there is any acid present. Nevertheless the extract when gradually heated is found capable of dyeing in the same way as madder itself. If the extract be made tolerably strong, it possesses a deep yellow colour and a very bitter taste; but if it be allowed to stand in a warm place for a few hours, it gelatinises, and the insoluble jelly which is formed is found to possess the whole of the tinctorial power of the liquid, which has also lost its yellow colour and bitter taste. Hence, it may be inferred that the substance which imparts to the extract its bitter taste and yellow colour is capable also of giving rise to the formation of a certain quantity of colouring matter.

In 1837 a memoir was published by Decaisne, containing the results of an anatomical and physiological examination of the madder plant, results which were considered so important that a prize was awarded to the author by the Royal Academy cf Sciences at Brussels. This investigation led the author to the conclusion, that the cells of the living plant contain no ready-formed red colouring matter, but are filled with a transparent yellow juice, which, on exposure to the atmosphere, becomes reddish and opaque in consequence of the formation of red colouring-matter. Hence he inferred that the insoluble red colouring-matter was simply a product of oxidation of the soluble yellow one, and that, consequently, the more complete the exposure of the triturated root to the atmosphere, the greater would be its tinctorial power; and he even went so far as to assert that all the proximate principles obtained from the root were derived ultimately from one single substance contained in the whole plant. That the fresh roots, before being dried, do indeed contain no colouring-matter capable of imparting to mordants colours of the usual appearance and intensity, may be proved by the following experiment:—If the roots, as soon as they are taken out of the ground, are cut into small pieces as quickly as possible, and then extracted with boiling spirits of wine, a yellow extract is obtained, which, after being filtered and evaporated, leaves a brownish-yellow residue. Now this residue, on being redissolved in water, is found incapable of imparting to mordants any but the slightest shades of colour; and, on the other hand, the portion of the root left after extraction with spirits of wine, on being subjected to the same test as the extract, is found to possess as little tinctorial power as the latter. If, however, the roots, instead of being treated with spirits of wine, are macerated in water, the liquor, on being gradually heated, dyes the usual colour as well as ordinary madder. Hence it may be inferred that by means of alcohol the colour-producing body of the root may be separated from the agent which, under ordinary circumstances, is destined to effect its transformation into colouring-matter, the one being soluble and the other insoluble in that menstruum. It was by this and other similar facts that Schunck was led to an examination of this part of the subject. He infers from his experiments that the colour-producing body of maddder is identical with its so-called bitter principle, to which he has given the name of *Rubian*. This body, when pure, has the following properties:—It is an amorphous, shining, brittle substance like gum, dark brown and opaque in mass, but yellow and transparent in thin layers. Its solutions are of a deep-yellow colour, and have an intensely-bitter taste. It is easily soluble in water and alcohol. The watery solution turns of a blood-red colour on the addition of caustic and carbonated alkalis, and gives dark-red precipitate with lime and baryta-water. The solution gives a copious light-red precipitate with basic acetate of lead, but yields no precipitate with any other metallic salt. On trying to dye with rubian in the usual manner, the mordants assume only the faintest shades of colour. If, however, the watery solution be mixed with sulphuric or muriatic acid and boiled, it gradually deposits a quantity of insoluble yellow flocks, which, after being separated by filtration and well washed, are found to dye the same colour as those obtained by means of madder. In fact, these flocks contain alizarine, to which they owe their tinctorial power, but they also contain a crystallised yellow colouring-matter, similar to, but not identical with, rubiacine, as well as two resinous colouring-matters, which Schunck has named *Verantine* and *Rubiretine*, and which are probably identical with the resinous colouring-matters before referred to as being obtained from ordinary madder. The liquid filtered from the flocks contains an uncrystallisable sugar, similar to that which is obtained from the madder itself. Rubian is not decomposed by ordinary ferments, such as yeast and decomposing-casein; but by extracting madder with cold water, and adding alcohol to the extract, a substance is precipitated in pale-red flocks, which possesses in an eminent degree the power of effecting the decomposition of rubian. If a watery solution of the latter be mixed with some of the flocculent precipitate (after having been collected on a filter, and washed with alcohol), and then left to stand in a warm place for some hours, the mixture is converted into a light-brown jelly, which is so thick that the vessel may be reversed without its falling out. This jelly, when agitated with cold water, communicates to the latter very little colour or taste, proving that the rubian has undergone complete decomposition by the action of the flocculent substance or ferment added to its solution. The cold water, however, extracts from the gelatinous mass a quantity of sugar, while the portion left undissolved contains alizarine, verantine, rubiretine, and a crystalline yellow colouring-matter, besides a portion of undecomposed ferment. Rubian, therefore, by the action of strong mineral-acids and of the peculiar ferment of madder, is decomposed, yielding sugar and a variety of colouring-matters, the principal of which is alizarine. It appears, therefore, that these colouring-matters are not originally contained as such in the root, but are formed by the decomposition of one parent substance, which alone is produced by the vital energies of the plant. In addition to this substance, the plant also contains another, which possesses the property of rapidly effecting the decomposition of the first. The two are, however, during the living state of the plant, prevented from acting on one another, either in consequence of their being contained in different cells, or because the vital energies of the plant resist the process of decomposition. During the drying and grinding of the root the decomposition of the colour-producing body commences and continues slowly during the period that the powder is kept before being used. It is finally completed during the process of dyeing itself, and hence no trace of colour-producing substance can be detected, either in the liquor or the residual madder, after the operation of dyeing is concluded. The presence of oxygen does not seem to be essential during this process of decomposition, as Decaisne supposed. Nevertheless, according to Schunck, rubian does in reality suffer a partial oxidation when its watery solution, mixed with some alkali or alkaline earth, is exposed to the action of the atmosphere, giving rise to a peculiar acid, called by him *rubianic acid.* When rubian is heated at a temperature considerably exceeding 212° Fahr., it is converted without much change of appearance into a substance which yields by decomposition resinous colouring-matters in the place of alizarine. The great excess of these colouring-matters contained in the madder of commerce arises, therefore, most probably from the high temperature employed in drying the root.

Employment of Madder in Dyeing.—After the account which has just been given of the composition of madder, it may easily be conceived that the chemical and physical phenomena which occur during the various processes of madder-dyeing, are of a rather complicated nature, and that many of these phenomena have not yet received a perfectly satisfactory explanation. Nevertheless, the present state of our knowledge on this subject may enable us to give a consistent explanation of the facts presented to us by the experience of the dyer, and even to indicate what direction our labours must take if we wish to improve this branch of the arts.

In order to produce perfectly-fast colours in madder-dyeing, it is necessary that the madder should contain a large proportion of carbonate of lime, and if the madder is naturally deficient in that salt, the deficiency may be supplied either by using calcareous water in dyeing, or by adding a quantity of ground chalk. If madder be treated with dilute sulphuric or muriatic acid, so as to dissolve all the lime contained in it, and then washed with cold water until the excess of acid is removed, its tinctorial power will be found to be very much diminished, but may be entirely restored, and even increased, by the addition of a proper quantity of lime-water or chalk. Hence, too, Avignon madder, which is grown in a highly-calcareous soil, and contains so much carbonate of lime as to effervesce with acids, affords the most permanent colours; whilst Alsace madder requires the addition of carbonate of lime in order to produce the same effect. This fact was first pointed out by Hausmann, who, after having produced very fine reds at Rouen, encountered the greatest obstacles in dyeing the same reds at Logelbach, near Colmar, where he went to live. Numerous trials, undertaken with the view of obtaining the same success in his new establishment, proved that the cause of his favourable results at Rouen existed in the water, which contained carbonate of lime in solution, whilst the water of Logelbach was nearly pure. He then tried a factitious calcareous water by adding chalk to his dye-bath. Having obtained the most satisfactory results, he was not long in producing here as beautiful and as solid reds as he had done at Rouen. This simple fact led to the production of a series of lengthy Memoirs on the part of some of the French chemists and calico-printers, which fully confirmed the results of Hausmann, without, however, leading to a satisfactory explanation of them. The experiments of Robiquet prove that in dyeing with pure alizarine the least addition of lime is rather injurious than otherwise, as it merely weakens the colours without adding to their durability. Hence the beneficial effect of lime can only be accounted for by some action which it exerts on other constituents of the root. Bartholdi imagined that this action consisted simply in the decomposition of the sulphate of magnesia, which he found to be contained in ordinary madder. It was asserted by others that the carbonate of lime served to neutralise some free acid, supposed by Kuhlmann to be malic acid, which was present in some madders, and which not only to a great degree prevented the colouring-matters from dissolving in the dye-bath, but also combined with the mordants to the exclusion of the latter. Though later researches have failed to detect the existence of malic acid in madder, still it is certain that all watery extracts of madder contain pectic acid, which probably exists in the root originally as pectine; and that this acid, when in a free state, acts most injuriously in dyeing with alizarine, but ceases to do so as soon as it is combined with lime. Nevertheless, it seems that madder which is naturally deficient in lime, cannot be made to replace entirely such madder as has been grown in a calcareous soil, however great an excess of chalk be used in dyeing. Hence Robiquet was led to the conclusion that the inferior kinds of madder, which are also the most deficient in lime, contain more purpurine and less alizarine than the superior kinds, and that the carbonate of lime serves partly to combine with the purpurine, and prevent it from uniting with the mordants, and thus producing less permanent dyes. The experiments of Schunck have proved that not only pectic acid, but also rubiacine and the resinous colouring-matters of madder, act detrimentally in dyeing with pure alizarine, by deteriorating the colours and sullying the white parts of the fabric, and that these effects are entirely neutralised by the addition of a little lime-water to the dye-bath. If in dyeing with madder the whole of the colouring-matters were in a free state, the resinous and yellow colouring-matters would, according to Schunck, unite with the mordants, to the exclusion of the alizarine, yielding colours of little permanency and of a disagreeable hue; but on adding lime, they combine with it, and the alizarine, being less electro-negative, then attaches itself to the mordants or weaker bases. A great excess of lime would of course have an injurious effect by combining also with the alizarine, and preventing it from exerting its tinctorial power. In practice a little less lime is added than is sufficient to take up the whole of the impurities with which the alizarine is associated, thus allowing a portion of the former to go to the mordants, to be subsequently removed by treatment with soap and other detergents. Lastly, it has been asserted by Köchlin and Persoz that when lime is used in dyeing with madder the colours produced are not simply compounds of colouring-matter with mordants, but contain also in chemical combination a certain quantity of lime, which adds very much to their stability. It is probable that all these causes contribute in producing the effect. The carbonates of magnesia and zinc, acetate and neutral phosphate of lime, and the protoxides of lead, zinc and manganese, act in a similar manner to carbonate of lime in madder-dyeing, but are less efficient.

Dambourney and Beckman have asserted that it is more advantageous to employ the fresh root of madder than that which has been submitted to desiccation, especially by means of stoves. But in its state of freshness its volume becomes troublesome in the dye-bath, and uniform observation seems to prove that it ameliorates by age up to a certain point. Besides, it must be rendered susceptible of keeping and carrying easily.

In dyeing printed calicoes with madder, the general course of proceeding is as follows:—The madder having been mixed in the dye-vessel with the proper quantity of water, and, if necessary, with chalk, the liquid is heated slowly by means of fire or steam, and the fabric is introduced and kept constantly moving until the dyeing is finished. (See Calico-Printing.) The temperature should be kept low at first, and should be gradually raised, without allowing it to fall, until it reaches the boiling-point; and the boiling may, if necessary, be continued for a short time. The chief object of the gradual heating seems to be to allow the ferment to exert its full power on the rubian or colour-producing body; for this process, like all processes of fermentation, is most active at a temperature of about 100° Fahr., and is arrested at 212° Fahr. In dyeing quickly less permanent colours are also produced, in consequence, probably, of the colouring-matters combining with the more superficial portions of the mordants, and not penetrating sufficiently into the interior of the vegetable fibre. The fastest colours are produced by dyeing at a moderate temperature, and not allowing the liquid to boil. By boiling the madder becomes more thoroughly exhausted, and a greater depth of colour is attained, but the latter resists less perfectly the action of soap and other agents, than the same shade dyed at a lower temperature. The time occupied in dyeing varies according to the nature and intensity of the colours to be produced; but there is little advantage in allowing it in any case to exceed 3 hours, since the gain in colour acquired is more than counterbalanced by the loss of time and increased expenditure of fuel caused by a long-continued ebullition. In dyeing ordinary madder colours, such as red, black, chocolate, and common purple, which do not require much treatment after dyeing, in order to give them the desired tone and intensity, strong but inferior qualities of madder may be used with advantage; and various other dye-stuffs, such as peach-wood, quercitron-bark, sumac, &c., are often added to the madder, in order to vary the shade and depth of colour. But for the finer colours, such as pink and fine purple, which after dyeing must be subjected to a long course of treatment with soap and acids before they assume the requisite beauty and delicacy of hue, it is necessary to employ the finest qualities of madder; for if dyed with inferior qualities they would resist only imperfectly the requisite after-treatment, and great care must be observed in regulating the temperature during dyeing. The addition of other dye-stuffs, in their case, would be not only useless, but positively injurious. The use of different kinds and qualities of madder in conjunction is often found to be attended with benefit, arising probably from the circumstance of one kind supplying some material or other, such as ferment or carbonate of lime, in which the other is deficient.

The chemical processes which take place during the operation of dyeing may be shortly described as follow:—In the first place, the water of the dye-bath extracts the more soluble constituents of the madder, such as the sugar, extractive matter, and bitter principle. The latter substance is decomposed by the ferment, and the colouring-matter thereby formed is added to that which already exists in the root. As the temperature rises the less soluble constituents, such as the alizarine, purpurine, rubiacine, the resinous colouring-matters, the pectine and pectic acid, begin to dissolve, and as they dissolve they combine partly with the mordants of the fabric, partly with the lime and other bases contained in the root or added to the dye-bath, and thus permit the liquid to take up fresh quantities from the madder. If the quantity of madder was exactly proportioned to the quantity of fabric to be dyed, then it becomes, in this way, gradually exhausted of all available colouring-matter. The extractive matter at the same time acquires a brown colour by the combined action of the heat and oxygen, and covers the whole surface of the fabric with a uniform brown tinge. When the dyeing is concluded the liquor appears muddy and of a pale dirty-red colour. It still contains a quantity of colouring-matter in a state of combination with lime and other bases from the madder, or with portions of the mordant mechanically detached from the fabric. The residual matter at the bottom of the liquor also contains a quantity of colouring-matter in a similar state of combination. By mixing the residue and the liquor with sulphuric or muriatic acid, boiling, and then washing with water, the various bases are removed, and the colouring-matter is thus made available for dyeing. Occasionally, when a very great depth of colour is required, it is found advisable to let the goods pass through a second dyeing operation, instead of obtaining the requisite shade at once.

After the calico has been removed from the dye-bath and washed in water, it presents a very unsightly appearance. The alumina-mordant has acquired a dirty brownish-red colour, and the iron-mordant a black- or brownish-purple, according to its strength, whilst the white portions are reddish-brown. In the case of ordinary colours the fabric is now passed through a mixture of boiling bran-and-water, or through a weak solution of chloride of lime, or it is exposed for some time on the grass to the action of air and light, or it is subjected to several of these processes in succession, by which means the impurities adhering to the mordants or the fibre are, in a great measure, either removed or destroyed, the white portions recovering their purity, and the red, black, purple, and chocolate, appearing afterwards sufficiently bright for ordinary purposes. That the colours, however, even after being thus treated, still contain in combination with the mordants other substances in addition to the red colouring-matters, may be proved by a very simple experiment. If a few yards of some calico, which has been treated as just described, be immersed in dilute muriatic acid in the cold, the mordants are removed, and the colours are destroyed; orange-coloured stains being left on the places where they were before fixed. After washing the calico with cold water, the orange-coloured matter may be dissolved in alkali, and the calico left entirely white. The solution, which is brownish-red, gives, with an excess of acid, a reddish-brown flocculent precipitate. This precipitate, after being collected on a filter and well washed with water, is found to be only partially soluble in boiling alcohol, a brown substance, consisting partly of pectic acid, being left undissolved. The yellow alcoholic solution leaves, on spontaneous evaporation, a brown crystalline residue, which is found on examination to contain alizarine, purpurine, a little rubiacine, or some similar compound, and a brown amorphous substance. The removal of these various impurities, associated with the alizarine, seems to be a principal object of the treatment to which madder-colours are subjected, when it is desired to give them the highest degree of brilliancy of which they are susceptible. This course of treatment, as applied to printed calicoes, may be shortly described as follows:—The goods, after being very fully dyed, generally with the addition of chalk, and then washed, are passed for some time through a solution of soap, which is heated to a moderate temperature. By this means a great deal of colour is removed, as may be seen by the red tinge of the soap-liquor, and the purity of the white portions is almost entirely restored. During this process the brown and yellow colouring-matters are probably removed by double decomposition, the alkali of the soap combining with and dissolving them, while the fat acid takes their place on the fabric. After being washed the goods are passed through a weak solution of acid, mostly sulphuric or oxalic acid, or an acid tin-salt, which causes the colours to assume an orange tinge. The point at which the action of this acid-liquid is to be arrested can only be ascertained by practice. The next step in the process is, after washing the goods, to treat them again with soap-liquor, which is gradually raised to the boiling-point, and they are lastly subjected to the action of soap-liquor in a close vessel under pressure. By exposing the goods on the grass for some time after the first soaping, the use of acid may be obviated, but the process then becomes much more tedious. In this way are produced those beautiful pinks and lilacs which, for delicacy of hue, combined with great permanence, are not surpassed by any dyed colours known in the arts. Whether the fat acid of the soap employed forms an essential constituent of these colours is not certainly known, but it is probable that it contributes to their beauty and durability. It is certain, however, that they always contain fat acid. If a piece of calico which has gone through the processes just described be treated with muriatic acid, the colour is destroyed, and a yellow stain is left in its place. This yellow stain disappears on treating the calico, after washing with water, with alkali, yielding a solution of a beautiful purple colour. This solution gives again with an excess of acid a yellow, flocculent precipitate, which, after filtration, dissolves almost entirely in boiling alcohol, and the solution on evaporation affords needle-shaped crystals of pure alizarine, mixed with white masses of fat acid. The latter, therefore, seems to occupy the place taken up by the impurities before the treatment with soap. This experiment serves also to prove that it is alizarine which forms the basis of the more permanent colours afforded by madder, though, on the other hand, as in dyeing the finer madder colours, it cannot be denied that the colouring-matters which are removed by the treatment with soap and acids contribute to the effect produced in dyeing ordinary madder colours.

The same result is attained in dyeing Turkey red, but the process employed is somewhat different and much more complicated. See Turkey Red.

The attempts which have been made at various times to obtain an extract of madder, capable of being applied in making so-called steam-colours for calico and other fabrics, have not been completely successful. A very beautiful pink has been produced by Gastard and Girardin, in France, by printing on calico, previously prepared with some mordant, an ammoniacal solution of an extract of madder called *colorine*, but it is not much superior, either as regards its hue or its degree of permanency, to what can be obtained by easier processes from dye-woods and other materials.

Madder is not so much employed in woollen dyeing, especially in this country, as in cotton dyeing and printing. Only ordinary woollen goods are dyed red with madder, since the colour is not so bright as that obtained from cochineal or lac, though it is more permanent and cheaper. A mixture of alum and tartar is employed as a mordant. The addition of a little muriate of tin in dyeing imparts to the colour a more scarlet tinge. The bath of madder, at the rate of from 8 or 16 ounces to the pound of cloth, is heated to such a degree as to be just bearable by the hand, and the goods are then dyed by the wince, without heating the bath more until the colouring matter is fixed. Vitalis prescribes as a mordant, $\frac{1}{4}$th of alum and $\frac{1}{16}$th of tartar; and for dyeing $\frac{1}{3}$rd of madder, with the addition of $\frac{1}{24}$th of solution of tin, diluted with its weight of water. He raises the temperature in the space of one hour to 200°, and afterwards he boils for three or four minutes, a circumstance which is believed to contribute to the fixation of the colour. The bath, after dyeing, appears to contain much yellow colouring-matter. Sometimes a little archil is added to the madder, in order to give the dye a pink tinge; but the effect is not lasting. By passing the goods after dyeing through weak alkali, the colour acquires a blueish tinge. By adding other dye-stuffs, such as fustic, peachwood, and logwood, to the madder in dyeing, various shades of brown, drab, &c., are obtained. Madder is also used in conjunction with woad and indigo in dyeing woollen goods blue, in order to impart to the colour a reddish tinge. See Indigo.

Silk is seldom dyed with madder, because cochineal affords brighter tints.

Preparations of Madder.—The numerous analytical investigations of madder, undertaken chiefly in consequence of the Société Industrielle de Mulhouse having offered in the year 1826 a premium for a means of discovering the real quantity of colouring-matter in the root, and of determining the comparative value of different samples of madder, led to many attempts on the part of chemists to improve the quality of this dye-stuff by means of chemical agents, and thus render it more fit for the purposes to which it is applied. Robiquet and Persoz were the first to point out the advantages which result from submitting madder, previous to its being used, to the action of strong acids. They showed that, by acting on madder with strong sulphuric acid, and then carefully washing out the acid with water, a product was obtained which not only possessed a greater tinctorial power than the original material, but also dyed much brighter colours. This important discovery, which was not, like so many others, arrived at by chance, but was purely the result of scientific investigation, did not at first receive, on the part of practical men, the appreciation which it deserved. The product obtained by the action of sulphuric acid on madder, which in the first instance was called *charbon sulfurique*, afterwards *garancine*, was first manufactured on a large scale by MM. Lagier and Thomas, of Avignon, but so great were the prejudices entertained by dyers and calico-printers against its use at the commencement, that years elapsed before they could be overcome; indeed they were partly justified by the imperfect nature of the product itself. The persevering efforts to improve the method of manufacture, and adapt it to the wants of the consumer were at last attended with success, so that at the present day garancine has come to be used to as great an extent as madder, and large quantities of it are now manufactured in France and other countries.

It was supposed by Robiquet, that by the action of sulphuric acid on madder the saccharine, mucilaginous, and extractive matters of the root were destroyed, and thus hindered from producing any injurious effects in dyeing, and that the woody fibre was at the same time charred, so as to prevent it from attracting and binding any of the colouring-matter. This explanation is not entirely correct, since it is not necessary to carry the action so far as actually to carbonise any of the constituents of the root, and it is also doubtful whether the woody fibre ever attracts the useful colouring-matters in any considerable degree. The account above given of the chemical constitution of madder, may easily lead us to the conclusion, that, during the action of the acid, the following processes take place:—1. The bitter principle or colour-producing body of the root is decomposed, yielding, among other products, a quantity of alizarine which did not previously exist. 2. The red colouring-matters are rendered by the acid insoluble in water, and thus it becomes possible to wash out the extractive matter, sugar, &c., without the madder losing any of its tinctorial power. 3. The lime, magnesia, and other bases which are combined in the root with colouring matter, or would combine with it during the dyeing process, are removed by the acid, and thus prevented from exerting any injurious action. The subsequent addition of a suitable quantity of lime, soda, or other base, serves to neutralise the effect of the excessive amount of pectic acid and resinous colouring matters, which were set free by the action of the mineral acid.

The method of manufacturing garancine, as practised at the present day, may be shortly described as follows:—The ground madder is mixed with water, and the mixture is left to stand for some hours. During this time it is probable that the rubian is decomposed by the ferment of the root, otherwise a great loss would be experienced. More water is now added, in order to remove all the soluble matters, and is then run off. The liquid contains sugar, and is employed on the Continent for the preparation of a kind of spirit, which on account of its peculiar smell and flavour cannot be consumed as a beverage, but is used in the arts for the preparation of varnishes and other purposes. A sufficient quantity of alcoholic spirit is thus obtained to pay for the whole cost of the process. The residue left after washing the madder may be employed for dyeing without any further preparation, and is then called *fleur de garance*. In order to convert it into garancine, it is mixed with sulphuric acid, and the mixture is heated and left to itself for some time. Water is then added in successive portions until the excess of acid is removed. The pectic acid of the root always retains a portion of the sulphuric acid in chemical combination; and the compound being but little soluble in water would require for its removal a very long washing. The addition of a small quantity of carbonate of soda, by neutralising this double acid, serves to abridge the time of washing very considerably. The residue is then filtered on strainers, pressed, dried, and lastly ground into a fine powder. This powder has a dark reddish-brown colour, and a peculiar odour, different from that of madder, but no taste. It communicates hardly any colour to cold water. Dyeing with garancine is attended with the following advantages:—1. The whole tinctorial power of the madder is exerted at once, and garancine is therefore capable of dyeing more than the material from which it is made. 2. The colours produced by its means are much brighter than those dyed with madder, and the parts of the fabric destined to remain white attract hardly any colour, so that very little treatment is required after dyeing. 3. Much less attention is required in regard to the temperature of the dye-bath and its gradual elevation than with madder, and a continued ebullition produces no injurious effects, but only serves to exhaust the material of all its colouring-matter. On the other hand, garancine colours are not so fast as madder colours, they do not resist so well the action of soap and acids, and hence garancine cannot be employed for the production of the more permanent colours, such as pink and fine purple. By the use of a product which was patented by Pincoffs and Schunck several years ago, and which is obtained by exposing garancine to the action of steam of high pressure it is indeed possible to dye as beautiful and as permanent a purple as with madder, and its use is attended by a considerable saving of time as well as of dyeing material and soap, but it is not so well adapted for dyeing pink. As yet therefore we have not succeeded in obtaining a preparation which shall serve as a perfect substitute for madder, and the latter consequently continues to be employed for some purposes.

The residue left after dyeing with madder as well as the dyeing liquor still contain some colouring-matter in a state of combination, as mentioned above. By acting on it with sulphuric acid it affords a product similar to garancine, which is called *garanceux*. This product is, however, adapted only for dyeing red and black, as it does not afford a good purple. (See Calico-Printing.) Numerous other methods of treating madder for the use of the dyer have been invented and patented of late years, but they are not sufficiently important to merit description within the limits of the present article.—E. S.

The following notes of a journey to the madder-growing districts of France, (October 1866), by James Higgin, who contributed the important article on Calico-Printing, will be found to have considerable interest:—'The part of the Comtat d'Avignon where madder is grown is a flat basin, bounded on the north and north-east by mountains of limestone, spurs of which, gradually declining in height, run east and west. This basin is plentifully watered: in the north by several streams which rise in the mountains towards the north-east, and run, in a south-westerly direction, into the Rhône; along the south-west boundary runs the fine river Durance, which, like all the other streams, joins the Rhône—in this case below the town of Avignon; between the Durance and the mountains, and about the centre of the Comtat rises the celebrated fountain of Vaucluse, or the river Sorgue. This remarkable river rises as a spring, in an amphitheatre of perpendicular rocks, about eighteen miles north-east of Avignon. A prodigious volume of water issues from a deep pool at the foot of a high precipice, and in the course of two hundred or three hundred yards the stream is augmented by numerous lateral springs; so that, at the distance of a quarter of a mile from the source, the fountain has become a considerable river, running at the rate of seven or eight miles an hour. After running a mile or two the stream divides into two main branches, which, lower down, subdivide; the one into four branches, the other into three, or seven streams in all, each of considerable volume. These seven streams permeate the central and southerly portions of the basin above described; and it is to these waters that I unhesitatingly ascribe the wonderful fertility of the district of which Avignon is the capital. The Sorgue waters are again subdivided, artificially, in a great variety of ways. Small streams run along the roadside and across the fields in every conceivable manner; the volume of water being so great and flowing so rapidly, that the agriculturist can divert it, dam it up, and irrigate his fields just as he wants, in the same manner as the people of the 'Garden of Valencia,' in Spain, apply the waters flowing through the old Moorish aqueducts, and produce thereby, with the aid of a southern sun, a fertility perhaps without parallel anywhere.

'The result of this abundance of water is that the soil is kept naturally *moist*; not, be it understood, *wet*, but to such a degree of moisture as naturally occurs when water is found anywhere from two to four yards below the surface. In some parts of the basin are patches of land, where formerly were small lakes, which have dried up. These patches were occupied during the drying-up, and for years subsequently, by a dense growth of reeds; and at the present time the ditches bordering these lands, and any portion of them still covered with water, grow plentifully, tall reeds. These ancient lakelets form the lands known as 'Paluds,' where the finest quality of madder grows. The soil here, when dry, is of a light drab colour, very pulverulent, and containing about half its weight of chalk, which has been washed down from the limestone hills. When freshly turned up, this soil is dark brown, showing the presence of considerable quantities of humus.

'In the higher portions of the basin grows the quality of madder called *Rosée.* The soil here contains more clay and less chalk, and when dry it is much more tenacious and not so easily powdered in the fingers. It is, when moist, of not quite so dark a colour as the *paluds* land. The course of cultivation for the *rosée* lands is to plough up and clean the land in autumn and winter. In spring, stable or cow manure is freely applied over the ground, and then ploughed in. Beds of about three feet wide are made by cutting trenches about one foot deep, and throwing the soil on the beds. Madder-seed is now sown in drills, running lengthwise down the beds, to the number of four or five to each bed. The quantity of manure given per acre varies with the number of cattle kept by the farmers; they give as much as they can muster, as they know very well that plenty of manure increases the yield of roots. In the trenches between the madder beds, or more generally only in every other trench, white-sugar beet is always sown; probably as the beet, when growing is a very bulky, leafy plant, the beds would be too much shaded from the sun by sowing it in every drill. Nothing is done during the summer but weeding, and before winter comes on the young plant is covered entirely with earth taken from the trenches after the beet-crop (three to five tons per acre) is removed. Next spring and summer nothing but weeding is done, if we except plucking the seed and sowing beet-root in the trenches which were left vacant the former year. In the late autumn, or about October, the crop is generally dug up, or at eighteen months old. The farmers know perfectly well that to leave the madder in the ground another year, or in all thirty months, is a gain to them both in quantity and quality, but they are generally poor, the French laws of inheritance tending to constantly subdivide the lands into very small farms, and they are obliged to realise upon the crop as soon as they possibly can, which is as soon as the roots are of a saleable size. The paluds madder is always planted in the spring, not sown, the plants being obtained from the year-old crops. I could not ascertain why this difference is made, further than that it is found to suit paluds land better than rosée.

'On the two great cardinal points I satisfied myself, viz.: that manure is always given, and that no artificial irrigation is practised, the natural freshness of the soil being sufficient. The farmers, however, always look for rain in the spring to facilitate the germination of the seed, and in autumn to facilitate the digging-up the roots; for the rest of the year it is not of any importance to have rain. Rotation of crops is usually practised, though in some districts madder is grown year after year upon the same soil, by giving plenty of manure. This, however, is not considered a wise plan, and all the farmers I talked with condemned it. The usual rotation is one madder crop, then a crop of wheat, and lastly lucerne for one or two years, generally the latter, lucerne being a good paying crop. I saw in October lucerne being cut and made into hay for the fourth time that year, and even then a splendid crop. Where it is practicable, they irrigate the lucerne three or four times a year. In many places this is very easy, by damming across one of the numerous streamlets of the fountain of Vaucluse water, so as to cause the water to cover the adjacent land. Thus, once manuring, with irrigation, lasts six years.

'The roots when pulled are spread out on sheets on the ground and dried in the sun, and sold in this state to the merchant or grinder. The farmers deliver them as damp as they dare; as soon as a bundle of them, taken in the hand and twisted round, breaks easily, the roots are considered commercially dry. On being stove-dried for grinding, the dried roots lose for paluds, 20 per cent.; for rosée, 18 per cent.

'The digging up of madder is evidently the most expensive part of the business, but it is not surprising when you see the leisurely way in which they go about it: a man digs down a breadth of a bed, and then puts down his *louche* (a sort of spade-hoe) and picks out the madder roots, shakes them, and throws them into a basket. By hiring children to follow the digger, to pick up and clear the roots, a great saving could be effected. A madder-digger gets three francs a day; the ordinary wages for other labourers is two and a half francs per day. It would seem easy to adapt horse machinery to digging up madder. I was told as one reason why the roots are often pulled up at eighteen months old, that if left in the ground longer they rotted; this, however, is only said of low-lying lands, and is not the case near the mountains. I am inclined to think, however, that poverty is more frequently the cause.

'I saw near Pernes, in the paluds country, some splendid madder that had been forty-two months in the ground; the farmer had been too busy in the autumn of 1865 to pull it at the usual time, and knew, he said, that he should be rather a gainer than a loser by letting it stay in the ground another year. This madder had all the appearance of good Turkey madder; and a French madder-grinder and garancine-maker, who was with me, told me that he had never seen any so good before.

'The rent of good madder-land is high. About Avignon the land that grows rosée roots is let at 20 francs to 25 francs per eminée per annum; an eminée being one-tenth of an hectare, or about a quarter acre English.[1] The rent of paluds land, near Orange and Pernes, is 30 francs to 35 francs per eminée; so that an acre (English) of rosée lands lets at 64*s.* to 80*s.* per annum. An acre of paluds land lets at from 96*s.* to 112*s.* per acre. The yield per acre is two tons for paluds roots; for rosée roots it is not so much.[2] The present price of rosée roots, as delivered by the farmer, is 55 francs per 100 kilos.; of paluds, 65 francs per 100 kilos. These prices correspond to 22*l.* per ton for rosée, and 26*l.* per ton for paluds. These prices are exceptionally low; and a madder-grinder told me that 55 francs per 100 kilos. only about covered the cost of rent, manure, and labour, and that 75 francs was a good paying price; 75 francs is at the rate of 30*l.* per ton. Colza-oil cake is used as a manure for grain crops and lucerne, when not following madder, but it does not suit madder—good farm-yard manure being what is required; superphosphate of lime does not appear to have been tried.

'Madder of very fine quality, almost paluds, is now grown in the alluvial lands of the Bouches du Rhône, near Arles, and even down nearly to Marseilles. This land is impregnated with salt, and I was told more than once that a little salt as a top dressing was useful to improve the yield of the lands in the Comtat of Avignon. It is a curious coincidence that in the district where madder is principally cultivated in Spain—that is, between Segovia and Valladolid—there are large salt lakes, though almost in the centre of Spain; indeed, salt is made from some of them.'

The following, extracted from 'A Practical Handbook on Dyeing and Calico-

[1] The eminée varies in size in different parts of the country; at Entraignes (terrains paluds) it contains 7 ares 85 centiares, at Avignon 8 ares 54 centiares, and at Orange 5 ares 84 centiares.

[2] This quantity is somewhat above the average. According to Mr. Pernod, an eminent garancine manufacturer at Avignon, 5 ares 84 centiares (Avignon eminée) yield 800 kilogrammes of fresh madder roots, equal to 200 kilogrammes of dry roots; one are or 100 square mètres equals 0·0247 of an English acre; 5·84 × ·0247 = 0·144248 acres, and 200 ÷ ·144248 = 1386·5 kilos, which × 2·2 = 3,050 lbs., or 27 cwts. 0·26 dry rosée roots per acre. This is for 18 months old roots. The quantity produced of 30 months old roots is one-third more, or an increased weight of one-third by keeping the roots another year in the ground, giving on above data 36 cwts. 1 qr. 6 lbs. for 30 months roots.

Printing, by William Crookes, F.R.S., contains some instructive matter connected with the application of mordants in the use of madder:—

'Aluminate of soda is largely made and used in France, since the discovery of the extensive deposits of bauxite in the southern parts of that country. It is obtained by roasting, in a reverberatory furnace, a mixture of soda-ash and bauxite, until a small sample taken from the fritted mass ceases to effervesce with acids. When the operation is finished, the aluminate of soda is extracted by lixiviation with boiling water, and the solution evaporated to dryness. It is a coarse powder, exhibiting a slightly greenish colour, due to a trace of vanadium. It is infusible at the highest furnace-heat, and readily soluble in hot and cold water. Dilute solutions (sp. gr. 1·072 to 1·089 = 14 and 17° Tw.) remain limpid and clear for a long time, but stronger solutions (sp. gr. 1·3 to 1·37 = 62° to 71½° Tw.) deposit granular alumina, while the supernatant liquor contains a subaluminate and excess of caustic soda. This aluminate of soda agrees in its properties with the corresponding potassa-salt. See ALUMINATE OF SODA; BAUXITE.

'Since bauxite is a very pure native hydrate of alumina, the aluminate of soda prepared with it is used for the production of acetate of alumina in the following manner:—The aluminate of soda is precipitated by the addition of a very slight excess of hydrochloric acid; the gelatinous alumina thus obtained is thoroughly washed with boiling water, and next dissolved in acetic acid. The percentage composition of the pure aluminate of soda is 47·21 soda and 52·79 alumina; the commercial product, as met with in the French market, is contaminated with about 9 per cent. of impurities, due to the presence of sulphate of soda, and chloride of sodium in the soda-ash.

'As regards the methods of fixing alumina upon woven fabrics, it must be in a perfect state of solution, while it is also necessary that the hydrate of alumina should be precipitated, in the best possible physical condition, within the fibre of the fabrics. W. Crum found that the microscopic examination of fibres mordanted with acetate of alumina and dyed, presented differences: inasmuch as, in the first instance, the coloured lake, or combination of alumina and colouring-matter, was chiefly accumulated within the central canal of the fibre; in the second case, however, the periphery of the fibre only was coloured.

'Alumina can be obtained in solution: (1) in the state of a saline solution of that base; (2) as a basic salt; (3) as a soluble modification of the earth itself; (4) in combination with alkali. Some of the salts of alumina can be brought into contact with the cotton fibre without any decomposition whatsoever ensuing, so that a simple washing in cold water eliminates all the alumina taken up. This happens, *e.g.*, with nitrate and sulphate of alumina and with alum. Whenever it may be desirable to apply such salts for the purpose of mordanting cloth it is necessary to pass the cloth, after it has been impregnated with the aluminous solution, through a bath containing substances capable of precipitating within the fibres either hydrate of alumina, or at least an insoluble basic salt of that base. Some of the salts of alumina are decomposed by moist heat (steam), thereby giving up to the fibres of the cloth the whole or a portion of the alumina on becoming converted into a basic salt. The acid set free is volatilised, or leaves the tissue. The chloride, acetate, and hyposulphite of alumina are salts of this description. These salts become fixed by exposing the saturated tissues to a warm and moist atmosphere. This result is not simply a dissociation of the constituent elements of the salt, but the intervention of the water is absolutely required for the formation of the hydrate of alumina. The action is, therefore, to be considered as a saponification, in the more extended sense of this word, as understood by chemists.

'It is here the proper place to give a few particulars concerning the process just mentioned, and known as "ageing." The mordants generally used for madder styles are the pyrolignites, or acetates of iron and alumina, which, under the influence of ageing—which we are about to describe—are so decomposed as to leave on the cloth either an insoluble oxide or a subsalt, which becomes the intermediate agent for fixing on the fabric the colouring-matters of madder. The fixing of mordants by ageing was first practically carried out by Mr. W. Crum, an eminent and highly scientific calico-printer. "On the proper ageing of printed goods," says Dr. Schunck, "depends in a great measure the success of many styles. Should a room be too hot or too dry, imperfect fixation of the colour ensues, and meagre and uneven tints are obtained in the subsequent operations." To give some idea of the importance of this step in calico-printing, we may here state that "ageing rooms," as they are called, are in several print-works of enormous dimensions, and generally constitute a separate building. Those of Messrs. Edmund Potter and Co., and Messrs. T Hogle and Sons, all at or near Manchester, may be particularised as forming quite a feature in their works. The process of ageing in calico-printing is that by which a mordant, after being applied to a cotton fabric, is placed in circumstances favourable to its being completely incorporated with and fixed in the fibre. It has generally been found desirable that calico printed with a mordant should, before dyeing, be exposed to the atmosphere for some time in the ageing room, in single folds, which generally speaking, requires several days, the object being to liberate the acetic acid from the acetates of iron or subacetates of alumina, and to oxidise the protoxide of iron. It was for many years believed that oxygen was the only necessary agent; and although some printers had observed that moisture facilitated the process, this fact was not generally known until Mr. J. Thom of Manchester claimed the introduction of moisture as an important agent in the process of ageing, in a patent which he took out in 1849. Mr. W. Crum was, however, the first printer who applied this principle practically. He describes the process as adopted at Thornliebank (near Glasgow), in the following words:—A building is employed, 48 feet long inside and 40 feet high, with a mid-wall from bottom to top, running lengthwise, so as to form two apartments, each 11 feet wide: in one of these apartments the goods first receive the moisture they require. Besides the ground floor, it has two open sparred floors, 26 feet apart, upon each of which is fixed a row of tin rollers, all long enough to contain two pieces of cloth in their breadth. The rollers being threaded, are set in motion by a small steam-engine, and the goods to be aged, which are at first placed in the ground floor, are drawn into the chamber above, where they are made to pass over and under each roller, issuing at last at the opposite end, where they are folded into bundles on one of the three stages which are placed there. These stages are partially separated from the rest of the chamber by woollen cloths. While the goods are traversing these rollers they are exposed to heat and moisture, furnished to them by steam, which is made to issue gently from three rows of trumpet-mouthed-shaped openings. The temperature is raised from 80° to 100° F. or more, a wet-bulb thermometer indicating at the same time 76° to 96° F., or always 4° less than the dry-bulb thermometer. In this arrangement 50 pieces of 25 yards each are exposed at one time; and, as each piece is a quarter of an hour under the influence of steam, 200 pieces pass through in an hour. Although workpeople need scarcely ever enter the warmest part of this chamber, a ventilator in the roof is opened when there is any considerable evolution of acetic acid. The mordant does not, however, become fully aged by this process alone, although it is acted upon as much as if it had hung a whole day in cold air. It has received, however, the requisite quantity of moisture, about 7 per cent. of the weight of the piece, and is thus enabled, if the mordant be iron, to take oxygen from the air, and to become changed with time into the sesquiacetate and sesquihydrate of oxide of iron. In order to be sufficiently aged, it must be left one, or two, or even three, days in an atmosphere still warm and moist.

'It had been ascertained long before, at Thornliebank, that exposure in single folds, after moistening, was not necessary. The experiments of the late Prof. T. Graham, on the diffusion of gases through small apertures, had served to suggest that, for the absorption of the small quantity of oxygen required, the goods might as well be wrapped up and laid in heaps. Accordingly, in the operation in question, the moistened goods are carried in bundles into the building on the opposite side of the mid-wall already mentioned, and laid upon the sparred floors, placed at heights corresponding with the stages in the first apartment. Upon these floors, 7,000 or 8,000 pieces may be laid at a time, and, since each piece is 25 yards long, 100 miles can be stored at once. It is necessary, of course, that an elevated temperature and a corresponding degree of moisture be preserved in the storing apartments, day and night, and 80° F. is sufficient with the wet-bulb thermometer at 76°. To effect this condition, a large iron pipe is placed along the ground floor underneath, and moderately heated by steam, while a row of small jets in the same position are made to project steam directly into the air of the room. The whole building is protected from external cold, and consequently from condensation of steam, by a warmed entrance-room, and by double windows, thick walls and a double roof. Small steam-pipes are also placed at other points, where they seem to be required; and the apartment which contains the rollers is specially heated when not in use by a couple of steam-pipes, which are placed under the ceiling of the ground floor.'

All who are interested in the application of mordants, and who are desirous of understanding the principles upon which the applications are made, are referred to the 'Handbook of Dyeing,' already quoted.

MADDER LAKE. The red pigment usually called *madder lake*, which is much used by painters, is made by treating madder, which has been previously washed with water, with a boiling solution of alum, filtering the red liquid, and adding a small quantity of carbonate of soda, taking care to leave an excess of alumina in solution, washing the red precipitate, which is a compound of colouring-matter and alumina, with water and drying. Persoz gives the following method for obtaining a madder lake of great brilliancy:—One part of madder, which has been previously submitted to fermentation or else washed with a solution of sulphate of soda, is treated with ten times its weight of a boiling solution of alum, containing one part of alum, for fifteen or twenty minutes. The filtered liquid is mixed, as soon as its temperature has fallen to about 100° F., with a solution of carbonate of soda containing one-eighth or one-tenth of the weight of the alum employed. This quantity is insufficient to cause any precipitate at that temperature, but on boiling the liquid, the lake falls down in the shape of a red powder. The madder must be treated several times with boiling alum-liquor, in order to extract the whole of the colouring-matter soluble in that menstruum. It is evident that these lakes contain chiefly purpurine and very little alizarine, the latter being hardly soluble in alum-liquor. See Lake.

MAGDALA RED. A name applied to naphthaline red.

MAGENTA. A full description of this and analogous colours will be found under Aniline Red. We extract the following from Mr. Crookes's 'Handbook of Dyeing and Calico-Printing':—

'The simplest method of testing a commercial sample of magenta both for intensity and for purity of tone, is to dissolve a known weight in boiling water and to dye with the strained decoction a known weight of fine white woollen yarn or cloth. By thus comparing different samples, their respective tinctorial power can be readily ascertained, and the presence of tarry matters, unconverted aniline, &c., may be detected by the flatness and brownish cast of the colour. Sugar is sometimes used as an adulterant. This may be detected by treating the sample with concentrated alcohol. The magenta dissolves and is filtered off, whilst the sugar remains behind undissolved.

'The following method is used to ascertain whether a magenta is a pure salt of rosaniline, or is contaminated with mauvaniline, violaniline, chrysotoluidine, &c. The colour is dissolved in as little alcohol as possible, the solution diluted with its own bulk of water or rather more, and a drop is taken up by means of a glass rod, and applied to a piece of white blotting-paper. If more than one colouring-matter is present, the different shades will diffuse themselves in concentric circles, and may be distinctly seen. This method is still more applicable to the aniline violets and blues, which are frequently heterogeneous.

'*Aniline Crimson.*—The crude magenta-cake, without any purification, is sold under this name, and is used in dyeing certain maroons, browns, clarets, and other compound colours.

'The colour well bruised or broken up into powder, is placed in a suitable stoneware vessel and well stirred up with its own weight of hydrochloric acid. During this process the fumes given off should be carefully avoided. After the colour has steeped for a short time in the acid, boiling water is added sufficient to dissolve the whole. The solution thus obtained is carefully strained, and is then ready for use. To correct the acidity of the colour, a small quantity of ammonia is added to the dye-bath. This preparation will in many cases supersede peachwood, producing brighter shades, with less trouble, and at a lower price. They are, however, more fugitive. Upon wool and silk, aniline crimson, like magenta, is a substantive colour. Upon vegetable fibres it requires to be fixed with a mordant—generally a per-salt of tin—and an astringent.'

MAGILP. A vehicle used by artists, of a gelatinous character. Much secresy prevails as to the manufacture of magilp. It appears to be essentially linseed-oil which has been exposed for some time to the oxidising influences of the air, mixed with good mastic varnish.

MAGISTERY is an old chemical term to designate white pulverulent substances, spontaneously precipitated in making certain metallic solutions; as magistery of bismuth.

MAGISTRAL, in the language of the Spanish smelters of Mexico and South America, is the roasted and pulverised copper pyrites, which is added to the ground ores of silver in their *torta*, or amalgamation-magma in the *patio* process for the purpose of decomposing the horn-silver (chloride of silver) present. For an account of this process of reduction, see SILVER.

MAGMA is the generic name of any crude mixture of mineral or organic matters in a thin pasty state.

MAGNANIER is the name given in the southern departments of France to the proprietor of a nursery in which silkworms are reared upon the great scale, or to the manager of the establishment. The word is derived from *magnans*, which signifies silkworms in the language of the country people. See SILK.

MAGNESIA (*Magnésie*, Fr.; *Bittererde*, *Talkerde*, Ger.) is one of the earths, first proved by Sir H. Davy to be the oxide of a metal, which he called *magnesium*. It is a fine, light, white powder, without taste or smell, which requires 5,150 parts of cold water, and no less than 36,000 parts of boiling water, for its solution. Its specific gravity is 2·3. It is fusible only by the heat of the hydroxygen blowpipe. A natural hydrate exists which contains 30 per cent. of water. Magnesia changes the purple infusion of red cabbage to a bright green. It attracts carbonic acid from the air, but much more slowly than quicklime. It consists of 61·21 parts of metallic basis and 38·79 of oxygen; and has, therefore, 20 for its equivalent upon the hydrogen scale. Its only employment in the arts is for the purification of fine oil, in the preparation of varnish.

Magnesia, popularly known as *Calcined Magnesia*, may be obtained by precipitation with potash or soda from its sulphate, commonly called Epsom salt; but it is usually procured by calcining the artificial or natural carbonate. There is a heavy calcined magnesia prepared by burning the dense carbonate. Mr. Lockyer has shown, however, that a very dense and pure magnesia could be obtained by calcining the ordinary pure carbonate in large masses, and at a very high temperature.

MAGNESIA, CARBONATE OF; properly speaking, a subcarbonate, consisting of 44·69 magnesia, 35·86 carbonic acid, and 19·45 water. It is prepared by adding to the solution of the sulphate, or the chloride (the *bittern* of sea-salt evaporation works), a solution of carbonate of soda, or of carbonate of ammonia distilled from bones in iron cylinders. Mr. Hugh Lee Pattinson introduced the manufacture of carbonate of magnesia from the dolomite rocks, availing himself of the different rates of solubility of the carbonates of lime and magnesia in water saturated with carbonic acid. (See DOLOMITE.) The subcarbonate, or *magnesia alba* of the apothecary, has been proposed by Mr. E. Davy to be added by the baker to damaged flour, to counteract its acescency.

MAGNESIA, NATIVE HYDRATE OF, or *Brucite*. This mineral consists of magnesia, 68·97, water, 31·03, according to analyses by Bruce. It accompanies other magnesian minerals in serpentine at Swinaness in Unst, one of the Shetland Isles, in the Ural Mountains, in France, and opposite to New York.

MAGNESIA, SILICATES OF. Compounds of this character are abundant in the mineral kingdom. Meerschaum, French Chalk or Steatite, Talc, Serpentine, and many other minerals are silicates of magnesia. (See *these articles*.)

MAGNESIA, SULPHATE OF, (*Epsom Salts*,) is generally made by acting upon magnesian limestone with somewhat dilute sulphuric acid. The sulphate of lime precipitates, while the sulphate of magnesia remains in solution, and may be made to crystallise in quadrangular prisms, by suitable evaporation and slow cooling. Where muriatic acid may be had in profusion for the trouble of collecting it, as in the soda-works in which sea-salt is decomposed by sulphuric acid, the magnesian limestone should be first acted upon with as much of the former acid as will dissolve out the lime, and then, the residuum being treated with the latter acid, will afford a sulphate at the cheapest possible rate; from which magnesia and all its other preparations may be readily made. Or, if the equivalent quantity of calcined magnesian limestone be boiled for some time in bittern, the lime of the former will displace the magnesia from the muriatic acid of the latter. This is the most economical process for manufacturing magnesia. See DOLOMITE.

MAGNESIAN LIMESTONE. See DOLOMITE; LIMESTONE.

MAGNESITE. *Carbonate of Magnesia; Rhomb Spar.* This native carbonate of magnesia, consisting of magnesia 47·6, carbonic acid 52·4, is found with serpentine and other magnesian rocks.

MAGNESIUM. The metal obtained from magnesia. It was first procured by Bussy, although previously shown to exist by Davy. It is now made by placing potassium or sodium in a platinum crucible, covering them with chloride of magnesium, fastening down the cover of the crucible, and exposing it to the heat of a spirit-lamp. It has been prepared by Bunsen by the action of the voltaic current; and the late Dr. Matthiessen obtained it by the electrolysis of fused chloride of magnesium.

We are much indebted to M. Sonstadt for removing the obstacles in the way of obtaining magnesium on the large scale for commercial purposes. The process pursued by Sonstadt is that of Deville and Caron, somewhat modified. Magnesium may, however, be obtained in much larger quantity, by heating a mixture of 600 grains of chloride of magnesium, 100 grains of fused chloride of sodium, and 100 grains of pulverised fluoride of calcium, with 100 grains of sodium, to bright redness, in a covered earthen crucible. The magnesium is thereby obtained in globules, which are afterwards heated nearly to whiteness in a boat of compact charcoal placed within an inclined tube of the same material, through which a stream of dry hydrogen is passed. The magnesium then volatilises and condenses in the upper part of the tube. Lastly, it is re-melted with a flux composed of chloride of magnesium, chloride of sodium, and fluoride of calcium, and is thus obtained in large globules. It still, however, usually retains portions of carbon, silicium, and nitrogen, from which it may be purified by careful distillation in a current of hydrogen.

Magnesium is an easily inflammable metal; a wire of considerable thickness can be ignited in the flame of a candle, and the light evolved by the combustion is of great intensity. It has been ascertained that a wire of 0·297 millimeter diameter will give as much light as 74 stearine candles of five to the pound. The powerfully actinic character of the light has been demonstrated by Mr. Brothers, of Manchester, and Mr. Sydney Smith, both of whom have produced good pictures by its use.

The metal is neither ductile nor very malleable. It cannot be drawn, but, by employing a method devised by Dr. Matthiessen, it can be forced in a softened state through a small opening in an iron cylinder, and thus strands of wire of considerable length can be formed. The wire has been found to burn more steadily when three or four strands are twisted into a rope; and a simple clockwork arrangement will deliver such a rope to a spirit- or oil-lamp, in the flame of which it may be burned.

Alloys of Magnesium.—Dr. T. L. Phipson has paid some attention to these. In a communication to the Chemical Society, he says:—

'I have examined only a few alloys of magnesium. Unlike zinc, magnesium will not unite with mercury at the ordinary temperature of the air. With tin 85 parts, and magnesium 15 parts, I formed a very curious alloy of a beautiful lavender colour, very hard and brittle, easily pulverised, and decomposing water with considerable rapidity at ordinary temperatures. If the air has access during the formation of this alloy the mixture takes fire; and if the crucible be then suddenly withdrawn from the lamp the flame disappears, but a vivid phosphorescence ensues, and the unfused mass remains highly luminous for a considerable time. A white powdery mass, containing stannic acid and magnesia, is the result. (With platinum, according to M. Sonstadt, magnesium forms a fusible alloy; so that platinum crucibles can be easily perforated by heating magnesium in them.) Sodium and potassium unite with magnesium and form very malleable alloys, which decompose water at the ordinary temperature. It is probable that an alloy of copper and magnesium, which I have not yet obtained, would differ from brass, not only in lightness, but by decomposing water at the usual temperature with more or less rapidity.'

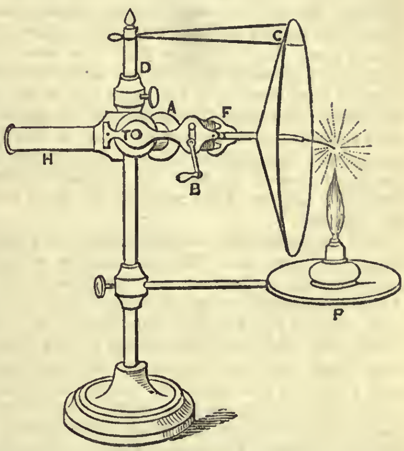
Photochemical Power of the Magnesium Flame.—To Professors Bunsen and Roscoe we are especially indebted for an examination of this question. Their experiments showed that a burning-surface of magnesium-wire which, seen from a point at the sea's level, has an apparent magnitude equal to that of the sun, effects on that point the same chemical action as the sun would do when shining from a cloudless sky at a height of 9° 58′ above the horizon. On comparing the chemical with the visible brightness of these two sources of light, it was found that the brightness of the sun's disc, as measured by the eye when the sun's zenith distance was 67° 22′, is 524·7 times as great as that of the burning magnesium-wire; whilst, at the same zenith distance, the chemical brightness of the sun is only 36·6 times as great. Hence the value of this light as a source of the chemically-active rays for photographic purposes becomes apparent.

Professors Bunsen and Roscoe say in their memoir: 'The steady and equable light evolved by magnesium-wire burning in the air, and the immense chemical action thus produced, render this source of light valuable as a simpler means of obtaining a given amount of illumination expressed in our terms of measurement of light. . . The combustion of magnesium constitutes so definite and simple a source of light for the purpose of photochemical measurement that the wide distribution of this metal becomes desirable. The application of this metal as a source of light may even become of technical importance. A burning magnesium-wire of the thickness of 0·297 millimeter evolves, according to a measurement we have made, as much light as seventy-four stearine candles, of which five go to a pound. If this light lasted one minute, 0·987 meter of wire, weighing 0·1204 grain, would be burnt. In order to produce a light equal to seventy-four candles burning for ten hours whereby about 20 lbs. of stearine is consumed, 72·2 grains of magnesium would be required. The magnesium-wire can be easily prepared by forcing out the metal from a heated steel press, having a fine opening at bottom; this wire might be rolled up in coils on a spindle, which would be made to revolve by clockwork, and thus the end of the wire, guided by passing through a groove, or between rollers, could be continually pushed forward into a gas- or spirit-lamp flame, in which it would burn.'

In the reports of Mr. Brothers' experiments upon the magnesium-light, he says, 'The result of an experiment I have just tried is, that in fifty seconds, with the magnesium-light, I have obtained a good negative copy of an engraving, the copy being made in a darkened room. Another copy was made in the usual way by daylight, and in fifty seconds the result was about equal to the negative taken by the artificial light. The sun was shining, but there was a good deal of fog in the atmosphere.'

Magnesium-Lamps have been invented and manufactured by F. W. Hart, London, for photochemical and other purposes. This invention includes the use of springs and wheels for self-acting propulsion and revolving of the ignited magnesium at the same time, thereby avoiding a drooping light, which for optical illumination is a great desideratum. These lamps are only made to order, as their mechanism is considered unnecessary for ordinary purposes, the action of the simplified lamp being as follows:—

1422



Hand-Lamp, for ribbon or one or more wires—if more than one wire, they should be twisted firmly together. Place the end in the clip on the inside of the flange of the reel A (*fig.* 1422); apply a slight pressure to the reel by turning the tension-screw T; then wind the magnesium on by turning the flange with the finger and thumb; in the more highly-finished lamps the winch, B, screws on the spindle of A for winding on quantities very regular. The loose end is then passed through the guide and feeding-rollers at F. Sufficient tension having been applied by the screw-head, T, the wire remains without uncoiling. *For use*, release the tension, and turn the winch, B, towards the reel, A. In the self-acting propelling-lamps above mentioned, a governor requires personal adjustment to the rate of burning—in the simplified *hand-lamps* the winch, B, is moved at the desired rate, which saves a considerable expense for common purposes. The wire should be ignited in the smokeless part of a flame, and *a spirit-lamp is recommended.* See Watts's 'Dictionary of Chemistry.'

MAGNET. A bar of steel, which, being imbued with a peculiar condition of electrical force, is possessed of polarity. The magnet has a special employment in the mariner's compass, as from the undeviating way in which—unless strong disturbing causes are in operation—it points north and south. The magnet is used also in surveying-instruments. The use of iron in ship-building has led to a very careful examination of the influence of iron on the ship's compasses. The late Dr. Scoresby, Professor Airy, and some others, have been peculiarly distinguished in this important inquiry, and to their memoirs on the subject the reader is referred. Magnetic machines have been constructed for developing electricity, and employed for the deposition of metals. See ELECTRO-METALLURGY.

MAGNETIC PYRITES. One of the native sulphides of iron. Its chemical composition is usually sulphur 40·15, iron 59·85. Its power of attracting the magnetic needle is probably due to the peculiar condition in which the iron exists. It is distinguished from the common pyrites (*Mundic*) by its inferior hardness and its bronze colour. See PYRITES.

MAGNETISM. A peculiar condition of electrical force. The phenomena of magnetism which are rendered in any way available in the arts are detailed in special articles; as ELECTRO-TELEGRAPHY, &c. &c. All bodies must now be regarded as existing in one of two known conditions of magnetism. It is understood that magnetism is manifested as a *polar force*, as in a bar of iron. Every one is familiar with the fact that a polarised bar, if free to move, places itself in a certain direction, which we call north and south. Besides iron, nickel and two or three other metals possess this property. Bismuth, silver, glass, wood, and nearly all other substances exhibit magnetic force of a different order, which is manifested in all these bodies by their placing themselves at right-angles to a magnet, or to the line of magnetic force. This condition has received the name of DIA-MAGNETISM, *which see.*

MAGNETITE. Oxydulated iron, or magnetic iron ore. One of the richest and most important ores of iron. See IRON.

MAGNET, NATIVE. See LOADSTONE and IRON.

MAHALEB. The fruit of this shrub affords a violet dye, as well as a fermented liquor like *Kirschwasser*. It is a species of cherry, cultivated in our gardens.

MAHOGANY. The wood of a tree (*Swietenia Mahagoni*), which is a native of the West Indies. This wood appears to have been first brought to England in 1724.

SPANISH mahogany is imported from Cuba, St. Domingo, the Spanish Main, and several of the West India Islands, in logs about 26 inches square, and 10 feet long. Its general character is well known from its extensive use in cabinet-work.

HONDURAS mahogany is generally lighter than the Spanish, and more open and irregular in its grain. This is imported in large logs, many of 4 feet square and 18 feet in length. Planks are sometimes obtained of 7 feet in width. According to Mr. Chief-Justice Temple, 'the cutting commences in the month of August. In April or May, in which months the ground has become perfectly hard from the continued dry weather, the wood is carried upon trucks drawn by bullocks to the water side; and about the middle of June, when the rivers are swollen by the floods, the logs are floated down about 10 miles from the mouths of the different rivers, where they are confined by a heavy boom drawn across the stream. Here the owners select their respective logs, form them into rafts, and so float them down to the sea. The mahogany is always trucked in the middle of the night, the cattle not being able to perform such laborious work during the heat of the day. It is a picturesque and striking scene—this midnight trucking. The lowing of the oxen, the creaking of the wheels, the shrill cries of the men, the resounding crack of their whips, and the red glare of their pine torches in the midst of the dense dark forest, produce an effect approaching to sublimity.

'An impression has latterly existed that almost all the mahogany in British Honduras has been cut. This, however, is a mistake. There is sufficient wood in the country, both on granted and ungranted land, to supply the European as well as the American markets for many years to come. A considerable quantity of mahogany has been, within the last few years, cut in the state of Honduras and on the Mosquito shore; but the mahogany-works in the former country have been almost entirely abandoned, partly on account of the wood, which is accessible, being nearly all cut, and partly on account of the extra freight and insurance which are required when vessels are loaded on that coast. From the Mosquito shore very few cargoes have been lately sent, for the wood which grows there, although it is very large, is of inferior quality. The mahogany-tree requires a rich dry soil. The best mahogany is found to the north of the river of Belize. In consequence of the nature of the soil in that district, in which there is a great quantity of limestone, the mahogany is longer coming to maturity, but, when fully grown, it is of a harder and firmer texture than that which is found in the southern portion of the settlement. There is no wood more durable than mahogany, and none that is so generally useful. It is stated in a little book called the "Mahogany-Tree" that furniture is being made, in the royal dockyards, out of the beautiful mahogany found in breaking up the old line-of-battle ship the *Gibraltar*, which was built in Havana 100 years ago. The English and French Governments purchase yearly a large amount of mahogany for their dockyards. During the last year the British Government required 12,000 tons, paying 10*l*. 17*s*. 6*d*. per ton. The French government took 3,000 tons at the same price. The royal yacht is built principally of Honduras mahogany. Private ship-builders are, however. reluctant to make use of mahogany for their vessels, as Lloyd's Committee exclude all ships of 12 years' standing in which the floors, futtocks, top-timber, keelson, stem and stern-post, transoms, knightheads, hawse-timbers, apron, and dead wood, are made of mahogany.

'Mahogany vessels of 10 years' standing they admit, but even these, I am informed, it is their intention very shortly to exclude. The reason which they assign is, that mahogany differs very much in quality, and it is impossible to know when a ship is built of good or bad wood. But this difference in quality depends entirely upon the district in which it has grown. If they restricted the ship-builders to the northern wood, they might admit vessels of 12 years' standing without any risk. In the year 1846 the Honduras merchants presented a memorial to Lloyd's Committee, praying for a removal of the existing limitations to the general use of mahogany in the building of vessels of the highest class. Attached to this memorial were numerous certificates from persons well qualified to give an opinion on the subject, speaking in the highest terms of mahogany for ship-building. Captain E. Chappel, R.N., Secretary of the Royal Mail Steam Packet Company, says he "has seen the *Gibraltar*, 80-gun ship, which was broken up at Pembroke. *This ship is entirely of mahogany;* captured of the Spaniards in 1780; *all her timbers sound as when put into her.* Tables for the Navy made of the timbers of the *Gibraltar.* The steamer *Forth*, built by Mr. Menzies of Leith, has as much mahogany put into her as could be obtained. The use of mahogany ought to be the *rule*, and not the exception." The qualities of mahogany, which render it peculiarly fitted for ship-building, are its lightness and buoyancy, its freedom from dry-rot, and its non-liability to shrink or warp. The price of mahogany varies according to the size, figure, and quality of the wood. One tree from the northern districts, which was cut into three logs, sold for 1,800*l.*, or 10*s.* per superficial foot of 1 inch; southern wood of small size and inferior quality has been sold at 3½*d.* per foot. The present prices in London for small-sized plain mahogany are from 5*d.* to 6*d.* per foot; for large-sized plain, from 7*d.* to 10*d.*; and for large, of good quality and figured, from 9*d.* to 1*s.* 6*d.*

'The yearly average quantity of mahogany exported from Honduras during the last ten years is about 8,000,000 feet, equal to 20,000 tons, or 200,000 tons in the whole ten years, requiring 160,000 trees.'

African mahogany (*Swietenia senegalensis*), from Gambia, has been used of late years for curriers' tables, mangles, &c., and may be used for turning. It is denied by some authors to be a *Swietenia*; but, if not so, it is a very closely-allied genus.

There are two or three varieties of the *Swietenia* in the East Indies which are ornamental woods, but not mahogany.

The importance of this wood will be seen from the following statement of the *Imports* of mahogany in 1868–70, and 1872:—

MAIZE. A genus of monocotyledonous plants belonging to the natural order *Gramineæ*—the grasses. There are only two species known, and these both belong to America. The *Zea mays* is the Indian corn or common maize; and the *Zea caragua*, the Chilian maize or Valparaiso corn. Both these varieties are largely cultivated as articles of food.

MAJOLICA, known also as Faenza and Raffaelle ware. A term for soft enamelled pottery, first introduced into Italy from Majorca about the twelfth century, and which was the work of the Moors.

The distinguishing points of the so-called majolica are coarseness of ware, and an opaque white enamel containing binoxide of tin, and decorated in colours. A large class ascribed, although possibly on insufficient grounds, to Valentia, is characterised by elaborate conformity of pattern, flushed with metallic lustre, on a greyish-white ground.

Of the positively Italian wares, though they were so greatly in request that most of the cities of the Romagna instituted manufactories of them, but little can be ascertained prior to the sixteenth century.

The towns most celebrated after A.D. 1500 for their artistic productions are Pesaro, Gubio, Ascanio, Bologna, Citacastellana, Ferrara, Forli, Fynlina, Pisa, Perugia, Rimini, Sienna, and Spello; and the first is considered the earliest site of a manufactory in Italy, notwithstanding the attempts of the ingenious Eugène Piot in favour of Deruta. So early as 1509 Guidobolato della Rovere, duke of Urbino, granted a patent to Jacques Lanfranco of Pesaro, for 'the application of gold to the Italian faïence,' by which is probably intended that lustre of a golden colour which so brilliantly sheds its prismatic hue on the fictile performances of this period. The next in antiquity is Gubio, which boasted, in Giorgio Andriolio, of one of the most famous masters in his art. In 1511, and subsequently, he, improving on the invention of Lanfranco, gave to his wares a ruby splendour, restricted to his works alone; for the artist and his secret died together. His works are usually inscribed at the back M°· G°· (Maestro Giorgio), which title he assumed on his ennoblement. At Gubio, also, Giorgio's son Vincent is said to have laboured in the same department.

It was, however, during a period extending from 1520 to 1560 that these wares attained perfection. The classical designs of Raffaelle, of Giulio Romano, and of Marc Antonio, were adopted and correctly developed; the most graceful figure-compositions, selected from the Grecian and Roman mythologies, were surrounded by borders of imaginative arabesques. The colours, less brilliant than before, were now more harmoniously combined, while the glaze became more transparent, and more evenly applied then ever. Plates, dishes, vases, cisterns, fountains, now came into being in full magnificence, while goblets, salt-cellars, and other appendages to the table receive the same careful ornamentation with works of greater pretension but less utility.

At Pesaro, in 1542, flourished Geronimo, and in 1550, Mathieu, when large dishes were first made, having a profusion of ornaments executed in relief. With these artists successfully competed Terenzio, son of Mathieu; Battista Franco, a skilful designer, entrusted with the direction of the works; Taddeo Zuccaro and the two Raffaelles—one Ciarla, the other dell Colle—both for a long time confounded with the immortal Sanzio. There, too, worked the brothers Flaminio, and Orazzio Fontana, of Urbino, on the dinner service which Guidobardo caused to be made for Charles V. and Philip II. Orazzio also worked at Castel Durante and Florence, as did the Chevalier Piccolpesso, a talented painter, and the author of a work on pottery. Rivalling also the above in fame, were Guido Selvaggio of Faenza, Francisco Xante de Rovigio, who was a support of the manufactory at Urbino, Frederico Brandini, and Guido Durantino. The works of Luca della Robbia gave much celebrity to the ware, owing to the brilliancy of his colours, the modelled relief of his designs, and the hardness of his enamel. The Dukes of Urbino patronized the art for nearly two hundred years; and the productions they issued are generally known as Raffaelle ware.

For an historical account of majolica, see Mr. Drury Fortnum's elaborate 'Descriptive Catalogue of the Majolica in the South Kensington Museum,' 1873.

MALACHITE, or *mountain green*, is native carbonate of copper of a beautiful green colour, with variegated radiations and zones; spec. grav. 3·5; it scratches calcspar, but not fluor-spar; by calcination it affords water and turns black. Its solution in the acids deposits copper upon a plate of iron plunged into it. Its consists of carbonic acid, 18·5; protoxide of copper, 72·2; water, 9·3.

It is found in great quantities and of a remarkably fine character, in the copper mines of the Ural mountains, and is in Russia manufactured into various kinds of furniture and highly ornamental articles. A very fine malachite has been obtained from the Burra-Burra mines in South Australia. It is found to exist in large quantities in Central Africa. See Copper.

MALATES are saline compounds of the bases with malic acid.

MALE FERN. *Lastrea* (*Aspidium*) *Filix-mas.* This fern grows in all parts of Europe and most parts of America, between New York and Virginia. Its root (rhizome) has been used for tanning. The best root is about 6 inches long and an inch broad; externally it is of a brown colour, internally yellowish or reddish white, with a peculiar but not very strong odour, and a sweetish bitter-astringent taste. Morrin states that the root contains volatile oil, fatty matter, gallic acid, acetic acid, tannin, uncrystallizable sugar, starch, ligneous matter, and gelatiniform matter. The root is collected in May and September.

MALIC ACID. (*Acide malique*, Fr.; *Aepfelsäure*, Ger.) This acid exists in the juices of many fruits and plants alone, or associated with the citric, tartaric, and oxalic acids; and occasionally combined with potash or lime. Unripe apples, sloes, barberries, the berries of the mountain-ash, elder berries, currants, gooseberries, strawberries, raspberries, bilberries, brambleberries, whortleberries, cherries, and ananas, afford malic acid; the house-leek and purslane contain the malate of lime.

The acid may be obtained most conveniently from the juice of the berries of the mountain-ash or barberries. This must be clarified, by mixing it with white-of-egg, and heating the mixture to ebullition; then filtering, digesting the clear liquor with carbonate of lead, till it becomes neutral; and evaporating the saline solution, till crystals of malate of lead be obtained. These are to be washed with cold water, and purified by re-crystallization. On dissolving the white salt in water, and passing a stream of sulphuretted hydrogen through the solution, the lead will be all separated in the form of a sulphide, and the liquor, after filtration and evaporation, will yield yellow granular crystals, or cauliflower concretions, of malic acid, which may be blanched by re-dissolution and digestion with bone-black, and re-crystallization.

Malic acid has no smell, but a very sour taste, deliquesces by absorption of moisture from the air, is soluble in alcohol, fuses at 150° Fahr., is decomposed at a heat of 348°, and affords by distillation a peculiar acid, the pyromalic. It consists, in 100 parts, of 41·47 carbon, of 3·51 hydrogen, and 55·02 oxygen; having nearly the same composition as citric acid. A crude malic acid might be economically extracted from the fruit of the mountain-ash, applicable to many purposes; but it has not hitherto been manufactured on the great scale.

MALLEABILITY is the property belonging to certain metals of being extended under the hammer by beating, or under the roller. Gold is a remarkable example of a malleable metal.

MALLEABLE IRON. See Iron.

MALM ROCK. A local name for the sandstones of Sussex and Surrey, called also *fire-stone*. It belongs to the Upper Greensand formation. This *Malm* forms the soil which produces the greater part of the hops for which these counties are celebrated. See Sandstone.

MALTHA. *Bitume glutineux*, or mineral pitch. It dissolves in alcohol, as also in naphtha, and oil of turpentine. It seems to be inspissated petroleum.

MALTING. The process by which barley or other grain is prepared by germination under artificial conditions, for the purpose of brewing. The changes produced in its constituents, and the requisite properties of good malt, having been already given in the article Beer, we now proceed to describe the requisites of a malt-house, and the mode of operation.

The necessary apparatus for the production of malt is extremely simple: that is to say, first, a cistern or vessel for steeping the grain; secondly, a floor on which it may be thinly spread and allowed to germinate; and, lastly, a kiln or stove in which the newly-formed malt may be dried. These need not be of any specific size, neither is any special position, or arrangement needed; but in this country, from the large amount of duty levied on this manufacture, fiscal regulations interfere with, and influence the whole arrangement.

The regulations as to the manufacture of malt are embodied in the acts 7 & 8 Geo. 4. c. 52, and 11 Geo. 4. c. 17. The former act is an admirable specimen of legislative injustice; the latter was intended to ameliorate the provisions of its predecessor, and does, in a degree, effect that object, The first contains no less than 83 clauses; and the regulations in it are enforced by 106 penalties, amounting in the aggregate to the incredible sum of 15,000*l.* How much of this is negatived by the subsequent act it is not very easy to determine, though, as far as it goes, the effect of No. 2 is to stultify the regulations of No. 1. The cistern or steeping vessel must be of a determinate form and construction; it must have been approved of by a supervising officer; its cubical contents must have been very accurately ascertained by actual admeasurement, and it must be placed in such a situation that the officer gauging it may have sufficient light, and a clear open space of 48 inches, at the least, above every part of such cistern, for the purpose of facilitating the process of gauging; and, lastly, if such light be an impossibility, from local obstacles, the maltster must enter into an engagement to keep, at his own expense, lamps or candles burning, for the convenience of the officer. From what we have now said, as well as from the notoriously uncertain character of grain, it might naturally be inferred that the process of steeping would be left entirely to the judgment of the maltster, who would determine according to his experience, and the nature of the resulting phenomena, when the grain had been steeped long enough in the water, and when it had not. The law, however, allows him no such privilege; whether the grain be old or dry, or new and moist, is all one,—'maltsters are required to keep their corn or grain covered with water for the full space of 40 hours, under the penalty of 100*l.*' Nor will any change occurring in the appearance of the grain, and seeming to require its immediate removal, justify or excuse the maltster in so doing, unless indeed he shall have anticipated the occurrence by giving notice of his intention to do so in his original notice *'to wet'*—which must date 24 hours previous to commencing that operation,—and to give the day and hour of the day for beginning the steep,—all under the usual penalty of 100*l*. Nor may he 'begin to wet at any other time than between the hours of eight in the morning and two in the afternoon,' under a penalty of 100*l*., nor may he take corn or grain from any cistern at any other time than between the hours of seven in the morning and four in the afternoon. To empty corn or grain out of any cistern, until the expiration of ninety-six hours from the time of the last preceding emptying of any cistern in the establishment, involves a penalty of 200*l*.; and the same infliction occurs, 'if the corn or grain be not emptied out of all such cisterns at one and the same time, or within three hours after the clearing of the first cistern was commenced.'

Maltsters are not to mix, either on the floor or kiln, any corn or grain of one wetting with corn or grain of another wetting, under a penalty of 100*l*. What is termed the couch, or place in which the grain, after being steeped, is laid together for the purpose of germination, is a supplementary apparatus of excise ingenuity, and no way necessary to the success of the malting process. Here the grain, after having been gauged in the steep, is again to be gauged with great care; and if the maltster should tread or compress the couch, so as to diminish its bulk, a penalty of 100*l*. is imposed, though it is obvious that a power of loosening or compressing this couch according to its temperature would greatly improve the formation of malt. However, 'all corn or grain emptied into the couch-frame is to be laid flat and level by the maltster, and so kept 24 hours at the least,' and similarly the floors are all to be placed level on pain of 100*l*. fine, so that any experimental essay at improvement is very likely to end in the Court of Exchequer. Again, it frequently happens, or rather we should say, it generally happens, that too little water is absorbed by the grain during the operation of steeping; the consequence of which is, that after being removed from the couch to the floor, the grain desiccates, and, ceasing to germinate, speedily evolves a sickly odour, and becomes mouldy,—the incipient radicles at the same time drying and shrinking up for want of moisture; in fact, the grain withers and perishes from the effect of drought, This condition is very frequent about the third and fourth day from the couch, and is easily and effectually put a stop to by the application of a little water. But now comes a rather awkward dilemma for the maltster: if the grain continue on the floor without being sprinkled, it is greatly damaged or altogether spoilt; if water be sprinkled upon it to restore vitality, the law says that 'corn or grain, making into malt, must not be wetted or sprinkled with water before the expiration of 12 days, or 288 hours, after the same shall have been taken from or out of the cistern, under a penalty of 200*l*.' Where, however, the steep has lasted for the full period of 50 hours, and where, consequently, the want of water is less likely to be felt, the maltster may sprinkle at the end of six days, or 144 hours; but in no case less than this,—though, as we have stated, the great urgency for the sprinkling process occurs generally on the third day; and it is an undeniable fact, that, in spite of the heavy risk incurred, maltsters do almost invariably sprinkle their floors at about this period, and are thus driven to the necessity of trusting in the good faith and discretion of some workman, to the injury of both parties. But the discriminating power confided to excise officers in these matters is incredible. 'Whenever there shall be reason to suspect, from the appearance of the grain on the floor, that it has been illegally wetted or sprinkled, the officer must give immediate notice to the maltster, or his servant, of such suspicion, and make a memorandum thereof, upon the specimen-paper, and in the memorandum-book, mentioning whether anything, and what, was stated by such maltster or any person on his behalf," &c. Nay, the views of the officer are ordered to be put on record, as to an immense number of fortuitous circumstances, all of which, of course, received an unfavourable signification: for instance, 'how the kiln was loaded, and whether fed by a brisk or slow fire?—whether the house seemed in a state for running or wetting, or committing any other and what fraud?—what the trader says, and what character he bears in his concerns with the revenue?'—and so on, in the most arbitrary spirit. Indeed, the officer is specially instructed to make sudden and unexpected returns or visits, at unusual periods, so as to discover any suspicious indications. Again, of the three separate gauges of malt which he may take, whether in the cistern, in the couch, or on the floor, the officer must select the largest for charging duty upon. Thus, if in the cistern he finds 78¼ bushels indicated, in the couch subsequently 81½ indicated, and on the floor 83½, then the latter is preferred; and so with regard to the highest wherever found,—the order being that 'when the cistern or couch gauge is equal to or exceeds the floor gauge, then the best cistern or couch gauge will be the charge; but if that be less than the floor gauge, then the floor gauge will be the charge.' Any accident or loss arising after the cistern gauge is therefore thrown wholly on the maltster, who, far from being able to employ his ingenuity in the improvement of his business processes, finds himself more than fully occupied in a perpetual effort to protect his interests from fiscal regulations conceived in a most hostile spirit. The carelessness and ignorance of common workmen may at any moment subject the most honest maltster in the kingdom, not merely to charges of dishonesty, but even to penal inflictions; which have ceased to carry moral degradation with them, only because of the popular belief of their injustice. It would be impossible, nor is it requisite, to follow out or recapitulate the innumerable annoyances to which the manufacturer of malt is subjected at present: we have thus briefly noted down a few, in order that the admirers of Bavarian and other foreign beers may take into account the very different state of the malt manufacture in this country, as compared with that brought about by an unrestricted liberty to use or apply any means which the nature of the grain, the condition of the atmosphere, or other accidental circumstances, may require during the process of germination.

Having thus seen the restrictions imposed by the legislature, we need only indicate that the capacities of the cistern, the couch, and the kiln should be adapted to contain respectively the whole quantity of barley or malt made at one steeping, and this should again have reference to the space allotted to the floor, which should allow of at least three steepings to be worked on it without interference in their different stages of growth and withering.

The process of malting consists of three successive operations: the steeping; the couching, sweating, flooring; and the kiln-drying.

It often happens from various reasons that the importance of extreme care in the selection of barley for malting is overlooked, but the injurious consequences resulting from such a laxity are so great that they cannot be too strongly impressed upon the attention of the party entrusted with this duty. All barleys that have been weathered in the field, or have got mow-burnt or musty in the stack, should be rigidly rejected; they are so easily detected that there is no room for accidental oversight. Weathered barley has a dull and often a dirty appearance, quite distinct from the bright shotty character of good samples, and frequently a sprouted corn or two may be seen amongst them, but the last is the least evil of the three, as the sprouted corns may to some extent be removed by carefully swimming the barley (at the time the cistern is charged) and floating off the lighter grains. But with mow-burnt and musty barley the grain has suffered so much that a sound wort out of malt made from mow-burnt barley cannot be obtained. This evil arises chiefly from the barley having been stacked in an insufficiently dry state; subsequently it has become overheated and its germinating principle destroyed; there is no remedy, it cannot be reclaimed, it is spoilt for malting purposes, more or less according to the circumstances immediately attending it. It may be detected by a peculiarly faint, sickly smell, perhaps the word 'stink' more nearly describes it; in addition to that, it may be at once suspected if some of the grains have a discolouration varying from red to black at the radicle end; such grains when thrown into the couch after steeping will often exhibit a brownish-red appearance from end to end; if broken they will display a red-tinted kernel and show an unmistakeable rottenness; on the floor they will impart that odour of rotten apples, so disheartening to the careful maltster, especially if he be brewer also; and after being dried on the kiln, a minute examination of them will disclose a kernel of a yellowish and sometimes a brownish tinge, which otherwise ought to be perfectly white and flowery. Beer brewed from such malt is liable to ferment with uncontrollable violence, and will soon turn sourish, bad, or stinking, according to the degree of injury the barley has suffered.

Musty barley of course can easily be detected by the smell, and a slight appearance of mould may generally be detected upon the ends and belly of the grain; if it is very slight indeed it need not condemn an otherwise good sample, but if it arises from being overheated in the hold of a vessel it should not be malted. Broken and bruised corns, and corns crushed by the feet or shovel upon the withering floor, have precisely the same effect and result as mow-burnt barley; for this reason, therefore, the thrashing-machines now in such general use have need of great improvement, as they break the corns to a fearful extent, the more so when the season has been exceptionally dry, and the finest and boldest corns suffer most.

Another unfavourable symptom is when the beard has not been entirely removed, some of the corns retaining portions of it attached; this is an indication that the mellowing in the stack has been imperfect when the grain was thrashed, the beard has therefore remained tough, and the operation has been unable therefore to detach them: it is generally attendant on weathered grain.

The Malting.—It is a good plan as a rule to have all barley shot into its binn as soon as possible, and there allowed to remain till it is wanted for malting; the mellowing is thereby somewhat encouraged, especially so if the season has been a very dry one, for the barley is likely to be intractable; it is advisable then to let it remain in heap for some weeks with that purpose.

But if on putting the hand into the sacks the feeling of sharpness and briskness is wanting, too much moisture may be suspected: it should then remain in dry sacks, or, if thought requisite, should be dried with a slow fire upon the kiln and turned frequently, after which it should be thoroughly cooled, and thrown into heap to mellow.

Whenever practicable, samples differing from each other should never be mixed before malting, but when unavoidable only such barleys should be mixed as are of the same weight per imperial bushel, the same in character and condition, and from similar districts, otherwise there will be a harassing irregularity upon the floor. And now before commencing operations, perhaps a word or two about the amount of work a man should do would not be out of place.

Previous to the operation of steeping, it will be found most profitable that the barley should be very thoroughly cleansed: all dirt, earth, stones, light grains, and small ones, should be carefully screened and swam out of it (for it is a waste to pay duty and wages for such things, and what is of more consequence, they tend to injure the quality of the malt while on the floors), and the steep commences.

It is a good arrangement to have at the overflow-end of the cistern a sieve or wire trough placed a few inches below the overflow on the outside of the cistern, so that the surplus water shall easily float away the light grains from the surface as they rise; there they will collect, and may eventually be taken away, dried on the kiln, and used for feeding purposes. The draining ability of the cistern should be as ample and expeditious as possible, and the water-supply should be equally good; some maltsters with commendable prudence provide a sort of shower-bath arrangement over their cisterns in place of the water-tap.

The steeping is performed in large cisterns made of wood or stone, which being filled with clear water up to a certain height, a quantity of barley is shot into them, and well stirred about with rakes.

The good grain is heavy and subsides; the lighter grains, which float on the surface, are the damaged ones, and should be skimmed off, for they would injure the quality of the malt and the flavour of the beer made with it. They seldom amount to more than 2 per cent.

More barley is successively emptied into the steep-cistern, till the water stands only a few inches, about five, above its surface; when this is levelled very carefully, and every light seed is removed.

The steep lasts from 40 to 84 hours, according to the circumstances of the season, condition, and weight per imperial bushel; new barley requiring a longer period than old, and big requiring much less time than barley.

In England it is the common practice, in order to escape as much as possible the excise duty, to allow the barley as a rule only 50 hours, but this is not sufficient for heavy or strong barleys: 60, 72, or even 84 hours will be found much more advantageous to the saccharific and friable qualities of the malt produced, and where the maltster is also the brewer it will well repay him the little extra excise duty he may pay on account of it, and the loss by solution in the steep-water will be found altogether inconsiderable. The Munich maltsters usually allow 96 hours, and take for their criterion that the pip shall have swollen almost to bursting, before the steeping is considered sufficient.

During this steep, carbonic acid is evolved from the grains, and combines with the water, which at the same time acquires a yellowish tinge and a strawy smell, from dissolving some of the extractive matter of the barley husks. The grain imbibes about one-half of its weight of water and increases in size by about one-fifth. By losing this extract the husk becomes about one-seventieth lighter in weight, and paler in colour.

The duration of the steep depends in some measure upon the temperature and state of humidity of the atmosphere, and the temperature and constitution of the water, and is the shorter the warmer the season.

The water most suitable for malting purposes is most certainly fresh spring-water from deep sources, at the temperature of about 52° Fahr.; this is generally obtainable in England; surface-water is not estimable, first, on account of its variable temperature, secondly, because it contains a variable amount of organic matter, and thirdly, because its solvent power is greater; whereas the salts of lime held in solution by nearly all spring-waters have a very beneficial effect upon the barley, as to some extent they neutralise the acid tendency, and must or mould.

Steeping has for its object, to expand the farina of the barley with humidity, and thus prepare the seed for germination, in the same way as the moisture of the earth prepares for the growth of the radicle and plumula in the seed. Too long continuance in the steep is injurious; because it prevents the germination at the proper time, and thereby exhausts a portion of the vegetative power: it causes also an abstraction of saccharine matter by the water. The maceration or steep is known to be complete when the skin of the barley has lost all wrinkle or curl, can be easily transfixed with a needle, and is swollen to its fullest size. The following is reckoned a good test:—If a barleycorn, when pressed between the thumb and fingers, continues entire in its husk, it is not sufficiently steeped; but if it sheds its flour on the fingers, it is ready.

When the substance exudes in the form of a milky juice, the steep has been too long continued, and the barley is spoiled for germination.

Unhealthy, damaged, and mutilated corns, frequently become pasty in the cistern, long before the sound portion of the charge has been steeped enough, and this the sooner, in proportion to the amount of injury the grain has suffered. All such grains are apt to become very damaging upon the withering floor, and to avoid this, and increase the profits as much as possible, it is a rule with some maltsters that the more indifferent a sample of barley is, the less steep must be given to it; he must force the acrospire on, by thick and warm floors, that it may be put on the kiln as quickly as possible, after it is wetted; by this means, the sample saves its appearance very considerably; but although the decomposing corns do not stink and mould quite so soon when thus worked, as they would if treated otherwise, their mischievous tendency is not at all diminished; for, by the short steep allowed, the sound corns are thrown on the floor in an intractable state, and by the thick flooring and consequent heat at which they are subsequently worked, tendencies to lactous fermentation and mould are greatly encouraged, first in the unsound corns, and then by contact through the whole floor.

In warm weather it sometimes happens that the water becomes acescent before the grain is thoroughly swelled. This accident, which is manifest to the taste and smell, must be immediately obviated by drawing off the foul water through the tap at the bottom of the cistern, and replacing it with fresh cold water. It does no harm to renew it two or three times at one steep.

The Couch.—The water being drawn off, and occasionally a fresh quantity passed through to wash away any slimy matter which may have been generated in warm weather, the barley is now laid on the couch-floor of stone flags in square heaps, from 12 to 16 inches high, and left in that position for twenty-four hours.

At this period, the bulk of the grain being at the greatest, it is usually gauged by the revenue officers, and the quantity then found multiplied by the decimal ·815 is that on which the duty is generally charged.

After a few hours, moisture leaves the surface of the barley so completely, that it imparts no dampness to the hands; but, in from fifteen to thirty hours, sooner or later, according to the circumstances at the time of the season, quality of barley, and efficiency or otherwise of the steep, it becomes warm, the temperature rises from 7° to 10° above that of the atmosphere, while an agreeable, fruity smell is evolved; if the hand is thrust into the grain as it lies in the couch, it not only feels warm, but it is bedewed with moisture. At this sweating stage, the fibrils of the radicles make an appearance at the base of every grain, in the form of a white elevation.

After remaining in the couch twenty-four hours, the time insisted upon by excise regulation, the couch is broken, that is, the planks composing the front of it are removed, and with a maltster's wood shovel, the grain is spread out to the depth of from 6 to 10 inches (according as required by the before-mentioned circumstances; and be it remembered, that these must be carefully considered at every stage of the working, from first to last). Some few hours after the radicles have begun to divide, the plumula may be discerned at the same point, proceeding beneath the husk, to the other end of the seed, in the form of a yellow leaflet.

The Flooring.—With this last operation, 'the flooring,' may be said to have commenced, and the experience and judgment of the maltster are now called into requisition, and will be taxed to their utmost to ensure a simultaneous start and equal degree of germination in every individual grain alike; he must not forget it for a moment, but carefully watch its progress, and as soon as the grains immediately below the surface appear glossy wet from sweating, the floor must be turned with the shovel, and thinned out from 2 to 4 inches in thickness, as he sees it desirable. The manner of handling the shovel is a matter of great importance, and it is only from careful practice that the required proficiency is attained; the upper stratum of the floor is skimmed off and rolled over, just in the immediate neighbourhood of the workman, step by step, shovelful by shovelful; the under portion is then well cleaned up, flung and spread with an inward turn of the wrists, as the arms are thrown across the front; by this motion, the grains are disposed into a thin, wide-spreading shower, driven through the air and falling evenly on the floor, at a considerable distance from where they were taken up by the shovel, and by the operation are separated and cooled; should any faint smell have been attained, it will afterwards be found to have passed off in a very great measure.

Thus the workman advances, proceeding across and recrossing the floor, taking alternately, first the upper stratum, and then the lower one at every step, throwing it out the further, the more cooling or 'check' he purposes to give to it, and also regulating its area accordingly. Sometimes it requires turning over, and lightening up, without being subjected to the cooling consequent upon the use of the shovel; and for this purpose the workman uses what is called the 'rake.' This is an iron blade, about 30 inches long and perhaps 2 inches broad, fixed at each end by holders, to a massive wood head, to which is attached a strong wood shaft, with a cross-head handle. This blade is dragged along the floor, passing under the barley, turning the bottom to the top and lightening it up considerably; but when turning only is required, he uses what is called the 'plough;' this is a long-handled tool, in shape very much resembling the scull of a boat, and in using it is made to pass through the grain, precisely as a scull is made to do in the water. The young floors will generally require some sort of tendance every three or four hours; this must be judged now by the appearance of the radicle as a principal indicator; when it is particularly white and vigorous, the floor requires a 'turn,' that is, the shovel preceded by the rake; if it requires nursing, and it is thought that a turn would check it too much, the rake alone is used; but if it requires a gentle turn over and careful nursing, then the plough alone is used; and thus these are employed, either alone, in turn or combined, in any way the workman may deem it desirable; but always before leaving his house, for the night, he must thoroughly disentangle the corns, the one from the other, give the floors a good turning and spreading, thin them out, and lay them light. In the old floors it will most likely be necessary to use all three tools about them; first the plough, and then the rake, till they are well disentangled and light, then with the shovel, thin out, turn, spread, and cool them.

With the young floors, perhaps, only the plough and the rake may be required, as it sometimes happens that nursing is necessary, owing to the coldness of the weather.

It will sometimes occur, most commonly from an insufficient steep, that the radicles will show signs of withering prematurely; and if the circumstance was to remain unheeded, the floor would die long before the germination had wrought the desired change in the constitution of the barley; the withering radicles would drop off even with the most careful handling, and then the grain would have to depend on those that remained to it for the support it needed to complete the change. To render the necessary help, at this time, recourse is had to 'sprinkling,' that is, water is administered to it from a 4-gallon watering-can, with a rose, in the proportion as a rule of about one can to the quarter (8 bushels); under some circumstances a floor will take nearly double that quantity, as in the case of the heavy Scotch barleys, with only 50 hours' steep, but with light free barleys, perhaps only half the quantity, the less the better in all cases, where quality is of more consequence than appearance; for the object being to supply a stimulant to the 'fainting' and perhaps wounded grain, the acrospire is forced up as it were, under the husk of the hide-bound grain; no good, or at any rate very little good, is done by the process, to really benefit the constitution of the grain; the application is too superficial, and where the quality of the saccharine constituent is the consideration, it cannot stand in competition with the properly administered steep. But for the sake of overmeasure or overweight, and it must be admitted a saving in appearance, it is adopted by the malting-trade generally, as a matter of routine. It is administered as follows:—

On the fourth or fifth day after the grain is thrown from the cistern, the radicles will have attained the length of nearly a quarter of an inch; the floor has then given to it about half a can-full of water to the 8 bushels; it is then well ploughed, raked and turned, so as to wet every grain possible, and then worked in the usual course. Next day, the remainder of the dose is given, or if much water is thought necessary, it is given two doses the second day, one in the morning and the other in the afternoon, and perhaps another dose next morning; the operation, of course, necessitates plenty of room, so it is usual to arrange for the main sprinkling on the day that the old floors are loaded on the kilns. If floors are closely observed about this time, it will be seen, that mould mostly appears immediately after the sprinkling; then it is that the mischievous effects of rotting, mutilated, and broken corns are most apparent, and with each hour the disease spreads from corn to corn, till sometimes, before the floor can be got ready for the kiln, the whole of the floor is literally impregnated with it, a kind of blue bloom is to be perceived upon it, and it may even affect the atmosphere above it, plainly showing that mould in the form of dust is present, ready to fall on everything; some of it may be made to disappear, after drying and screening the malt; but the taste is permanently attached to the malt, and follows it through the remainder of its existence, even after it has changed its state; not that mould can be always detected in the beer made from such malt, for unless it is very bad indeed, it can be overpowered by the hop; but there is a perceptible deficiency in that fine, clean flavour, which is the perfection of a glass of good beer, its place being usurped by a flavour coarse and tangey, and tending to acidity, the more so in proportion as the disease has ravaged the malt; for let it not be forgotten, that mould and acidity always go hand-in-hand. Therefore, where it is found necessary to malt an indifferent sample of barley, it is much the wiser plan to treat it with a sufficient steep, and work it as cool as possible upon the floors, giving it plenty of time; for heats approaching 60°, and especially between 60° and 70° encourage disease in barley on the floors, just as it does also upon an unsound wort in the fermenting tin; such malts should always be set apart to be brewed by themselves for a quick consumption.

If the heat on the floor should by any chance rise to temperatures between 70° and 75°, it is almost a certainty that much of the saccharine constituent will have changed into the lactic state. It is sometimes asserted that sprinkled malt will yield more gravity per quarter than unsprinkled malt will do: the extra gravity is caused by an excess of the albuminous constituent present in the wort, and this is but an increase of trouble, disappointment, and loss to the brewer; but the difference between sprinkled and unsprinkled barley is perceived at once by the taste, being in favour of the latter, from the superior sweetness in the mouth, and it far exceeds the former in the brightening and keeping ability of its product, and in the general excellence of the beer. The attentive reader will perhaps ere this have surmised from the mention of the old floor, the young floor, and the floor to be sprinkled, that there must generally be three steeps upon the floor at the same time, and under very exceptional circumstances there may even be four floors, exclusive of those on the kiln, and in either the cistern or the couch. This of course necessitates plenty of area in the withering floor; there should be allowed 28 square yards at least to the quarter of barley steeped. Therefore for one man-kiln, 15 quarters being steeped every four days nearly, the withering-floor area should be 15×28 yards $= 420$ yards, including the couch-frame; about 30 feet in width is a nice arrangement for a kiln of this size, and is even a convenient width for any sized kiln, for where the floors are much wider, the sides and middle work vary unevenly, and cause an amount of labour that is likely to be the cause somewhat of neglect; forty feet should be the extreme limit for a kiln of the largest size; of course the wider the floor is the less throwing forward it requires, and this is a consideration; the height of the place should be about six feet under the beams, which should be underdrawn; the windows should be glazed with blue glass, and the ventilation and temperature of the place should be under complete control. At times the grain on the floors will suffer mutilation and crushing by the feet; the excise officer must trample upon it, for the purpose of gauging, but it is quite unnecessary that any one else should. Some, to relieve the floor from injury by the tread, have moveable gangways suspended from the beams above, or supported from the walls, so that the workmen can pass from floor to floor the whole length of the house without treading on the grain.

The system of working upon the floors is of such extreme importance to brewers, that it is necessary that we should give very special attention to the consideration of the several points of guidance, which experience has established as incontrovertible.

The first and most essential of these, is the selection and cleansing of the barley, and this has already been treated in detail in an early part of the present article; the next is the class and temperature of the water, and this has also been treated upon, and we must now consider the rule that must be adopted to produce a malt that shall have the least amount of the albuminous constituent in its composition along with the greatest amount of good sound saccharum as free as possible from acid tendency, and perfectly free from mould.

In the first place, in order to make good sound malt from carefully-selected barley, the efficient steep is of paramount importance; then the cooler it is worked upon the floors, and the longer it can be made to take in growing the acrospire right up to the opposite end of the grain, the better will be the saccharific excellence of the malt. The heat of the floors should never be allowed to attain 60° Fahr., and it should be kept on the floors from twelve to fifteen days, including couching.

There is no danger of mould if the turning is properly attended to, and no more sprinkling allowed than is absolutely necessary to keep the germination alive; in season-made malt, sprinkling is but very seldom required, but an exceptional warmth or dryness of the atmosphere may make it at times a necessity.

If the rootlets or radicles appear languid, shrivelled, and of a dull yellowish tint, lay the floor a little thicker; it may be that the barley is more intractable than was supposed at first; and if in the course of two or three hours its appearance is not materially improved, then administer the sprinkling, about a good third of a can-full to the quarter (i.e. 8 bushels), well plough, rake, turn, and thin out; but let it carefully be borne in mind that whatever is done in the way of increasing or decreasing the vigour of the germination must be done most gradually, or the radicles will be liable to break off, therefore leaving the grain maimed, and less able to attain the desired result, and as a consequence the quality of the malt will be impaired. On the other hand, if the rootlets appear robust and vigorous, the floor must be well turned and thinned out, or the middle of the floor will become the warmer, and an uneven germination will result; when a floor has been allowed to remain too long unturned, it may easily be perceived from the faint smell that attends it, and also it may be observed that the main or centre radicle is of unusual length and strength in comparison with its mates; great care must then be exercised, for to be checked too rapidly would certainly cause them to break off, and prove an injury; this must particularly be attended to in the young floors. If all has gone on as it should have done, when the grain has spent the moisture absorbed in the steep, the acrospire will have attained about three-fourths the length of the grain, and the culm (rootlets) somewhere about half an inch in ordinary English barley, but more than that in the strong Yorkshire barleys, and more still in the heavy Scotch; this excitation will occupy from perhaps nine to twelve days, according to the circumstances, of the kind of barley, and state of the atmosphere, and the culm will then begin to grow languid, fade, and wither, and of course will cease to develope any more; the acrospire too will remain almost stationary, though not quite so, for germination is not extinct, but only retarded. The floor must now be laid thicker, very gradually, frequently disentangled and turned, but kept just warm enough to cause most of the remaining moisture to pass away from the grain till when taken up in the hand it feels light and dry, and when the kernel is forced out from the husk with the thumb-nail, it should rub abroad between the thumb and forefinger easily and smooth; this process is called the 'mellowing,' and occupies from two and a half to four days; it is then ready for the kiln.

The Kiln-Floor.—The mellowed floor is then loaded into baskets, craned up to the kiln-floor, upset in regular heaps over it, and when all the charge is in, it should immediately be griped over and levelled. In area the kiln-floor should allow at least three square yards to every quarter of barley steeped, thus for a 15-quarter cistern, the area for the kiln-floor should be at least 45 square yards, this will allow the barley to lie from 7 to 9 inches thick upon the kiln, and that thickness is a medium between extremes. In England coke is most commonly used for the kiln-fires, and there should be from 15 to 25 feet below the centre of the kiln-floor; the greater the height the better the draught.

Immediately above the fire-place, and supported at the four corners, a disperser is placed from 6 to 9 feet above the fire-bars, according to the strength of the draught and character of malt it is intended should be made usually; it is well to have all the draught-course, both above and below the malt, under perfect control, so as to at all times cause the stream of heated air passing from the fire to disperse itself to the extreme limits of the kiln-floor; but with all the aid that art and experience can give, nothing can relieve the workman from that careful watching and regulating of the fires, that is the real secret of success in the finishing of malt. The 'old floor' being now 'loaded' on the kiln and griped over, the fire is placed and regulated so that the heat shall accumulate in the space under the floor-tiles, and fill it to the remotest corner with a temperature of about 90°, which must be the same throughout the whole area of the floor, no one place being hotter than another, or the finishing will be freckled and uneven: the advantage of having a good height over the spreader will be now seen, by reason of its allowing a better opportunity for the thorough mixture and attemperating of the atmosphere and also decreasing the liability to a hot-air current through any particular portion of the floor.

In a short time the heat may be increased three or four degrees, but the floor should not be molested till all apparent moisture or steam has been driven from it; this will take about 12 hours, when it may be griped over, again turning the top to the bottom; fires damped up and left for the night; next morning the floor must be griped again, and turned with the shovel, the fires may be broken up, and the heat increased 3 or 4 degrees more, and the floor must be turned 3 or 4 times with the shovel, and by the following morning it will most likely be dry; the finish must then be given, that is, the particular colour and flavour required must now be attained.

For pale malt, the heat should not exceed 120°.

For the amber colours, heats ranging from 120° to 160°, according to the colour desired.

For brown malt for porter-brewing, oak sticks are blazed on the fire, and the heat raised to 180° or above; the floor must not be laid more than an inch thick, and be kept constantly on the move by turning; it is therefore a very hot and laborious process. In finishing for the pale and amber malts, it is better to subject the floors to a low and long-continued heat, rather than a high and sharp one, for the culm colours much sooner than the body of the grain, owing to its slightness in substance, and the workman is often deceived by this circumstance; for pale malts, say 100° or a little above; for amber, about 125° or so.

When the malt has attained the colour required, it is immediately heaped in the middle of the kiln-floor, and the fires allowed to die down; in about two or three hours after, the kiln is 'teemed,' that is, the malt is taken off and stored in its bin: it is decidedly the best plan to let this be done while the malt is in a good hot state, for it will keep right all the longer, and the culm should go with it to aid in keeping out the atmosphere; but although malt should be kept in the store-bin as dry as possible, it is not thought a good plan to use it for brewing purposes until it has got quite cold in the heap, or it will prove somewhat intractable in the mash-tun, and the beer from it will not work kindly in the fermenting-tun, and prove somewhat difficult to fire.

During the kiln-drying, the roots and acrospire of the barley become brittle, and fall off; and are separated by a wire-sieve whose meshes are too small to allow the malt itself to pass through.

A quantity of good barley which weighs 100 pounds, being judiciously malted, will weigh, after drying and sifting, 80 pounds. Since the raw grain, dried by itself at the same temperature as the malt, would lose 12 per cent. of its weight in water, the malt process dissipates out of these remaining 88 pounds, only 8 pounds, or 8 per cent. of the raw barley. This loss consists of—

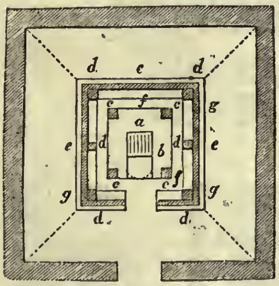
$1\frac{1}{2}$	per cent.	dissolved out in the steep water,
3	,,	dissipated in the kiln,
3	,,	by the removal of the fibrils,
$0\frac{1}{2}$	,,	of waste.

The bulk of good malt exceeds that of the barley from which it was made by about 8 or 9 per cent.

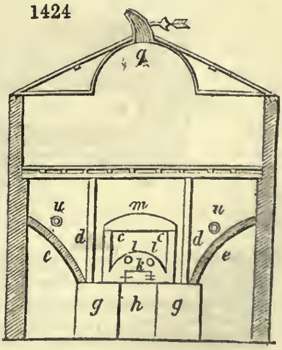
MALT KILN. (*Darre*, Ger.) The requisite conditions of a good malt kiln are, that the temperature should be under perfect control; the malt not exposed too near the direct action of the fire; and the vapour from the heated grain rapidly carried off.

Figs. 1423, 1424, 1425, 1426 exhibit the construction of a well-contrived *malt kiln*. *Fig.* 1423 is the ground plan; *fig.* 1424 is the vertical section; and *figs.* 1425 and 1426, a horizontal and vertical section in the line of the malt-plates. The same letters

1423

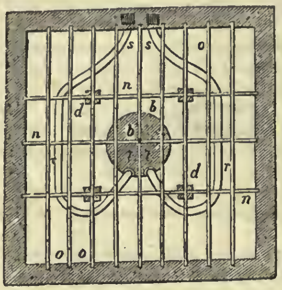


1424

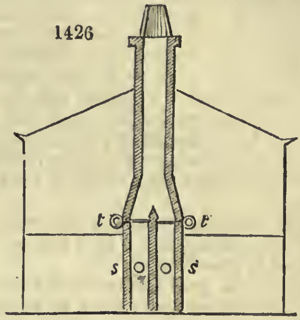


denote the same parts in each of the figures. A cast-iron cupola-shaped oven is supported in the middle upon a wall of brickwork four feet high; and beneath it are the grate and its ash-pit. The smoke passes off through two equidistant pipes into the chimney. The oven is surrounded with four pillars, on whose top a stone lintel is laid: *a* is the grate, 9 inches below the sole of the oven *b*; *c c c c* are the four nine-inch strong pillars of brickwork which bear the lintel *m*; *d d d d* are strong nine-inch pillars, which support the girder and joists upon which perforated plates repose; *e* denotes a vaulted arch on each of the four sides of the oven; *f* is the space between the kiln and the side arch, into which a workman may enter to inspect and clean the kiln; *g g*, the walls on either side of the kiln, upon which the arches rest; *h*, the space for the ashes to fall; *k*, the fire-door of the kiln; *l l*, junction-pieces to connect the pipes *r r* with the kiln; the mode of attaching them is shown in *fig.* 1425. These smoke-pipes lie about three feet under the iron plates, and at the same distance from the side walls; they are supported upon iron props, which are made fast to the arches. In *fig.* 1424, *u* shows their section; at *s s*, *fig.* 1425, they enter the chimney, which is provided with two register or damper plates, to regulate the draught through the

1425



1426

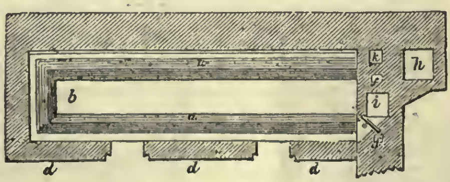


pipes. These registers are represented by *t t*, *fig.* 1426, which shows a perpendicular section of the chimney. *m*, *fig.* 1424, is the lintel, which causes the heated air to spread laterally, instead of ascending in one mass in the middle, and prevents any combustible particles from falling upon the iron cupola. *n n* are the main girders of iron for the iron beams *o o*, upon which the perforated plates *p* lie; *q*, *fig.* 1424, is the vapour-pipe in the middle of the roof, which allows the steam of the drying malt to escape. The kiln may be heated either with coal or wood.

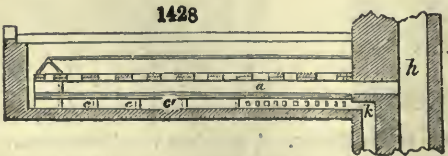
The size of this kiln is about 20 feet square; but it may be made proportionally either smaller or greater. The perforated floor should be large enough to receive the contents of one steep or couch.

The perforated plate might be conveniently heated by steam-pipes, laid zigzag, or in parallel lines under it; or a wire-gauze web might be stretched upon such pipes. The wooden joists of a common floor would answer perfectly to support this steam-range, and the heat of the pipes would cause an abundant circulation of air. For drying the pale malt of the ale-brewer, this plan is particularly well adapted.

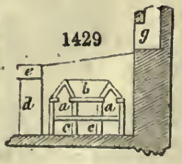
1427



1428



1429



The improved malt kiln of Pistorin is represented, *fig.* 1427, in a top view; *fig.* 1428, in a longitudinal view and section; and *fig.* 1429, in transverse section. *a*, *a*, are two quadrangular smoke-flues, constructed of fire-tiles, or fire-stones, and covered with iron plates, over which a pent-house roof is laid; the whole bound by the cross pieces *b* (*figs.* 1428, 1429). These flues are built above a grating *c c*, which commences at *c'*; in front of *c'* there is a bridge of bricks. Instead of such a brick flue covered with plates, iron pipes may be used, covered with semi-cylindrical tiles, to prevent the malt that may happen to fall from being burned. *d d*, are the breast walls of the kiln, 3 feet high, furnished with two apertures shut with iron doors, through which the malt that drops down may be removed from time to time. *e* is a beam of wood lying on the breast wall, against which the hurdles are laid down slantingly towards the back wall of the kiln; *f f* are two vertical flues left in the substance of the walls, through which the hot air, discharged by open pipes laid in a subjacent furnace, rises into the space between the pent-house roof and the iron plates, and is thence allowed to issue through apertures in the sides. *g* is the discharge-flue in the back wall of the kiln for the air now saturated with moisture; *h* is a smoke-pipe, from which the smoke passes into the anterior flue *a*, provided with a side-plate for modifying the draught; the smoke thence flows off through a flue, fitted also with a damper-plate, into the chimney *i*. *k* is a smoke-pipe of a subsidiary fire, in case no smoke should pass through *h*. The iron pipes are 11 inches in diameter; the air-flues *f*, 5 inches, and the smoke-pipe *h*, 10 inches square; the brick flues 10 inches wide, and the usual height of bricks.

The following is an account of the total number of bushels of malt made in the United Kingdom from 1861 to 1870, distinguishing such as were charged with duty from such as were free of duty, exported on drawback or free of duty, and the quantities returned for home consumption:—

The Quantities of Malt charged with duties of Excise in the United Kingdom, quantities exported on drawback, and returned for home consumption.

Years	Charged with duty	Free of duty [1]	Exported on drawback or free of duty [2]	Retained for home consumption
	Bushels	Bushels	Bushels	Bushels
1861 . . .	44,141,422	3,793,192	1,284,514	46,650,100
1862 . . .	41,118,172	4,069,883	1,499,447	43,688,608
1863 . . .	46,269,842	4,679,829	1,876,856	49,072,815
1864 . . .	48,544,125	4,837,742	1,584,889	51,796,998
1865 . . .	45,190,374	522,828	1,641,685	43,548,689
1866 . . .	45,982,397	551,423	1,687,344	44,295,053

1870 [3] . . .	47,005,803	402,455	1,462,226	45,603,577

MALVACEÆ. The petals of the plant known as *Althæa rosea*, belonging to the natural order *Malvaceæ*, contain a peculiar colouring-matter, soluble in water and alcohol, but insoluble in ether. 'The aqueous solutions of the petals, freed previously from the calyx and stamens, exhibit a violet-red colour, which is turned crimson by the addition of acids and green by alkalis. The alcoholic tincture of the leaves is purplish-red, and leaves on evaporation a deep red residue, free from nitrogenous matter. Cotton mordanted with iron is turned blue or bluish-black by an aqueous infusion of the petals. With an aluminous mordant a violet-blue, and with tin mordants a bluish-violet is produced. Woollen fabrics, previously mordanted with bichloride of tin, assume a deep violet, and when mordanted with iron a bluish-black or grey; if mordanted with antimonic-acid salts, a bluish-violet is obtained; silk mordanted with tin salts takes a violet.

'For calico-printing purposes the alcoholic extract suits better than the aqueous infusion. The colours produced are faster than those yielded by logwood, but they do not stand clearing with soap.

'The colouring matter is yet, and was formerly far more so, in great request for the artificial colouration of wines. Latterly it has come into use as a dye-ware, and is chiefly so applied in Germany and more particularly in Bavaria.'

MAMMEE. A tree growing in Honduras. Its dried leaves are very powerfully

[1] Including the estimated quantity used in beer exported.
[2] On the 14th of August 1855, malt was made free of duty for distillery purposes and for exportation, and spirits were allowed to be distilled free of duty for exportation.
[3] The Board of Trade has not published any later return.

narcotic; the bark is, however, stated to possess some tonic properties. The flowers of the tree are used in flavouring a *liqueur* made in some parts of the West Indies, called *crême des créoles.—Temple.*

MANCHESTER YELLOW. A name by which naphthaline yellow is known in commerce.

MANCHINEEL. A large tree of a very poisonous character, growing in South America, and in some parts of the West Indies. The wood is of a yellow-brown colour, beautifully clouded, and very close and hard. It is sometimes used instead of mahogany. This tree is the *Hippomane mancinella*, one of the *Euphorbiaceæ*

MANDIOCA. Cassava starch. See STARCH.

MAN-ENGINE. (*Machine d'Ascension*, Fr.; *Fahrkunst*, Ger.) The name given to a machine by which the men working in deep metalliferous mines are enabled to descend or ascend without much fatigue. The labour of climbing from the bottom of the deep mines of the Hartz and of Cornwall has long been known to produce an injurious effect upon the men. It has therefore long been deemed of the utmost importance to devise some means by which relief might be afforded.

It was not till 1833 that the circumstance of two water-wheels having been thrown out of work by the opening of the deep George adit in the Hartz mines suggested the idea of employing the pump-rods for aiding the ascent of the miners, and in such manner that every man should, as on the simple ladder plan, depend on himself alone for his safety; the ascent to be effected by means of the water-wheels' power. There was sufficient room in the shaft, which was perpendicular, and an experiment of 100 fathoms was set in operation. The rods were entirely of wood, of a very simple and solid construction. The spars were cut 4×6, and joggled into each other one inch, and bolted together, so that the whole was 7×6; at the joints iron plates 20 inches long were put on and screwed together, so as to render the whole equally strong; tearing asunder, as long as the timber remains sound, being nearly impossible. The whole length was then divided into 22 stages, and from the top downwards, on alternate sides for each stage, the steps were fastened, at distances of 4 feet, by iron rests. In like manner, hand-holds were fastened at convenient distances. Between the two rods ordinary ladders were placed against one side of the shaft, for the sake of safety should anyone become confused, or should the machinery from any accident stand still. On a given signal, the machine was set in motion by the man at the engine, who regulates the supply of water according to the number of men on at a time. This number was not allowed to exceed 20 men for this machine (except in cases of necessity) although of sufficient strength to support a much greater number.

The perpendicular rods were supported at every stage by rollers, which were always placed where there is no step. They were of fir, 10 inches long, 12 inches in diameter, and a cast-iron flange of 1½ inch fastened to them at each end, to prevent the rods slipping off; at five different points it was so arranged that the rods could not fall farther than to the next stage, or at the utmost 48 inches, that being the length of stroke. The ascent on the machine requires no description; the miners, after the second trial, felt familiar with it, nor was there any more danger than if they were on the ordinary ladder. This machine, or *power-ladder*, was calculated to ease the toil of ascent; but it has also been used in descending, when of course it requires little or no water to set it in motion; and in cases of want of water, the descending miners might bring up the men who had finished their shift, the water-wheel only regulating the motion and overcoming friction and other prejudicial resistances. This first machine surpassed expectation; short as the length of ascent was, many invalids of the district found new sources of employment, and the descent by this was used by many, especially during winter, who could reach far-removed mines by underground communication. Gradually the most prejudiced were attracted to the machine, and it is received as a blessing. Thoroughly convinced of the excellence of the contrivance, 200 fathoms of the 340 fathoms of Duke George William shaft, from grass downwards, were in 1838 provided with a power-ladder similar in construction to the above described, with this difference only, that this being on the vein which falls at an angle of 70°, only certain distances of 5, 8, 12 fathoms are taken on the machine, and intermediate of 5 to 10 fathoms on the usual ladders, which divides the strain on the machine, provides against catching colds, and in some degree against the danger of falling. Thus one of the deepest shafts was rendered easy of ascent, more than half the depth being furnished with power for raising the miners.

In 1836 another machine was completed in the Schreibfeder Schacht. Here the machine-rods must also serve as *pump-rods* in time of flood, and therefore the notion of making the rods of iron wire, thrown out by Albert, could not be brought to bear, but a combination of timber and iron wire was adopted. The rods were of the best spars joggled, as in the former cases; but in the two grooves run in these there were let in two iron-wire ropes of 12 wires each. The two spars were screwed tight upon the ropes, which were steeped in prepared tar. Thus the ropes formed a core to the wooden rods, which in themselves were sufficiently strong for the strain, but the ropes were a protection, should the wood decay, against any misfortune, while the wood gave sufficient stiffness to the rope-rod. These rods were not above half the weight of the former per fathom.

It was very fairly objected to this construction, that it was uncertain what strain came on the wood, what on the iron, and that damage on the iron wire could not be observed. 124 fathoms of the 265 were provided with a power-ladder of this construction. The ascent on it is not continuous, but alternating, as in the Duke George William shaft, so that of 143⅝ fathoms, 124½ are by the machine, 19⅛ on the fixed ladders.

These being accomplished, several experiments were begun in 1836 to endeavour to arrive at a construction of rod, at once lighter and mechanically more perfect. First, a wire-rope ladder, as it were, laid along planks as a continuous bearing, and having here and there rollers, so attached as to keep the rope down on the planks, was tried. Steps and hand-holds were made fast to the rope, so that no injury resulted to the rope. The necessary stiffness was wanting, the small rollers were insufficient, and the planks were very rapidly worn. Second, a wire rod, as it were, of four ropes in a square, nine wires in a rope, with inch boards on one side running on fixed rollers. The four ropes made a parallelogram of 6 and 7 inches, between which hand-holds and steps were fastened. The boards were protected by iron friction-pieces, where they ran on the rollers; ten fathoms weighed 42·9 lbs., and cost about one hundred thalers. The only objection to this was, that the four ropes could not be depended upon as being equally strained. Third, Albert's proposal to have two ropes of the wire parallel to each other, 2-inch and 10-inch deals to be attached to the back of these, without any other connection: to let these run as usual on rollers, and fastening the steps and hand-holds to the ropes. It was tried in Duke George William's shaft, and found the most noiseless and easiest in go, and on the whole, most perfectly fulfilling the required conditions. This construction, with some modifications by M. Jordan, was finally determined upon, and has since been carried out in the Samson shaft, in Andreasberg, 345 fathoms deep, and now to be particularly described.

In this case there was the advantage and disadvantage of having to provide everything for the express purpose of the ascending machine. A new wheel-room had to be executed, new watercourses to be driven, new wheels to be built;—an advantage, so far as the whole was perfectly adapted to the end in view; a disadvantage, inasmuch as the expense was very greatly increased. The fact, however, proves the importance attached to the means of facilitating the miner's operations. Any further mention of the arrangements for the necessary power, than that the mover is water and the machine an ordinary water-wheel, over-shot, 42 feet in diameter, 4 feet on the breast, making from two to two and a half revolutions per minute, is unnecessary. The letting-on of the water is regulated from the top of the shaft, where there is a miniature machine moved by rods and gear, connected with the power-ladder, indicating exactly the relative position of everything below ground. A system of signals, too, has been adopted, by which most of the circumstances occurring in connection with the working of the ladder can be immediately made known above ground. The *Spannschütze*, a sluice or pen-trough of admirable construction, is applied to this wheel, as its load is very variable. The crank is 3 × 6 feet long, of cast iron, and is attached by a connecting rod with framed rods that work the crosses at the shaft head in the usual manner.

The method of hanging the ladders deserves attention, as it is perfectly successful and very simple. In the history of the machines there have been several arrangements tried, but this is the last and considered the best. The power-ladders are hung on the cross-head of a knife-edge by two iron slings, 6 × 2 inches. They were in this ladder first hung by passing the ropes round a segmental frame, but the friction of the knife-edge induced a continual bending of the rope; through a very small angle, it is true, but such, that under its effects the wires gave way at the end of three months. This led to an arrangement by which the ropes are bound between timbers bolted and screwed together, and thus the whole hung to the things above-mentioned.

Perhaps the most efficient construction would be the passing the ropes round an arched head, as was the connection between the beam of the steam-engine and piston-rod of old, only passing the ropes over a greater segment than was or is customary.

The ropes at the top consist of 36 wires, viz., three ropes of 12 wires in each rope, and these together cable laid. In the timbers, grooves are cut of such dimensions that the screw bolts may have the effect of so pressing the timbers together, that the ropes are held in place by the friction thus induced. The length of these timbers is 4½ fathoms; this great length is a consequence of local circumstances.

The rope diminishes gradually, viz., four wires less for each 50 fathoms descent. The estimate of the strength required was made thus :—

	lbs.
1. The weight of the rope	5,600
2. Weight of steps and handles, &c.	2,200
3. Weight of 50 men	7,500
4. 185 fathoms of deal and 90 fathoms slide-bar . .	6,795
	22,095

And assuming that the double rope of 36 wires would bear, at the utmost, $2 \times 36 \times 1{,}100$ lbs. $= 79{,}200$ lbs., the load of 22,095 lbs. would be 28 per cent. of the ultimate strength.

For safety in case of the accident of the power-ladder breaking, several good arrangements have been adopted, so that any serious accident is not likely to occur, should even a side of the power-ladder give way. At several parts of the length, the two sides of the ladder are connected together by a very strong chain; this chain passes over a fixed pulley; and it is evident that, if on either side the ladder were to break above this, its fall, if not entirely checked, would be very much broken by the counterbalancing weight of the other side, acting by means of the chain.

Again, at various stages there are wedge-shaped blocks attached to the planks, in which are fixed the friction pieces, and these wedges would fall into wedge-shaped bearings, that are secured by timbering in the shaft, and so, having broken at any point above these, the fall is limited to 7 feet at the utmost.

In conclusion, it may be mentioned that in order to ascertain the exact state of the wires, several pieces of the rope have been kept exposed in different parts of the shaft; these are from time to time examined, but since 1837, when the power-ladder of iron wire was erected in Andreasberg, the progress has been so very slow, that little is to be apprehended from the effects of rust, so long as care is taken to keep the ropes properly tarred.

The total cost of one side was 607 Prussian thalers, and therefore the total cost of power-ladder was 1,214 thalers = 182*l*. 10*s*.

The mines in Cornwall being as deep as those in the Hartz, it became a question of moment to adopt some machine for the relief of the miner in that county. Medical men had long expressed their conviction that much of the lung disease prevalent amongst the men working in the deep mines of the Gwennap district was due to the violent exertion of climbing on perpendicular ladders from a depth varying from 200 to upwards of 300 fathoms. At length the subject was taken up by the Royal Cornwall Polytechnic Society, and a man-engine was introduced, which in most respects resembled the German power-ladders.

The following is a short account of the principal phases of its introduction, due entirely to the ready and generous initiative taken by the Polytechnic Society :—

At the first general meeting of the society in 1834 Mr. Charles Fox offered three prizes for the perfection of the means then in use for the descent and the ascension of miners. The first project was that of Michael Loam the engineer, the same who afterwards constructed the machine at Tresavean. The competition remained open for many years; several plans were produced, and the prizes awarded. In 1838 Mr. Fox offered 100*l*. to the first mine that would make a trial in the desired way; this example was followed by other individuals, and the sum of 530*l*. was put into the hands of a committee, who were charged with sending circulars to the mines. The adventurers of Tresavean accepted the proposed conditions, and in January 1842, two rods moving alternately, conducted by an hydraulic wheel, were working to a depth of 26 fathoms. The steps were 12 feet distant from each other, and each rod moved 6 feet; so that the men changed their position at each step. By the advice of Mr. Loam, it was decided to substitute a steam-engine for the hydraulic wheel, so that the motive power could not fail, and at the same time it was judged advisable to increase the stroke of the rods 12 feet; the number of the steps and the distance between them remaining the same, so that the men had only to change at every other one, and the same number of miners could ascend and descend at once.

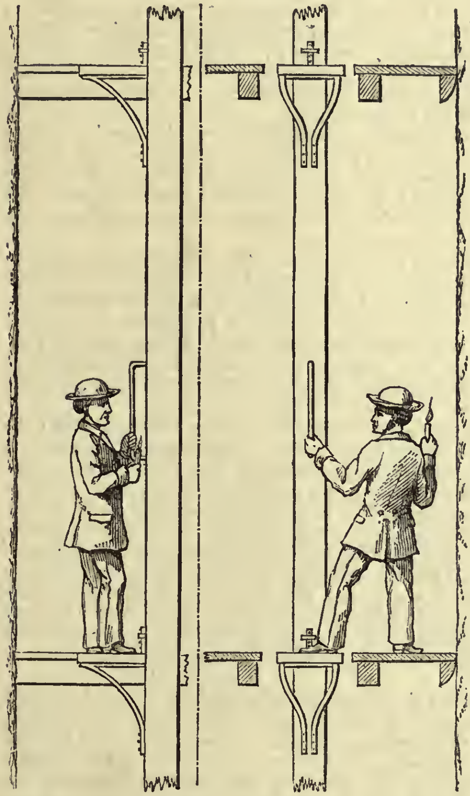
On October 25, 1842, the machine, thus modified, had attained to the depth of 140 fathoms, and on June 20, 1843, it was finished; its length being 290 fathoms, and the mine being at this time 311 fathoms deep below the adit.

The second man-engine was constructed by Hocking and Loam, in 1845, at the Great United Mines in Gwennap. The temperature was 120° Fahr. at the bottom of the mine, and it was an urgent necessity to diminish the fatigue of the miners as much as possible. They contented themselves with copying the plan which had succeeded so well at Trevesean, only making some slight differences in detail.

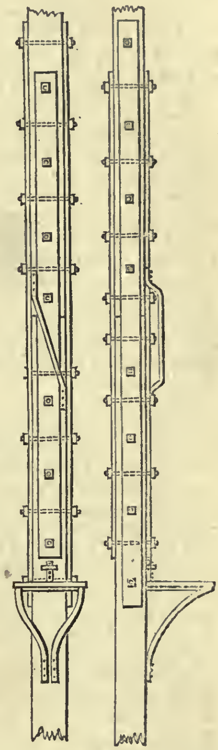
In 1851 the late Captain Puckey and Mr. West, an engineer, adopted a new system for the Fowey Consols mine.

A single rod, furnished with steps, worked in the shaft; a series of platforms are fixed at different parts of the shaft; these have, like the steps, spaces of 12 feet

1430



1431



between them, and they are placed on a level corresponding with the steps at the extremity of the stroke of the rod. The miner, quitting one step, waits on the platform until the next reaches him. This man-engine can also be used at the same time by miners ascending and by miners descending. The stoppage at the platform is of sufficient length for one man to pass on to the step which another has just abandoned.

The machine with a single rod has been since applied by Mr. Hocking to Levant mine, and in 1854 to that of Dolcoath. It may thus be considered as being now the most used in Cornwall, and it possesses an incontestable superiority over machines with two rods.

The man-engines in the Cornish mines are so much alike in their construction, that it is quite unnecessary to describe each of them. Their general characters will be understood by examining the accompanying woodcuts, *figs.* 1430 and 1431.

At Fowey Consols the machine is worked by a water-wheel of about 50 horse-power, but all the other man-engines are worked by the ordinary Cornish steam-engine, that is, with a cylinder vertical and balanced; and always double-acting. The outer end of the beam of the machine is attached by a sweep-rod to two small wheels which are situated on the shaft; these drive two larger wheels, so that the engine makes several strokes to one revolution of the wheels. In some of the mines the engine, besides giving motion to the man-engine, is used for crushing the ores and performing other work, while in others it is merely employed for raising and lowering the miners. The rods are generally about 7 or 8 inches square, slightly decreasing in size as they descend. When there are two rods the steps are so placed that there is a distance of about 6 inches between them when the man passes from one to the other. The weight of the rod is counterbalanced sometimes by levers and sometimes by balance-bobs attached to it in different levels. The greatest object gained in the use of levers is a considerable saving in expense, both in the materials of which they are made, and in the size of the piece of ground that must be excavated to receive the balance-bobs. There are twelve feet of space between the step on the rod, and 4 feet above each step are round bars of iron fixed vertically into the rod, to serve as hand-holds, and maintain the miner in his position on the step with perfect safety. In case of accident happening to any part of the machinery, there are catches placed at every few fathoms, so that the fall cannot be great.

The man-engine with a single rod is generally used in Cornwall, because it possesses so many advantages over that with two: the expense of erection is much less, it enables the miner to mount and descend in as short a space of time, and the number who can do so per minute is doubled; the work performed by the machine is also increased. There are signals connected with the man-engine, by which the miner can communicate with the surface from every platform.

The usual speed of the engine is 15 strokes per minute, by which each rod makes 3 strokes during that time. Therefore, the rate at which it travels is 12 fathoms per minute ascending and descending: this speed enables a miner to travel in 24 minutes a space that he would otherwise take 60 minutes to perform. In case of any accident happening to the man-engine, there are always ladders placed by the side of it; sometimes they only go from platform to platform; in other mines there are bars nailed on the rod, so that the miner can climb on them until he regains the principal ladders.

The man-engine possesses almost innumerable advantages over the ladders; the greatest is the immense saving of fatigue to the miner. When there are only ladders in a mine, he sometimes takes an hour or more to reach the place where he is working, and then only with immense bodily exertion; on a man-engine he can reach the same place in about a third of the time, and as free from fatigue and ready for hard work as when he started from the surface. Even those who have never been in a mine cannot but appreciate the great blessing this simple invention is to the miners, if they have only seen the exhausted state in which they reach the surface after having ascended by ladders from any great depth. At first it was feared the man-engine might be dangerous, that the speed at which it worked would not allow time for the men to step from one platform to another, but after one or two trials it was found that no fears need be entertained on that account, and it was pronounced by the miners as perfectly safe as ladders.

In 1845 M. Warocqué constructed similar machines in Belgium. These have been described in the *Revue Scientifique et Industrielle*, under the several denominations of 'Fahrkunst,' 'Man-Engine,' 'Warocquière,' 'Machine d'Ascension,' and 'Échelles Mobiles.' The first application was made, as we have already said, by M. Warocqué at the pit of St. Nicholas, belonging to the colliery of Mariemont, to a depth of 220 mètres—about 240 yards. A full account of these machines will be found in the *Annales des Travaux publics*, tome v., p. 79, by M. Delvaux de Fenffe; in the *Traité d'Exploitation* by M. Combes; *Notice sur les Appareils de Translation des Mineurs dans les Puits*, by M. A. De Vaux; also in the *Annales des Travaux publics de Belgique*; and by M. Moissenet in the *Annales des Mines*.

MANGANATES; PERMANGANATES; CONDY'S FLUID. Dr. Hofmann, in his report on the chemical products of the Exhibition of 1862, has the following excellent remarks on *soluble saline oxidising disinfectants*. Of this variety of oxidising disinfectants the alkaline manganates and permanganates are the best examples; and in this cursory sketch, attention may be confined to these as types of their class.

Alkaline Manganates and Permanganates.—Chemists have long known and turned to account, in laboratory operations, the powerful oxidising action of the salts of permanganic acid. The rapidity and definiteness of their action, and the marked change of colour by which their loss of oxygen is attended, renders these compounds invaluable as instruments of analytical researches. And the same properties, coupled with their perfectly innocuous character, adapts them admirably for disinfecting purposes. Their action is certainly superior to that of chloride of lime and alkaline hypochlorites; for although these are also oxidising disinfectants, they act indirectly by decomposing water, from which the chlorine takes hydrogen to form hydrochloric acid, thus liberating oxygen for the supply of the putrefying matter. The manganates and permanganates, on the contrary, are agents of direct oxidation, yielding up, as they do, part of their own oxygen to the combustible elements of putrescible compounds. The manganates thus supply one-fourth, the permanganates no less than three-eighths, of the oxygen they respectively contain, peroxide of manganese being in both cases precipitated, and the alkaline base remaining in solution in the form of carbonate.

Their Efficacy as Disinfectants.—Dr. Hofmann has had many opportunities of satisfying himself of their efficacy as disinfectants. Waters taken from stagnating ponds highly charged with organic matter in a state of most active putrefaction, and emitting the most repulsive odour, were instantaneously deodorised by a comparatively small quantity of permanganate, or even manganate of potassium or sodium. After the brown precipitate of peroxide of manganese had been allowed to subside, the waters examined by Dr. Hofmann had become perfectly clear and colourless, having permanently lost their offensive smell and taste. The taint of some of these waters had survived the action of even very considerable quantities of the usually-applied metallic salts. Their deodorisation by chloride of lime was likewise rapid and permanent; but, though entirely deprived of their original putrid odour, the chlorine-treated waters retained a faint, peculiar smell, probably due to the chloride of nitrogen, generated by the action of free chlorine upon their ammoniacal constituents.

For freeing river or other waters from ammoniacal impregnations, the disappearance of the colours of the manganates and permanganates, in proportion as their oxidising action goes on, particularly adapts them. By the fading of the colour (emerald, if manganate is used; purple, if permanganate) the operator can follow the process of oxidation, and graduate his additions with the utmost accuracy. By careful manipulation he may completely free the water from organic impurity, introducing into it, in exchange, only a minute quantity of an alkaline carbonate. This is rarely an objectionable, frequently rather a serviceable, addition; especially in the case of hard waters, which are thus softened.

Their minor applications.—The innocuous character of these substances has already been referred to; and it is not the least valuable of their properties. It permits of their being used for a variety of purposes to which disinfectants have hitherto been almost entirely inapplicable. Among them are some of great value, such as disinfection of all parts of the living animal body (deodorisation of the breath, disinfection of ulcers, wounds, &c.). Scarcely less important is the service they are capable of rendering to the vegetable organism when suffering from blight and similar pernicious influences. They may also be advantageously employed for the purification of tainted provisions, &c. It may be of some interest to the smokers of tobacco to know that by rinsing out the mouth with a dilute solution of permanganate of sodium every trace of the odour of tobacco is almost instantaneously got rid of. Among the numerous applications of minor importance which Mr. Condy suggests for the manganic disinfectants is their use by wine-tasters for refreshing their palates when engaged in the important duties of their profession. They are also said to subdue the irritation caused by the bites of gnats and other still more disagreeable insects.

The manganic disinfectants are thus seen to possess a combination of properties which in many cases may render their application preferable to that of the hypochlorites. These latter, however, have the superiority as atmospheric disinfectants, on account of their exhalation of chlorine gas, in a more or less dilute state, when acted on by acids, or acid salts, or even by the atmosphere itself. This property of chloride of lime will always secure it a field of application, in which it is not likely to be superseded by non-volatile disinfectants of any kind.

Their Manufacture.—It only now remains to say a few words concerning the manufacture of the alkaline manganates and permanganates, which is accomplished by a very simple and easy process.

For laboratory purposes the potassic permanganates are usually preferred to the corresponding sodic compound, on account of the superior crystallising properties of the former salt, and the facilities thus afforded for its purification. For industrial purposes, on the other hand, where cheapness is far more important than perfect purity, the manganate and permanganate of sodium are always used. Mr. Condy manufactures manganates of sodium simply by mixing caustic soda with finely-divided peroxide of manganese, and exposing the mixture in shallow vessels, for

48 hours, to a dull red heat. The proportions employed by Mr. Condy are 1½ ton of soda-ash, caustified in the usual way, to 7 cwts. of peroxide of manganese. The product of the reaction is treated with a sufficient quantity of water to convert (partly, at all events) the manganate into permanganate; and the solution is evaporated to an appropriate state of concentration or to dryness. In some cases Mr. Condy transforms the manganate into the permanganate by the addition of sulphuric acid. On evaporating the solution thus formed, crystals of sulphate of sodium separate; these are fished out, and the liquid is ultimately boiled down to dryness. See DISINFECTANTS.

MANGANESE (Eng. and Fr.; *Mangan*, *Braunsteinmetall*, Ger.) is a greyish-white metal, of a fine-grained fracture, very hard, very brittle, with considerable lustre, of specific gravity 8·013, and requiring for fusion an extreme heat. It should be kept in closely-stoppered bottles, under naphtha, like potassium, because with contact of air it speedily gets oxidised, and falls into powder. It decomposes water slowly at common temperatures, and rapidly at a red heat. Pure oxide of manganese can be reduced to the metallic state only in small quantities, by mixing it with lamp-black and oil into a dough, and exposing the mixture to the intense heat of a smith's forge, in a luted crucible; which must be shaken occasionally to favour the agglomeration of the particles into a button. Thus procured, it contains, however, a little carbon. Some improvements in the reduction of manganese have recently been effected by Mr. Hugo Tamm.

Manganese is supposed to perform an important part in the compound of iron, known as *Spiegeleisen*, which is now so largely employed in the manufacture of the Bessemer Steel. See SPIEGELEISEN and STEEL.

MANGANESE, ORES OF. There are two principal ores of this metal, which occur in great masses; the peroxide, and the hydrated oxide; but all the ores of manganese are described in the following paragraphs:—

Pyrolusite, or grey manganese ore, has a metallic lustre, a steel-grey colour, and affords a black powder. Specific gravity 4·85. Scratches calc-spar. It effervesces briskly with borax at the blowpipe, in consequence of the disengagement of oxygen gas. This is the most common ore of manganese, and a very valuable one, being the substance mostly employed in the manufacture of chloride of lime and of flint glass. It is the peroxide. It contains manganese, 63·3; oxygen, 36·7. Great quantities are found near Tavistock in Devonshire and Launceston in Cornwall.

Braunite is a dark brown substance of glassy metallic lustre, affording a brown powder. Specific gravity 4·8. It scratches felspar, but is scratched by quartz. Infusible at the blowpipe, and effervesces but slightly when fused with glass of borax. It is the sesquioxide, containing manganese, 69·68; oxygen, 30·32. It gives out at a red heat only 3 per cent. of oxygen. *Hausmannite* is a rarer ore, consisting of the protoxide and sesquioxide of manganese.

Manganite is brownish-black or iron-black, powder brown, with somewhat of a metallic lustre. Specific gravity 4·3. Scratches fluor-spar. Affords water by calcination in a glass tube; infusible at the blowpipe; and effervesces slightly when fused with glass of borax. It consists of manganese, 62·68; oxygen, 27·22; water, 10·10; and is therefore a hydrated sesquioxide.

Manganese-blende, or sulphide of manganese, has a metallic aspect; is black or dark steel-grey. Specific gravity 3·95. Has no cleavage; cannot be cut. Infusible, but affords, after being roasted, distinct evidence of manganese by giving a violet tinge to soda at the blowpipe. Soluble in nitric acid; solution yields a white precipitate, with the ferrocyanide of potassium. It consists of sulphur, 37·90; manganese, 62·10.

Diallogite; Carbonate of Manganese. Specific gravity 3·4. Affords a green frit by fusion with carbonate of soda; is soluble, with some effervescence, in nitric acid; solution, when freed from iron by succinate of ammonia, gives a white precipitate, with ferrocyanide of potassium. Carbonic acid, 38·20; protoxide of manganese, 61·80.

Rhodonite, or *Hydrosilicate of Manganese*, is a brownish-red-looking substance, which yields a yellowish-brown powder, and water by calcination; is acted on by muriatic acid, but affords no chlorine. It consists of silica, 45; protoxide of manganese, 54·1.

Wad, or *Bog Manganese*, is the old English name of the hydrated peroxide of manganese. It occurs in various imitative shapes, in froth-like coatings upon other minerals, as also massive. Some varieties possess imperfect metallic lustre. The external colour is a dark brown of various shades, and similar in the streak, only shining. It is opaque, very sectile, soils and writes. Its specific gravity is about 3·7. Mixed with linseed-oil into a dough, black wad forms a mass that spontaneously inflames. The localities of wad are particularly Cornwall and Devonshire, the Hartz, and Piedmont. Wad from Devonshire gave—oxide of manganese, 79·12; oxygen, 8·82; water, 10·06.

The manufacturer of flint glass uses a small proportion of the black manganese ore, to correct the green tinge which his glass is apt to derive from the iron present in the sand he employs. To him it is of great consequence to get a native manganese containing as little iron oxide as possible; since, in fact, the colour or limpidity of his product will depend altogether upon that circumstance. See GLASS.

The peroxide of manganese is used also in the formation of glass-pastes, and in making the black enamel of pottery.

The restoration of manganese to the state of peroxide, for the chemical arts in which it is so extensively consumed, has been long a desideratum in manufactures.

The chief use of 'manganese' (binoxide of manganese) is in the manufacture of chlorine for bleaching-powder. The spent manganese may now be regenerated by Mr. Walter Weldon's process. See CHLORINE.

Sulphate of manganese has of late years been introduced into calico-printing, to give a chocolate or bronze impression. It is easily formed by heating the black oxide, mixed with a little ground coal, with sulphuric acid. See CALICO-PRINTING.

For some of the other uses of manganese in the arts, see BLEACHING and CHLOROMETRY.

For a simple method of ascertaining the value of this substance in the production of chlorine, and the manufacture of the chlorides and chlorates, see CHLOROMETRY.

Imports of manganese in 1869–72, and 1873:—

	1869		1870		1872		1873

MANGANESE, OXIDES OF. Manganese is susceptible of five degrees of oxygenation:—

1. The *Protoxide* may be obtained from a solution of the sulphate by precipitation with carbonate of potash, and expelling the carbonic acid from the washed and dried carbonate, by calcination in a close vessel filled with hydrogen gas, taking care that no air have access during the cooling. It is a pale-green powder, which slowly attracts oxygen from the air, and becomes brown; on which account it should be kept in glass tubes containing hydrogen, and hermetically sealed. It consists of metal, 77·57; oxygen, 22·43. It forms, with 24 per cent. of water, a white hydrate; and with acids, saline compounds, which are white, pink, or amethyst coloured. They have a bitter acerb taste, and afford with hydrogenated sulphide of ammonia a flesh-red precipitate, but with caustic alkalis one which soon turns brown-red, and eventually black.

2. The *Sesquioxide of Manganese* exists native in the mineral called *Braunite*; but it may be procured either by calcining at a red heat the proto-nitrate, or by spontaneous oxidisement of the protoxide in the air. It is black; when finely pulverised, dark brown; and is convertible, on being heated in acids, into protoxide, with disengagement of oxygen gas. It consists of metal, 69·75; oxygen, 30·25. It forms with 10 per cent. of water, a liver-brown hydrate, which occurs native under the name of *Manganite*. It dissolves readily in tartaric and citric acids, but in few others. This oxide constitutes a bronze ground in calico-printing.

3. *Peroxide of Manganese*, or *Pyrolusite*, occurs abundantly in nature. It gives out oxygen freely when heated, and becomes an oxidulated deutoxide. It consists of metal, 63·36; oxygen, 36·64.

4. *Manganic Acid* forms green-coloured salts, but has not hitherto been insulated from the bases. It consists of metal, 53·55; oxygen, 46·45.

5. *Hypermanganic Acid* consists of metal, 49·70; oxygen, 50·30. See Watts's 'Dictionary of Chemistry.'

MANGLE. (*Calandre*, Fr.; *Mangel*, Ger.) This is a well-known machine for smoothing linen and cotton furniture. As usually made, it consists of an oblong, rectangular wooden chest, filled with stones, which load it to a degree of pressure that it should exercise upon the two cylinders on which it rests, and which, by rolling backwards and forwards over the linen spread upon a polished table underneath, render it smooth and level. The moving wheel, being furnished with teeth upon both surfaces of its periphery, and having a notch cut out at one part, allows a pinion, uniformly driven in one direction, to act alternately upon its outside and inside, so as to cause the reciprocating motion of the chest. This elegant and much-admired English invention, called the mangle-wheel, has been introduced with great advantage into the machinery of the textile manufactures.

Mr. Warcup, of Dartford, obtained a patent several years ago for a mangle in which the linen, being rolled round a cylinder revolving in stationary bearings, is pressed downwards by heavy weights hung upon its axes, against a curved bed, made to slide to and fro, or traverse from right to left, and left to right, alternately.

Mr. Hubie, of York, patented in June 1832 another form of mangle, consisting of three rollers placed one above another in a vertical frame, the axle of the upper roller being pressed downwards by a powerful spring. The articles intended to be smoothed are introduced into the machine by passing them under the middle roller, which is made to revolve by means of a fly-wheel; the pinion upon whose axis works in a large toothed wheel fixed in the shaft of the same roller. The linen, &c. is lapped, as usual, in protecting cloths. This machine is merely a small CALENDER.

MANGROVE. Several tropical trees yield woods to which this name has been applied. Colonel G. A. Lloyd informs us, that 'the timbers are very much valued for ship-building; and a large quantity comes from Crab Island and Porto Rico.' Most of the mangroves belong to the *Rhizophoraceæ*.

MANILLA. One of the hemps, derived from the *Musa textilis*. See HEMP.

MANIOC is the Indian name of the nutritious matter of the shrub *Jatropha Manihot*, from which *cassava* and *tapioca* are made in the West Indies. See CASSAVA; TAPIOCA.

MANNA is the concrete saccharine juice of the *Fraxinus ornus*, a tree much cultivated in Sicily and Calabria. It is now little used, and that only in medicine.

MANNHEIM GOLD. A brass, containing 80 per cent. of copper and 20 per cent. of zinc.

MANURE. Under the auspices of the British Association, Professor Liebig, in the year 1840, first promulgated his views on agriculture, from which date we may trace a spirit of investigation into it, such as had not previously existed in this country. Among other labourers in this field, we must state that Mr. J. B. Lawes, of Rothamstead in Hertfordshire, was occupied several years prior to the first edition of Professor Liebig's work, in investigating the action of different chemical combinations when applied as manures to the more important crops of the farm; and having ever since continued his experimental researches with all the lights of science with which he is familiar, aided by Dr. J. H. Gilbert, a skilful analytical chemist, he has been able to arrive at conclusions of greater value and precision than the merely theoretical determinations of the German Professor. In the course of this inquiry, the whole tenor of the results of Messrs. Lawes and Gilbert, and also of information derived from intelligent agricultural friends, upon every variety of land in Great Britain, has forced upon them opinions different from those of Professor Liebig, on some important points; and more especially, in relation to his so-called 'mineral theory,' which is embodied in the following sentence, to be found at page 211 of the third edition of his work on Agricultural Chemistry, where he says 'the crops on a field diminish or increase in exact proportion to the diminution or increase of the mineral substances conveyed to it in manure.'

Of the vast importance, both in a scientific and practical point of view, of correct ideas on the subject here at issue, a judgment may be formed from the manner in which Liebig himself speaks of the mineral theory in this edition of his 'Letters on Chemistry.' Thus he says of the agriculturists of England, that 'sooner or latter they must see that in the so-called mineral theory, in its development and ultimate perfection, lies the whole future of agriculture.' Messrs. Lawes and Gilbert published the following paper in reply to Liebig. It is of so important a nature that, acting on the advice of the best authority in this country, it has been retained:—

'Looking upon the subject in a chemical point of view only, it would seem that an analysis of the soil upon which crops were to be experimentally grown, as well as a knowledge of the composition of the crop, should be the first points ascertained, with the view of deciding in what constituents the soil was deficient; and, at the commencement of our more systematic course of field experiments, the importance of these points was carefully considered. When we reflect, however, that an acre of soil six inches deep may be computed to weigh about 1,344,000 lbs. (though the roots of plants take a much wider range than this), and taking the one constituent of ammonia or nitrogen as an illustration, that in adding to this quantity of soil a quantity of ammoniacal salt, containing 100 lbs. of ammonia, which would be an unusually heavy and very effective dressing, we should only increase the percentage of ammonia in the soil by 0·0007, it is evident that our methods of analysis would be quite incompetent to appreciate the difference between the soil before and after the application,—that is to say, in its state of exhaustion, and of highly productive condition, so far as that constituent is concerned; and, from our knowledge of the effects of this substance on wheat, we may confidently assert that the quantity of it supposed above would have given a produce at least double that of the unmanured land. The same kind of argument might, indeed, be adopted in reference to the more important of those constituents of a soil which are found in the ashes of the plant grown upon it, and we determined, therefore, to seek our results in another manner. Indeed, the imperfection of our knowledge of the productive quality of a soil, as derived from its percentage composition, has been amply proved by the results of analysis which have been published during the last ten years; and in corroboration, we need only refer to the opinions of Professor Magnus on this subject, who, in his capacity of chemist to the 'Landes-Oekonomie Kollegium' of Prussia, has published the result of many analyses of soils. The truth is, that little is as yet known of what a soil either is, or ought to be, in a chemical point of view; but when we call to mind the investigations of Professor Mulder in relation to the organic acids found in soils, and of Mr. Way and others as to the chemical and physical properties of soils in relation to the atmosphere and to saline substances exposed to their action in solution, we may at least anticipate for chemistry that she will ere long throw important light on this interesting but intricate subject.

'In our field experiments, then, we have been satisfied with preserving specimens of the soils which were to be the subjects of them, and have sought to ascertain their deficiency, in regard to the production of different crops, by means which we conceive to be not only far more manageable, but in every way more conclusive and satisfactory in their result. To illustrate: What is termed a rotation of crops is at least of such universality in the farming of Great Britain, that any investigation in relation to the agriculture of that country may safely be grounded on the supposition of its adoption. Let us, then, direct attention for a moment to some of the chief features of rotations. What is called a *course* of rotation is the period of years which includes the circle of all the different crops grown in that rotation or alternation. The crops which thus succeed each other, and constitute a rotation, may be two, three, four, or more, varying with the nature of the soil and the judgment of the farmer; but whatever *course* be adopted, no individual crop—wheat, for example--is grown immediately succeeding one of the same description, but it is sown again only after some other crops have been grown, and at such a period of the rotation, indeed, as by experience it is known that the soil will, by direct manure or other means, have recovered its capability of producing a profitable quantity of the crop in question.

'On carefully considering these established and well-known facts of agriculture, it appeared to us that, by taking soils either at the end of the rotation, or at least at that period of it when in the ordinary course of farming farmyard manure would be added before any further crop would be grown, we should then have the soils in what may be termed a *normal*, or, perhaps better still, a *practically* and *agriculturally* exhausted, state.

'Now, if it is found, in the experience of the farmer, that land of any given quality, with which he is well acquainted will not, when in this condition of practical exhaustion, yield the quantity he usually obtains from it of any particular crop, but that after applying farmyard manure it will do so, it is evident that if we supply to different plots of this *exhausted land* the constituents of farmyard manure both individually and combined, and if by the side of these plots we also grow the crop both without manure of any kind and with farmyard manure, we shall, in the comparative results obtained, have a far more satisfactory solution of the question as to what constituents were, in this ordinary course of agriculture most in defect in respect to the proportion of the particular crop experimented upon, than any analysis of the soil could have given us. In other words, we should have before us very good ground for deciding to which of the constituents of the farmyard manure the increased produce was mainly due on the plot provided with it, in the case of the particular crops: not so, however, unless the soil had been so far exhausted by previous cropping as to be considered *practically* unfit for the growth of the crop without manure. We lay particular stress on this point, because we believe that the vast discrepancy in the results of comparative trials with different manures, by different experiments, arises more from irregularity in what may be called the *floating* capital of the soil, than from irregularities in the original character of the soil itself, or from any other cause, unless we include the frequent faulty methods of application.

'It is, then, by this *synthetic* rather than by the analytic method that we have sought our results: and in the carrying out of our object we have taken *wheat* as the type of the *cereal* crops, *turnips* as the type of the *root* crops, and *beans* as the representative of the *leguminous corn* crop most frequently entering into rotation; and having selected for each of these a field which, agriculturally considered, was *exhausted*, we have grown the same description of crop upon the same land, year after year, with different chemical manures, and in each case with one plot or more continuously unmanured, and one supplied every year with a fair quantity of farmyard manure. In this way 14 acres have been devoted to the continuous growth of *wheat* since 1843, 8 acres to continuous growth of *turnips* from the same date, and 5 to 6 acres to that of *leguminous corn* crops since 1847. And of field experiments, beside these, which amount in each year to from 30 to 40 on wheat, upwards of 90 on turnips, and 20 to 30 on beans, others have been made, viz. some on the growth of clover, and some in relation to the chemical circumstances involved in an actual course of rotation, comprising turnips, barley, clover, and wheat, grown in the order in which they are here stated.

'It may be stated, too, that in addition to these experiments on wheat, and the other crops usually grown upon the farm, as above referred to, we have for several years been much occupied also with the subject of the feeding of animals, viz. bullocks, sheep, and pigs; as well as in investigating the functional actions of the growing plant in relation to the soil and atmosphere; and in connection with each of these subjects much laboratory labour has constantly been in progress.

'The scope and object of our investigation has been therefore to examine in the field, the feeding-shed, and the laboratory, into the chemical circumstances connected with the agriculture of Great Britain in its four main features; namely—

'First, the production of the cereal grain crops; secondly, that of root crops; thirdly, that of the leguminous corn and fodder crop; and, fourthly and lastly, that of the consumption of food on the farm, for its double produce of meat and manure.

'So much then for the rationale and general plan of the experiments themselves, and we now propose to call attention to some of the results which they have afforded us.

'It is to field experiments on wheat that we shall chiefly confine our attention on this occasion; for wheat, which constitutes the principal food of our population, is with the farmer the most important crop in his rotation, all others being considered more or less subservient to it; and it is, too, in reference to the production of this crop in agricultural quantity that the mineral theory of Baron Liebig is perhaps more prominently at fault than in that of any other. It is true, that in the case of vegetation in a native soil manured by art, the mineral constituents of the plants being furnished from the soil, the atmosphere is found to be a *sufficient* source of the nitrogen and carbon; and it is the supposition that these circumstances of *natural vegetation* apply equally to the various crops when grown *under cultivation* that has led Baron Liebig to suggest that, if by artificial means we accumulate within the soil itself a sufficiently liberal supply of those constituents found in the ashes of the plant, essentially soil constituents, we shall by this means be able in all cases to increase thereby the assimilation of the vegetable or atmospheric constituents in a degree sufficient for agricultural purposes. But agriculture is itself an *artificial* process; and it will be found that, as regards the production of wheat more especially, it is only by the accumulation within the soil itself of nitrogen *naturally* derived from the atmosphere, rather than of the peculiarly soil constituents, that our crops of it can be increased. Mineral substances will, indeed, materially develope the accumulation of vegetable or atmospheric constituents when applied to *some* of the crops of rotation; and it is thus chiefly that these crops become subservient to the growth of the cereal grains; but even in these cases it is not the constituents, *as found collectively in the ashes of the plants to be grown*, that are the most efficient in this respect; nor can the demand which we find thus made for the production of crops in *agricultural quantity* be accounted for by the mere idea of supplying the *actual* constituents of the crop. It would seem, therefore, that we can only arrive at correct ideas in agriculture by a close examination of the actual circumstances of growth of each particular crop when grown under cultivation. We now turn to the consideration of our experiments upon this subject. It has been said that all the experimental fields were selected when they were in a state of agricultural exhaustion. The wheat fields, however, after having been manured in the usual way for turnips at the commencement of the previous rotation, had then grown barley, peas, wheat, and oats, without any further manuring; so that when taken for experiment in 1844, it was, as a grain-producer, considerably more exhausted than would ordinarily be the case. It was, therefore, in a most favourable condition for the purposes of our experiments.

'In the first experimental season, the field of 14 acres was divided into about 20 plots, and it was by the *mineral theory* that we were mainly guided in the selection of manures: mineral manures were therefore employed in the majority of cases. *Ammonia*, on the other hand, being then considered of less importance, was used in a few instances only, and in these in very insignificant quantities. Rape-cake, as being a well-recognised manure, and calculated to supply, besides some minerals and nitrogen, a certain quantity of carbonaceous substance in which both corn and straw so much abound, was also added to one or two of the plots.

TABLE I.—*Harvest* 1844. *Summary.*

Description of the manures	Dressed corn per acre, in bushels and pecks		Total corn per acre, in lbs.	Straw per acre, in lbs.
	bush.	pecks	lbs.	lbs.
Plot 3. Unmanured	16	0	923	1120
„ 2. 14 tons of farmyard manure	22	0	1276	1476
„ 4. The ashes of 14 tons of farm manure	16	0	888	1104
„ 8. Minimum produce of 9 plots, with artificial mineral manures: Superphosphate of lime, 350 lbs. Phosphate of potass, 364 lbs.	16	1	980	1160
„ 15. Maximum produce of 9 plots with artificial mineral manures: Superphosphate of lime, 350 lbs. Phosphate of magnesia, 168 lbs. „ potass, 150 lbs. Silicate of potass, 112 lbs.	17	3¼	1096	1240
Mean of the 9 plots with artificial mineral manures	16	3¾	1009	1155
Mean of 3 plots with mineral manures, and 65 lbs. each of sulphate of ammonia	21	0	1275	1423
Mean of 2 plots with mineral manures, and 150 lbs. and 130 lbs. of rape-cake respectively	18	1¾	1078	1201
Plot 18. With complex mineral manure, 65 lbs. of sulphate of ammonia, and 150 lbs. of rape-cake	22	3¼	1368	1768

'The indications of the table are seen to be most conclusive, as showing what was the character of the exhaustion which had been induced by the previous heavy cropping, and what therefore, should be the peculiar nature of the supply in a rational system of manuring. If the exhaustion had been connected with a deficiency of mineral constituents, we might reasonably have expected that by some one at least of the nine mineral conditions,—supposing in some cases an abundance of every mineral constituent which the plant could require,—this deficiency would have been made up; but it was not so.

'Thus, taking the column of bushels per acre as given in this summary as our guide, it will be seen that whilst we have without manure only 16 bushels of dressed corn, we have by farmyard manure 22 bushels. The *ashes* of farmyard manure give, however, no increase whatever over the unmanured plot. Again, out of the 9 plots supplied with artificial mineral manures, we have in no case an increase of two bushels by this means; the produce of the average of the 9 being not quite 17 bushels. On the other hand, we see that the addition to some of these purely mineral manures of 65 lbs. of sulphate of ammonia—a very small dressing of that substance, and containing only about 14 lbs. of ammonia—has given us an average produce of 21 bushels. An insignificant addition of rape-cake too, to manures otherwise ineffective, has given us about 18½ bushels; and when, as in plot 18, we have added to the inefficient mineral manures 65 lbs. of ammoniacal salts, and a little rape-cake also, we have a produce greater than by the 14 tons of farmyard manure.

'The quantities of rape-cake used were small, and the increase attributable to it also small, but it nevertheless was much what we should expect when compared with that from the ammoniacal salts, if, as we believe is the case, the effect of rape-cake on *grain-crops* is due to the nitrogen it contains.

'Indeed, the coincidence in the slight or non-effect throughout the mineral series on the one hand, and of the marked and nearly uniform result of the nitrogenous supply on the other, was most striking in the first year's experimental produce, and such as to lead us to give to nitrogenous manures in the second season even greater prominence than we had done to minerals in the previous one. This is, in some respects, perhaps, to be regretted, as had we kept a series of plots for some years continuously under minerals alone, the evidence, though at present sufficiently conclusive, would have carried with it somewhat more of *systematic* proof.

'In Table II. we have given a few results selected from those obtained at the harvest of 1845, the second of the experimental series. By the table it would seem that we have, at the harvest of 1845, a produce of rather more than 23 bushels without manure of any kind, instead of only 16 as in 1844; and in like manner the farmyard manure gives 32 bushels in 1845, and only 22 in 1844.

TABLE II.—*Harvest* 1845. *Selected Results.*

Description and quantities of the manures per acre	Dressed corn per acre, in bushels and pecks	Total corn per acre, in lbs.	Straw per acre, in lbs.
Section 1.	bush. pecks	lbs.	lbs.
Plot 3. No manure	23 0¾	1441	2712
„ 2. 14 tons of farmyard manure . . .	32 0½	1967	3915
Section 2.			
„ *5a.* No manure	22 2¼	1431	2684
„ *5b.* Top-dressed with 252 lbs. of carbonate of ammonia (dissolved) at 3 times, during the spring	26 3¾	1732	3599
Section 3.			
„ 9. {Sulphate of ammonia, 168 lbs. Muriate of ammonia, 168 lbs.} top-dressed at once	33 1½	2131	4058
„ 10. {Sulphate of ammonia, 168 lbs. Muriate of ammonia, 168 lbs.} top-dressed at 4 times	31 3¼	1980	4266

'We assume, then, 23 bushels or thereabouts to be the standard produce of the soil and season, without manure, during this second experimental year; and as part of plot 5 (previously manured with superphosphate of lime), and which is now also without manure, gives rather more than 22½ bushels of dressed corn, the correctness of the result of plot 3, the permanently unmanured plot, is thereby fully confirmed.

'This plot No. 5, previously two thirds of an acre, was, in this second year, divided into two equal portions: one of these ('plot *5a*') being, as just said, unmanured, and the other ('plot *5b*') having supplied to it in solution, by top-dressings during the spring, the *medicinal carbonate of ammonia*, at the rate of 250 lbs. per acre; and it is seen that we have, by this pure but highly volatile ammoniacal salt alone, the produce raised from 22½ bushels to very nearly 27 bushels!

'In the next section of the Table are given the results of plots 9 and 10, the former of which had in the previous year been manured by superphosphate of lime and a small quantity of sulphate of ammonia, and the latter by superphosphate of lime and silicate of potass. To each of these plots 1½ cwt. of sulphate and 1½ cwt. of muriate of ammonia were now supplied. Upon plot 9 the whole of the manure was top-dressed, *at once*, early in the spring; but on plot 10 the salts were put on at four successive periods. The produce obtained by these salts of ammonia alone is 33 bushels and three-eighths, when sown all at once, and nearly 32 bushels when sown at four different times —quantities which amount to about 10 bushels per acre more than was obtained without manure. In the case of No. 9, indeed, the produce exceeds by 1¼ bushel that given by farmyard manure, and in that of No. 12 it is all but identical with it. And if we take the weights of total corn, instead of the *measure* of the dressed corn, to which latter we chiefly refer, merely as a standard more conventionally understood, No. 10 by ammonia only, has given both more corn and more straw than the farmyard manure, with all its minerals and carbonaceous substance.

'Let us see whether this almost specific effect of nitrogen, in restoring, for the reproduction of corn, a corn-exhausted soil, is borne out by the results of succeeding years.

'We should have omitted all reference to the results obtained with the wheat manure of Professor Liebig, but that whilst fully admitting the failure of the manure—the composition of which, to use his own words when commenting upon it, 'could be no secret, since every plant showed by its ashes the due proportion of the constituents essential to its growth'—he implied that the failure was due to a yet imperfect knowledge of the mechanical form and chemical qualities required to be given to the necessary constituents in order to fit them for their reception and nutritive action on the plant, rather than to any fallacy in the theory which would recommend to practical agriculture the supply by artificial means of the constituents of the ashes of plants as manures.

'The following Table gives our selection of the results of the third season, 1846:—

TABLE III.—*Harvest* 1846. *Selected Results.*

'At this third experimental harvest we have on the continuously unmanured plot, namely, No. 3, not quite 18 bushels of dressed corn, as the normal produce of the season; and by its side we have on plot 10*b*—comprising one half of the plot 10 of the previous years and so highly manured by ammoniacal salts in 1845, but now unmanured,—rather more than 17½ bushels. The near approach, again, to identity of result from the two unmanured plots, at once gives confidence in the accuracy of the experiments, and shows us how effectually the preceding crop had, in a practical point of view, reduced the plots, previously so differently circumstanced both as to manure and produce, to something like an uniform standard as regards their grain-producing qualities. We take this opportunity of particularly calling attention to these coincidences in the amount of produce in the two unmanured plots of the different years, because it had been objected against our experiments, as already published, that confirmation was wanting as to the natural yield of soil and season.

'Plot 2 has, as before, 14 tons of farmyard manure, and the produce is 27¼ bushels, or between 9 and 10 bushels more than without manure of any kind.

'On plot 10*a*, which in the previous year gave with ammoniacal salts alone a produce equal to that of the farmyard manure, we have again a similar result: for 2 cwts. of sulphate of ammonia has now given 1850 lbs. of total corn, instead of 1826 lbs., which is the produce on plot 2. The straw of the latter is, however, slightly heavier than that by the ammoniacal salt.

'Again, plot 5*a*, which was in the previous season *unmanured*, was now subdivided: on one half of it (namely, 5*a*[1]) we have the ashes of wheat-straw alone, by which there is an increase of rather more than 1 bushel per acre of dressed corn; on the other half (5*a*[2]) we have, besides the straw-ashes, 2 cwts. of sulphate of ammonia put on as a top-dressing; 8 cwts. of sulphate of ammonia have, in this case, only increased the produce beyond that of 5*a*[1] by 7⅞ bushels of corn and 768 lbs. of straw, instead of by 9⅝ bushels of corn and 789 lbs. of straw, which was the increase obtained by the same amount of ammoniacal salt on 10*a*, as compared with 10*b*. It will be observed, however, that in the former case the ammoniacal salts were top-dressed, but in the latter they were drilled at the time of sowing the seed; and it will be remembered that in 1845 the result was better *as to corn* on plot 9, where the salts were sown earlier than on plot 10, where the top-dressing extended far into the spring. We have had several direct instances of this kind in our experience, and we would give it as a suggestion, in most cases applicable, that manures for wheat, and especially ammoniacal ones, should be applied before or at the time the seed is sown; for, although the apparent luxuriance of the crop is greater, and the produce of straw really heavier, by spring rather than autumn sowings of Peruvian guano and other ammoniacal manures, yet we believe that that of the *corn* will not be increased in an equivalent degree. Indeed, the success of the crop undoubtedly depends very materially on the progress of the underground growth during the winter months; and this again, other things being equal, upon the quantity of available nitrogenous constituents within the soil, without a liberal provision of which, the range of the fibrous feeders of the plants will not be such as to take up the minerals which the soil is competent to supply, and in such quantity as will be required during the after-progress of the plant for its healthy and favourable growth.

'The next result to be noticed is that obtained on plot 6, now also divided into two equal portions, designated respectively 6*a* and 6*b*. Plot No. 6 had for the crop of 1844 superphosphate of lime and the phosphate of magnesia manure, and for that of 1845 superphosphate of lime, rape-cake, and ammoniacal salts. For this the third experimental season, it was devoted to the trial of the wheat-manure manufactured under the sanction of Professor Liebig, and patented in this country.

'Upon plot 6*a*, 4 cwts. per acre of the patent wheat-manure were used, which gave 20½ bushels, or rather more than two bushels beyond the produce of the unmanured plot; but as the manure contained, besides the minerals peculiar to it, some nitrogenous compounds, giving off a very perceptible odour of ammonia, some, at least, of the increase would be due to that substance. On plot 6*b*, however, the further addition of 1 cwt. each of sulphate and muriate of ammonia to this so-called 'mineral manure' gives a produce of 29¼ bushels. In other words, the addition of ammoniacal salt to Liebig's mineral manure has increased the produce by very nearly 9 bushels per acre beyond that of the mineral manure alone, while the increase obtained over the unmanured plot by 14 tons of farmyard manure was only 9¼ bushels.

'If, then, the "mechanical form and chemical qualities" of the so-called "mineral manure" were at fault, the sulphate of ammonia has, at least, compensated for the defect; and even supposing a mineral manure, founded on a knowledge of the composition of the ashes of the plant, be still the great desideratum, the farmer may rest contented, meanwhile, that he has in ammonia, supplied to him by Peruvian guano, by ammoniacal salts, and by other sources, so good a substitute.

'It surely is needless to attempt further to justify, by the results of individual years, our assertion, that in practical agriculture nitrogenous manures are peculiarly adapted to the growth of wheat. We shall therefore conclude this part of our subject by directing attention to the history of a few of the plots throughout the entire series of years, as compared with that of the unmanured plot during the same period.

'In support of the view that leguminous plants do possess a superior power of reliance upon the atmosphere for their nitrogen, and, indeed, that it is to this property that they materially owe their efficacy in rotation with grain, we may refer to the admirable investigations into the chemistry of agriculture of M. Boussingault. His experiments, however, have not received the attention which they merit from the agriculturists of this country; probably on account of the small amounts of produce which he obtained. But it must be remembered that his investigation had for its object to explain the practices of agriculture as he found them in his own locality, before attempting to deviate from its established rules. M. Boussingault states the rotation usually adopted at Bechelbronn, and throughout the greater part of Alsace, to be as follows:—

"Potatoes or beet-root;" "Wheat;" "Clover;" "Wheat;"

and that the average of wheat so obtained is, after potatoes 19½ bushels, after beet-root 17 bushels, and after clover 24 bushels. Now we find by reference to his table that the first crop of wheat, grain, and straw removed 17 lbs. of phosphoric acid and 24 lbs. of potash and soda; the following clover crop, 18 lbs. of phosphoric acid and 77 lbs. of potash and soda; and after this removal of alkalis and phosphates by the clover, a *larger* crop of wheat is obtained. Surely it would seem impossible to reconcile this result with a theory which supposes the produce of wheat to rise and fall with the quantity of minerals available within the soil. If, however, we admit that the first crop of wheat could not take up the mineral matters existing in the soil for want of nitrogenous supply, and that the clover crop, not being so dependent upon *supplied* nitrogen, was able to take up the minerals required for its growth, and that it moreover left in the soil sufficient ammonia or its equivalent of nitrogen in some form, to give the *increased* crop of wheat, we have a much more consistent and probable solution of the results. There is little doubt that M. Boussingault could have increased his produce of wheat by means of ammoniacal salts: whether he could have done so economically is another question, depending of course upon the relative prices of grain and ammonia.

'The striking effect of phosphoric acid upon the growth of the turnip, indeed, is a fact so well known to every intelligent agriculturist in Great Britain, that it would seem quite superfluous to attempt to illustrate it by any direct experiments of our own. However, as Professor Liebig has again, in the recent edition of his 'Letters,' expressed an opinion entirely inconsistent with such a result, we will refer to one or two of the results obtained in our experimental turnip-field, which bear on the opinion he has reiterated as follows:—thus, speaking of the exhaustion of phosphate of lime and alkaline phosphates by the sale of flour, cattle, &c., he says:—"It is certain that this incessant removal of the phosphates must tend to exhaust the land and diminish its capability of producing grain. The fields of Great Britain are in a state of progressive exhaustion from this cause, as is proved by the rapid extension of the cultivation of turnips and mangold-wurzel, plants which contain the least amount of the phosphates, AND THEREFORE REQUIRE THE SMALLEST QUANTITY FOR THEIR DEVELOPMENT." Now we do not hesitate to say that, however small the quantity of phosphates contained in the turnip, the successful cultivation of it is more dependent upon a large supply of phosphoric acid in the manure than that of any other crop.

'In the following Table, then, is given the amount of bulb, from 1843 to 1850.

First, the continuously unmanured plot:—
Secondly, that with a large amount of the superphosphate of lime alone each year; and
Thirdly, that with a very liberal supply of potash, with some soda and magnesia also in addition to superphosphate of lime.

Years	Plot continuously unmanured				Plot with Superphosphate of Lime alone every year				Plot with superphosphate of lime and mixed alkalis

Means .	...		...		8	4	2	4	7	15	2	20

'It is seen, then, that in the third season, viz. 1845, the produce of the unmanured plot is reduced to a few hundredweights, and since that period the size of the bulbs had been such that they had not been considered worth weighing. On the other hand, on the plot with *superphosphate of lime alone* for eight successive years, we have an average produce of about 8¼ tons of bulb! varying however exceedingly year by year, according to the season. We see, too, that by the addition to superphosphate of lime of a large quantity of the alkalis, much greater than could be taken off in the crop, the average produce is not so great by nearly half a ton as by the superphosphate of lime alone. It must be admitted that this extraordinary effect of superphosphate of lime cannot be accounted for by the idea of merely supplying in it the actual constituents of the crop, but that it is due to some special agency in developing the assimilative processes of the plant. The opinion is favoured by the fact that in the case where the superphosphate of lime is at once neutralised by alkalis artificially supplied, the efficacy of the manure would seem to be thereby reduced. And, from this again, we would gather that the effect of the phosphoric acid, as such, cannot be due merely to the liberation within the soil of its alkalis, or we should suppose that the artificial supply of these would at least have been attended with some increase of produce. But this is not the case, notwithstanding that by means of superphosphate of lime alone there has been taken from the land more of the alkalis in which the ash of the turnip so peculiarly abounds, than would have been lost to it in a century under the ordinary course of rotation and home manuring! Collateral experiments also clearly prove the importance of a liberal supply of organic substance rich in *carbon*—which always contains a considerable quantity of nitrogen also—if we would in practical agriculture increase the yield much beyond the amount which can be obtained by mineral manures alone, and these conditions being fulfilled, the direct supply of nitrogen, on the other hand, is by no means so generally essential. And it is where we have provided a liberal supply of constituents for organic formations, in addition to the mineral manures, that we have found the use of alkalis not to be without effect.

'But it is at any rate certain that phosphoric acid, though it forms so small a proportion of the ash of the turnip, has a very striking effect on its growth when applied as manure; and it is equally certain that the extended cultivation of root crops in Great Britain cannot be due to the deficiency of this substance for the growth of corn, and to the less dependence upon it of the root crops, as supposed by Baron Liebig.

'These curious and interesting facts in relation to the growth of turnips, as well as those which have been given in reference to wheat and to the leguminous crops, are sufficient to prove how impossible it is to form correct opinions on agricultural chemistry without the guidance of direct experiment in the field. And we are convinced that if Baron Liebig had watched the experiments which we have had in progress during the last eight years, he would long ago have arrived at conclusions in the main agreeing with those to which we have been irresistibly led.

'So much, then, for the results of experiments in the field, and for the considerations in relation to the functional actions of plants, as bearing upon the character of the manure required for their growth in a course of practical agriculture. Let us now consider for a few moments what really are the main and characteristic features of practical agriculture, as most generally followed in this country.

'Let us suppose that the rotation adopted is that of Turnips, Barley, Clover, Wheat: that the turnips and clover are consumed upon the farm by stock, and that the meat thus produced, 40 bushels of barley, and 30 bushels of wheat, are all the exports from the farm; the manure from the consumed turnips and clover, and the straw, both of barley and of wheat, being retained on the farm. We have in this case, by the sale of grain, a loss of minerals to each acre of the farm of only 20 to 24 lbs. of potass and soda, and 26 to 30 lbs. of phosphoric acid, in the centre of the rotation, or an average of 5 to 6 lbs. of potass and soda, and 6½ to 7½ lbs. of phosphoric acid per acre per annum. In the sale of the animals there would of course be an additional loss of phosphoric acid, though especially if no breeding-stock were kept, this would be even much less considerable than in that of the grain; and the amount of the alkalis thus sent off the farm would, according to direct experiments of our own upon calves, bullocks, lambs, sheep, and pigs, probably be only about one-fourth that of the phosphoric acid. It has, however, long been decided in practical agriculture that phosphoric acid may be advantageously provided in the purchase of bones or other phosphatic manures, though in practice these are not found applicable as a direct manure for the wheat crop; and as we have already said, even when employed for the turnip, its efficacy is not to be accounted for merely as supplying a sufficiency of that substance to be stored up in the crop.

'In conclusion, then: if the theory of Baron Liebig simply implies that the growing plant must have within its reach a sufficiency of the mineral constituents of which it is to be built up, we fully and entirely assent to so evident a truism; but if, on the other hand, he would have it understood that it is of the mineral constituents, as would be *collectively* found in the ashes of the exported produce, that our soils are deficient relatively to other constituents, and that, in the present condition of agriculture in Great Britain, "we cannot increase the fertility of our fields by a supply of nitrogenised products, or by salts of ammonia alone, but rather that their produce increases or diminishes, in a direct ratio, with the supply of mineral elements capable of assimilation," we do not hesitate to say that every fact with which we are acquainted, in relation to this point, is unfavourable to such a view. We have before stated, however, that, if a *cheap* source of ammonia were at command, the available mineral constituents might in their turn become exhausted by its excessive use.'

MANURE, ARTIFICIAL. Agricultural writers usually divide manures into two classes, natural and artificial.

The first division includes farmyard manure, liquid manure, and the various composts that are occasionally made by farmers from excrementitious matters, earth, lime, and all sorts of refuse matters found or produced on the farm.

In the second division we find guano, bone-dust, nitrate of soda, sulphate of ammonia; also the waste of slaughter-houses, night-soil, the refuse of glue-makers, wool waste, and other refuse materials of certain factories; and likewise superphosphate of lime, blood manure, and a great variety of saline mixtures, which are now extensively manufactured in manure works, for the purpose of supplying farmers with special chemical fertilisers, such as wheat-, barley-, oat-, potato-, flax-manure, &c. The term artificial manure thus includes a great variety of different materials, and is frequently applied to products which, like guano, are in point of fact much more natural than farmyard manure, in the successful preparation of which a certain amount of skill is required on the part of the farmer. The evident anomaly of considering guano, bones, blood, and nitrate of soda (Chili saltpetre) as artificial manures, has led some agricultural writers to describe them under natural manures. Again, others apply the term artificial only to compound saline manuring mixtures, such as wheat- and grass-manures, or to manures the preparation of which necessitates a certain acquaintance with chemical principles and the use of chemical agents. All this confusion can be avoided entirely, if manures, instead of being divided into natural and artificial, were separated into home-made manures, that is, manures produced from the natural resources of the farm, and into imported manures, that is, fertilisers which are introduced on the farm from foreign sources.

The term 'artificial,' more appropriately, is given to all simple or compound fertilisers in the production of which human art has been instrumental. In this signification we shall use the term 'artificial manure.'

Not many years ago farmyard manure was universally considered the only efficient fertiliser to restore the fertility of land, impaired by a succession of crops. Recent agricultural experience, however, has shown that, in a great measure, artificial manures may be employed with advantage instead of yard manure, nay, that in several respects artificial manures are preferable to ordinary dung. Indeed, the present advanced state of British agriculture is intimately connected with the success with which artificial manures have been introduced into the ordinary routine on the farm.

The variety of artificials in present use amongst English farmers is very great. Some, like well prepared samples of superphosphate, are unquestionably manures distinguished for high fertilising properties; others are less efficacious, or of a doubtful character; and not a few hardly repay the cost of carriage beyond a distance of 10 miles. The fact that in almost every market-town artificial manures are sold, which, if not altogether worthless, offer, to say the least, no profitable investment to the occupier of land, shows plainly that the principles which ought to regulate the manufacture of artificial manures are not so generally understood as it is desirable they should be. In comparison with other branches of industrial art, the manufacture of manures is comparatively simple, and involves no very expensive machinery beyond steam-power for the pulverisation of the raw materials; nor does it necessitate extensive practical experience, or the possession of a large stock of chemical knowledge, on the part of the manufacturer. The limits of this article preclude the detailed description of all the artificial manures that find their way at present into the manure market; nor does it appear to us necessary to mention in detail the various proportions in which the numerous refuse materials used by manure-makers may be blended together into efficacious fertilisers; for a manufacturer who is thoroughly acquainted with the nature of artificial manures, and the legitimate uses to which they ought to be applied, will find little or no difficulty when working up into artificial manures the raw materials or refuse matters for the acquirement of which a particular locality may offer peculiar advantages. A right conception of the relative commercial and agricultural value of the different constituents that enter into the composition of manures is the chief desideratum for the manufacturer of artificial manure. We therefore propose to refer, in the following pages, briefly to the more important principles which ought to be kept steadily in view in establishments erected for the supply of artificial fertilisers.

The high esteem in which good farmyard manure is held by practical men, its uniformly beneficial effect upon almost every kind of crop, and the economical advantages with which it is usually applied to the land, have induced many to regard farmyard manure as the model which the manufacturer of artificial manure should endeavour to imitate. But this proposition is wrong in principle, as will be shown presently, and its adoption in manure-works has led to disappointment and ruin. It would be foreign to our object to give in this place a full account of the peculiar merits that belong to yard manure, and to compare them with those exhibited by artificial manures. Each has its peculiar merits and disadvantages, upon which we need not dwell in this article. It will help us, however, in properly comprehending what is really required in a good artificial manure, if we inquire briefly into the composition of good yard manure. We therefore subjoin an analysis, made some time ago by Dr. Voelcker, of well-rotted farmyard manure (see next page):—

Farmyard manure contains all the constituents which our cultivated crops require to come to perfection, and is suited for every description of agricultural produce. As far as the inorganic fertilising substances are concerned, we find in farmyard manure potash, soda, lime, magnesia, oxide of iron, phosphoric acid, sulphuric acid, hydrochloric and carbonic acid; in short, all the minerals that are found in the ashes of agricultural crops.

Of organic fertilising substances, we find in farmyard manure some which are readily soluble in water, and containing a large portion of nitrogen; and others insoluble in water, and containing, comparatively speaking, a small proportion of nitrogen. The former readily yield ammonia, the latter principally give rise to the formation of humic acids, and similar organic compounds. These organic acids constitute the mixture of organic matters, which in practice pass under the name of humus.

Composition of Farmyard Rotted Dung (Horses', Cows', and Pigs'), in 100 *parts.*

Farmyard manure thus is a perfect manure, for experience and analysis alike show that it contains all the fertilising constituents required by plants, in states of combination which appear to be especially favourable to the luxuriant growth of our crops.

On most farms the supply of common yard manure is inadequate to meet the demands of the modern system of high farming. Hence the endeavour of enterprising men to supply this deficiency by converting various refuse materials into substitutes for farmyard manure. Artificial manures likely to approach farmyard manure in their action should contain all the elements in the latter, and in a state of combination, in which they are neither too soluble nor too insoluble; for it is evident that a plant can grow luxuriantly, and come to perfect maturity only when all the elements necessary for its existence are presented to it in a state in which they can be assimilated by the plant.

But the question arises, Is it desirable to produce by art perfect substitutes for common dung? We think not, for the following reasons:—

In the first place, well-rotted dung contains in round numbers two-thirds of its weight of water, and only one-third of its weight of dry matter. A large bulk therefore contains, comparatively speaking, but a small proportion of fertilising-matters. In every 3 tons of manure we have to pay carriage for 2 tons of water; and it may be safely asserted that no manure, however efficacious it may be in a dry condition, will be found an economic substitute for farmyard manure, if it cannot be produced in a much drier condition than common yard manure.

Again, several of the constituents which greatly preponderate in farmyard manure are present in most soils in abundant quantities; they need not, therefore, be supplied to the land in the form of manure; or, should they be wanting in the soil, they can be readily obtained almost everywhere at a cheap rate. If, therefore, these inexpen-

sive and more widely distributed substances are dispensed with in compounding a manure, and those are selected which occur in soils only in minute quantities, a very valuable and efficacious fertiliser is obtained, which possesses the great advantage of containing in a small bulk all the essential fertilising substances of a large mass of home-made dung.

That the effect which every description of manure is capable of producing depends on its composition is self-evident; and as the different constituents which generally enter into the composition of manures produce different effects upon vegetation, it is of primary importance to the manufacturer of manure that he should be acquainted with the special mode of action of each fertilising constituent.

We shall therefore make some observations on the practical effects, and the comparative value, of the various constituents that enter into the composition of manures.

To guard against misapprehension, we would observe that, in one sense, all the fertilising-agents are alike valuable; for they are all indispensable for the healthy condition of our cultivated crops, and consequently the absence of one is attended with serious consequences, though all others may be present in abundance. Thus the deficiency of lime in the land is attended with as much injury to the plant as that of phosphoric acid. In this sense lime is as valuable as phosphoric acid; but inasmuch as lime is generally found in most soils in abundant quantities, or, if deficient, can be applied to the land economically in the form of slaked lime, marl, shell-sand, &c., its presence in an artificial manure is by no means a recommendation to it.

The principal constituents of manures are:—

1. Nitrogen (in the shape of ammonia, nitric acid, and nitrogenised organic matters).
2. Phosphoric acid (bone-earth and soluble phosphates).
3. Potash (carbonate and silicate of potash).
4. Soda (common salt).
5. Lime and magnesia (carbonate and sulphate of lime and magnesia).
6. Soluble silica.
7. Humus-forming organic matters (vegetable remains of all kinds).
8. Sulphuric acid (sulphate of lime).
9. Chlorine (common salt).
10. Oxide of iron, alumina, silica (clay, earth, and sand).

We have here mentioned these constituents in the order which expresses their comparative commercial value.

1. *Nitrogen.*—This element may be incorporated with artificial manures in the shape of ammoniacal salts or nitrates, or nitrogenised organic matters.

The cheapest ammoniacal salt is sulphate of ammonia; the cheapest nitrate is Chili saltpetre, or nitrate of soda; hence sulphate of ammonia and nitrate of soda are exclusively employed by manure manufacturers for the preparation of nitrogenised manures, when no organic refuse-matters containing nitrogen, such as horn-shavings, bone-dust, woollen rags, blood, glue-refuse, &c., are available.

Nitrogen in any of these forms exercises a most powerful action in manure, especially when applied to plants at an early stage of their growth; at a later period of development the application of ammoniacal salts or nitrate of soda appears much less effective, and sometimes even useless. For this reason nitrogenised manures, such as guano, soot, specially-prepared wheat-manures, &c., ought to be applied either in autumn or in spring, immediately after the young blade has made its appearance above ground.

Ammoniacal salts, nitrate of soda, and decomposed nitrogenised organic matters, have a most marked effect upon the leaves of plants; they induce a rapid and luxuriant development of leaves, and may therefore be called leaf-producing or forcing manures. Grass, wheat, oats, and other cereals, when grown upon soils containing abundance of available mineral elements, are strikingly benefited by a nitrogenised manure; but, on account of their special action, they ought to be used with caution in the case of corn-crops, and always more sparingly on light than on heavy land; otherwise, fine straw, but little and an inferior sample of grain, will be obtained.

As a general rule, ammoniacal salts or nitrate of soda should not be used by farmers in a concentrated state, and exceptionally only. However useful sulphate of ammonia or nitrate of soda may be in a particular case, it ought to be remembered that generally such manures produce beneficial effects only in conjunction with mineral matters. If, therefore, a proper amount of available mineral substances does not exist in the soil, it has to be supplied in the manure. Ammoniacal salts, nitrate of soda, animal matters, &c., are therefore almost always blended together with phosphates, common salt, gypsum, &c., by manufacturers of manures.

Whilst we thus fully recognise the importance of the presence of ammonia, ammoniacal salts, nitrates, or animal matters furnishing ammonia on decomposition in manures, especially in manures for white crops, we cannot agree with those who estimate the entire value of manuring-substances by the proportion of nitrogen which they contain.

In a purely commercial sense, nitrogen in the shape of ammonia or nitric acid, or animal nitrogenised matters, is the most valuable fertilising constituent, for it fetches a higher price in the market than any other manuring constituent.

2. *Phosphoric Acid.*—Next in importance follows phosphoric acid. This acid exists largely in the grain of wheat, oats, barley, in leguminous seeds, likewise in turnips, mangolds, carrots, in clover, meadow-hay, and, in short, in every kind of agricultural produce. Whether we grow, therefore, a cereal crop or a fallow crop, there must be phosphoric acid in sufficient quantity in the soil, or if insufficient it must be added to the land in the shape of manure.

The proportion of phosphoric acid in even good soils is very small, and as the agricultural produce in almost every case removes from the soil more of phosphoric acid than of any other soil-constituent, the want of available phosphoric acid makes itself known very soon. This is especially the case with quick-growing crops, such as turnips, mangolds, &c. The whole period of vegetation of these green crops extends only over 4 or 5 months, and the fibrous roots of these crops are unable to penetrate, like wheat, the soil to any considerable depth. For these reasons, phosphoric acid in some form or other has to be abundantly supplied to root-crops; and experience has shown that no description of fertilising matter benefits roots so much as superphosphate and similar manures, which contain phosphate of lime in a state in which it is readily assimilated by plants.

In artificial manures phosphoric acid commonly occurs in the shape of bone-dust, boiled bones, bone-shavings (refuse of knife-handle makers, turners of ivory, button-makers, &c.), or in the state of biphosphate of lime, purposely manufactured from bone materials or from phosphatic minerals.

The phosphate of lime which occurs in fresh bones, practically speaking, is insoluble in water. In water charged with carbonic acid, and still more so in water containing some ammonia, it is more soluble than in pure water. On fermenting bone-dust in heaps it becomes a much more effective manure. Such fermented bone-dust is added with much benefit to general artificial manures.

All really good artificial manures should contain a fair proportion of phosphate—say from 25 to 40 per cent., according to the uses for which the manure is intended. Generally speaking, manures for turnips, and root-crops in general, should be rich in phosphates especially soluble phosphates (biphosphate of lime); such manures need not contain more than 1 to 1½ per cent. of ammonia, and, when used on land in a tolerably good agricultural condition, ammonia can be altogether omitted in the manure without fear of deteriorating the efficacy of the manure.

3. *Potash.*—Salts of potash unquestionably are valuable fertilising constituents, for potash enters largely into the composition of the ashes of all crops. Root-crops especially require much potash; hence these crops are much benefited by wood-ashes, burnt clay, liquid manure, and other fertilisers containing much potash.

The commercial resources of potash are limited, and salts of potash have generally been far too expensive to be employed largely in the manufacture of artificial manures. Fortunately potash exists abundantly in most soils containing a fair proportion of clay. Its want in artificial manures therefore is not perceived, at least not in the same degree in which the deficiency of phosphates in a manure would be felt. Of late years however valuable deposits of potash-salts have been discovered at Stassfurt in Prussian Saxony, and have been extensively employed for various industrial purposes, including the preparation of manures.

4. *Soda.*—Salts of soda are much less efficacious fertilising matters than salts of potash. There are few soils which do not contain naturally enough soda, in one form or the other, to satisfy the wants of the crops which are raised upon them. However, common salt is largely employed in the manufacture of artificial manures; if it does no good, it certainly does no harm; and in this country it is one of the cheapest diluents which can be employed for reducing the expenses of concentrated fertilising mixtures to a price at which they can be sold to farmers. In continental districts common salt proves more efficacious as a manure than in England, where the neighbourhood of the sea provides the majority of soils with plenty of salt, which by the winds is carried landwards with the spray of the sea to very considerable distances.

Salt, however, even in England, is usefully applied to mangolds, and enters largely into the composition of most artificial manures expressly prepared for this crop.

5. *Lime and Magnesia.*—All plants require lime and magnesia in smaller or larger quantities. Many soils contain lime in superabundance; in others it is deficient. To the latter soils it must be added. This can be done by lime-compost, by slaked lime, by marl, shell-sand, or gypsum. All these calcareous manures are cheap almost everywhere, for lime and magnesia are among the most widely distributed, and most abundant mineral substances.

The addition of chalk, marl, and even gypsum, to artificial manures, should therefore be avoided as much as possible.

At the best, carbonate and sulphate of lime in artificial manures must be regarded as diluents.

6. *Soluble Silica.*—The artificial supply of soluble silica to the land, as far as our present experience goes, has done no good whatever to cereals, the straw of which soluble silica is supposed to strengthen.

In the absence of reliable practical experiments with soluble silica, we cannot venture to recommend the use of silicate of soda or soluble silica to manure-manufacturers.

7. *Organic substances; Humus.*—The importance of organic matters free from nitrogen, as fertilising agents, is very trifling. Formerly the value of a manure was estimated by the amount of organic matter it contained, and little or no difference was made whether the organic matter contained nitrogen or not. Under good cultivation, the organic matter in the soil regularly increases from year to year; there exists therefore no necessity of supplying it in the shape of manure.

In artificial manures we should certainly exclude all substances that merely add to the bulk, without enhancing the real fertilising value of the manure. Peat, saw-dust, and similar organic matters, &c., are useful to the manure-maker only as diluents and absorbents of moisture.

8. *Sulphuric acid* is another constituent of manure, which possesses little value. In artificial manures sulphuric acid chiefly occurs as gypsum.

9. *Chlorine.*—Exists in manures principally as salt.

10. *Oxide of Iron, Alumina, Silica.*—These constituents exist sometimes in manures in the shape of burnt-clay, earth, brick-dust, and sand.

It is hardly necessary to remark that good artificial manures should contain as little as possible of these matters.

It will appear from the preceding observations, that nitrogen in the shape of ammoniacal salts, nitric acid or decomposed animal matters, and phosphoric acid are the most valuable fertilising constituents.

The manufacturers of artificial manure should therefore endeavour:

1. To produce manures containing as little water as possible.

2. To incorporate as much of nitrogenised organic matters, or ammoniacal salts, or nitrates and phosphates, in general manuring mixtures, as is possible at the price at which artificial manures are usually sold.

3. To avoid as much as possible gypsum, salt, peat-mould, chalk, and other substances that chiefly add to the bulk, without increasing the efficacy, of the manures.

He should also endeavour to produce uniform finely-pulverised articles, that run readily through the manure drill.

It likewise devolves on the manufacturer of manures to render more effective, that is to say, more rapid and energetic in their action, refuse materials which may remain inactive in the soil for years before they enter into decomposition, and to reduce by chemical means into a more convenient state for assimilation, raw materials, which like coprolites, apatite, &c., produce little or no beneficial effects upon vegetation, even when added to the land in a finely-powdered condition.

At the present time, two classes of artificial manures may be distinguished: 1, general manures, *i.e.* manures which profess to suit equally well every kind of agricultural produce; and 2, special manures, *i.e.* manures specially prepared for a particular crop only.

The requirements of different crops, or perhaps, more correctly speaking, the conditions that regulate the assimilation of food, vary so much, that we doubt the policy of manure-makers to prepare *general* artificial manures. At the same time, we doubt the necessity of preparing artificial manures for every description of crop. Special manures are extremely useful to farmers, if they are prepared by intelligent manufacturers, who possess sufficient chemical knowledge to take advantage of every improvement that is made in manufacturing chemistry, and at the same time know sufficient of agriculture to understand what is really wanted in a soil. In other words, except a manufacturer is a good practical chemist and a tolerably good farmer, he will not be able properly to adapt the composition of special fertilisers to the nature of the soil, and the peculiar mode of treatment which the land has received on the part of the farmer.

However, nearly all special artificial manures, generally speaking, may be arranged under two heads. They are either: 1. Nitrogenised Manures, or, 2. Phosphatic Manures. The first may be used with almost equal advantage for wheat, barley, oats, for rye, and on good land likewise for grass. The second are chiefly used for root-crops.

Nitrogenised artificial manures frequently are nothing more than guano, diluted with gypsum, salt, peat-mould, earth, &c. In fact, guano is the cheapest ammoniacal manure; for which reason it is so largely employed for compounding low-priced wheat-manures, grass-manures, &c. &c.

Good manures for cereals may be made by blending together fine bone-dust, or bone-dust dissolved in sulphuric acid, sulphate of ammonia, salt, and gypsum. These manures will be the better the more sulphate of ammonia they contain. In 1873 we imported 70,055 tons of bones of animals and fish for this purpose.

Turnip-manures, and artificial manures for root-crops in general, consist principally of dissolved bones, or dissolved coprolites and other mineral phosphates. They are, in fact, superphosphates of various degrees of concentration. The more soluble phosphate a root-manure contains, the better is it adapted to the purpose for which it is used.

Most samples of superphosphate contain little or no ammonia, or nitrogenised organic matters.

Blood-manure is a superphosphate, in the preparation of which some blood is used.

In preparing superphosphate from bones, it is essential that they should be reduced to fine dust. This is moistened with about $\frac{1}{3}$ its weight of water, after which another third to one half of brown sulphuric acid is added. The pasty mass is allowed to cool, in the mixing vessel, or when large quantities are prepared, the semi-liquid mass in the mixer is run out still hot, fresh quantities of bone-dust, water, and acid are put in the mixer, and after 5 or 10 minutes the contents allowed to run out, and a fresh quantity prepared as before. The successive mixings are all kept together in one heap for 1 or 2 months; the heap is then turned over, and if necessary, the partially-dissolved bones are passed through a riddle.

In a similar manner, coprolites, bone-ash, apatite and other phosphatic minerals are treated with acid. It ought to be observed, however, that the quantity of brown sulphuric acid necessary for dissolving coprolites must be at least $\frac{3}{4}$ths of the weight of coprolite powder, for coprolites contain much carbonate of lime, which neutralises sulphuric acid. Even 75 per cent. of brown acid are not always sufficient to dissolve completely coprolite powder, and as the proportion of carbonate of lime in coprolites and phosphatic minerals varies considerably, it cannot be stated definitely what amount of oil of vitriol should be used in every case. The safest plan, therefore, for the manufacturer is, to ascertain from time to time whether the proportion of acid which he has used has converted nearly the whole of the insoluble phosphates in coprolites into soluble phosphates, and if necessary to add more acid. In the case of bone-dust, it does not matter if the whole of the bone-earth is not rendered soluble; bones even partially acted upon by oil of vitriol, become sufficiently soluble in the soil to prove efficacious for the turnip crop. But the case is different, if mineral phosphates, such as apatite or coprolite powder, are employed in the manufacture of superphosphate. Insoluble phosphates in the shape of coprolite powder are not worth anything in an artificial manure, for they are too insoluble to be taken up by the turnip crop. It is therefore essential to employ a quantity of acid, which is amply sufficient to convert the whole of the insoluble phosphate of lime in coprolites into soluble, or biphosphate of lime.—A. V. See Apatite; Coprolites; Phosphates.

We exported, in 1873, artificial manures to the value of 671,550*l.*

MAPLE, or *Plane.* (*Érable,* Fr.; *Ahorn,* Ger.) *Acer campestre,* the English or field maple. The wood of this tree is compact and finely veined; it is used in France and other parts of the Continent for furniture, and it makes excellent charcoal.

Acer platanoides. The Norway maple. This wood is soft, but being finely grained is capable of receiving a good polish, and looks well.

Acer pseudo-platanus. Sycamore, great maple, or false plane. The wood is of a compact grain, and does not warp or become worm-eaten.

Acer saccharum. Sugar maple. This tree is extensively cultivated in America for the sugar which is extracted from it. The wood is frequently used for furniture, having a silky lustre when polished.

Acer striatum. Striped barked maple. This tree is grown in America, and as the wood is finely grained and white, it is much used as a substitute for holly by furniture-makers.

The Russian maple is thought to be the wood of a birch-tree. It differs in many respects from the American maple, but is sometimes used as a substitute for it.

The bird's-eye maple is the American variety, the best being obtained from Prince Edward's Island. The mottled maple is a commoner variety.

MARBLE. This title embraces such of the primary, transition, and purer compact limestones of the secondary formation, as may be quarried in solid blocks without fissures, and are susceptible of a fine polished surface. The finer the white, the more beautifully variegated the colours of the stone, the more valuable, *cæteris paribus*, is the marble. Its general characters are the following:—

Marble effervesces with acids; affords quicklime by calcination; has a conchoïdal scaly fracture; is translucent only on the very edges; is easily scratched by the knife; has a spec. grav. of 2·7; admits of being sawn into slabs; and receives a brilliant polish. These qualities occur united in only three principal varieties of limestone: 1, in the saccharoid limestone, so called from its fine granular texture resembling that of loaf-sugar, and which constitutes modern statuary marble, like that of Carrara; 2, in the foliated limestone, consisting of a multitude of small facets formed of little crystalline plates applied to one another in every possible direction, constituting the antique statuary marble, like that of Paros; 3, in many of the Devonian and Carboniferous, or *encrinitic* limestones, which occur below the coal formation.

The saccharoid and lamellar, or statuary marbles, belong entirely to metamorphic districts. The greater part of the close-grained coloured marbles belong also to the same geological localities; and become so rare in the more recent limestone formations, that immense tracts of these occur without a single bed sufficiently entire and compact to constitute a workable marble. The limestone lying between the Great Oolite and the Cornbrash of the lower oolite, and which is called 'Forest marble' in England, being susceptible of a tolerable polish, and variegated with imbedded shells, has sometimes been worked into ornamental slabs in Oxfordshire, where it occurs in the neighbourhood of Wychwood forest; but this case can hardly be considered as an exception to the general rule. Even higher in the geological series, marbles may occasionally be worked; thus the Purbeck and Wealden series yield shelly bands of freshwater limestone, which, under the names of Purbeck marble, Sussex marble, &c., have been largely used for the clustered shafts in Gothic architecture.

To constitute a profitable marble-quarry, there must be a large extent of homogeneous limestone, and a facility of transporting the blocks after they are dug. On examining these natural advantages of the beds of Carrara marble, we may readily understand how the statuary marbles discovered in the Pyrenees, Savoy, Corsica, &c. have never been able to come into competition with it in the market. In fact, the two sides of the valley of Carrara may be regarded as mountains of statuary marble of the finest quality.

The various tints of ornamental marbles generally proceed from oxides of iron; but the blue and green tints are sometimes caused by minute particles of hornblende, as in the slate-blue variety called Turchino, and in some green marbles of Germany. The black marbles are coloured by carbon, mixed occasionally with sulphur and bitumen; when they constitute 'stinkstone.'

Brard divides marbles, according to their localities, into classes, each of which contains eight subdivisions:—

1. Uni-coloured marbles; including only the white and the black.
2. Variegated marbles; those with irregular spots or veins.
3. Madreporic marbles, presenting animal remains in the shape of white or grey spots, with regularly disposed dots and stars in the centre.
4. Shell marbles; with only a few shells interspersed in the calcareous base.
5. Lumachella marbles, entirely composed of shells.
6. Cipolin marbles, containing veins of greenish talc.
7. Breccia marbles, formed of a number of angular fragments of different marbles, united by a common cement.
8. Pudding-stone marbles; a conglomerate of rounded pieces.

Antique marbles.—The most remarkable of these are the following:—*Parian marble*, called *Lychnites* by the ancients, because its quarries were worked by lamps; it has a yellowish-white colour, and a texture composed of fine crystalline facets, lying in all directions. The celebrated Arundelian marbles at Oxford consist of Parian marble, as does also the Medicean Venus. *Pentelic marble*, from Mount Penteles, near Athens, resembles the Parian; but is somewhat denser and finer grained, with occasional greenish zones produced by greenish talc, whence it is called by the Italians *Cipilino statuario.* The Parthenon, Propylæum, the Hippodrome, and other principal monuments of Athens, were of Pentelic marble; of which fine specimens may be seen among the Elgin collection, in the British Museum. *Marmo Greco*, or Greek white marble, is of a very lively snow-white colour, rather harder than the preceding, and susceptible of a very fine polish. It was obtained from several islands of the Archipelago, as Scio, Samos, Lesbos, &c. *Translucent white marble, Marmo statuario* of the Italians, is very much like the Parian, only not so opaque. Columns and altars of this marble exist in Venice, and several towns of Lombardy; but the quarries are quite unknown. *Flexible white marble*, of which five or six tables are preserved in the house of Prince Borghese, at Rome. The *White marble of Luni*, on the coast of Tuscany, was preferred by the Greek sculptors to both the Parian and Pentelic. *White marble of Carrara*, between Spezzia and Lucca, is of a fine white colour, but often traversed by grey veins, so that it is difficult to procure moderately large pieces free from them. It is not so apt to turn yellow as the Parian marble. This quarry was worked by the ancients, having been opened in the time of Julius Cæsar. Many antique statues remain of this marble. Its two principal quarries at the present day are those of Pianello and Polvazzo. In the centre of its block very limpid rock crystals are sometimes found, which are called 'Carrara diamonds.' As the finest qualities are becoming excessively rare, it has risen in price to about 3 guineas the cubic foot. The *White marble* of Mount Hymettus, in Greece, was not of a very pure white, but inclined a little to grey. The statue of Meleager, in the French Museum, is of this marble.

Black antique marble, the *Nero antico* of the Italians. This is more intensely black than any of our modern marbles; it is extremely scarce, occurring only in sculptured pieces. The *red antique marble, Egyptum* of the ancients, and *Rosso antico* of the Italians, is a beautiful marble of a deep blood-red colour, interspersed with white veins and with very minute white dots, as if strewed over with grains of sand. There is in the Grimani Palace at Venice a colossal statue of Marcus Agrippa in *rosso antico*, which was formerly preserved in the Pantheon at Rome. *Green antique marble, verde antico*, is a kind of breccia, whose paste is a mixture of talc and limestone, while the dark green fragments consist of serpentine. Very beautiful specimens of it are preserved at Parma. The best quality has a grass-green paste, with black spots of noble serpentine, but is never mingled with red spots. *Red spotted green antique marble* has a dark green ground marked with small red and black spots, with fragments of *entrochi* changed into white marble. It is known only in small tablets. *Leek marble*; a rare variety of that colour of which there is a table in the Mint at Paris. *Marmo verde pagliocco* is of a yellowish-green colour, and is found only in the ruins of ancient Rome. *Cervelas marble*, of a deep red, with numerous grey and white veins, is said to be found in Africa, and highly esteemed in commerce. *Yellow antique marble, giallo antico* of the Italians; colour of the yolk of an egg, either uniform or marked with black or deep yellow rings. It is rare, but may be replaced by Sienna marble. *Red and white antique marbles*, found only among the ruins of ancient Rome. *Grand antique*, a breccia marble, containing shells, consists of large fragments of a black marble, traversed by veins or lines of a shining white. There are four columns of it in the Museum at Paris. *Antique Cipolino marble*: Cipolin is a name given to all such marbles as have greenish zones produced by green talc; their fracture is granular and shining, and displays here and there plates of talc. *Purple antique breccia marble* is very variable in the colour and size of its spots. *Antique African breccia* has a black ground, variegated with large fragments of a greyish-white, deep red, or purplish wine colour; and is one of the most beautiful marbles. *Rose-coloured antique breccia* marble is very scarce, occurring only in small tablets. There are various other kinds of ancient breccia, which it would be tedious to particularise.

Modern Marbles.—1. British. Black marble is found at Ashford, Matlock, and Bonsaldale in Derbyshire; and in the south part of Devonshire. The variegated marbles of Devonshire are generally reddish, brownish, and greyish, variously veined with white and yellow, or the colours are often intimately blended; the marbles from Torbay and Babbacombe display a great variety in the mixture of their colours; the Plymouth marble is either ash-coloured with black veins, or blackish-grey and white shaded with black veins; the cliffs near Marychurch exhibit marble quarries not only of great extent, but of superior beauty to any other in Devonshire, being either of a dove-coloured ground with reddish-purple and yellow veins, or of a black ground mottled with purplish globules. The green marble of Anglesea is not unlike the *verde antico*; its colours being greenish-black, leek-green, and sometimes dull purplish irregularly blended with white. The white part is limestone, the green shades proceed from serpentine and asbestos. There are several fine varieties of marble in Derbyshire; the mottled-grey in the neighbourhood of Moneyash, the light-grey being rendered extremely beautiful by the number of purple veins which spread upon its polished surface in elegant irregular branches; but its chief ornament is the multitude of *entrochi* with which this limestone marble abounds. Much of the transition and carboniferous limestone of Wales and Westmoreland is capable of being worked up into agreeable dark marbles.

In Scotland a fine variety of white marble is found in beds at Assynt in Sutherlandshire. A beautiful ash-grey marble, of a very uniform grain, and susceptible of a fine polish, occurs on the north side of the ferry of Ballachulish in Invernessshire. One of the most beautiful varieties is that from the hill of Belephetrich in Tiree, one of the Hebrides. Its colours are pale blood-red, light flesh-red, and reddish-white, with dark-green particles of hornblende, or rather sahlite, diffused through the general base. The compact marble of Iona is of a fine grain, a dull-white colour, somewhat resembling pure compact felspar. It is said by Bournon to consist of an intimate mixture of tremolite and carbonate of lime, sometimes with yellowish or greenish-yellow spots. The carboniferous limestone of many of the coal-basins in the Lowlands of Scotland may be worked into a tolerably good marble for chimney-pieces.

In Ireland the Kilkenny marble is the one best known, having a black ground more or less varied with white marks produced by fossils. The spar which occupies the place of the shells sometimes assumes a greenish-yellow colour. An exceedingly fine black marble has also been raised at Crayleath in the county of Down. At Louthlougher, in the county of Tipperary, a fine purple marble is found. The county of Kerry affords several variegated marbles not unlike the Kilkenny; and a fine reddish marble is quarried in the county Cork. A serpentinous limestone in Connemara forms a prettily variegated green marble known as 'Irish green.'

France possesses a great many marble quarries, which have been described by Brard, and of which a copious extract is given under the article *Marble*, Rees's *Cyclopædia*.

The territory of Genoa furnishes several beautiful varieties of marble, the most remarkable of which is the *polzevera di Genoa*, called in French the *vert d'Egypte* and *vert de mer*. It is a mixture of granular limestone with a talcose and serpentine substance disposed in veins; and it is sometimes mixed with a reddish body. This marble was formerly much employed in Italy, France, and England, for chimney-pieces, but its sombre appearance has put it out of fashion. Among the Genoese marbles we may notice the highly-esteemed variety called *portor*, on account of the brilliant yellow veins in a deep black ground. The most beautiful kind comes from Porto Venese; and Louis XIV. caused a great deal of it to be worked up for the decoration of Versailles. It costs now 2*l.* per cubic foot.

Corsica possesses a good statuary marble, of a fine close grain, and pure milky-whiteness, quarried at Ornofrio; it will bear comparison with that of Carrara: also a grey marble (*bardiglio*), a cipolin, and some other varieties. The island of Elba has immense quarries of a white marble with blackish-green veins.

Among the innumerable varieties of Italian marbles, the following deserve especial notice:—

The *rovigio*, a white marble found at Padua. The white marble of St. Julien, at Pisa, of which the cathedral and celebrated slanting tower are built. The Biancone marble, white with a tinge of grey, quarried at Maguerega for altars and tombs. Near Mergozza a white marble with grey veins is found, with which the cathedral of Milan is built. The black marble of Bergamo is called *paragone*, from its black colour, like touchstone; it has a pure, intense tint, and is susceptible of a fine polish. The pure black marble of Como is also much esteemed. The *polveroso* of Pistoya is a black marble sprinkled with dots; and the beautiful white marble with black spots, from the Lago Maggiore, has been employed for decorating the interior of many churches in the Milanese. The Margorre marble, found in several parts of the Milanese, is bluish veined with brown, and composes part of the dome of the cathedral of Milan. The green marble of Florence owes its colour to a copious admixture of serpentine. Another green marble, called *verde di Prado*, occurs in Tuscany, near the little town of Prado. It is marked with spots of a deeper green than the rest, passing even into blackish-blue. The beautiful Sienna marble, or *brocatello di Siena*, has a yellow colour like the yolk of an egg, which is disposed in large irregular spots, surrounded with veins of bluish-red, passing sometimes into purple. At Montarenti, two leagues from Sienna, another yellow marble is met with, which is traversed by black and purplish-black veins. The Brema marble is yellow, with white spots. The *mandelatò* of the Italians is a light-red marble with yellowish-white spots, found at Luggezzana, in the Veronese. The red marble of Verona is of a red rather inclining to yellow or hyacinth; a second variety, of a dark red, composes the vast amphitheatre of Verona. Another marble is found near Verona, with large white spots in a reddish and greenish paste: very fine columns have been made of it. The *occhio di pavone* is an Italian shell-marble, in which the shells forms large orbicular spots, red, white, and bluish. A madreporic marble, known under the name of *pietra stellaria*, much employed in Italy, is entirely composed of star madrepores, converted into a grey-and-white substance, and is susceptible of an excellent polish. The village of Bretonico, in the Veronese, furnishes a splendid breccia marble, composed of yellow, steel-grey, and rose-coloured spots. That of Bergamo consists of black and grey fragments in a greenish cement. Florence marble, called also ruin and landscape marble, is an indurated calcareous marl.

Sicily abounds in marbles, the most valuable of which is that called by the English stone-cutters Sicilian jasper; it is red, with large stripes like ribands, white, red, and sometimes green, which run zigzag with pretty acute angles.

Of Cutting and Polishing Marble.—The marble-saw is a thin plate of soft iron, continually supplied during its sawing-motion with water and the sharpest sand. The sawing of moderate pieces is performed by hand, but that of large slabs is most economically done by a proper mill.

The first substance used in the polishing process is the sharpest sand, with which the marble must be worked till the surface becomes perfectly flat. Then a second, and even a third sand of increasing fineness is to be applied. The next substance is emery of progressive degrees of fineness, after which tripoli is employed; and the last polish is given with tin-putty. (See PUTTY-POWDER.) The body with which the sand is rubbed into the marble is usually a plate of iron; but for the subsequent process, a plate of lead is used with fine sand and emery. The polishing-rubbers are coarse linen cloths, or bagging, wedged tight into an iron planing-tool. In every step of the operation a constant trickling supply of water is required.

MARCASITE, or white iron pyrites, is of a pale bronze-yellow, or iron-grey colour, with a metallic lustre. It is a bisulphide of iron, composed of iron 46·7, sulphur 63·3. Specific gravity 4·678 to 4·847.

The mineral was formerly much used for various ornaments, as shoe- and knee-buckles, pins, bracelets, setting of watch-cases, &c.; and, although the taste for it has considerably declined now, probably owing in some degree to its abundance, immense quantities are still cut and manufactured at Geneva and in the French Jura.

The marcasite of commerce is generally small, rarely attaining the size of a stone of two carats. It takes a good polish, and is cut in facets like rose-diamonds. In this state it possesses all the bright blue of polished steel, without the tendency of the latter to become oxidised by exposure to the action of the atmosphere. It is principally procured from Germany and the Jura.—H. W. B. See PYRITES.

MARCASITE. Bismuth was formerly so called. See BISMUTH.

MARGARATES are saline compounds of margaric acid with the bases.

MARGARIC ACID (*Margarine*) is one of the acid fats produced by saponifying tallow with alkaline matter, and decomposing the soap with dilute acid. The term *margaric* signifies pearly-looking.

The physical properties of the margaric and stearic acids are very similar; the chief difference is that the former is more fusible, melting at 140° Fahr. The readiest mode of obtaining pure margaric acid is to dissolve olive-oil soap in water, to pour into the solution a solution of neutral acetate of lead, to wash and dry the precipitate, and then to remove its oleate of lead by ether, which does not affect its margarate of lead. The residuum being decomposed by boiling-hot muriatic acid, affords margaric acid. When heated in a retort this acid boils. It is insoluble in water, very soluble in alcohol and ether; it reddens litmus-paper, and decomposes, with the aid of heat, the carbonates of soda and potash.

Margaric acid is obtained most easily by the distillation of stearic acid. The humidity at the beginning of the process must be expelled by a smart heat, otherwise explosive ebullitions are apt to occur. Whenever the ebullition becomes uniform, the fire is to be moderated. See OILS.

MARINA. A name given to madder after it has undergone a peculiar treatment. See Crookes's 'Handbook of Dyeing.'

MARINE ACID. Hydrochloric acid was formerly so called because it could be obtained from sea-water. See HYDROCHLORIC ACID and MURIATIC ACID.

MARINE METAL. A name for Wetterstedt's alloy, which was introduced as a sheathing for ships. It consisted of lead 94·4, antimony 4·3, and mercury 1·3. It was said not to be attacked by sea-water, and to remain free from vegetable or animal growth.

MARINE SALT. See SALT.

MARJORAM. The *Origanum majorana*, one of the *Labiatæ*, is used as an aromatic herb, and yields *oil of marjoram* on distillation.

MARL (*Marne*, Fr.; *Mergel*, Ger.) is a mixed earthy substance, consisting of carbonate of lime, clay, and siliceous sand, in very variable proportions; it is sometimes compact, sometimes pulverulent. According to the predominance of one or other of these ingredients, marls are distributed into calcareous, clayey, and sandy.

MARLSTONE. One of the members of the Lias formation. The Cleveland iron ore occurs in the marlstone, or middle lias. See LIAS.

MARMATITE. A variety of blende, in which part of the zinc is replaced, sometimes by iron, and sometimes by cadmium. It is found at Marmato in Popayan.

MAROON. A peculiar deep-red colour produced, according to Crookes ('Handbook of Dyeing') in the following manner:—

Boil 20 lbs. of cudbear, or 25 lbs. of orchil, and 4 ounces of magenta crystals, for ten minutes. Cool the dye to 175° Fahr.; enter the wool; increase the temperature to 212°; remove, rinse, and dry.

MAROOL. A vegetable fibre from the *Sanseviera Zeylanica.* See FIBRES.

MARQUETRY is a peculiar kind of cabinet-work, in which the surface of wood is ornamented with inlaid pieces of various colours and forms. The *marqueteur* puts gold, silver, copper, tortoise-shell, mother-of-pearl, ivory, horn, &c., under contribution. These substances, being reduced to laminæ of proper thinness, are cut out into the desired form by punches, which produce the full pattern or mould, and the empty one, which enclosed it; and both serve their separate purposes. A mosaic wood-work was much practised in Italy in the fifteenth century which very much resembled marquetry. It was called Tarsia (*Tarsiatura*, Ital.). The art was cultivated to the greatest extent in the Venetian territories, and was much employed in decorating the choirs of churches, the backs of seats, and the panels of doors. In Mrs. Merrifield's 'Ancient Practice of Painting' it is well described. See TARSIA; PARQUETRY.

MARSH-GAS. Light carburetted hydrogen. This gas is the fire-damp of the coal-miner. See FIRE-DAMP INDICATOR; VENTILATION.

MARSH ROSEMARY. (*Statica Carolinianæ.*) This plant is found along the sea-coast in marshy situations from Maine to Florida. The root has been used for tanning. According to Professor Parrish, it contains 12 per cent. of tannin.

MARTIAL. Belonging to iron; from Mars, the old name of this metal.

MARTIUS-YELLOW. A name sometimes applied to naphthaline yellow.

MASSICOT. Yellow oxide of lead. The old name of litharge. See LITHARGE.

MASTIC (Eng. and Fr.; *Matsix*, Ger.) is a resin produced by making incisions in the *Pistacia lentiscus*, a tree cultivated in the Levant, and chiefly in the island of Chios. It comes to us in yellow, brittle, transparent, rounded tears; which soften between the teeth, with bitterish taste and aromatic smell, and a specific gravity of 07·1. Mastic consists of two resins; one soluble in dilute alcohol. Its solution in spirit of wine constitutes a good varnish. It dissolves also in turpentine. See VARNISH.

MASTIC CEMENT. A mixture of lime, sand, litharge, and linseed-oil.

MATCHES. See LUCIFER MATCHES.

MATRASS is a bottle with a thin, egg-shaped bottom, much used for digestions in chemical researches.

MATTE is a crude black copper, reduced, but not refined, from sulphur and other heterogeneous substances. A matte is simply a regulus, or fused sulphide.

MAUVE, or *Perkin's Violet.* The earliest aniline colour introduced into commerce has lost much of its importance. Kunge had previously called attention to the violet coloration produced on treating aniline with chromic acid or the hypochlorites. In August 1856 Mr. Perkin patented his process for the production of a violet colouring-matter from aniline. See ANILINE-VIOLET.

Among the very large number of new methods proposed for the manufacture of this dye, especially after the spring of the year 1859, we may notice the following:—

Messrs. Depouilly and South's method, patented in June 1860, consisted in adding to a salt of aniline a solution of chloride of lime, which yielded a purple insoluble precipitate. This was repeatedly washed in slightly-acidulated water, dissolved in concentrated sulphuric acid, and re-precipitated by the addition of an excesssof water. It was then simply necessary to wash the precipitate thoroughly, in order to render it fit for use if dissolved in alcohol or methylated spirit. The chloride of lime process gives a more abundant yield than the bichromate method, but the tone of the violets obtained is redder and less pure. We may here mention that Mr. W. H. Perkin has lately succeeded in obtaining the product of Runge's experiment in the solid condition. He finds that it dissolves in alcohol, forming a solution of a nearly pure blue colour, which is changed to a brownish-red by the action of caustic alkali; it therefore differs essentially from the mauve; an alcoholic solution of which, if treated with caustic alkali, passes from purple to violet. The blue product, which the author proposes to call 'Runge's blue,' undergoes a very remarkable change when subjected to the action of heat. It is rapidly converted into a purple colouring-matter, which is found to be the true mauve. Indeed, Runge's blue is so prone to change into the more stable mauve, that its composition cannot be satisfactorily determined.

Mr. Kay, in January 1860, took out a patent for producing purple-aniline—most absurdly called 'harmaline'—by adding to sulphate of aniline peroxide of manganese, and heating this mixture to 100° Fahr., when the 'harmaline' so produced remained in solution, and was separated from an insoluble deposit. The dissolved colour was precipitated by adding to the solution ammonia in sufficient quantity to neutralise the acid, after which the insoluble colour was washed, dried, and dissolved in methylated alcohol.

In January 1860 Mr. Greville Williams patented the use of permanganate of potassa as a means of oxidising aniline and producing purples and other colours.

At about the same time Dr. D. Price took out a patent for acting on sulphate of aniline by means of the peroxide of lead.

In 1860 Dale and Caro patented the use of chloride of copper, in the proportion of six equivalents to one of a neutral salt of aniline. In place of chloride of copper, a mixture of sulphate of copper and common salt may be used in equivalent proportions. The quantity of water necessary to dissolve the mixture is added, and the whole is then boiled till a precipitate appears, which contains the colouring-matter. At the expiration of three or four hours the process is completed. The precipitate is collected on a filter, and washed with a solution of soda or carbonate of soda so long as the washings contain chlorides. The residue is then extracted with boiling water, so long as anything dissolves. The solutions thus obtained are filtered, and precipitated with a small quantity of soda or carbonate of soda. The colour thus obtained is ready for use. The matter insoluble in boiling water still contains a violet, which may be extracted by treatment with boiling dilute alcohol in a displacement-apparatus.

On January 12, 1861, another interesting process to obtain aniline-purple was patented by M. A. Girard. Pure aniline-red (known as magenta) is mixed with an equal weight of aniline, and the mixture heated for several hours to 329° Fahr., when the mass is changed to a fine purple colour, requiring only to be mixed with water and hydrochloric acid to remove any aniline or red dye in excess, leaving the purple insoluble; but, on being well washed with water, this becomes soluble in alcohol, acetic acid, wood-naphtha, and boiling water slightly acidulated with acetic acid.

The French call this—*Violet Impérial*. See ANILINE.

MAZÉAGE. The French name for a process identical with our Refinery.

MEADOW-ORE is bog-iron ore. See IRON.

MEASURES, WEIGHTS, and **COINS.** See WEIGHTS AND MEASURES.

MEATS, PRESERVED. The interest which has of late attached to the subject of such meats warrants us in bringing under examination the principles and practice on which this important branch of industry is based. The art itself is of modern invention, and differs in every respect from the old or common modes of preserving animal food. These, as is well known, depend upon the use of culinary salt, saltpetre, sugar, or similar substances.

Our remarks will not apply solely to raw or uncooked meats; but the practical bearing of meat-preserving really points to those which are, more or less, cooked or preserved.

The first successful attempt at the preservation of unsalted meats is of French origin, and due to the inventive skill of M. Appert. This gentleman, so long ago as the year 1810, received from the Board of Arts and Manufactures of Paris the sum of 12,000 francs for his discovery of a mode of preserving animal and vegetable substances; the results of which had been then amply attested by a prolonged experience in the French navy. Shortly after this period Appert induced a Mr. Durant to visit London, for the purpose of taking out a patent; and this was accordingly done towards the end of the year 1811. In this patent, however, the claims were ridiculously wide; so much so, that the patent-right was subsequently infringed with impunity. The claims included all kinds of fruit, meat, and vegetables, when subjected to the action of heat in closed vessels, more or less freed from air. As, however, the Society of Arts in London had presented in 1807 a premium to a Mr. J. Suddington, for 'a method of preserving fruit without sugar for house or sea stores'—which method is exactly the same as that of M. Appert—the validity of Durant's patent was at once called in question. Nevertheless, so satisfactory were the results when applied to animal food, or mixed provisions, that the patent was eventually purchased from Durant by Messrs. Donkin, Hall, and Gamble; and the firm, thus established, became at once the sole manufacturers of preserved meats in this country. The process of Appert was, however, extremely defective in a manufacturing point of view. Nothing but glass bottles were to be used for containing the meats, and M. Appert remarks: 'I choose glass for this purpose, as being the most impenetrable to air, and have not ventured to make any experiment with a vessel made of any other substance.' Of course the fragility of this material, and the great difficulty of hermetically sealing the bottles with corks, threw impediments in the way of the process as a commercial undertaking. Nor was it until after a long series of experiments that Messrs. Donkin, Hall, and Gamble were able to overcome the primary difficulties of this invention, and produce provisions successfully preserved in tin-plate vessels.

The process of Appert certainly does not depend upon the exclusion of oxygen from the provisions he preserved, nor is this principle included in the improved process still practised by the firm of Gamble. Appert seems to have had a doubt as to the sufficiency of the oxygen theory, for he tells us that, 'fire has a peculiar property, not only of changing the combination of the constituent parts of vegetable and animal productions, but also of retarding, for many years at least, if not of destroying altogether, the natural tendency of these same products to decomposition.' And this opinion is confirmed from many startling facts, which cannot be reconciled to the supposition that oxygen is the sole or even principal agent of decomposition. Thus milk, which has been merely scalded, will keep much longer from the effects of this process, even though freely exposed to, or purposely impregnated with, oxygen gas. Now the method of Appert, as improved by Gamble, is to render the albumen of the meat or the vegetable insoluble, and therefore scarcely if at all, susceptible of the action of atmospheric oxygen. By this means the total exclusion of air from the tin cases is rendered unnecessary, for even if a small quantity of air remain in the case, it will exert no more influence than happens to a piece of coagulated albumen, or hard boiled white-of-egg, which, as is well known, may be exposed to the air for years without sensible alteration, though in its uncoagulated state it immediately putrefies. It appears, therefore, that the essential characteristics of Gamble's process may be referred not to the exclusion of air, but to the thorough coagulation of the albumen. The heat employed also destroys all organic germs that may be present, and thus prevents their development. In this process, the meat, more or less cooked, is placed, with a quantity of gravy, in a tin vessel, capable of being hermetically sealed with solder; it is then heated, for some time, in a bath of muriate of lime, and the aperture neatly soldered up. After this it is again exposed to the action of the heated bath for a period, which varies with the size and nature of the contents of the vessels; and to prove that this latter operation is really the most important of the whole, it sometimes happens that cases which have begun to decompose are opened, resoldered, and again submitted to the muriate-of-lime bath, with the most perfect success, as regards the ultimate result.

Although by no means free from occasional failures and certainly requiring improvement, the system of Gamble has in practice worked well; and provisions have been kept in this way, for a long period of years, without the slightest alteration in their particular qualities.

Mr. Goldner, some few years ago, adopted the idea originally conceived by Sir Humphry Davy, of enclosing cooked provisions in a complete vacuum. For this purpose the provisions, slightly cooked on the surface, were enclosed in canisters, similar to those of Gamble, but stronger, and provided with a small opening in the cover. At this moment a slight condensation was effected by the application of a cold and damp rag or sponge, and simultaneously with this the small opening was soldered up. In theory, nothing could seem better adapted to insure success; but, the practical working of the invention afforded anything but a satisfactory result. Nor is there much difficulty in conceiving how this may arise, as in the first place the application of a sudden heat to non-conducting materials, is almost certain to give rise to that peculiar condition by which the interior of the meat will be as thoroughly protected from the effect of heat as if no heat were applied. Hence, even though steam in abundance may issue from the small opening in the cover, this is no proof that the meat in the centre of the vessel is even warmed; and still less does it warrent the supposition that the soluble albumen is thoroughly coagulated; and without which, as we have stated, preservation is scarcely possible.

Redwood's Process.—This process, invented by Professor Redwood, consists in the immersion of fresh meat in melted paraffin, at a temperature of 240° Fahr. (115° Centigrade), for a sufficient time to effect a concentration of the juices of the meat and the complete expulsion of air; after which the meat, in its condensed state, is covered with an external coating of paraffin, by which air is excluded and decomposition prevented.

The concentration of the juices may thus be carried to any required extent. If the meat is to be kept in hot climates its weight should be reduced by evaporation to about one-half, in which state it will contain all the nutriment of twice its weight of fresh meat, the portion driven off by evaporation consisting only of water. Thus prepared it will be fully cooked (by the heat applied in the process), and it may be eaten without further preparation, but it will also be applicable for the preparation of a variety of made-dishes, including stews, hashes, soups, gravies, etc. For cold climates a less amount of heating and concentration will suffice, so that the meat may retain its original juicy condition, and, when further cooked, present the appearance, and possess all the characters, of fresh unpreserved meat.

The paraffin used in the process is a perfectly innocuous substance; it is entirely free from taste and smell, and is not subject to change from keeping. It may be removed from the surface of the meat by putting the latter into a vessel containing boiling water, when the paraffin as it melts will rise to the surface of the water, and may be taken off in a solid cake when cold, while at the same time the meat will become softened and prepared for cooking in any suitable way.

Messrs. Gillon stated from long experience that if the meat could be kept in a hot room at a temperature of about 100° Fahr. for eight or ten days without change, it would keep for lengthened periods in any climate, and they are accustomed to submit their preserved provisions to this method of testing before sending them out. It was found, however, that although meat preserved by Prof. Redwood's process would keep for a year or more in the temperate zone, it soon became rancid in tropical regions.

Mr. Richard Jones, in the Society of Arts' "Journal" for January 20, 1872, describes a process carried out by him. He states that the tins are filled with the raw material and placed in a bath, either of boiling water or of chloride of calcium. Before being immersed in the liquid, they are attached, by means of a tube soldered to the cover, and joined to a pipe communicating with a vacuum chamber. On the tins being attached and the tap opened, all the air from the tins is drawn into it. They are then immersed in the liquid at a low temperature, which is gradually raised, if chloride of calcium is used, to 270° Fahr., and the meat is exposed to this heat for a period varying from one to two hours.

Numerous other processes have been employed, many of them partaking in some respects of the characters of one or the other of those described. It cannot, however, be said that any of them have been entirely successful. The chemical processes in all cases impart some peculiar flavour to the meat; and the meat preserved by cooking or partially cooking it in tins, was not palatable, being in most cases softened in the process. The preservation of fish and vegetables has been carried out far more efficiently.

MEDALS. A piece of metal, usually of gold, silver, or bronze, impressed as coins are, but not intended to serve the same purposes as coins. They are made to celebrate some great event in the history of a people, or to perpetuate the memory of some one who has in some way rendered himself illustrious, or they may be for the purpose of giving distinction to men. The ancients, who produced many excellent examples of the medallist's art, struck their medals with a hammer; the moderns now use the coining press. Upon the medals produced in modern times the engraver's art has been bestowed, and some of them are very beautiful. The late Mr. Wyon, of the Royal Mint, produced during his life-time many medals, which may be regarded as superior examples of the medallist's art. Medalets are small medals, often used in Catholic countries, impressed with figures of the saints. Medallions were a larger kind of medals, struck as gifts by the Roman emperors. The process of producing a medal is as follows:—

A metal die is first formed; steel of an uniform texture and kind being selected, it is forged, softened by annealing, and the face and check for the collar turned. The design engraved at, the die-sinker proceeds to cut away those parts of the greatest depth by means of small chisels; the more minute details are taken out by gravers, round-edged, and pointed steel tools fitted into wood handles very short, and to fit the palm of the hand. As the work proceeds, proofs are taken in wax; when deficient in form, the cutting is corrected, and when deficient in relief, it is sunk deeper. It will of course be borne in mind that what will be relievo in the medal is intaglio in the die. The inscription is introduced by means of small letter-punches. Then follows the hardening of the die, a stage of the business the most critical, as a defect in the steel will at once be made apparent thereby, and the labour of months rendered useless in a few minutes. If the die endures this, it has only another test, viz., the making of a "hub," or copy of the die in steel, and used for the correction of the duplicate copies of the die. The danger in this case arises from the want of uniformity of hardness. If irregular, the portions of the die most softer, and become valueless.

Medal-making or stamping is thus carried on:—The press consists of a large and three-threaded screw, to the top of which a large wheel is attached horizontally. The bed of the press is fitted with screws to secure the die in its place; when this is done the collar which gives the thickness of the medal is fitted on, then the die forming the reverse of the medal is attached to the screw, and a blank (a piece of metal cut out to form the medal) is then introduced. Motion is imparted to the wheel, which operates on the screw; a blow is given, and if the impression is soft and shallow, a medal is produced; but if deep, repeated blows are given to bring the impression up. When bronze or silver is the material of which the medal is to be produced, as many as 20 or even 30 blows are necessary. The medal is then taken out of the press, the edge turned, and the operation is complete.

By 'collar die,' is meant that portion which gives the thickness to the medal or coin in its strength. All medal-dies are of three parts, viz., the obverse, reverse, and collar. The smaller class of dies are cut in steel entirely; the larger kinds for brass-founding and other purposes are 'laid' or covered with steel on a foundation of iron. When indentations occur, the die is what is called 'followed' or hollowed, and the steel follows the same in a parallel thickness. See MINT.

MEEKRAP. The Dutch commercial name for Madder-root. See MADDER.

MEERSCHAUM (Ger.; Sea-froth, Eng.; Écume de Mer, Magnésie carbonatée silicifère, Fr.) is a white mineral, of a somewhat earthy appearance; always soft, but dry to the touch, and adhering to the tongue. Specific gravity, [illegible] to [illegible]; when moist, nearly [illegible]; affords water by calcination; fuses with difficulty before the blowpipe into a white enamel; and is acted upon by acids. It consists, when pure, of silica, [illegible]; magnesia, [illegible]; water, [illegible]. An analysis by Berthier gave silica 50, magnesia 25, water 25. It occurs in veins or kidney-shaped nodules, among rocks of serpentine, chiefly at Eskishehr in Asia Minor; also in the island of Negropont, Hrubschitz in Moravia, Brussa at the foot of Mount Olympus, at Baldissero in Piedmont, &c.

When first dug up, it is soft, and lathers like soap; on which account, and from its absorbing grease, it is used by the Tartars in washing their linen. The well-known Turkey tobacco-pipes are carved from it. The bowls of the pipes, when imported into Germany, are prepared for sale by soaking them first in tallow, then in wax, and finally by polishing them with shave-grass.

'The most extensive deposits of meerschaum in Asia Minor (or Lületasch—the Pipe-stone—of the Turks), is a short way S.E. from the town of Eskishehr, the ancient Dorylæum, the population of which, about 12,000 Armenians and Turks, is mostly engaged in the working and sale of it. It is brought from the galleries of pits 8 to 30 metres in depth. In one quarter with 40 to 50 miners; and these, forming a society, share the profits from the mineral. The size of the stones, which are generally very irregular, varies from that of a nut to a cubic foot or more. The mineral, fresh from the ground, is covered about a finger thick with red clay earth, and is so soft that one can cut it with a knife. Its preparation is slow and troublesome. After removal of the earth, it is dried 5 to 6 days in the sun or 8 to 10 in a hot chamber; then it is cleaned again and polished with wax. Then the different kinds, of which there are ten, are sorted and carefully packed with wool in boxes. By cleaning and drying, the stones lose about two-thirds of their weight and volume. The largest quantities are sent to Austria (Vienna) and Germany, and the annual export is about 8,000 to 10,000 boxes, representing a value of 1,200,000 francs. The Turkish Government imposes a tax of 12½ per cent. at the place of excavation of the raw material, and a further tax of 12½ per cent. on the sale.'

MELAMINE ([illegible]). An alkali produced from melam under the influence of boiling potash. It is isomeric with cyanamide, from which it may be produced by the action of heat. Melam is obtained by the distillation of sulphocyanide of ammonium.

MELLITE. (Eng. and Fr.; Honigstein, Ger.) See HONEYSTONE.

MELLITIC ACID, which is associated with alumina in the preceding mineral, crystallises in small colourless needles, is without smell, of a strongly acid taste, permanent in the air, soluble in water and alcohol, unaltered on boiling with concentrated sulphuric acid, but is decomposed by hot nitric acid, and consists of [illegible] carbon, and [illegible] oxygen. It is carbonised at a red heat, without the production of any inflammable oil. See WATTS's 'Dictionary of Chemistry.'

MELLONE (Syn. Mellon) is a compound of carbon and nitrogen, discovered by M. Liebig, by heating bi-sulpho-cyanide of mercury. The mellone remains at the bottom of the retort under the form of a yellow powder. See WATTS's 'Dictionary of Chemistry.'

MELTING POTS, or Crucibles. The best crucibles are formed from a pure fire-clay, mixed with finely-ground cement of old crucibles and a portion of black lead or graphite. Some pounded coke may be mixed with the plumbago. The clay should be prepared in a similar way as for making pottery ware; the vessels, after being formed, must be slowly dried, and then properly baked in the kiln. Crucibles formed of a mixture of 8 parts in bulk of Stourbridge clay and cement, 5 of coke, and 4 of graphite, have been found to stand 30 meltings of 70 pounds of iron each, in the Royal Berlin Foundry. Such crucibles resisted the greatest possible heat that could be produced, in which even wrought iron was melted, equal to 150° or 155° Wedgwood, and bore sudden cooling without cracking.

Another composition for brass-founding crucibles is the following:—2 Stourbridge clay; $\frac{1}{4}$ burned-clay cement; $\frac{1}{8}$ coke-powder; $\frac{1}{8}$ pipe-clay. The pasty mass must be compressed in moulds. The Hessian crucibles from Great Almerode and Epterode are made from a fire-clay which contains a little iron, but no lime; it is incorporated with siliceous sand. The dough is compressed in a mould, dried and strongly kilned. They stand saline and leaden fluxes in assaying operations very well; are rather porous on account of the coarseness of the sand, but are thereby less apt to crack from sudden heating or cooling. They melt under the fusing-point of bar-iron. Beaufay in Paris has lately succeeded in making a tolerable imitation of the Hessian crucibles with a fire-clay found near Namur in the Ardennes.

Berthier has published the following elaborate analyses of several kinds of crucibles:—

	Hessian	Beaufay	English for cast steel	St. Etienne for cast steel	Glass-pots at Nemours	Bohemian glass-pots	Glass-pots of Creusot
Silica . .	70·9	64·6	63·7	65·2	67·4	68·0	68·0

Black-lead crucibles are made of two parts of graphite and one of fire-clay, mixed with water into a paste, pressed in moulds, and well dried, but not baked hard in the

[1] This crucible had been analysed before being baked in the kiln

kiln. They bear a higher heat than the Hessian crucibles, as well as sudden changes of temperature; have a smooth surface, and are therefore preferred by the melters of gold and silver. This compound forms excellent small or portable furnaces.

The crucibles from Passau or Ipser are made from one part plastic clay from Schildorf, and from two to three parts of an impure graphite, which, according to Berthier's analysis, consists of—

Carbon	34
Silica	41
Alumina	15
Oxide of iron	8
Magnesia, water	2
	100

Berthier has examined the crucibles of different districts; his results are as follow:—

	Silica	Alumina	Oxide of iron	Magnesia
Crucibles from Gros Almerode	70·9	24·8	3·8	...
" Paris	64·6	34·4	1·0	...

Glass pots from Nemours	67·4	32·0	0·8	...
" Bohemia	68·0	29·0	2·2	0·5

Mr. Anstey describes his patent process for making crucibles as follows:—Take two parts of fine-ground raw Stourbridge clay, and one part of the hardest gas-coke, previously pulverised, and sifted through a sieve of one-eighth of an inch mesh (if the coke is ground too fine, the pots are very apt to crack). Mix the ingredients together with the proper quantity of water, and tread the mass well. The pot is moulded by hand upon a wooden block, supported on a spindle which turns in a hole in the bench; there is a gauge to regulate the thickness of the melting pot, and a cap of linen or cotton placed wet upon the core before the clay is applied, to prevent the clay from sticking partially to the core, in the taking-off; the cap adheres to the pot only while wet, and may be removed without trouble or hazard when dry. He employs a wooden bat to assist in moulding the pot; when moulded, it is carefully dried at a gentle heat. A pot dried as above, when wanted for use, is first warmed by the fire-side, and is then laid in the furnace with the mouth downwards (the red cokes being previously damped with cold ones in order to lessen the heat); more coke is then thrown in till the pot is covered, and it is now brought gradually to a red heat. The pot is next turned and fixed in a proper position in the surface, without being allowed to cool, and is then charged with cold iron, so that the metal, when melted, shall have its surface a little below the mouth of the pot. The iron is melted in about an hour and a half, and no flux or addition of any kind is made use of. A pot will last for fourteen or even eighteen successive meltings, provided it is not allowed to cool in the intervals; but if it is cool, will probably crack. These pots, it is said, can bear a greater heat than others without softening, and will, consequently, deliver the metal in a more fluid state than the best Birmingham pots will.

The Cornish crucible has been long known, and valued for all assaying purposes. They are prepared in large quantities for the ordinary assays made in the county, and are exported in considerable numbers. The base of these crucibles is the Poole and Stourbridge clay, which is mixed with a certain proportion of sand obtained from St. Agnes, and ground pots.

Dr. Percy has favoured us with his analysis of the Cornish crucible:—

Silica	72·29
Alumina	25·32
Peroxide of iron	1·07
Lime	0·38
Magnesia	trace
Potash.	1·14

MENACCANITE. An ore of *titanium*, found in the bed of a rivulet which flows into the valley of Menaccan in Cornwall.

MERCURY, or *Quicksilver*. This metal is distinguished by its fluidity at common temperatures; its specific gravity = 13·6; its silver-blue lustre; and its extreme mobility. A cold of 39° below zero of Fahrenheit, or −40° Cent., is required for its congelation, in which state its density is increased in the proportion of 10 to 9, or it becomes of specific gravity 15·0. At a temperature of 662° F. it boils and distils off in an elastic vapour of specific gravity 6·976, which, being condensed by cold, forms purirified mercury.

Mercury combines with great readiness with gold, silver, zinc, tin, and bismuth, forming, in certain proportions, fluid solution of these metals. Such mercurial alloys are called *amalgams*. This property is extensively employed in many arts; as in extracting gold and silver from their ores; in gilding, plating, making looking-glasses, &c. (See AMALGAM.) Humboldt estimates at 16,000 quintals, of 100 lbs. each, the quantity of mercury annually employed in the treatment of the ores of the mines of New Spain; three-fourths of which came from European mines.

The mercurial ores belong principally to the following four species:—

1. *Native quicksilver.*—It occurs in most of the mines of the other mercurial ores, in the form of small drops attached to the rocks, or lodged in the crevices of other ores.

2. *Native silver amalgam.*—It has a silver-white colour, and is more or less soft, according to the proportion which the mercury bears to the silver. Its density is sometimes so high as 14. A moderate heat dissipates the mercury, and leaves the silver. Klaproth states its constituents at silver 36, and mercury 64, in 100; but Cordier makes them to be, 27½ silver and 72½ mercury. It occurs crystallised in the cubic system. It has been found in the territory of Deux-Ponts; at Rozenau and Niderstana, in Hungary, in a canton of Tyrol, at Sala in Sweden, at Kolyvan in Siberia, and at Allemont in Dauphiny; in small quantity at Almaden in Spain, and at Idria in Carniola. In the rich silver mines of Arqueros, near Coquimbo, this mineral occurs, having the composition, silver 86·49, mercury 13·51. This is the *arquerite* of Domeyko. By the chemical union of the mercury with the silver, the amalgam, which should by calculation have a specific gravity of only 12·5, acquires that of 14·11. See AMALGAM; ARQUERITE.

3. *Sulphide of Mercury*, commonly called *Cinnabar*, is a red mineral of various shades; burning at the blowpipe with a blue flame, volatilising entirely with the smell of burning sulphur, and giving a quicksilver coating to a plate of copper held in the fumes. Even the powder of cinnabar rubbed on copper whitens it. Its density varies from 6·9 to 10·2. It becomes negatively electrical by friction. Analysed by Klaproth, it was found to consist of mercury 84·5, sulphur 14·75. Its composition, viewed as a bisulphuret of mercury, is, mercury 86·2, sulphur 13·8. Its chief localities are Idria, in Carniola; Almaden, in Spain; and New Almaden, in California. It is found also at Wolfstein, in Rhenish Bavaria; in Saxony, in the Hartz; in Carinthia, Styria, Bohemia, Hungary, and Tuscany; in the Ural and Altai; in China, Japan, Queensland, Mexico, and Peru. See CINNABAR.

A *bituminous sulphide of mercury* appears to be the base of the great exploration of Idria; it is of a dark liver-red hue, and of a slaty texture, with straight or twisted plates. It exists in large masses in the bituminous schists of Idria. M. Berard mentions also the locality of Münster-Appel, in the duchy of Deux-Ponts, where the ore includes impressions of fishes, curiously spotted with cinnabar.

The compact variety of Idria ore seems very complex in composition, according to the following analysis of Klaproth:—Mercury, 81·8; sulphur, 13·75; carbon, 2·3; silica, 0·65; alumina, 0·55; oxide of iron, 0·20; copper, 0·02; water, 0·73; in 100 parts. M. Berard mentions another variety from the Palatinate, which yields a large quantity of bitumen by distillation; and it was present in all the specimens of these ores analysed by Dr. Ure for the German Mines Company. At Idria and Almaden the sulphides are extremely rich in mercury.

4. *Chloride of mercury*, or *Native Calomel*, commonly called *Horn-mercury*. This mineral, which is very rare, occurs in very small crystals of a pearl-grey or greenish-grey colour, or in small nipples which stud, like crystals, the cavities, fissures, or geodes among the ferruginous gangues of the other ores of mercury. It is brittle, and entirely volatile at the blowpipe; characters which distinguish it from horn silver. See CALOMEL.

Ores of mercury are found in rocks of almost every geological age. At Almaden, in Spain, they occur in deposits at the contact of Silurian slates with a metamorphic rock locally called *fraylesca*. At Ripa, in Tuscany, the veins traverse mica-slate. The deposits at Deux-Ponts, or Zweibrücken, in the Palatinate, are said to be in red sandstones of Permian age, and in the *zechstein*, or magnesian limestone. At Idria, in Carniola, the ores are disseminated through shales and black compact limestones of the Jurassic period; and at New Almaden, in California, the rocks containing the cinnabar belong to the Cretaceous period. Cinnabar is now in course of formation in some of the siliceous deposits thrown down from the hot springs of California and Nevada.

The great mines of Idria in Friuli, in the county of Goritz, were discovered in 1497, and the principal ore mined there is the bituminous cinnabar. The workings of this mine have been pushed beyond the depth of 280 yards. The product in quicksilver might easily amount annually to 6,000 metrical quintals = 600 tons British; but, in order to uphold the price of the metal, the Austrian Government has restricted the production to 150 tons. The memorable fire of 1803 was most disastrous to these mines. It was extinguished only by drowning all the underground workings. The sublimed mercury in this catastrophe occasioned diseases and nervous tremblings to more than 900 persons in the neighbourhood.

The mines of Almaden according to Pliny supplied the Greeks with red cinnabar 700 years before the Christian era; and Rome, in his time, annually received 700,000 pounds from the same mines. Since 1827, the Almaden mines have produced 22,000 cwts. of mercury every year, with a corps of 700 miners and 200 smelters; and, indeed, the veins are so extremely rich, that though they have been worked pretty constantly during so many centuries, the mines have hardly reached the depth of 330 yards, or something less than 1,000 feet. The lode actually under exploration is from 14 to 16 yards thick, and it becomes thicker still at the crossing of the veins. The ores yield in their smelting works only 10 per cent. upon an average; but there is no doubt, that nearly one-half of the quicksilver is lost, and dispersed in the air, to the great injury of the workmen's health, in consequence of the barbarous apparatus of aludels employed in its sublimation; an apparatus which has remained without any material change for the better since the days of the Moorish dominion in Spain. M. Le Play, who published, in the *Annales des Mines*, his *Itinéraire* to Almaden, says, that the mercurial contents of the ores are *notablement plus élevées* than the product.

These veins extend all the way from the town of Chillon to Almadenejos. Upon the borders of the streamlet Baldo Alogues, a black slate is also mined which is abundantly impregnated with metallic mercury.

These celebrated mines, near to which lie those of *Las Cuebas* and of *Almadenejos*, after having been the property of the religious knights of *Calatrava*, who had assisted in expelling the Moors, were farmed off to the celebrated Fugger merchants of Augsburg; and afterwards explored on account of the government, from the date of 1645. Their produce was, till very lately, entirely appropriated to the treatment of the gold and silver ores of the New World.

The mines of the Palatinate, situated on the left bank of the Rhine, though they do not approach in richness and importance to those of Idria and Almaden, merit, however, all the attention of the government that farms them out. They are numerous, and varied in geological position. Those of Drey-Königszug, at Potzberg, near Kussel, deserve particular notice. The workings have reached a depth of more than 220 yards; the ore being a sandstone strongly impregnated with sulphuret of mercury. The produce of these mines is estimated at about 30 tons per annum.

There are also in Hungary, Bohemia, and several other parts of Germany, some inconsiderable mines of mercury, the total produce of which is valued at about 30 or 40 tons on an average of several years.

The mines of Huancavelica, in Peru, are the more interesting, as their products are directly employed in treating the ores of gold and silver which abound in that portion of America. These quicksilver mines have been explored since 1570, the actual produce of the explorations being, according to Helms, about the beginning of this century, from 170 to 180 tons per annum.

In 1782 recourse was had by the South American miners to the mercury extracted in the province of Yun-nan, in China.

The mercurial mines of California are thus described by Dr. Tobin:—

'That part of California where I have been residing, and that which I have just visited, consists of three long ranges of trap mountains, with two wide valleys dividing them, the valley of the San Joaquin, and the valley of Santa Clara. Near this last place are the quicksilver mines of New Almaden, where I have been working. The matrix of the cinnabar ore is the same trap of which the mountain ranges are com posed, and as yet only one great deposit of this ore has been found, though *traces* of quicksilver ores have been discovered in other places. The ores are composed solely of sulphuret of mercury (averaging 36 per cent.), red oxide of iron, and silica; and, had the mine been properly worked from the commencement, almost any quantity of ore might be extracted; it now, however, more resembles a gigantic rabbit-warren than a mine. Its greatest depth is about 150 feet, and the weekly extraction of ores varies from 100 to 150 tons. 16 cylinders are at work, producing 1,400 to 1,500 lbs. daily.

Mr. Russell Bartlett, the United States Commissioner on the Mexican and United States Boundary Question, who visited California in 1853, states that the quantity of quicksilver produced annually at New Almaden, exceeds 1,000,000 lbs. During the year 1853 the total exports from San Francisco amounted to 1,350,000 lbs., valued at 683,189 dollars. All this, together with the large amount used in California, was the product of the New Almaden mine in the Santa Clara county, 12 miles from the town of San José, which is 54 miles from the city of San Francisco. The working of the mine was begun in the year 1846–7 by an English company, but for some reasons was not profitable; in 1849–50 it fell into American hands.

The analysis compared with that of the Old Almaden ore furnished the following results to Mr. Bealey ('Quarterly Journal of Chemical Society,' vol. iv.):—

	New Almaden	Old Almaden
Mercury	60·90	37·79
Sulphur	11·29	16·22
Iron	1·23	10·36
Lime	1·40	35·12 silica and alumina.

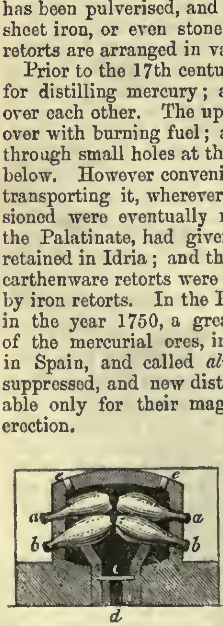
Metallurgy of Quicksilver.—The metallurgic treatment of the quicksilver ores is tolerably simple. In general, when the sulphuret of mercury, the most common ore, has been pulverised, and sometimes washed, it is introduced into retorts of cast iron, sheet iron, or even stoneware, in mixture with an equal weight of quicklime. These retorts are arranged in various ways.

Prior to the 17th century, the method called *per descensum* was the only one in use for distilling mercury; and it was effected by means of two earthen pots adjusted over each other. The upper pot, filled with ore, and closed at the top, was covered over with burning fuel; and the mercurial vapours expelled by the heat, passed down through small holes at the bottom of the pot, to be condensed in another vessel placed below. However convenient this apparatus might be, on account of the facility of transporting it, wherever the ore was found, its inefficiency and the losses it occasioned were eventually recognised. Hence, before 1635, some smelting works of the Palatinate, had given up the method *per descensum*, which was, however, still retained in Idria; and they substituted for it the furnaces called *galleries*. At first earthenware retorts were employed in these furnaces; but they were soon succeeded by iron retorts. In the Palatinate this mode of operating is still in use. At Idria, in the year 1750, a great distillatory apparatus was established for the treatment of the mercurial ores, in imitation of those which previously existed at Almaden, in Spain, and called *aludel-furnaces*. But, since 1794, these aludels have been suppressed, and new distillatory apparatus have been constructed at Idria, remarkable only for their magnitude; exceeding, in this respect, every other metallurgic erection.

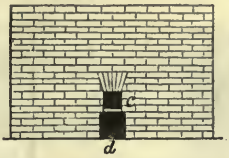


There exist, therefore, three kinds of apparatus for the distillation of mercury: 1, the furnace called a *gallery;* 2, the furnace with *aludels;* and 3, the *large apparatus* of Idria. We shall describe each of these briefly, in succession.

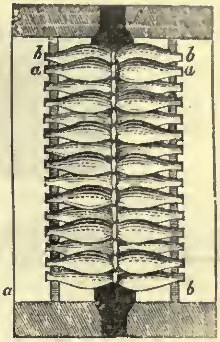
1. *Furnace called Gallery of the Palatinate.*—The construction of this furnace is disposed so as to contain four ranges, *a a'*, *b b'*, of large retorts, styled cucurbits, of cast iron, in which the ore of mercury is subjected to distillation. This arrangement is shown in *fig.* 1432, which presents a vertical section in the line *a b* of the ground plan, *fig.* 1433. In the ground plan, the roof *e e*, of the furnace (*fig.* 1432) is supposed to be lifted off,

in order to show the disposition of the four ranges of cucurbits upon the grate *c f*, *figs.* 1432, 1434, which receives the pit-coal employed as fuel. Under this grate extends an ash-pit. *d*, *fig.* 1434, which exhibits an elevation of the furnace, points out this ash-pit, as well as one of the two doors *c*, by which the fuel is thrown upon the grate *c f*. Openings *c e* (*fig.* 1432) are left over the top arch of the furnace, whereby the draught of air may receive a suitable direction. The grate of the fireplace extends over the whole length of the furnace, *fig.* 1433, from the door *c* to the door *f*, situated at the opposite extremity. The furnace called *gallery* includes commonly 30 cucurbits, and in some establishments even 52. Into each are introduced from 56 to 70 pounds of ore, and 15 to 18 pounds of quicklime, a mixture which fills no more than two-thirds of the cucurbit; to the neck a stoneware receiver is adapted, containing water to half its height. The fire, at first moderate, is eventually pushed, till the cucurbits are red hot. The operation being concluded, the contents of the receivers are poured out into a wooden bowl placed upon a plank above a bucket; the quicksilver falls to the bottom of the bowl, and the water draws over the *black mercury*, for so the substance that coats the inside of the receivers is called. This is considered to be a mixture of sulphide and oxide of mercury. The *black mercury*, taken out of the tub and dried, is distilled anew with excess of lime: after which the residuum in the retorts is thrown away as useless.

1434

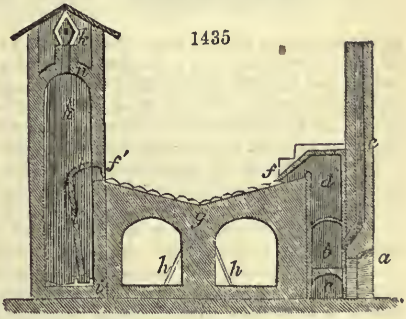


1433

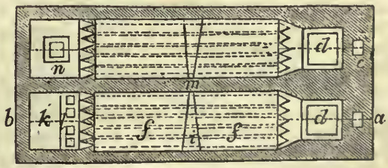


2. *Aludel-furnaces of Almaden.*—*Figs.* 1435 to 1438 represent the great furnaces with aludels in use at Almaden, and anciently in Idria; for between the two establishments there was in fact little difference before the year 1794. *Figs.* 1435 and 1438 present two vertical sections; *figs.* 1436 and 1437 are two plans of two similar furnaces, conjoined in one body of brickwork. In the four figures the following objects are to be remarked: a door *a*, by which the wood is introduced into the fire-place *b*. This is perforated with holes for the passage of air; the ash-pit *c*, is seen beneath. An upper chamber *d*, contains the mercurial ores distributed upon open arches, which form the perforated sole of this chamber. Immediately over these arches, there are piled up in a dome form, large blocks of a limestone, very poor in quicksilver ore; above these are laid blocks of a smaller size, then ores of rather inferior quality, and stamped ores mixed with richer minerals. Lastly, the whole is covered up with soft bricks, formed of clay kneaded with *Schlich*, and with small pieces of sulphide of mercury. Six ranges of aludels or stoneware tubes *f f*, of a pear shape, luted together with clay, are mounted in front of each of the two furnaces on a double sloping terrace, having in its lowest middle line two gutters *t*, *v*, a little inclined towards the intermediate wall *m*. In each range the aludel placed at the line *t m v*, *fig.* 1436, that is to say at the lowest point, *g*, *figs.* 1435, 1438, is pierced with a hole. Thereby the mercury which had been volatilised in *d*, if it be already condensed by the cooling in the series of aludels *f g*, may pass into the corresponding gutter, next into the hole *m*, *fig.* 1436, and after that into the wooden pipes *h h'*, *fig.* 1435, which conduct it across the masonry of the terrace into cisterns filled with water; see *g*, *fig.* 1437, which is the plan of *fig.* 1438.

1435

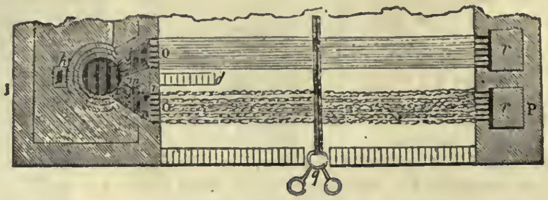


1436



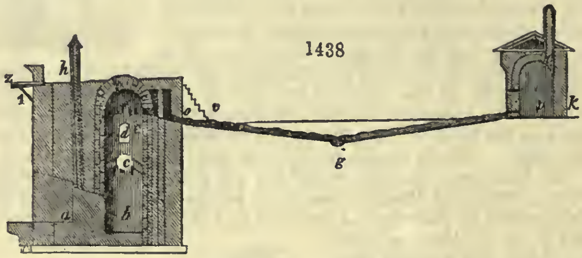
The portion of mercury not condensed in the range of aludels, *f g*, which is the most considerable, goes in the state of vapour into a chamber *k*; but in passing under a partition *l l*, a certain portion is deposited in a cistern *i*, filled with water. The greater

1437



part of the vapours diffused in the chamber *k'* is thereby condensed, and the mercury falls down upon the two inclined planes which form its bottom. What may still exist

1438



as vapour passes into an upper chamber *k'* by a small chimney *n*. On one of the sides of this chamber there is a shutter which may be opened at pleasure from below upwards, and beneath this shutter there is a gutter into which a notable quantity of mercury collects. Much of it is also found condensed in the aludels. These facts prove that this process has inconveniences, which have been tried to be remedied by the more extensive but rather unchemical grand apparatus of Idria.

Details of the Aludel Apparatus.—25 aludels are set in each of the 12 ranges, seen in *figs.* 1437, 1438, constituting 300 pear-shaped stoneware vessels, open at both ends, being merely thrust into one another, and luted with loam. *a*, is the door of the fire-place; *c*, the perforated arches upon which the ore is piled in the chamber *c*, through the door *d*, and an orifice at top; the latter being closed during the distillation; *f f* are vents for conducting the mercurial vapours into two chambers *i*, separated by a triangular body of masonry *m n*; *h* is the smoke-chimney of the fire-place; *o o* are the ranges of aludels, in connection with the chamber *i*, which are laid slantingly towards the gutter *q*, upon the double inclined plane terrace, and terminate in the chamber *h q*; this being surmounted by two chimneys *t*. The mercury is collected in these aludels and in the basins at *q* and *p*, *fig.* 1437. *r* is a thin stone partition set up between the two principal walls of each of the furnaces. *v* is the stair of the aludel terrace leading to the platform which surmounts the furnace; *z* is a gutter for conducting away the rains which may fall upon the buildings, *fig.* 1438.

3. *Great Apparatus of Idria.*—Before entering into details of this laboratory, it will not be useless to state the metallurgic classification of the ores treated in it: 1. The ores in large blocks, fragments, or shivers, whose size varies from a cubic foot to that of a nut. 2. The smaller ores, from the size of a nut to that of grains of dust.

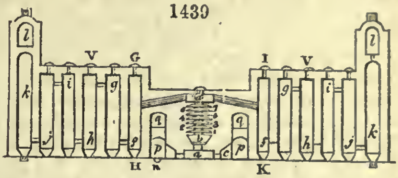
The first class of *large* ores comprises three subdivisions, namely: *a*, blocks of metalliferous rocks, which is the most abundant and poorest species of ore, affording only 1 per cent. of mercury; *b*, the massive sulphide of mercury, the richest and rarest ore, yielding 80 per cent. when it is picked; *c*, the fragments or splinters proceeding from the breaking and sorting, and which vary in value from 1 to 40 per cent.

The second class of small ores comprises: *d*, the fragments or shivers extracted from the mine in the state of little pieces, affording from 10 to 12 per cent.; *e*, the kernels of ore separated on the sieve, yielding 32 per cent.; *f*, the sands and paste called *schlich*, obtained in the treatment of the poorest ores, by means of the stamps and washing tables; 100 parts of this *schlich* give at least 8 of quicksilver.

The general aspect of the apparatus is indicated by *figs.* 1439, 1440, 1441, and 1442.

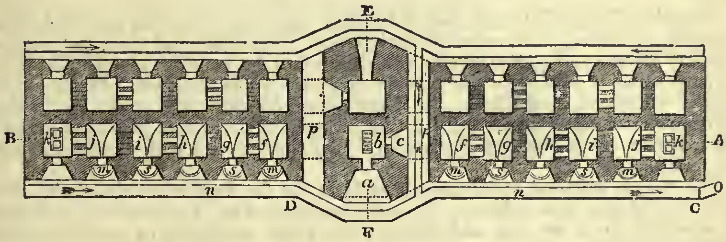
Fig. 1441 represents the exterior, but only one half, which is enough, as it resembles exactly the other, which is not shown. In these three figures the following objects may be distinguished: *figs.* 1439, 1440, *a*, door of the fire-place; *b*, the furnace in which beech-wood is burned mixed with a little fir-wood; *c*, door of the ash-pit, extended beneath; *d*, a space in which the ores are deposited upon the seven arches, 1 to 7, as indicated in *figs.* 1439 and 1442; *e e* brick tunnels, by which the smoke of the fuel and the vapours of mercury pass, on the one side, into successive chambers *f k*.

1439



f g h i j k l are passages which permit the circulation of the vapours from the furnace *a b c d*, to the chimneys *l l*. *Figs.* 1439 and 1440 exhibit clearly the distribution of these openings on each side of the same furnace, and in each half of the apparatus, which is double, as *fig.* 1440 shows; the spaces without letters being in every respect similar to the spaces mentioned below. *Fig.* 1440 is double the scale of *fig.* 1439.

1440



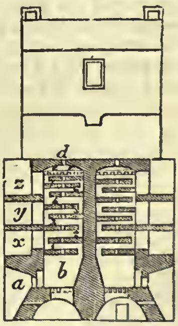
m m', *fig.* 1440, are basins of reception, distributed before the doors of each of the chambers *f k f' k'*. The condensed mercury which flows out of the chambers is conveyed thither. *n n'* is a trench into which the mercury, after being lifted into the basins *m*, is poured, so that it may run towards a common chamber *o*, in the sloping direction indicated by the arrows. *o* leads to the chamber where the mercury is received into a porphyry trough; out of which it is laded and packed up in portions of 50 or 100 lbs. in sheep-skins prepared with alum.

p p', *fig.* 1439, are vaulted arches, through which a circulation may go on round the furnace *a b c d*, on the ground level. *q q'* are the vaults of the upper stories. *r r'*, *fig.* 1441, vaults which permit access to the tunnels *e' e''*, *fig.* 1442.

s s' and *t t'*, *fig.* 1441, are the doors of the chambers *f k* and *f' k'*. These openings are shut during the

1441

1442



distillation by wooden doors faced with iron, and luted with a mortar of clay and lime. *u u'* is the door of the vaults 1 to 7 of the furnace represented in *fig.* 1439. These openings are hermetically shut, like the preceding. *v v*, *fig.* 1439, are superior openings of the chambers, closed during the operation by luted plugs; they are opened afterwards to facilitate the cooling of the apparatus, and to collect the mercurial soot. *x y z*, *fig.* 1442, are floors which correspond to the doors *u u'*, of the vaults 1 to 7, *fig.* 1441. These floors are reached by stairs set up in the different parts of the building which contains the whole apparatus.

On the lower arches the largest blocks of metalliferous rock are laid, over these the less bulky fragments are arranged, which are covered with the shivers and pieces of less dimension. On the middle vaults, the small ore is placed, distributed in cylindrical pipkins of earthenware, of 10 inches diameter and 5 inches depth. The upper vaults receive likewise pipkins filled with the sands and pastes called *schlich.*

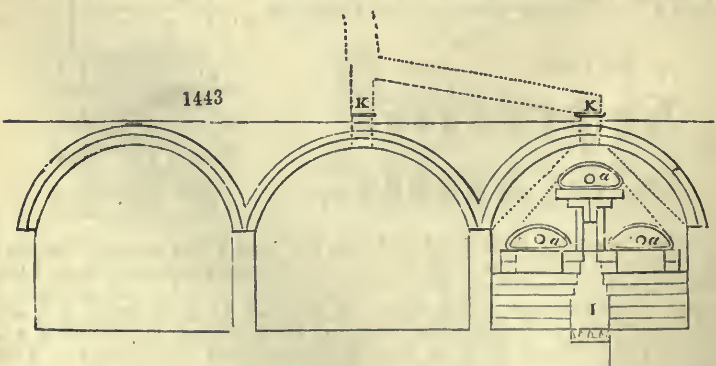
In 3 hours, by the labours of 40 men, the two double sets of apparatus are charged, and all the apertures are closed. A quick fire of beech-wood is then kindled, and when the whole mass has become sufficiently heated, the sulphuret of mercury begins to vaporise; coming into contact with the portion of oxygen which had not been carbonised by combustion, its sulphur burns into sulphurous acid, while the mercury becomes free, passes with the other vapours into the chambers for condensing it, and precipitates in the liquid form at a greater or less distance from the fire-place. The walls of the chambers and the floors, with which their lower portion is covered, are soon coated over with a black mercurial soot, which, being treated anew, furnishes 50 per cent. of mercury. The distillation lasts from 10 to 12 hours; during which time the whole furnace is kept at a cherry-red heat. A complete charge for the two double apparatus consists of from 1,000 to 1,300 quintals of ore, which produce from 80 to 90 quintals of running mercury. The furnace takes from 5 to 6 days to cool, according to the state of the weather; and if to that period be added the time requisite for withdrawing the residuums, and attending to such repairs as the furnace may need, it is obvious that only one distillation can be performed in the course of a week.

It has been long well known, that quicksilver may be most readily extracted from cinnabar, by heating it in contact with quicklime. The sulphur of the cinnabar combines, by virtue of a superior affinity with the lime, to the exclusion of the quicksilver, to form sulphide of calcium, which being fixed, remains in the retort, while the mercury is volatilised by the heat. In a few places, *Hammerschlag*, or the iron cinder driven off from the blooms by the tilting hammer, has been used instead of lime in the reduction of this mercurial ore, whereby sulphurous acid and sulphide of iron are formed.

The modes practised at Almaden and Idria are far from economical; the ores being heated upon open arches, and the vapours attempted to be condensed by enclosing them within brick or stone and mortar walls, which can never be rendered either sufficiently tight or cool.

To obviate all these inconveniences and sources of loss, the proper chemical arrangements suited to the present improved state of the arts ought to be adopted, by which labour, fuel, and mercury might all be economised to the utmost extent. The only apparatus fit to be employed is a series of cast-iron cylinder retorts, somewhat like those employed in the coal-gas works, but with peculiarities suited to the condensation of the mercurial vapour. Into each of these retorts, supposed to be at least one foot square in area, and 7 feet long, 6 or 7 cwts. of a mixture of the ground ore with the quicklime may be easily produced from a measured heap by means of a shovel. The specific gravity of the cinnabar being more than 6 times that of water, a cubic foot of it will weigh more than 3½ cwts.; but supposing the mixture of it with quicklime (when the ore does not contain the calcareous matter itself) to be only thrice the density of water, then 4 cubic feet might be put into each of the above retorts, and still leave 1½ cubic foot of empty space for the expansion of volume which may take

1443



place in the decomposition. The ore should certainly be ground to a moderately fine powder, by stamps, iron cylinders, or an edge-wheel, so that when mixed with quicklime, the cinnabar may be brought into intimate contact with its decomposer, otherwise much of it will be dissipated unproductively in fumes, for it is extremely volatile.

Figs. 1443, 1444, 1445 represent a cheap and powerful apparatus contrived by Dr. Ure at the request of the German Mines Company of London, and which was mounted at Landsberg, near Obermoschel, in the Bavarian Rhein-Kreis.

1444

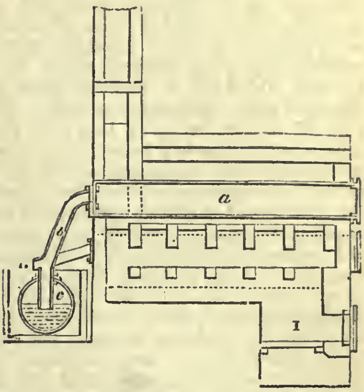


Fig. 1440 is a section parallel to the front elevation of three arched benches of retorts, of the size above specified. Each bench contains 3 retorts of the form represented by *a a a*. I is the single fire-place or furnace, capable of giving adequate ignition by coal or wood to the three retorts. The retorts were built up in an excellent manner by an English mason perfectly acquainted with the best modes of erecting coal-gas retorts, who was sent over on purpose.

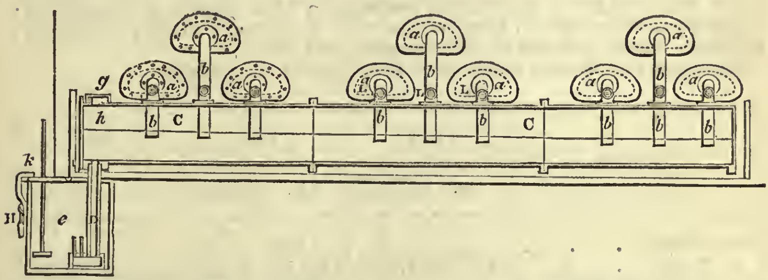
In the section, *fig.* 1444, *a* is the body of the retort; its mouth at the right-hand end is shut, as usual, by a luted iron lid, secured with a cross-bar and screw-bolts; its other end is prolonged by a sloping pipe of cast iron, 4 inches in diameter, furnished with a nozzle-hole at L, closed with a screw-plug. Through this hole a wire rammer may be introduced, to ascertain that the tube is pervious and to cleanse it from the mercurial soot, when thought necessary. *c* is a cross section of the main condenser, shown in a longitudinal section at C C, *fig.* 1445. This

1445



pipe is 18 inches in diameter, and about 20 feet long. At *a a*, &c., the back ends of the retort are seen, with the slanting tubes *b b*, &c., descending through orifices in the upper surface of the condenser-pipe, and dipping their ends just below the water-line *h i*. *g* is the cap of a water-valve, which removes all risk from sudden expansion or condensation. The condenser is placed within a rectangular trough, made either of wood or stone, through which a sufficient stream of water passes to keep it perfectly cool, and repress every trace of mercurial vapour, and it is laid with a slight inclination from *i* to *h*, so that the condensed quicksilver may spontaneously flow along its bottom, and pass through the vertical tube, D, into the locked-up iron chest, or magazine, *e*. This tube, D, is from the beginning closed at bottom, by immersion in a shallow iron cup, always filled with mercury. *k* is a graduated gauge-rod, to indicate the progressive accumulation of quicksilver in the chest, without being under the necessity of unlocking it.

The air-tight apparatus was erected some years ago, and was found to act perfectly well. The whole cost of the nine large retorts, with their condensing-apparatus, iron-magazine, &c., was very little more than *two hundred pounds*! As the retorts are kept in a state of nearly uniform ignition, like those of the gas-works, neither they nor the furnaces are liable to be injured in their joints by the alternate contractions and expansions, which they would inevitably suffer if allowed to cool; and being always ready heated to the proper pitch for decomposing the mercurial ores, they are capable of working off a charge, under skilful management, in the course of 3 hours. Thus, in 24 hours, with a relay of labourers, 8 charges of at least 5 cwts. of ore each might be smelted = 2 tons with 3 retorts, and 6 tons with 9 retorts; with a daily product from the rich ores of Almaden, or even Idria, of from 12 cwts. to 20 cwts.

The following detailed account of the apparatus for smelting in California is given by Mr. Ruschenberger:—A kind of reverberatory-furnace 3 feet by 5, is arranged at the extremity of a series of chambers of nearly, if not exactly of the same dimensions: namely 7 feet long, 4 feet wide, and 5 feet high. There are 8 or 10 of these chambers in each series; they are built of brick, plastered inside, and secured by iron rods, armed at the end with screws and nuts as a protection against the expansion by heat. The tops are of boiler-iron, luted with ashes and salt. The first chamber is for a wood fire. The second is the ore-chamber, which is separated from the first by a net-work partition of brick. The flame of the fire passes through the square holes of this partition, and plays upon the ore in the ore-chambers, which, when fully charged, contains 10,000 lbs. of cinnabar; next to the ore-chamber is the first condensing-chamber, which communicates with it by a square hole at the right upper corner; and the communication of this first with the second condensing-chamber is by a square hole at the left lower corner. An opening at the right upper corner of the partition, between the second and third condensing-chambers, communicates with the latter. The openings between the chambers are at the top, and to the right, and at the bottom, and to the left alternately; so that the vapours from the ore-chamber are forced to describe a spiral in their passage through the 8 condensers. The vapour and smoke pass from the last condensing-chamber through a square wooden box, 8 or 10 feet long, in which there is a continuous shower of cold water, and finally escape into the open air by tall wooden flues. The floor, or bottom, of each condensing-chamber is above 2 feet above the ground, and is arranged with gutters for collecting the condensed mercury, and conveying it out into an open conduit along which it flows into an iron receptacle, from which it is poured into the iron flasks through a brush, to cleanse it of the scum of oxide formed on the surface on standing. 70 lbs. weight are poured into each flask. There are 14 of these furnaces and ranges of condensers, with passages of 8 or 10 feet in width between them. A shed is constructed above the whole at a sufficient elevation to permit free circulation of the air.

According to Dumas, the following mines yield annually as follow:—Almaden in Spain, from 2,700,000 to 3,456,000 lbs. avoirdupois; Idria, 648,000 to 1,080,000 lbs.; Hungary and Transylvania, 75,600 to 97,200 lbs.; Deux Points, 43,000 to 54,000 lbs.; Palatinate, 19,440 to 21,600 lbs.; Huancavelica, 324,000 lbs.

The *Imports* of mercury for the years 1868–72 have been as follow:—

Mercury is a substance of paramount value to science. Its great density, and its regular rate of expansion and contraction by increase and diminution of temperature, give it the preference over all liquids for filling barometric and thermometric tubes. In chemistry it furnishes the only means of collecting and manipulating, in the pneumatic trough, such gaseous bodies as are condensible over water. To its aid, in this respect, the modern advancement of chemical discovery is pre-eminently due.

This metal, alloyed with tin-foil, forms the reflecting surface of looking-glasses, and, by its ready solution of gold or silver, and subsequent dissipation by a moderate heat, it becomes the great instrument of the art of gilding and silvering copper and brass. The same property makes it so available in extracting these precious metals from their ores. This amalgam is used for electric machines. The anatomist applies it elegantly, to distend and display the minuter vessels of the lymphatic system, and secretory systems, by injecting it with a syringe through all their convolutions. It is the basis of many very powerful medicines.

The nitrate of mercury is employed for the *secretage* of rabbit- and hare-skins, that is, for communicating to fur of these and other quadrupeds the faculty of felting, which they do not naturally possess. With this view, the solution of that salt is applied to them lightly in one direction with a sponge.

The only mercurial compounds which are extensively used in the arts are factitious cinnabar or VERMILION, and CORROSIVE SUBLIMATE, which see.

MERCURY, CHLORIDE OF; PROTOCHLORIDE (*Deutochlorure de mercure*, Fr.; *Aetzendes quecksilber sublimat*, Ger.) is made by subliming a mixture of equal parts of persulphate of mercury and sea-salt in a stoneware cucurbit. The sublimate rises in vapour, and incrusts the globular glass capital with a white mass of small prismatic needles. It is a very deadly poison; raw white-of-egg, swallowed in profusion, is the best antidote. See CORROSIVE SUBLIMATE.

MERCURY, FULMINATING. For this compound of mercury with fulminic acid, see FULMINATING MERCURY.

MERCURY, PERIODIDE OF, is a bright but fugitive red pigment. It is easily prepared by dropping a solution of iodide of potassium into a solution of corrosive sublimate, as long as any precipitation takes place, decanting off the supernatant muriate of potash, washing and drying the precipitate.

MERCURY, SUBCHLORIDE OF; *Calomel.* (*Protochlorure de mercure*, F ; *Versüsstes quecksilber*, Ger.) See CALOMEL.

MERINO. For the following we are indebted to the 'History of the Woollen Trade of Bradford,' by John James:—

George III., ever desirous of the welfare of his people, though oftimes mistaken in the means for accomplishing his wishes, amongst other improvements projected by him in agriculture and husbandry, imported in 1786 a few merino sheep from Spain, for the purpose of improving the wool of England. Unquestionably this variety of sheep sprung from the English flock which Edward III. permitted to be exported to Spain, where, by assiduous care and crossing, the fleece had become the finest in its staple of any in the world. His Majesty made from time to time considerable accession to his original flock, which throve well, and increased very fast, so that in a few years, by distribution and sale, they had come into the hands of the most eminent sheep-breeding gentlemen in the kingdom. Among these the late Lord Western stood the most distinguished for his breeding and culture of merino sheep. His flock had its origin in a gift from His Majesty of 40 ewes, selected from 500 merinos sent by the Cortes of Spain to the king for distribution among his subjects. His lordship's chief care in his improvement of the fleece was to adapt it for the finest articles of worsted, and he certainly succeeded well in his object. Many other sheep-breeders in the kingdom also devoted much attention, with great success, to the breeding of merino sheep, so that at this period (1826) large quantities of such wool were produced in the country.

Contemporaneous with these efforts made in England, the propagation of the merino sheep, which had been obtained from Spain, was carried on to a great extent in Saxony, where the ruling monarch, like our own, took much interest in the enterprise. The government of Saxony was amply rewarded for the pains which had been taken to spread the breeds so as to become a portion of the public wealth. Hence from this source arose the large supply which enabled Saxony to send to this country large quantities of wool, chiefly for the making of fine woollen cloth, as it, on the whole, ranged in staple shorter than English or Spanish merino. Nor were the French idle in availing themselves of the excellent properties of the Spanish sheep by transplanting them to their soil, and manufacturing from the wool fine stuffs to which they gave the name of merinoes.

From the merino wool produced in France and Germany were manufactured fine descriptions of stuffs named after the sheep. A Bradford spinner in 1826, being desirous of extending his export trade in Germany, instituted inquiries respecting the stuffs made there, and received in answer the following information:—No worsted yarn of any amount was made on the Continent, except by hand. As the laws prohibiting the exportation of English machinery still remained in force, the continental nations could not obtain our improved frames, and either their handicraftsmen were unable to construct them with sufficient skill, or their capitalists were disinclined to embark in the enterprise. Much yarn was spun by hand in the neighbourhood of Hamburgh. Then, as to the weaving of stuffs, a few merinoes were made at Leipzig, and some of them from English yarn spun to No. 46. At Waldenberg, Eisenach, and Langensalza, Berlin, Altona, and Erfurt, merinoes were made. For some of these English yarn was used, but the German manufacturers preferred, most likely for its durability, their own yarn. Whilst the French and Germans were weaving merino pieces, a fabric bearing the same name, but widely differing in structure, arose in the English market, and imparted a most beneficial impulse to the stuff trade of the West Riding.

A brief narration of the origin of English merinoes will at this point, find an appropriate place. The wearing of worsted stuffs, after many changes of fashion, had again become very common amongst people of every degree in England. But it was perceived as the taste for fabrics of fine texture increased, that plainbacks and other worsted articles of that kind were not sufficiently delicate in structure for the higher classes. This idea having been mentioned by one of the partners in the house of Messrs. Todd, Morrison, and Co., warehousemen, London, to Messrs. Mann of Bradford, merchants, the latter began to reflect on the best method of supplying the void. It occurred to them that a plainback made with the finest yarn, and spun from merino and other fine wools, would answer the object.

Accordingly they employed Messrs. Garnett of Bradford to spin yarn and manufacture such a stuff, who accomplished the task to the full satisfaction of their employers. Some beautiful pieces were the result; three-quarters wide, made from 40's to 52's weft, and 32's to 34's warp; in every respect they resembled Cashmere, except in being finer. From the period of their introduction, these stuffs pleased the public taste, and were rapidly sold at high prices. They were originally sold at from 75*s.* to 80*s.* the piece; but when the article became known, many manufacturers entered into competition, and making lower sorts, reduced the prices from 40*s.* to 50*s.* the piece according to qualities.

About a year after the full introduction of the three-quarters merino into the market, it was found that, owing to the narrowness of the piece, it did not cut up conveniently or economically for dresses; and the six-quarter variety of merino was brought into the market, where it for many years had a large demand, bringing as much in some instances as 120*s.* a piece.

MESSENGER. A hawser, or small cable, about sixty fathoms long, wound round the capstan, and having its two ends lashed together. See CABLE.

METACINNABAR. An amorphous dark-coloured sulphide of mercury found in California.

METAL. This term is sometimes applied by smelters to a regulus, or fixed sulphide, such as the 'coarse metal' and 'blister metal' of the copper-smelter. The molten glass is spoken of in glass-works as 'metal.'

METAL LEAF. A name commonly applied to the Dutch leaf to distinguish it from gold-leaf. There was of metal leaf not gold *imported* in 1868–72:—

METALLOGRAPHY. A process invented by M. Abate, and published by him in 1851. It consists of printing from engraved wood-blocks upon metallic surfaces, so as to produce imitations of figures and ornaments inlaid in wood. This effect he obtained by using, as a printing menstruum to wet the block with, solutions of such metallic or earthy salts as are decomposed when brought into contact with certain metals, and produce, through an electro-chemical action, an adhesive precipitate of a coloured metallic oxide, or any other chemical change upon the metal.

METALLOÏDS. Davy proposed this name for sodium and potassium, and other substances of which the metallic character was not well defined. Berzelius used the term to distinguish the *non-metallic* elementary substances from the metals. Dr. Apjohn published a 'Manual of the Metalloïds,' in which he adopted this meaning. The word metalloïd signifying *like a metal*, its use in this sense is unfortunate.

METALLURGY. (*Hüttenkunde*, Ger.) The art of extracting metals from their ores. Under the heads of the different metals respectively, the metallurgical processes to which they are subjected are given. See ANTIMONY, COPPER, GOLD, IRON, &c. A full description of the processes of preparing the minerals for the operations of the metallurgist will be found under the head of DRESSING OF ORES.

When it is intended to wash certain ores, an operation founded on the difference of their specific gravities, it may happen that by slightly changing the chemical state of the substances that compose the ore, the earthy parts may become more easily separable, as also the other foreign matters. With this view, the ores of tin are subjected to a roasting, which, by separating the arsenic and oxidising the copper which are intermixed, furnishes the means of obtaining, by the subsequent washing, an oxide of tin much purer than could be otherwise procured. In general, however, these are rare cases; so that the washing almost always immediately succeeds the picking and stamping; and the roasting comes next, when it needs to be employed. See ROASTING ORES.

METALS (*Métaux*, Fr.; *Metalle*, Ger.) are by far the most numerous class of undecomposed bodies in chemical arrangements. They amount to 51; of which 7 form, with oxygen, bodies possessed of alkaline properties: these are, 1. potassium; 2. sodium; 3. lithium (bases of the alkalis); 4. barium; 5. strontium; 6. calcium; 7. magnesium (bases of the alkaline earths, for even magnesia, the last and feeblest base, tinges turmeric brown, and red cabbage green). The next seven metals form with oxygen the earths proper: they are, 8. yttrium; 9. glucinum; 10. aluminium; 11. zirconium; 12. thorium; 13. erbium; 14. terbium. The remaining 37 may be enumerated in alphabetical order, as they hardly admit of being grouped into subdivisions with any advantage. They are as follow: 15. antimony; 16. arsenic; 17. bismuth; 18. cadmium; 19. cerium; 20. chromium; 21. cobalt; 22. copper; 23. didymium; 24. gold; 25. iridium; 26. iron; 27. lead; 28. lanthanum; 29. manganese; 30. mercury; 31. molybdenum; 32. nickel; 33. niobium; 34. osmium; 35. palladium; 36. platinum; 37. rhodium; 38. ruthenium; 39. silver; 40. tantalum; 41. tellurium; 42. tin; 43. titanium; 44. tungsten; 45. vanadium; 46. uranium; 47. zinc; and lately by spectrum analysis the following have been discovered, 48. cœsium; 49. indium; 50. rubidium; and 51. thallium.

1. They are all, more or less, remarkable for a peculiar lustre, called the *metallic lustre*. This property of strongly reflecting light is connected with a certain state of aggregation of their particles, but is possessed, superficially at least, by mica, animal charcoal, selenium, polished indigo, and bodies which are not at all metallic.

2. The metals are excellent conductors of heat, and most of them also of electricity, though probably not all. According to Despretz, they possess the power of conducting heat proportionately to the following numbers:—Gold, 1,000; platinum, 981; silver, 973; copper, 898; iron, 374; zinc, 363; tin, 304; lead, 179·6.

Becquerel gives the following table of metals, as to electrical conduction:—

Copper, 100; gold, 93·6; silver, 73·6; zinc, 28·5; platinum, 16·4; iron, 15·8; tin, 15·5; lead, 8·3; mercury, 3·5; potassium, 1·33.

The metals which hardly, if at all, conduct electricity, are zirconium, aluminium, tantalum, in powder, and tellurium.

3. Metals are probably opaque; yet gold-leaf, as observed by Newton, seems to transmit the green rays, for objects placed behind it in the sunbeam appear green. This phenomenon has, however, been ascribed to the rays of light passing through an infinite number of minute fissures in the thinly-hammered gold.

4. All metals are capable of combining with oxygen, but with affinities and in quantities extremely different. Potassium and sodium have the strongest affinity for t; gold and the platinum-group of metals the feeblest. Many metals become acids by a sufficient dose of oxygen, while, with a smaller dose, they constitute salifiable bases.

5. Metals combine with each other, forming a class of bodies called alloys, except when one of them is mercury, in which case the compound is styled an amalgam.

6. They combine with hydrogen into *hydrurets* or *hydrides*; with carbon, into *carburets* or *carbides*; with sulphur, into *sulphurets* or *sulphides*; with phosphorus, into *phosphurets* or *phosphides*; with selenium, into *seleniurets* or *selenides*; with boron, into *borides*; with chlorine, into *chlorides*; with iodine, into *iodides*; with cyanogen, into *cyanides*; with silicon, into *silicides*; and with fluorine, into *fluorides*.

7. Metallic salts are definite compounds—mostly crystalline—of the metallic oxides with the acids.

METALS, NATIVE. The metals which are found in the condition of obvious metallic existence are but few. *Gold* is almost always found native, generally combined with a small percentage of silver, and sometimes with other rarer metals. *Silver* is frequently discovered in an almost pure metallic state. *Platinum* is another metal, which, like gold, is generally found in the metallic state, but this metal is almost always combined with palladium, osmium, and other metals of that type. *Copper* is very often found in the native state, and in a condition of great purity. The occurrence of large masses of copper—copper rocks, indeed—is one of the most striking features of the Lake Superior copper deposits. *Lead* is said to have been found native at Grassington, in Yorkshire. Recently it is reported to have been discovered in Victoria, Australia, and again in California. *Bismuth* is often found native; and *Iron*, the meteoric variety, is occasionally met with in this condition.

METALS, NOBLE. This term was applied to gold and silver in ages when the principles of chemical science were unknown. The name was intended to convey the fact that these metals were slow to combine with the 'baser ones,' such as iron. The term is not now employed scientifically.

METEORITES. (*Aérolithe*, Fr.) The name of mineral bodies which have been known to fall from the region beyond the earth's atmosphere to the surface of the earth. There are, however, a certain number of bodies found on the surface in various parts of the world, which are thought to be of meteoric origin, and are hence called *Meteorites*, which correspond in chemical composition and structure with those which have been seen to fall. They are usually divided into *Meteoric Iron* and *Meteoric Stones*. The meteoritic irons have been termed *Siderites*, whilst the term *Aerolites* has been retained for the stony meteorites. The following may be regarded as the average composition of meteoric iron: Iron, 85·54; nickel, 8·55; cobalt, 1·50; copper, 0·20; magnesia, 2·04; chromic oxide, 0·21; silica, 3·0; phosphorus, 0·12; with traces of carbon, sulphur, tin, and manganese. For numerous analyses, see Watts's 'Dictionary of Chemistry.' See AEROLITES.

METHYLAMINE. C^2H^5N (**CH^5N**). The most volatile of the organic bases. It is formed by similar reactions to ethylamine; it is regarded as ammonia in which an equivalent of hydrogen is replaced by methyle; it is gaseous at ordinary temperatures; it is the most soluble in water of all known gases, one volume of water at 54° dissolving 1,150 volumes.

METHYLATED SPIRIT. When ordinary alcohol is mixed with 10 per cent. of 'wood alcohol' (*Methyle*), it is, according to an excise regulation, sold duty free under this name. Methylated spirit is extensively used in the manufacture of varnishes, lacquers, &c. See Watts's 'Dictionary of Chemistry.'

METHYLENE, a peculiar liquid compound of carbon and hydrogen, extracted from pyroxilic spirit, which is reckoned to be a bi-hydrate of *methylène*.

METRIC SYSTEM. See WEIGHTS AND MEASURES.

MICA is a finely-foliated mineral, of a pearly metallic lustre. It is harder than gypsum, but not so hard as calc-spar; flexible and elastic; spec. grav. 2·65. It is an ingredient of granite and gneiss. The large sheets of mica exposed for sale in London are mostly brought from Siberia. They are used, instead of glass, to enclose the fire, without concealing the flame, in certain stoves.

The mica of Fahlun, analysed by Rose, afforded silica, 46·22; alumina, 34·52;

peroxide of iron, 6·04; potash, 8·22; magnesia, with oxide of manganese, 2·11; fluoric acid, 1·09; water, 0·98. From an American authority we quote as follows:—

'The increased demand for gas-stoves has naturally introduced to a wider notice the really valuable and useful mineral known under the name of mica. Every schoolboy can pick out the mica in a piece of granite, but it is not so well known that the 'glass' forming the front of many kinds of gas-stoves is also mica. The minerals which form the group of micas divide readily into two divisions; those which are silicates of alumina and an alkali, and those which are silicates of magnesia. They are all notable for their lustre, and for their distinct cleavage, which permits of their being separated into thin sheets. In granite, the plates are rarely seen of a useful size, although in the coarser descriptions of that rock plates are occasionally found a foot and more in width; but, in limestone formations, it is often found in masses of considerable size, plates having been met with in Siberia several feet in diameter. The micas chiefly met with in commerce are Muscovite and Lepidolite (or lithia mica) of the first division, and Phlogopite (rhombic mica) and Biotite of the latter division, or magnesian micas. Of these, the most extensively used in the arts are Muscovite and Phlogopite. The former is mainly a silicate of alumina and potash, with traces of iron, fluorine, chromium, &c., which impart colour to the otherwise grey or silver-white plates of mica. The crystals of Muscovite are usually six-sided; the colour varying from black through grey to green, chromium being invariably present in the crystal of the last-mentioned tint. This variety of mica is proof against acids, is very refractory, the thin edge only fusing before an ordinary blowpipe, while the laminæ are very tough and flexible. Phlogopite, or rhombic mica, as it is sometimes called, is mostly found in limestone, and is composed mainly of silica, alumina, and magnesia, with traces of iron, potash or soda, and fluorine. Its colour varies from brown, through brownish yellow, to grey. If it is previously reduced to fine powder, it is attacked by hot sulphuric acid, but, like Muscovite, although it whitens in the blow-pipe-flame and fuses on the thin edges, it is virtually refractory to anything short of an intense heat. These extraordinary properties, combined with toughness and elasticity, and the peculiar facility with which it splits into thin sheets, some of which approach closely to transparency, led naturally to the use of mica for windows, and especially to its employment in lanterns. For many years it has been used in Russia for windows, and in some parts is still to be found, though it is of course rapidly giving way to the more transparent glass. So common, however, was its employment for this purpose at one time in Russia, that it was frequently called 'Muscovy glass.' It is found in Siberia, Sweden, and Moravia, which also supply the Lepidolite, or lithia mica. In America it is found in various parts, as North Carolina, New Jersey, and Canada. In some coarse granite rocks of the first-named State the mica is found in considerable abundance, and there are unmistakable evidences that it was worked many years ago. The commercial value of mica varies through a wide scale: the large, sound, and clear sheets being naturally the highest priced, fetching as much as 40*s.* a pound. In the United States, where large quantities are used for what is called 'stove glass,' that is, for the fronts of gas and other stoves, the utilisation of mica has been carried further than in this country. The small and waste-stuff is there made into a coarse powder and sprinkled over tar in roof-making; finely ground, it is used as a lubricant, and is sometimes used in packing deed-boxes and safes to render them fireproof. The finer sheets are used for such purposes as the dials of compasses, for the letters of fancy signs, and the very finest and thinnest pieces are sometimes employed in lieu of enamel for covering photographs; but one of the principal uses to which the better qualities are put is the construction of shades for lamps, the nature of the material rendering its decoration a comparatively easy process: chromo-lithography being extensively employed in this manufacture. The preparation of the mica is very easy. When first obtained it is in plates and crystals of various sizes, from a quarter of an inch to even occasionally a foot in thickness, and from six inches to a foot and upwards in diameter.

'The facility with which they can be bent into various shapes, and the power they possess of resisting heat, together with their transparency and naturally beautiful appearance, make these thin sheets of mica of peculiar value in many situations. They have been used as reflectors for some years, and a patent has recently been obtained for an improved process of silvering plates of mica, the inventor being a resident of Philadelphia. The flexible nature of the material to be silvered will probably insure its introduction into the arts and industries to a greater or lesser extent, and it is perhaps not impossible that it may be employed in the manufacture of telescopes, although it must be confessed that its utilisation for that purpose is rather improbable. In the process recently patented, sheets of mica, as free from metallic deposit as can be obtained, are thoroughly washed in nitric acid, and then rinsed in water. They are then placed upright in suitable vats or baths, being arranged in pairs, back to back, so as to expose only one side to the coating solution. This latter is tolerably well known, and is made by dissolving 1 oz. of nitrate of silver in a quart of distilled water, and in a separate vessel 1 oz. of glucose in a quart of distilled water. When the silver has dissolved, a small quantity of liquor ammoniæ is added, and the solution becomes cloudy, the cloudiness disappearing on the addition of a little more ammonia. When this stage has been arrived at, the two solutions are mixed together and poured into the bath containing the mica plates, the bath being placed in a warm room, to facilitate the deposition of the silver. When the mica plates are sufficiently coated they are withdrawn from the bath, thoroughly rinsed in water and stood away to dry, after which they may, if deemed necessary, be coated with spirit-varnish.

The mica plates thus prepared may be mounted on frames of tin, sheet iron, paper, or plastic composition. Many other applications of these mica reflectors will suggest themselves to our readers, though their principal use is undoubtedly for illuminating purposes.'

MICACEOUS IRON. One of the varieties of hæmatite; so called from its micaceous structure. See IRON.

MICA-SLATE or **SCHIST.** (*Schisma*, Ger. a splitting.) A foliated rock composed of mica and quartz. The first name is not correctly applied.

MICROCOSMIC SALT. A term given to a salt extracted from human urine. It is a phosphate of soda and ammonia; and is now prepared by mixing equivalent proportions of phosphate of soda and phosphate of ammonia, each in solution, evaporating and crystallising the mixture. A small excess of ammonia aids the crystallisation.

MILDEW, MANCHESTER. From imperfect manufacture—or from corrupt practices—it appears that a peculiar mildew has often developed itself in cotton goods sent to India, to which this name has been given. The Manchester Chamber of Commerce has just (1874) received a letter from the Shanghai General Chamber of Commerce respecting 'mildewed shirtings,' which will probably open the eyes of those concerned in the matter to the fact that, after all, honesty is perhaps the best policy, and that there is a point beyond which swindling cannot be carried without its evil effect recoiling on its authors. The Chairman of the Shanghai Chamber, writing on December 17, 1872, calls attention to the widespread deterioration by mildew of cotton piece goods imported to China from Manchester. The losses from this cause have for some time been very large; but towards the end of 1871 parcel after parcel of grey shirtings, principally if not wholly consisting of second and lower qualities, were rejected by the Chinese buyers as 'spotted,' and during the past year the evil has become so general that in September last it was estimated that 75 per cent. of the entire stock of grey shirtings and T cloths in Shanghai were unmerchantable as sound goods. The trade was, in fact, completely disorganised. The cause of the deterioration is, there is strong reason to believe, owing to the use of 'size' in undue quantity and of a nature deleterious to the fabric employed to work up inferior cotton and to increase the weight of the cloth. The results of the extensive importations of unsound goods into China are that large quantities of cloth are forced off at reduced and irregular prices, by which means the tone of the market is lowered and the value of even sound goods is depreciated. Bales are no longer, as was once the case, accepted unopened on the faith of the sample, but the wrappers have to be cut into in order that the condition of every package may be ascertained. The inconvenience, delay, and loss arising from this practice are obvious. The trouble and waste of time entailed by the necessity of minute inspection, the frequent resales of rejected parcels, and the uncertainty as to the completion of any sale, until full examination of the contents of the packages has been made, all represent a positive burden on the trade. The destruction of the packages is, moreover, a loss to the native merchant, who can never again pack his goods so securely for inland transport. More important, perhaps, than all, is the fact that the confidence of native dealers and merchants in foreign goods is shaken; for they are no longer sure of carrying their purchases to the end of a long journey in a merchantable condition. Such general want of confidence in the soundness of foreign cotton goods must tend, it is urged, to render them unpopular among the Chinese; and, considering that foreign imports, though cheaper, have great difficulty even under favourable circumstances in competing with the more durable native manufactures, the trade is not in a position to bear any additional burden. Although, therefore, the first losses from mildew fall upon the importing merchant, while the manufacturers appear to escape altogether, yet such an unequal distribution of the responsibility cannot continue, if for no better reason than that the magnitude of the losses will soon put it beyond the power of the merchants to bear them, were they ever so willing. The result will, therefore, ultimately affect the Manchester manufacturers as seriously as the China merchants, and the latter urge the Manchester Chamber of Commerce to join with them in a strict investigation into the circumstances with a view of putting an end to 'a crying evil affecting not only the interests of the most important branch of British industry, but also the honour and reputation of British commerce.'

MILFOIL. (*Millefolium*, Lat. a thousand leaves.) The herb yarrow, belonging to the genus *Achillea*, one of the *Compositæ*.

MILK. A well-known nutritious fluid, which, as it has no especial use in the arts, need not be described. See BUTTER.

MILK, CONDENSED. The following information on the processes for condensing milk successfully is obtained from two journals known as the 'Farmer' and 'Moore's Rural':—

In the first place, arrangements must be made for obtaining good, clean, healthy milk, and this imposes a sort of education upon those producing milk, of the utmost importance to the successful prosecution of the condensing business. Dirty milk—milk foul with the drippings of the stable—cannot be condensed into a clean-flavoured product. The success of the condensing factory depends almost entirely upon the ability to put a fine-flavoured, perfect article into the market. The milk must be uniformly good. An inferior condensed milk is more readily detected than an inferior article of cheese or butter. At least, imperfections in these may perhaps be tolerated, and the goods may find a place in the market; but a factory continuing to send out imperfect or badly-flavoured milk, must soon cease to be remunerative, and must inevitably close its doors.

To obtain any success in this business, there is absolute necessity for clean, healthy milk in the first instance; and this matter should be well understood and well considered before any manufacture can be attempted. The great success attained by the late Gail Borden, the inventor of the process for condensing *in vacuo*, was in a great measure due to the system he inaugurated among his patrons for supplying milk free from all taint and unobjectionable in quality. He instituted a set of rules for the guidance of dairymen furnishing milk to his factories, which he rigidly enforced, and men were regularly employed to visit the farms from time to time, to see in what manner the cows were managed as to pasturage, water, driving to the yard, milking, cooling and care of milk; and as he bought, or accepted only such milk as would pass the closest scrutiny of an expert, he was able, after a time, to enforce an observance of his printed regulations, which he put into the hands of his dairymen. He adopted also, the practice of cleaning and steaming his patrons' delivery milk-cans at the factory, because he feared—and with good reason too—that this work might not be properly done at the farm.

The Borden process for condensing milk, the only process, we believe, which has stood the test of time and proved to be a success, may be briefly described as follows:—'After the milk is received at the factory it passes through a strainer to the receiving vat; from this it is conducted off through another strainer into the heating cans, each holding about 20 gallons; these cans are set in hot water, and the milk is held in them till it reaches a temperature of 150° to 175° Fahr.; it then goes through another strainer into a large vat, at the bottom of which is a coil of copper-pipe, through which steam is conducted, and here the milk is heated up to boiling point. Then the best quality of white granulated sugar is added in the proportion of 1½ lb. of sugar to 1 gallon of milk, when it is drawn into the vacuum-pan. The milk remains in the vacuum-pan subjected to steam for about three hours, during which time about 75 per cent. of its bulk in water is removed, when it is drawn off into cans holding about 40 quarts each.

These cans are only partially filled, and then set in a large vat containing cold water, the water being of a height equal to that of the milk in the cans. Here it is stirred until the temperature of the condensed fluid is reduced to a little below 80° Fahr. It is then turned into large draining cans with faucets, in order to facilitate the filling of the smaller cans. The draining cans stand in a room which is set apart for the purpose, and around the outside of which runs a table or work-bench. Here the milk is drawn from the faucets into small tin cans, holding 1 lb. each, when they go to the table, and are immediately soldered, to exclude the air. The cans next have the proper labels pasted upon them, and are then ready for market.

Somewhat recently Mr. Borden introduced a machine for filling the cans, which does the work with accuracy and rapidity. The work of filling the cans, soldering the tops and labelling, is usually performed by females. A number of small soldering furnaces are placed along the tables, where the girls, each with a set of soldering irons, seal the cans as fast as they are brought forward by the fillers.

For a small factory, say for the milk of from 200 to 300 cows, the estimated cost will be about 13,000 dols., as follows:—Erection of the building, 16 ft. by 50 ft., ready for machinery, &c., 2,500 dols.; vacuum-pan and condenser, from 3 ft. to 4 ft. in diameter, 1,800 dols.; 1 duplex 14-inch pump and engine, 1,500 dols.; 1 boiler, 60-horse power and fitting-up, 3,000 dols.; 1 pump for boiler, 100 dols.; outside water-pipes, 500 dols.; 1 cooling tank for receiving and storage, 500 dols.; 1 heating tank and pipes for milk, 300 dols.; hot water tank and steam-pipes for washing cans and 2 rinsing sinks, 600 dols.; 1 steamer-bath for scalding cans and pipes, 150 dols.

It will be seen from the above, that a well-furnished factory, with all the needful appliances, is somewhat expensive; but the profits from the business are also considerable. The cost of condensing will probably be no more than one-half per cent. per quart. It takes about 3 pints of milk to make 1 lb. of the sugared condensed milk, which sells in the market for 25 cents and upward. It is not easy to give the exact cost of condensing, since that will depend upon the amount of milk worked and the economy with which the factory is managed; but we should say that 1*d.* per quart ought to cover all the expenses for condensing. The cans, and the labour of filling and soldering, are an additional expense, which our readers can figure approximately, so that some idea of the profits may be obtained.

There are two kinds of condensed milk in the market:—the sugared, as above described, and which will keep for long periods, and the plain condensed milk, which contains no sugar, and is sold for immediate use. This last will only keep sound for a few days. It is made in the same way as the other, except that no sugar is used in its manufacture. A less price is obtained for it in the market than for sugared milk, it being sold by the quart from large carrying cans, and regularly furnished to consumers from time to time.

One great difficulty in the way of establishing new factories, is in obtaining skilled workmen to conduct the business of condensing. There are comparatively few persons who have had experience in the work of a factory, and these are, for the most part, retained by these factories now in successful work. As these factories have built up a good trade and have a 'good thing,' they do not care to open their doors for instruction or to educate any person in the business who would engage in a new factory. In cheese-making or in butter-making there are always plenty of skilled hands to be had, but the case is quite different in the condensing business, and this fact has deterred many from entering upon the work.

MILL, THE. A name given to the cylinder used by the calico-printers, in which the impression is obtained by a process like that of a milling tool, from a cylinder engraved by hand, called *the Die.* See CALICO-PRINTING.

MILL-STONE, or *Buhr-Stone.* This interesting form of silica, which occurs in great masses, has a texture essentially cellular, the cells being irregular in number, shape, and size, and are often crossed by thin plates, or coarse fibres of silex. The buhr-stone has a straight fracture, but it is not so brittle as flint, though its hardness is nearly the same. It is feebly translucent; its colours are pale and dead, of a whitish, greyish, or yellowish cast, sometimes with a tinge of blue.

The Buhr-stones usually occur in beds, which are sometimes continuous, and at others interrupted. These beds are placed amid deposits of sand, or argillaceous and ferruginous marls, which penetrate between them, filling their fissures and honeycomb cavities. Buhr-stones constitute a very rare geological formation, being found in abundance only in the mineral basin of Paris, and a few adjoining districts. Its geological position is well ascertained: it forms a part of the lacustrine, or fresh-water formation, which, in the locality alluded to, lies above the upper eocene gypsum, and the stratum of sand and marine sandstone which cover it. Buhr-stone constitutes, therefore, in the locality in which it is found, the uppermost solid stratum of the crust of the globe; for above it there is nothing but alluvial soil, or diluvial gravel, sand, and loam.

Buhr-stones sometimes contain no organic forms; at others they seem as if stuffed full of fresh-water shells, or land-shells and vegetables of inland growth. There is no exception known to this arrangement; but the shells have assumed a siliceous nature, and their cavities are often filled with crystals of quartz. The best buhr-stones for grinding corn have about an equal proportion of solid matter and of vacant space. The finest quarry of them is upon the high ground, near *La Ferté sous Jouarre.* The stones are quarried in the open air, and are cut out in cylinders from one to two yards in diameter, by a series of iron and wooden wedges, gradually but equally inserted. The pieces of buhr-stones are afterwards cut into parallelopipeds, called *panes,* which are bound with iron hoops into large millstones. These pieces are exported chiefly to England and America. Good millstones of a bluish-white colour, with a regular proportion of cells, when 6½ feet in diameter, fetch 1,200 francs apiece or 48*l.* sterling. A coarse conglomerate sandstone or breccia is, in some cases, used as a substitnte for buhr-stones; but it is a poor one.

In addition to the French buhr-stone, other materials are employed as millstones. Thus the lava of Niedermendig, near Andernach, on the Rhine, has been extensively worked as a millstone since the time of the Romans. This lava is a nepheline dolerite, frequently enclosing blue masses of the mineral called Hauyne. The Rhenish millstones are sent down the Rhine to Holland, and were formerly imported into this country under the name of 'Dutch blues.'

MILLSTONE GRIT. A geological term applied to a series of coarse sandstone rocks, belonging to the Coal-measure formations. 'The term gritstone is perhaps most applicable to the harder sandstones, which consist most entirely of grains of quartz most firmly compacted together, by a purely siliceous cement. The angularity of the particles cannot be taken as a character, since the rock commonly called *millstone grit* is generally composed of perfectly round grains, sometimes as large as peas, and even larger; the stone then commencing to pass into a conglomerate.'—*Jukes.*

MINERAL ALKALI. Soda was formerly so called.

MINERAL CANDLES. See CANDLES.

MINERAL CARBON. See ANTHRACITE.

MINERAL GREEN. *Scheele's Green.* Arsenite of copper. See SCHEELE'S GREEN.

MINERAL OILS. Several hydro-carbon compounds are known under this name. Generally it is applied to petroleum, and other fluid hydro-carbons which issue from the earth. These will be described under the several heads of NAPHTHA; PETROLEUM; SHALE OIL.

Lately the mineral oils of Puxière La Grose and Cordessa have been attracting attention. A few words on those will not be out of place here. They have been examined by Joffre in order to ascertain in what points they differ from the petroleum of America. These oils, obtained by distilling bituminous schists, present at first sight a close analogy with the petroleums. They agree very closely in colour, fluidity, specific gravity, and in boiling point. But on the application of certain reagents a difference is at once recognised. The American petroleums, composed of hydro-carbons of the general formula C^nH^{2n+2}, are not attacked by fuming sulphuric acid, and monohydrated nitric acid does not form with them nitro-compounds. On the other hand, if our mineral oils are treated with the former of these agents, about the half is absorbed. If they are acted on by the second, about the half also is attacked with formation of nitro-compounds. These oils, therefore, are composed of a mixture of several bodies, some of which resist sulphuric and nitric acids while the others are attacked by them. Both these portions have been studied. The oils were first purified by rectification over sodium; and they were then divided by fractional distillation into several groups according to the boiling-point. The portion not attacked by fuming sulphuric acid presents all the reactions of the saturated or formenic hydro-carbons, C^nH^{2n+2}. It resists the action of the most energetic reagents. Neither fuming nitric acid nor a mixture of nitric and sulphuric acids attacks it in the cold. At a boiling heat, however, it is attacked, under formation of acid products which remain dissolved in the excess of oil. The boiling-points and specific gravities correspond with those of the saturated hydro-carbons. Elementary analysis gives results which point to the general formula C^nH^{2n+2}. This part of the mineral oils, is therefore, formed of saturated or formenic hydro-carbons. They seem either identical or at least isomeric with those which Pelous and Cahours extracted from the American petroleums. By acting upon portions of the oil with more or less elevated boiling-points each of the hydro-carbons of the saturated series is obtained, from the hydride of octyle C^8H, to the hydride of myristyle $C^{14}H^{30}$. In the portions which distil over at the end we find the hydrides of pentadecyle $C^{15}H^{32}$, of hexadecyle $C^{16}H^{34}$, and of heptadecyle $C^{17}H^{36}$. The proportion of the saturated is about 50 per cent. The portion attacked by acids consists of hydro-carbons of the ethylenic series C^nH^{2n}, mixed with a certain quantity of hydro-carbons still less hydrogenised. These oils contain neither benzole nor naphthalin. At first sight we might be surprised at the absence of the two bodies so generally met with among pyrogenous products. But on further reflection we cannot help admitting that this is quite natural. The manufacturer of mineral oils seeks to distil the schists at the lowest possible temperature in order to avoid the formation of gas and to secure the largest possible yield of oil.

The following facts cannot be too widely known:—

A number of patents have been taken out in different countries for 'inexplosive' gazoline, naphtha, and benzine. Oils of this nature, quite as dangerous as they were originally, before the patented treatment, are sold under such names as 'liquid gas,' 'Aurora oil,' 'safety gas,' 'puroline,' 'petroline,' 'black diamond,' 'septoline,' &c. They are mere mixtures of the ordinary light explosive oils, with roots, gums, barks, and salts. The following are some of the mixtures, as recorded in the Patent List of 1866:—

No. 57,095. Gazoline, 40 gallons; gum olibanum, 1 lb.; cascarilla bark, ½ lb.; lichen, (probably Iceland moss), ½ lb.

No. 57,390. Bark of white oak, 2 lbs.; alkanet root, 2 lbs.; salt, 2 lbs.; alcohol, ½ litre; cyanide of potassium, 30 grammes; to be added to 3 gallons of naphtha.

No. 57,749. Naphtha, 40 gallons; carbonate of soda, 3 lbs.; alum, 2 lbs.; hydrate of lime, 2 lbs.; red ash, 2 lbs.; camphor, ½ lb.; oil of saffron, 12 grammes; essence of tar, 30 grammes.

No. 58,180. Naphtha, 40 gallons; potatoes, 50 lbs.; lime, 4 lbs.; salt of soda, 4 lbs.; turmeric, 3 lbs.

No. 58,905. Gazoline, 40 gallons; salt of soda, 1 lb.; cream of tartar, 1 lb. If the oil of *Gautheria procumbens* is added the offensive odour of the mixture is said to be quite overcome.

No. 59,797. Gazoline, 40 gallons; sulphur, 5 lbs.; rust of iron, 100 lbs.; onions, 1 bushel; resin, 5 lbs.

No. 60,559. Naphtha, 40 lbs.; caustic soda, 1 lb.; alum, 1 lb.; salt 1 lb.; manganese, 30 grammes; water, 120 grammes.

None of these additions can have any effect, save to disguise the colour or smell of the oils, and to diminish their utility, when burnt in a lamp, by clogging up the wick. They cannot in the least obviate their explosive nature. This will be at once apparent, if we reflect that it is not the oil itself which explodes, but merely its vapour, when mixed with a certain proportion of oxygen or of common air. Hence an oil is called explosive when it gives off vapour at low temperatures. That any addition can prevent this escape of vapour without occasioning a complete decomposition of the oil is impossible.

These dangerous and deceptive oils are palmed off upon dealers and consumers by a very ingenious stratagem. It is not generally known that the vapour of a volatile oil or other hydro-carbon requires to be mixed with a very considerable proportion of air to form an explosive mixture. Eight or nine measures of air to one of the vapour is the most explosive proportion, while a mixture of equal parts burns quietly without any explosion at all. In fact, to produce at will the most explosive mixture requires both dexterity and experience, while it is very easy to avoid its generation entirely. When it is desired to prove the complete safety of a dangerous oil, its vapour is allowed to mix with a very little air; a lighted match is then thrust in, and as no explosion follows, the oil is recognised as non-explosive, and used as safe till some serious accident makes its insecurity manifest and puts an end to its sale in the district.

Many of the substances added in the above-mentioned patents subside to the bottom of the cask with as little effect as a handful of pebbles or small shot.

MINERAL PURPLE. Purple of Cassius—which see.

MINERAL STATISTICS of the United Kingdom.

Within our limited space, an attempt will be made to show the value of our mineral produce—and to some extent of our metallurgical operations.

Mr. Carne has given a table in the 'Transactions of the Geological Society of Cornwall,' of the production of tin in Cornwall from 1750 to 1837. We adopt this table from 1800 to 1837, after which, until 1848, no exact return could be obtained. From 1848 the progress of tin mining to 1859 is given as a continuation of the same table. From 1860 to 1873 the production of tin ore and metallic tin is given in a separate table.

The following is a complete statement of the produce of the mines and collieries of the United Kingdom in 1873:—

Minerals	Quantities Tons	Cwts.	Value £
Coal	127,080,385	0	47,689,144
Iron Ore	15,577,449	0	7,573,676
Copper Ore	80,188	10	342,708
Tin Ore	14,884	17	1,056,835
Zinc Ore	15,969	0	61,166
Lead Ore	73,400	10	1,130,367
Iron Pyrites	58,924	3	35,485
Manganese	8,671	6	57,766
Salt	1,780,000	0	890,000
Barytes	10,269	11	7,993

Metals obtained from these Ores.

Pig Iron	Tons	6,545,451	£17,999,989
Tin	,,	9,972	1,329,766
Copper	,,	5,240	502,822
Lead	,,	56,035	1,305,622
Silver	Ounces	537,707	134,427
Zinc	Tons	4,471	120,999

Produce of British Tin Mines since 1800.

Years	Tons	Years	Tons	Years	Tons	Years	Tons
1800	2,522	1815	2,941	1830	4,444	1845	...
1801	2,365	1816	3,348	1831	4,300	1846	...
1802	2,669	1817	4,121	1832	4,323	1847	...
1803	2,960	1818	4,066	1833	4,065	1848	6,613
1804	3,041	1819	3,315	1834	2,989	1849	6,952
1805	2,785	1820	2,990	1835	4,228	1850	6,729
1806	2,905	1821	3,373	1836	4,054	1851	6,143
1807	2,465	1822	3,278	1837	4,790	1852	6,287
1808	2,371	1823	4,213	1838	5,130	1853	5,763
1809	2,548	1824	5,005	1839	...	1854	5,947
1810	2,036	1825	4,358	1840	...	1855	6,000
1811	2,385	1826	4,603	1841	...	1856	6,177
1812	2,373	1827	5,565	1842	...	1857	6,582
1813	2,324	1828	4,931	1843	...	1858	6,920
1814	2,611	1829	4,434	1844	...	1859	7,100

Mr. Carne again informs us that the prices paid to the tinner in Cornwall, between the years 1746 and 1781, varied from 60*s.* the cwt. to 72*s.* the cwt. In a Report of a Select Committee of the House of Lords, on the state of the British Wool Trade, is a table compiled by Edward Charles Hohler, giving the average prices of several articles, amongst others of tin, from 1783 to 1828 inclusive. From this table the following extract is made:—

	£	*s.*	*d.*			£	*s.*	*d.*	
1783 . .	4	1	7	per cwt.	1810 . .	7	9	8	per cwt.
1789 . .	3	10	3	"	1815 . .	7	3	0	"
1794 . .	5	0	3	"	1820 . .	3	15	9	"
1800 . .	5	4	2	"	1825 . .	4	16	6	"

This does not differ materially from the prices given by Mr. Carne as the prices paid to the tinner in Cornwall: the apparent discrepancies arise from the fact, that the above table is the price of tin in the metal market, therefore we have to add, to the price for tin ore, the cost of bringing it into the metallic state.

The value of the metallic tin produced in 1853, when the price varied from 112*l.* to 118*l.* per ton, may be estimated at 700,000*l.* In 1854 the range of prices, not very different from those of the previous year, gives a total value of 690,000*l.* The average prices of 1855 were: English blocks, 125*l.*; bars, 126*l.*; refined, 129*l.* In 1858, the mean average price was 119*l.* per ton. In 1868 it was 98*l.* In 1870 it rose to 127*l.*, and in 1872 to 152*l.* In 1873 it fell again to 133*l.*

Summary of Produce for each Year since 1859, *with the respective Values, &c.*

Years	No. of Mines	Tin Ore		Metallic Tin	
		Quantity	Value	Quantity	Value
		tons	£	tons	£
1860	148	10,400	812,160	6,656	866,306
1861	148	10,963	793,698	7,016	857,706

1873	217	14,936	1,056,126	10,006	1,334,300

Production of the Dutch Tin Mines since 1855.

This is so important in relation to the British Tin trade, that the preservation of the details is desirable.

Years	Banca[1]		Billiton, estimated

1854	96	180,687	0	11,779	14	0	0	1,153,756	3	6	140	2	0

After this period the quantities given are those produced in the year ending December 31.

The following summary for the United Kingdom for the period, ending 1873, will show the falling off in the production of that metal :—

Years	No. of Mines	Copper ore	Value	Copper	Value
		tons	£	tons	£
1863	222	210,947	1,100,554	14,247	1,409,608
1864	201	214,604	1,155,171	13,302	1,350,699
1865	203	198,298	927,938	11,888	1,134,664
1866	173	180,378	759,118	11,153	1,019,168
1867	164	158,544	699,693	10,233	831,761
1868	152	157,335	642,103	9,817	761,602
1869	136	129,953	519,912	8,291	644,065
1870	124	106,698	437,851	7,175	551,309
1871	122	97,129	387,118	6,280	475,143
1872	117	91,893	443,738	5,703	583,232
1873	122	80,188	342,708	5,240	508,822

[1] The produce of the mines for the years 1789 to 1794 cannot be obtained.

	1786	1787	1788	1794	1795
Years	1786	1787	1788	1794	1795
Tons	39,895	38,047	31,541	42,815	43,589
Amount	237,237*l.*	190,738*l.*	150,303*l.*	320,875*l.*	326,189*l.*

[2] This includes the last five years of the last century only.

The earliest accounts of the Swansea sales which we have been enabled to obtain are from 1804, when first the copper sales were published in the 'Cambrian' newspaper. The publication of the printed ticketing-papers commenced in 1839. As these returns show a very remarkable extension of the copper trade of Swansea, the amount sold for each year is given :—

Copper Ores sold at Swansea from the year 1804 *to* 1847.

Date	English	Welsh	Irish	Date	English	Welsh	Irish	Foreign

1825	2,061	1,191	5,350	1847	406	340	14,373	35,700

The accounts after 1847 were somewhat irregularly kept; but for the ten years ending 1849 the Cornish and Devonshire copper mines sold 1,480,551 tons of copper ore, which produced 114,665 tons of metallic copper. During the same period there were sold at Swansea 6,399 tons of English copper ore, 8,850 tons of Welsh, and 116,182 tons of Irish ore. After that date we are unable to separate in a satisfactory manner the British ores sold at Swansea from the colonial and foreign ores sold in each year. The following Table for each fifth year will, however, fairly represent the Swansea sales of this period.

Years	Ore	Copper				Value		
	tons	tons	cwts.	qrs.	lbs.	£	s.	d.
1850	41,586	7,108	8	1	11	549,258	3	6

The difference between this and the 365,450 tons given on the preceding page arises from the deficiency of returns from some of the smaller ports.

The total increase in the quantity of coal carried by railways and by canals in 1872, as compared with that distributed in 1871, *as shown in the returns obtained*, is, as stated, 4,305,617 tons. There are some not very important lines carrying coal, from which returns have not been received; and we have no returns of the quantities carried by carts, or private railways or trams, directly from the pit's mouth to the manufactory, or for the supply of towns. This, however, would not appear to have been largely increased over former years. The following computation of the coal used in our metallurgies, which is based upon information received directly from the smelters and ironmasters, shows that in that direction the increase in consumption has been very small:—

Coal used in Smelting, Refining, Desilverising, &c., of Metals in the United Kingdom.

Total of increase and decrease					371,605	365,532
Actual increase in the coal consumed in the above metallurgies in 1872					6,073	

The consumption of coal in the iron manufacture is computed, upon the information furnished to the Royal Coal Commission, at the rate of three tons of coal used, for all purposes, to each ton of *pig-iron* produced. For the year 1872 the Mining Record Office sought and obtained returns of the coal used for nearly all the blast-furnace establishments. As the result of the economy which has been rigidly pursued since the advance in the price of coal, we have only 51 cwts. of coal given as used for each ton of pig-iron produced. This will give the *quantity used in* 1872 as 17,191,918 tons only. As it is probable that the quanity given in 1871 is in excess, both years have been computed in the Table at the same rate, for strict comparison.

The returns of coals produced, as given by the inspectors, differ from those which appear in the mineral statistics for 1872, as shown below, by the addition of the coal raised in Ireland:—

Years	Coal raised in the United Kingdom	Increase	Coal raised in Great Britain (Inspector's Return)	Increase
	tons	tons	tons	tons
1871 . .	117,352,028	...	117,439,251	...
1872 . .	123,497,316	6,172,288	123,393,853	5,954,602

It has been shown that the increased quantity of coal carried by the railways is above 4,305,617 tons. It is thought, however, that the following estimation, made with great care, will have a very close approximation to the truth, as showing the total increase:—

	Tons
Railways and canals, 1872, increased . .	4,600,000
Exports, 1872, increased	450,505
Iron and other metallurgies, 1872, increased .	6,073
The quantities used at collieries and in mines, *estimated* increase	10,000
Coal carted, or sent by private rail- or tram-roads, to iron-works, manufacturers, and towns, which does not appear in the above returns, *estimated* increase.	250,000
	5,316,578
Coastwise shipments, decrease	300,214
Actual *estimated* increase in 1872 over the production of 1871	5,016,364

MINERAL TALLOW. See HATCHETTINE.

MINERAL WATERS. See SODA-WATER; and WATER.

MINES. (*Bergwerke*, Ger.) The miner, in sinking into the earth, soon opens up numerous springs, whose waters percolate into the excavations which he digs. When his workings are above the level of some valley and at no great distance, it is possible to get rid of the waters by leading them along an *adit-level* or *gallery of efflux*. This forms always the surest means of drainage; and, notwithstanding the great outlay which it involves, it is often the most economical. Many adit-levels are several miles in length, and are so contrived as to discharge the waters of several mines, as in the Gwennap district of Cornwall, and in the environs of Freiberg, in Saxony. Such an amount of slope should be given them as is barely sufficient to make the water run, at the utmost from $\frac{1}{200}$ to $\frac{1}{400}$, so as to drain the mine to the lowest possible level.

Whenever the workings are extended below the natural means of drainage, or below the level of the plain, recourse must be had to mechanical aids. In the first place, the quantity of percolating water is diminished as much as possible by planking, walling, or *tubbing*, with the greatest possible care, those pits and excavations which traverse the water-levels; and the lower workings are so arranged that all the waters may unite into *sumps* or wells placed at the bottom of the shafts or inclined galleries; whence they may be pumped up to the day, or to the level of the *gallery of efflux*. In most mines simple lifting-pumps are employed, but in those districts where the necessity of raising large volumes of water from great depths has led to improvement, forcing-pumps or *plunger*-lifts are introduced, placed over each other at intervals of from 180 to 240 feet, although, for convenience, a lifting-pump or *drawing-lift* occupies the deepest extremity of the shaft, whence it raises the water to the first plunger, and that again forces the stream upward through the column, or *trees*, to the one next above it, and so on up to the adit-level, or to the surface.

These draining-machines are set in motion by that mechanical power which happens to be least costly in the place where they are established. In almost the whole of England, and over most of the coal-mines of France and Silesia, the work is done by steam-engines; in the principal metallic mines of France, and in almost the whole of Germany and Hungary by hydraulic-machines; and in other places, by machines moved by horses, oxen, or even by men. If it be requisite to lift the waters merely to an adit-level, advantage may be derived from the waters of the upper parts of the mine, or even from waters turned in from the surface, in establishing in the adit-level water-pressure machines, or overshot water-wheels, for pumping up the lower water. This method is employed with success in several mines of Hungary, Bohemia, Germany, Derbyshire, Cornwall, in those of Poullaouen in Brittany, &c. It has been remarked, however, that the copious springs are found rather towards the surface of the soil than in the greater depths.

Transport of Ores to the Surface.

The ore being extracted from its bed, and having undergone, when requisite, a first sorting, it becomes necessary to bring it to the day: an operation performed in different ways, according to circumstances and localities, but too often according to a blind routine. There are some few mines at the present day where the interior transport of ore is executed on the backs of men: a practice the most disadvantageous possible, but which is gradually wearing out. The carriage along galleries is usually effected by means of sledges, barrows, or, still better, by little waggons. In many continental countries these consist of frames resting on four wheels; two larger, which are placed a little behind the centre of gravity, and two smaller, placed before it. When this carriage is at rest, it bears on its four wheels, and inclines forwards. But when the miner, in pushing it before him, leans on its posterior border, he makes it horizontal; in which case it rolls only upon the two larger wheels. Thus the friction due to four wheels is avoided, and the roller or trammer bears no part of the burden, as he would do with ordinary wheel-barrows. To ease the draught still more, two parallel rails of wood or iron are laid along the floor of the gallery, to which the wheels of the carriage are adjusted. It is especially in metallic mines, where the ore is heavy and the galleries often crooked, that these peculiar waggons are employed. In coal-mines larger waggons, or frames carrying large baskets, are preferred. The above wain, called on the Continent a *dog* (*chien*, *Hund*), is now often replaced by a larger tram or waggon with flanged wheels, running on edge-rails of wrought iron.

In the great mines, such as many of the coal and salt mines of Great Britain, the salt mines of Gallicia, the copper mines of Fahlun, and the lead mines of Alston Moor, horses have long been introduced into the workings to drag heavier waggons, or a train of waggons attached to one another. These animals often live many years under ground without ever revisiting the light of day, whilst in other cases they are brought to the surface at stated intervals, sometimes daily. In a few of the largest collieries it has been found preferable to establish stationary engines under ground, which bring the train of waggons, by means of an endless rope, along the galleries to the bottom of the shaft. In other mines, such as those of Worsley in Lancashire, subterranean canals are cut, upon which the mineral is transported in boats.

When the operations of a mine are commencing, and the works are of little depth, and employ few men, it is sufficient to place over the shaft a simple windlass, by means of which a few hands may raise the water-barrels and tubs or kibbles filled with stone or ore; but this method soon becomes inadequate, and must be replaced by *horse-whims* or more powerful machines.

Accessory Details.

Few mines can be travelled entirely by means of galleries: more usually there are shafts for mounting and descending. In the pits of many mines, especially of collieries, the men go down and come up by means of the machines which raise the mineral. In some mines of Mexico, Northern England, and the North of Europe, pieces of wood, fixed into each side of the pit, form the rude steps of a ladder by which the workmen pass up and down. In other mines, steps are cut in the rock or the mineral, as in the quicksilver mines of Idria and the Palatinate, in the salt mines of Wieliczka, and some of the silver mines of Mexico. In the last, as in the East, they serve for the transport of the ore, which is carried up on men's backs. Lastly, some mines, as in the Austrian Alps, are descended by means of sloping timbers, some of which have an inclination of more than 30°. The workmen in sliding down, in a sitting position, regulate the velocity of the descent by holding a cord, which is fixed along the upper side or roof of the inclined shaft. For description of machines used to facilitate the ascent and descent of miners in shafts, see Man-Engine.

Miners derive light from candles or lamps. They carry the former in a lump of moist clay, or in a kind of socket, terminated by an iron point, which serves to fix it to the side of the excavation, or to the timbering. The lamps are made of iron, tinplate, or brass, hermetically closed, and so suspended that they may not readily droop or invert, and spill the oil. They are generally hung on the thumb by a hook, so as to leave the rest of the hand at liberty for climbing. Miners also employ small lanterns suspended from a button-hole or from the girdle. Many precautions and much experience are requisite to enable them to carry these lights in a current of air, or in a vitiated atmosphere. It is especially in coal mines liable to the disengagement of carburetted hydrogen, or *fire-damp*, that measures of precaution are indispensable against explosions. The appearance of any halo round the flame must be carefully watched, as indicating danger, and the lights should be carried near the bottom of the gallery. The great protectors against these deplorable accidents are ventilation and the safety-lamp. See SAFETY-LAMP.

We cannot conclude this general outline of the working of mines without giving some account of the miners. Most men have a horror at the idea of burying themselves, even for a short period, in these gloomy recesses of the earth. Hence mining operations were at first so much dreaded, that in early times they could only be carried on by the employment of slaves. This dislike has diminished in proportion to the improvements made in mining; and finally, a profitable and respected source of gain, requiring a more than average exercise of skill and intellect, has given mining its proper rank among the other branches of industry; and that *esprit de corps*, so conspicuous among seamen, has also arisen among miners, and adds dignity to their body. Like every society of men engaged in perilous enterprise, and cherishing the hopes of great success, miners get attached to their profession, which, as they advance in intelligence, they regard with pride, and eventually in their old age they look upon other occupations with something like contempt. They form in certain countries, such as Germany and Sweden, a body formally constituted, which enjoys considerable privileges; and the disgrace of being ejected from that body appears to exert in those countries a good moral influence. Miners work usually for eight hours at a time, this being called a *core* or *shift* (*poste* in French, *Schicht* in German).

Miners wear in general a hat or cap capable of withstanding a blow, and a dress suited to protect them as much as possible from the annoyances caused by water, mud, or strong draughts of air. One of the most essential parts of the costume of the German miner is an apron of leather, fitted on behind, so as to protect him when seated on a moist surface or on angular rubbish. In England the miners mostly wear flannel next to the skin, though they frequently in deep mines strip off all their clothes except their trousers. In most countries the hammer and small pick or wedge, the instruments with which before the employment of gunpowder all mining was performed (called in German, *Schlägel* and *Eisen*), disposed in a St. Andrew's cross, are the badge of miners, and are engraved on their buttons, and on everything belonging to mines.

Many of the enterprises executed in mines, or in subserviency to them, occupy a distinguished rank in the history of human labours. Several mines in the Hartz, in Bohemia, and in Cornwall, have been worked to a depth of above and near 2,000 feet; those, indeed, of Kuttenberg in Bohemia are said to have penetrated to 3,000 feet below the surface of the soil.

A great many descend beneath the level of the ocean; and a few even extend far under its billows, and are separated from them by a thin partition of rock, which allows their noise and the rolling of the pebbles to be heard.

In 1792 there was opened at Valenciana in Mexico, an octagonal pit, fully 7½ yards wide, destined to have a depth of 560 yards, to occupy 23 years in sinking, and to cost 240,000*l.*

The great drainage-gallery of the mines of Clausthal, in the Hartz, is 11,377 yards, or 6½ miles long, and passes upwards of 300 yards below the church of Clausthal. Its excavation was commenced at thirty different points, lasted from the year 1777 till 1800, and cost about 66,000*l.* This adit, known as the *Georg Stolln*, having been found inadequate to the drainage of the mines, a deeper gallery was commenced in 1851. This deep adit, known as the *Ernst August Stolln*, was completed in 1864, at a cost of 85,500*l.* The *great adit* (which drains so many of the important mines in the parish of Gwennap in Cornwall to the depth of from 30 to 60 fathoms) amounts, with its branches, to 30 miles in length. Several other galleries of efflux might also be adduced as remarkable for their great length and expense of formation.

The coal and iron mines subservient to the iron-works of Mr. Crawshay, at Merthyr-Tydvil, in Wales, has given birth to the establishment, interiorly and above ground, of iron railways, whose total length, many years ago, was upwards of 100 miles.

The carriage of the coal extracted from the mines in the neighbourhood of Newcastle to their points of embarkation is executed almost entirely, both under ground and on the surface, on iron railways, extending over some thousands of miles.

There is no species of labour which calls for so great a development of power as that of mines; and accordingly it may be doubted if (with the exception of some few engines for the large ocean-steamers) man has ever constructed machines so powerful as those which are now employed for the working of some mineral excavations. The waters of several mines of Cornwall are pumped out by means of steam-engines, whose force is equivalent, in some instances, to the simultaneous action of many hundred horses.

General Summary of Mines.

Mines may be divided, generally, into three great classes:—1. Mines in unstratified rocks and the geological formations anterior to the coal strata. 2. Mines in the carboniferous and secondary formations. 3. Mines in alluvial districts.

The first are opened, for the most part, upon veins, masses, and metalliferous beds.

The second, on strata of combustibles, as coal; and metalliferous or saliferous beds.

The last, on deposits of metallic ores, disseminated in clays, sands, and other alluvial matters, geologically superior to the chalk and tertiaries, and of far more recent formation.

The mines of these three classes, placed for the most part in very different physical localities, differ no less relatively to the mode of working them, and their mechanical treatment, than in a geological point of view.

The progress of geological science, however, shows that these divisions cannot be so definitely made as was formerly supposed, and that same of the rocks which were considered to be very ancient, are, in fact, among the more modern of the secondary strata. Thus, most of the metalliferous formations of the Andes, and of Hungary, ought, in strictness, to be classed with the upper secondary, or even the tertiary strata, although they have often been so metamorphosed as to present an appearance very similar to the older rocks.

The following grouping, it will be understood, refers the mines to physical and not to political boundaries:—

Mines of the Hartz.

The name Hartz is given generally to the country of Forests, which extends a great many miles round the *Brocken*, a mountain situated about 55 miles W.S.W. of Magdeburg, and which rises above all the mountains of North Germany, being at its summit 1,226 yards above the level of the sea. The Hartz is about 43 miles in length from SS.E. to NN.W., 18 miles in breadth, and contains about 450 square miles of surface. It is generally hilly, and covered two-thirds over with forests of oaks, beeches, and firs. This rugged and picturesque district corresponds to a portion of the *Silva Hercynia* of Tacitus. As agriculture furnishes few resources there, the exploration of mines is almost the only means of subsistence to its inhabitants, who amount to about 50,000. The principal towns, *Andreasberg*, *Clausthal*, *Zellerfeld*, *Altenau*, *Lautenthal*, *Wildemann*, *Grund*, and *Goslar*, bear the title of mine-cities, and enjoy peculiar privileges; the people deriving their subsistence from working in the mines of lead, silver, and copper, over which their houses are built.

The most common rock in the Hartz is greywacke. It incloses the principal veins, is associated with clay-slate, Lydian stone, or siliceous slate, and greenstones; and is succeeded in geological order by a limestone referable, with a large proportion of the slaty beds, to the Devonian system. The granite of which the Brocken is formed supports all this system of rocks, forming, as it were, their nucleus.

The veins of lead, silver, and copper, which constitute the principal wealth of the Hartz, do not pervade its whole extent. They occur chiefly near the towns of Andreasberg, Clausthal, Zellerfeld, and Lautenthal; are generally directed from E. to W., and dip to the N.E. in the Andreasberg, and to the S. in the Clausthal district, at an angle of about 80° with the horizon.

The richest silver mines are those of the environs of Andreasberg, among which may be distinguished the Samson and Neufang mines, worked to a depth of 2,740 English feet or 456 fathoms. In the first of them there is the greatest *step* exploitation to be met with in any mine. It is composed of 80 *underhand stopes*, and is more than 650 yards long. These mines were discovered in 1520, and the city was built in 1521. They produce argentiferous galena, with silver ores properly so called, such as red silver ore, and ores of cobalt.

The district which yields most argentiferous lead is that of Clausthal. It comprehends a great many mines, several of which are worked to a depth of above 300 fathoms. Such of the mines as are at the present day most productive, have been explored since the first years of the 18th century. Two of the most remarkable ones are the mine of Dorothea, and the mine of Carolina, which alone furnish a large proportion of the whole net product. The grant of the Dorothea mine extends over a length of 257 yards, in the direction of the vein, and through a moderate breadth perpendicularly to that direction. Out of these bounds, apparently so small, but which however surpass those of the greater part of the *concessions* in the Hartz, there were extracted from 1709 to 1807 inclusively, 883,722 marcs of silver, 768,845 quintals of lead, and 2,385 quintals of copper. This mine and that of Carolina have brought to their shareholders in the same period of time more than 1,120,000*l.* profit; and have besides powerfully contributed by loans without interest to carry on the exploration of the less productive mines. It was in order to effect the drainage of the mines of the district of Clausthal, and those of the district of Zellerfeld adjoining, that the great Adit Levels have been excavated.

Below George III.'s Deep Adit (*Georg Stolin*) a still deeper gallery has been constructed, known as the Ernest Augustus Adit (*Ernst August Stolln*), and to complete the drainage of the mines in this district a water-level is in course of construction, 126 fathoms below the Deep Adit, or about 320 fathoms below the surface.

Next to the two districts of Clausthal and Zellerfeld, and Andreasberg, comes that of Goslar, the most important working in which is the copper mine of the *Rammelsberg*, opened since the year 968, on a mass of copper pyrites, disseminated through quartz, and mingled with galena and blende. It is worked by shafts and galleries, with the employment of fire to break down the ore. This mine produces annually from 1,200 to 1,300 metric quintals (about 275,000 lbs. avoird.) of copper. The galena extracted from it yields a small quantity of silver and a very little gold. The latter metal amounts to only the five-millionth part of the mass explored; and yet means are found to separate it with advantage. The mine of *Lauterburg* is worked solely for the copper, and it furnishes annually nearly 66,000 lbs. avoird. of that metal.

Besides the explorations just noticed, there are a great many mines of iron in different parts of the Hartz, which give activity to important forges and furnaces. The principal ores are sparry iron, and red and brown hæmatites, which occur in veins, beds, and masses.

The territory of Anhalt-Bernberg presents, towards the S.E. extremity of the Hartz, lead and silver mines, which resemble closely those of the general district. They produce annually 33,000 lbs. avoird. of lead.

At the southern foot of the Hartz, at Ihlefeld, there is a mine of manganese.

The exploration of the Hartz mines may be traced back for about 900 years. The epoch of their greatest prosperity was the middle of the 18th century. Their gross annual amount was, in 1808, upwards of one million sterling. Lead is their principal product, of which they furnish annually 100,000 quintals, with 44,000 marcs, or 22,000 lbs. avoird. of silver, about 360,000 lbs. avoird. of copper, and a very great quantity of iron. Some of these mines are worked by the Government, others by companies of adventurers. They are celebrated for the excellence of their mining operations, for the systematic application of the processes for dressing the ores, and for the activity, patience, and skill of their workmen.

The Hartz is referred to especially for the manner in which the waters are collected, and economised for floating down the timber, and impelling the machinery. With this view, dams or lakes, canals and aqueducts, have been constructed, remarkable for their good execution. The watercourses are formed either in the open air round the mountain sides, or through their interior as subterranean galleries. The open channels collect the rain-waters, as well as those proceeding from the melting of snows, from the springs and streamlets, or small rivers that fall in their way. The subterranean conduits are in general the continuation of the preceding, whose circuits they cut short. These watercourses present a development in all, of above 125 miles. The banks of some of the reservoirs are of an extraordinary height. In the single district of Clausthal there are 63 ponds, which supply water to a great number of overshot wheels; of those attached to the mines, 46 wheels are at the surface, 21 and 3 water-pressure engines underground, whilst 50 wheels are applied to the dressing machinery, and 39 to the smelting furnaces.

In the mines of the Upper Hartz alone 5,000 persons are employed.

Mines of the East of Germany.

We shall embrace under this head the mines opened in the primary and transition territories, which constitute the body of a great portion of Bohemia, and the adjacent parts of Saxony, Bavaria, Austria, Moravia, and Silesia.

Among the several chains of small mountains that cross these countries, the richest in deposits of ore is the one known under the name of the *Erzgebirge*, which separates Saxony from Bohemia on the left bank of the Elbe.

The *Erzgebirge* contains a great many mines, whose principal products are silver, tin, and cobalt. These mines, whose exploration remounts to the 12th century, and particularly those situated on the northern slope within the kingdom of Saxony, have been long celebrated. The school of mines established at Freiberg has been considered the most complete in the world. This is a small city near the most important workings, 8 leagues W.S.W. of Dresden, towards the middle of the northern slope of the Erzgebirge, 440 yards above the level of the sea, in an agricultural and trading district, well cleared of wood. These circumstances have modified the working of the mines; and render it difficult to draw an exact parallel between them and those of the Hartz, which are their rivals in good exploration. They are peculiarly remarkable for the perfection with which the engines are constructed both for drainage and extraction of ores, all moved by water or horses; for the regularity of almost all the subterranean labours; and for the beauty of their *walling* masonry. In the portion of these mountains belonging to Saxony, the underground workings employ directly from 9,000 to 10,000 men, who labour in more than 400 distinct mines, all associated under the same plan of administration.

The silver mines of the *Erzgebirge* are opened on veins which traverse gneiss; and though quite different in this respect from the argentiferous veins of *Clausthal*, *Guanaxuato*, *Schemnitz*, and *Zmeof*, present but a moderate thickness, rarely exceeding a few feet. They form several groups, whose relative importance has varied very much at different periods.

For a long time back, those of the environs of Freiberg have been much the most productive; and their prosperity has been always on the advance, notwithstanding the increasing depth of the excavations. Many of the mines now exceed 220 fathoms in depth, and with a view of relieving them of a part of the height through which the water has to be raised, an Adit Level from the valley of the Elbe at Meissen, a distance of above 18 miles is brought up. The most productive and the most celebrated in the present century have been the mines of Himmelsfürst, Himmelfahrt, and that of Beschertglück.

Among the explorations of the Erzgebirge there are none which were formerly so flourishing as those of Marienberg, a small town situated seven leagues SS.W. of Freiberg. In the 16th century ores were frequently found there, even at a short distance from the surface, which yielded 85 per cent. of silver. The disasters of the Thirty Years' War put a term to their prosperity. Since that period they have continually languished; and their product now is very small.

Our limits do not permit us to describe in detail the silver mines that occur near *Ehrenfriedersdorf*, *Johann-Georgenstadt*, *Annaberg*, *Oberwiesenthal*, and *Schneeberg*. Those of the last three localities produce also cobalt.

The mines of Saint-George near Schneeberg, opened in the 15th century as iron mines, became celebrated some time after as mines of silver. Towards the end of the 15th century, a mass of ore was found there which afforded 400 quintals of silver. On that lump, Duke Albert's dinner was served at the bottom of the mine. Their richness in silver has diminished since then; but they have attained more importance during the last 200 years, as mines of cobalt, than they ever had as silver mines. Saxony is the country where cobalt is mined and extracted in the most extensive manner. It is obtained from the same veins with the silver. Smalt, or cobalt-blue, is the principal substance manufactured from it. A little bismuth is extracted from the mines of Schneeberg and Freiberg. Some manganese is found in the silver mines of the Erzgebirge, and particularly at Johann-Georgenstadt.

The mines of Saxony produce a little argentiferous galena and argentiferous grey copper; but the ores of lead and copper may be regarded almost as only accessory products of the silver lodes, from which 78,000 centner or cwts. of the first of these metals are annually extracted, and 341 cwts. of copper. The actual minerals of silver are the more important ores. They were treated partly by amalgamation, at the excellent establishment of Halsbrücke, which was closed in 1859, and partly by smelting processes, the principal works for which are on the Mulde, near Freiberg. The average richness of the silver ores throughout Saxony is only from 3 to 4 oz. per quintal; viz. nearly equal to that of the ores of Mexico, and very superior to the actual richness of the ores of Potosi. The silver extracted from them contains a little gold. The Saxon mines produced, in 1856, 55,500 lbs. of silver. Of these, the district of Freiberg alone furnished 54,000; and among the numerous mines of that district, that of Himmelsfürst of itself used to produce 10,000 marcs.

Silver mines exist also on the southern declivity of the Erzgebirge, which belongs to Bohemia, at *Joachimsthal* and *Bleistadt*, to the N.E. of Eger. Argentiferous galena is principally extracted from the latter, from lodes in the crystalline slates.

The mines of Joachimsthal have been explored to a depth of 650 yards. They were formerly very flourishing; but in 1805 they were threatened with an impending abandonment. More active operations have recently been commenced; and the minerals raised are various ores of silver, and ores of cobalt, nickel, uranium and bismuth. The ancient mines of Kuttenberg, situated farther east, near Gitschin, have been excavated, according to old authors, to the depth of 500 fathoms, but have long been abandoned.

Mines of silver and lead are also worked in gneiss at Ratiborzitz; Adamstadt, near Budweis, which yielded in 1852, 1,200 marcs of silver; Michelsberg, near Plan; Klostergrab, near Teplitz; and Mies, 25 leagues W.S.W. of Prague, at the base of the Böhmerwaldgebirge, a chain of mountains which separates Bohemia from Bavaria.

The most important in the country, and some of the most flourishing in Europe, are at *Przibram*, 12 leagues S.W. of Prague, at the extremity of the mountains which separate the Beraun from the Moldau. In this district, the argentiferous galena is accompanied by blende, in which the presence of cadmium has been observed. These mines, which are worked with all the newest appliances, and have reached in places above 300 fathoms in depth, yield annually 45,000 marcs of silver, and 20,000 cwts. of lead. The lodes, about 50 in number, are most productive in the greywacke, and course N.E. and S.W.

Gold, which in early times was obtained in large quantity from the rivers of Bohemia, has been extracted from veins in gneiss at Bergreichenstein and at Eule, and in granite at Tok and Mileschow.

The copper ore at present worked in several localities is very unimportant.

Next to the silver mines, the most important explorations of the Erzgebirge are those of tin. This metal occurs in veins, massive, and disseminated in masses of vitreous grey quartz, imbedded in the granite. It is also found in alluvial sands. The most important tin mine of the Erzgebirge is that of Altenberg, in Saxony, which has been working since the 15th century. Some tin is mined also near Geyer, Ehrenfriedersdorf, Johann-Georgenstadt, Scheibenberg, Annaberg, Seiffen, and Marienberg, in Saxony. At Zinnwald it is also found; where the stanniferous district belongs partly to Saxony and parly to Bohemia; important mines also occur in the latter territory at Schlackenwald, Graupen, and Abertham, and slightly productive ones at Platten and Joachimsthal. In several of these mines, particularly at Altenberg and Geyer, fire has been employed for attacking the ore, because its matrix is extremely hard. In almost the whole of them, chambers of too great dimensions have been excavated, whence have arisen, at different epochs, serious sinkings of the ground. One of these may still be seen at Altenberg, which is 130 yards deep, and nearly 50 in breadth. The mines of Abertham are explored to a depth of 550 yards; and those of Altenberg to 330. The tin mines of the Erzgebirge produce annually 2,500 cwts. of this metal.

The tin ores are accompanied by arsenical pyrites, which, in the roasting or calcination that it undergoes, produces a certain quantity of arsenious acid.

The Erzgebirge presents also a great many iron mines, particularly in Saxony, at *Rothenberg*, near Schneeberg, where the lode is of fine hæmatite, and from 12 to 24 feet in thickness. In Bohemia, at Platten, where may be remarked especially the great explorations opened in the vein called the *Irrgang*; at Horzowicz, where an excellent hæmatite is worked; at Ransko, and many other places.

There is also in the Erzgebirge a mine of anthracite (stone-coal) at *Schönfeld*, near Frauenstein in Saxony.

The ancient rock formations which appear in the remainder of Bohemia, and in the adjacent portions of Bavaria, Austria, Moravia, and Silesia, are much less rich in metals than the Erzgebirge. No explorations of much importance exist there.

The *Fichtelgebirge*, a group of mountains standing at the western extremity of the Erzgebirge, between Hof and Bayreuth, contains some mines, among which may be noticed, principally, mines of magnetic black oxide of iron and of antimony.

The N.E. slope of the Riesengebirge (Giant Mountains), which separate Bohemia from Silesia, presents also several explorations. The argentiferous copper mines of *Rudolstadt* and of *Kupferberg* have been stated as producing annually a considerable quantity of copper, and from 600 to 700 marcs of silver; the mine of arsenical pyrites at Reichenstein, in the circle of Glatz, yields also a very small proportion of gold. Chrysopase has been found in the mountain of Kosenitz.

Mines of the Alps and Italy.

The mines of the Alps by no means correspond in number and richness with the extent and mass of these mountains. On their western slope, in the department of the High and the Low Alps, several lead and copper mines are mentioned, all inconsiderable and abandoned at the present time, with the exception of some workings of galena, which furnish also a little graphite.

During some of the last years of the 18th century, there was mined at *La Gardette* in the *Oisans*, department of the Isère, a vein of quartz which contained native gold and auriferous pyrites; but the product never paid the expenses, and the mine has been abandoned. The workings were resumed in 1837. See description in *Journal des Mines*, t. xx.

The department of the Isère presented a more important mine, worked with regularity from 1768 to 1815; but it also has been given up; it was the silver mine of *Allemont* or *Chalanches*. The ore consisted of different mineral species, more or less rich in silver, disseminated in a clay which filled the clefts and irregular cavities in the middle of talcose and hornblende rocks. This mine yielded annually, towards the conclusion of the 18th century, as much as 2,000 marcs of silver; along with some cobalt ore. Among the great number of mineral species, which occurred in too small quantities to be worked to advantage, there were native antimony, sulphuret of mercury, &c. In the High Alps the mine of argentiferous galena called *L'Argentière* has been resumed.

From the entrance of the valley of the *Oisans* to the valley of the *Arc* in Savoy, there occur, on the N.W. slope of the Alps, a great many mines of sparry iron. The occurrence of this ore is here very difficult to define. It appears to form sometimes beds or masses, and sometimes veins amid the talcose rocks. Some is also found in small veins in the first course of the calcareous formation which covers these rocks. These mines are very numerous, the most productive occur united in the neighbourhood of *Allevard*, department of the Isère, and of *Saint Georges d'Hurctières* in Savoy. Those of *Forneaux* and *Laprat*, in the latter country, are also mentioned. The irregularity of the mining operations surpasses that of the deposits. The mines have been from time immemorial in the hands of the inhabitants of the adjoining villages, who work in them, each on his own account, without any pre-arrangement, or other rule than following the masses of ore which excite hopes of the most considerable profit in a short space of time. What occurs frequently in mines of sparry iron, is also to be seen here, most imprudent workings. The mine called the *Grande Fosse*, at *Saint Georges d'Huretières*, is prolonged, without pillars or props, through a height of 130 yards, a length of 220 yards, and a breadth equal to that of the deposit, which amounts in this place to from 8 to 13 yards; thus a void space is exhibited of nearly 300,000 cubic yards. The sparry iron extracted from these different mines supplies materials to 10 or 12 smelting furnaces, the cast-iron of which, chiefly adapted for conversion into steel, is manufactured in part in the celebrated steel works of *Rives*, department of the Isère. There occurs in some parts of the mines of *Saint Georges d'Huretières* copper pyrites, which is smelted at *Aiguebelle*.

Savoy presents celebrated lead mines at *Pesey* and at *Macot*, 7 leagues to the E. of Moutiers. Galena, accompanied with quartz, sulphate of baryta, and ferriferous carbonate of lime, occurs in mass in talcose rocks. The mine of Pesey was taken up in 1792 by the French Government, which established there a practical school of mines; and in its hands the mine produced annually as much as 440,000 lbs. avoird. of lead, and 2,500 marcs of silver. That of *Macot*, opened a few years ago, has given considerable returns. The mine of copper pyrites of *Servoz*, in the valley of the Arve, may also be mentioned. The ore occurs both in small veins and disseminated in a clay slate; but the exploration is now suspended. Lastly, slightly productive workings of anthracite are mentioned in several points of these mountains and in the conterminous portions of the Alps.

There exist in Piedmont some small mines of argentiferous lead. The copper mines of *Allagne*, and those of *Ollomont*, formerly yielded considerable quantities of this metal. Their exploration is now on the decline. The manganese mines of *Saint-Marcel* have been but feebly developed. Mines of plumbago, little worked, occur in the neighbourhood of *Vinay* and in the valley of *Pellis*, not far from *Pignerol*. Some mines of auriferous pyrites have also been worked in this district of country; among others, those of *Macugnaga*, at the eastern foot of Monte Rosa. The pyrites of this mine afforded by amalgamation only 11 grains of gold per quintal; and this gold, far from being fine, contained ¼ of its weight of silver. They became less rich in proportion as they receded from the surface. Several similar mines are working in the valleys of Anzasca, Toppa, and Antrona, in the province of Pallanza; the value of the produce being about 20,000*l.* annually.

The most important mines in this country are those of iron. These generally consist of masses of magnetic oxide of iron, of a nature analogous to those of Sweden; the principal ones being those of Cogne and Traversella, which are worked in open quarries. Some others, less considerable, are explored by shafts and galleries. These ores are reduced in smelting cupolas, and Catalan forges. There are considerably above one hundred refinery hearths. The whole produce is stated to be from 10,000 to 15,000 tons of bar iron.

There is a mine of black oxide of iron, at present abandoned, at *Bovernier*, near Martigny, in the Valais. There is also another iron mine at Chamoissons, in a lofty calcareous mountain on the right bank of the Rhône. The ore presents a mixture of oxide of iron and some other substances, of which it was proposed to make a new mineral species, under the name of Chamoissite.

The district of the Grisons possesses iron mines with very irregular workings, situated a few leagues from *Coire*.

In Tyrol, the mines of Kitzbühel and Röhrerbüchel were formerly worked with great activity, and in the middle of the eighteenth century had attained the depth of 440 fathoms; they were then considered the deepest in Europe, but were soon afterwards abandoned. The ores, copper pyrites, and argentiferous *fahlerz* occurred in clay-slate. The products of some small mines in this locality, certain of which are worked in a secondary limestone (as as Rattenberg), are carried to the foundry of Brixlegg, four leagues from Schwatz. The mines of the Tyrol furnished, on an average of years, towards 1759, 10,000 marcs of silver; at anterior periods, their product had been double; but now it is a little less. This region contains also gold mines whose exploration goes back a century and a half. They occur near the village of Zell, eight leagues from Schwatz. The auriferous veins traverse clay-slates and quartzose-slates. The richer portions contain 16 to 20 loth (at ½ an oz.) of gold in 100 cwts. of vein-stone; the remainder only ½ to ¾ of a loth in the same quantity.

At Borgo near Trient, and Pfundererberg near Clausen, lodes occur in clay-slate and greenstone-porphyry, from which are extracted ores of silver, lead, copper, and zinc. An unimportant occurrence of mercury has also been mentioned in that country, near the *Brenner*.

In the territory of Salzburg there are some copper mines; at Zell am See, Brenn thal, Muhl, and Mitterberg, near Werfen. In the lofty-mountain region near Gastein auriferous lodes have been worked for centuries at the Rathausberg, Sieglitz, and Rauris. From 118 marcs of gold in the earlier part of the century, the annual yield has diminished to 80.

At Leogang and Nockelberg an inconsiderable amount of cobalt and nickel ore is raised.

There are mines of argentiferous copper, some of them also yielding nickel and cobalt, analogous to those of the Tyrol, at Schladming, Feistritz, Walchern, and Kallwang; in Styria; at Gross-Fragant and Arza in Carinthia. In the last-mentioned province, the mines of St. Marein and Saversnig yield considerable quantities of lead; whilst at Agordo, in the Venetian Alps, copper ores are raised on a large scale.

At Radlberg and Lassnigberg, in Carinthia, about 321 cwts. of antimony were annually produced a few years since.

Other lead mines of this portion of the Alps, as those of Bleiberg and Raibl, are worked in limestones belonging to the secondary period.

In the Tyrol and in Salzburg, at Schwartz, Pillersee, Bischofshofen, &c., various ores of iron are worked. But the portion of the Alps most abundant in mines of this metal is the branch stretching towards Lower Austria. We find here, both in Styria and in Austria, a very great number of explorations of sparry iron. The deposits of the ores of sparry iron of Eisenerz, Erzberg, Admont, and Vordernberg, deserve notice. The latter are situated about 25 leagues S.W. of Vienna.

The southern flank of the Alps contains also a great many mines of the same kind, from the Lago Maggiore to Carinthia. Those situated near Bergamo, and those of Wolfsberg, Hüttenberg, and Waldenstein, in Carinthia, are among the more notable.

All these mines of sparry iron are opened in the midst ef rocks of different natures, which belong to the old transition district of the Alps. They seem to have close geological relations with those of Allevard.

The branch of the Alps which extends towards Croatia, present important iron mines, in the mountains of Adelsberg, 10 leagues S.W. from Laybach in Carniola.

The iron mines just now indicated in the part of the Alps that forms a portion of the Austrian Empire, supply materials to a great many smelting-works. In Styria and in Carinthia more than 400 furnaces or forges may be enumerated, whose annual product has increased within the last few years from 20,000 to upwards of 100,000 tons of pig-iron. These two provinces are famous for the steel which they produce, and for the good iron and steel tools which they manufacture, such as scythes, &c. Carniola contains also a great many forges, and affords annually about 5,000 tons of iron.

The limestones surmounting the southern slope of the Alps contain also some lead mines; but the quicksilver mine of Idria, situated in Carniola, 10 leagues N.W. of Trieste, is worthy of particular notice. It lies beneath a limestone which everything leads us to refer to the *trias* and Halstatt beds, the most ancient of the secondary limestone; but it is uncertain whether the shales in which the cinnabar occurs, and their underlying limestone, belong to the carboniferous or to an older series. About 2,500 cwts. of quicksilver are produced annually.

There has been worked for a few years a mine of chromate of iron at Gassin, department of the Var.

The Apennines, which may be considered as a dependence of the Alps, present a small number of mines, most of them worked on repositories of ore which have a marked relation to the occurrence of serpentine. Thus a most successful copper mine has been in active operation for some years at Monte Catini, in Tuscany; and in the same district of the Maremme several other localities have been worked for copper, mercury, and antimony.

Before quitting these regions we ought to notice the iron mines of the isle of Elba. They have been famous for 18 centuries; Virgil denotes them as inexhaustible, and supposes them to have been open at the arrival of Æneas in Italy. They are explored by open quarries, working on an enormous mass of specular iron ore, perforated with cavities bespangled with quartz-crystals. The island possesses two explorations, called Rio and Terra Nuova; the last having been brought into play at a recent period. The average amount extracted per annum is 25,000 tons of ore, which are smelted in the furnaces of Tuscany, Liguria, and other parts of Italy, and in the island of Corsica. The island of Sardinia contains many indications of silver, lead, and copper ores; but few important mines have been opened in modern times. Zinc and lead ores are, however, worked in Sardinia.

'In the kingdom of Italy, there are 116 mines in operation, about one quarter of the whole number in the country: 45 are iron, 34 copper, 13 argentiferous lead, 14 auriferous pyrites; the other are, 10 zinc, mercury, nickel, and manganese. The metallurgical works treating Italian ores are 335, subdivided as follow:—Iron works, 299; copper, 21; argentiferous, 10; gold, 2; others, 3. The iron ores of Italy are specular, and oligiste iron ores in the islands of Elba, at Cogne, Valley of Aosta, and Tebro in the Valtelina, besides several deposits in Sardinia; hæmatite at Penedoletto in Valtelina, and Pizzano in South Italy; spathic iron, slightly manganiferous, in the Red Sandstone of the Trias; spathic iron, highly manganiferous, and spathic iron in veins. Of the 45 iron mines in operation, 29 are situated in Lombardy, 8 in Piedmont, 5 in Tuscany; Sardinia, Calabria, and Emilia having the three others. The iron mines employ 1,888 workmen and 324 children. The smelting works are 336 in number, of which 299 are in operation, and 37 closed; the former using a motive-power of 5,588 horses, of which 4,353 are produced by water and 1,190 by steam. Italy has 38 blast-furnaces. The iron works have 2,510 skilled workmen and 5,667 labourers; the former receive 3·05 francs a day, the latter 1·80 franc, and the children 0·80 franc. The number of working days is about 300 a year. There are, besides, three mines of iron pyrites near Turin, for the fabrication of sulphuric acid and copperas.'

Mines of the Vosges and the Black Forest.

These mountains contain several centres of exploration of argentiferous ores of lead and copper, iron ores, and some mines of manganese and anthracite.

At *Lacroix-aux-Mines*, department of the Vosges, a vein of argentiferous lead has been worked, which, next to the veins of Spanish America, is one of the greatest known. It is several fathoms thick, and has been traced and mined through an extent of more than a league. It is partly filled with *débris*, among which occurs some argentiferous galena. It contains also phosphate of lead, ruby-silver ore, native silver, &c. It runs from N. to S. nearly parallel to the line of junction of the gneiss, and a porphyroid granite, that passes into syenite and porphyry. In several points it cuts across the gneiss; but it probably also occurs between the two rocks. It has never been worked below the level of the adjoining valley. The mines opened on this vein produced, it is said, at the end of the 16th century 26,000*l.* per annum; they were still very productive in the middle of the last century, and furnished, in 1756, 2,640,000 lbs. avoird. of lead, and 6,000 marcs, or 3,230 lbs. avoird. of silver.

The veins explored at *Sainte Marie-aux-Mines* also traverse the gneiss; but their direction is nearly perpendicular to that of the vein of *Lacroix*, from which they are separated by a barren mountain of syenite. They contain, besides galena, several ores of copper, cobalt, and arsenic; all more or less argentiferous. There is found also, at a little distance from *Saint Mary of the Mines*, a vein of sulphuret of antimony. The mines of *Sainte Marie*, opened several centuries ago, are among the most ancient in France; and yet they have been worked very little below the level of the adjoining valleys.

There has been opened up in the environs of *Giromagry*, on the southern verge of the Vosges, a great number of veins, containing principally argentiferous ores of lead and copper. They run nearly from N. to S., and traverse porphyries and clay-slates. The workings have been pushed as far as 440 yards below the surface. These mines were in a flourishing state in the 14th and 16th centuries; and became so once more at the beginning of the 17th, when they were undertaken by the house of Mazarin. In 1743 they still produced 100 marcs, fully 52 lbs. avoird. of silver in the month.

The mines of *Lacroix*, of *Sainte Marie-aux-Mines*, and of *Giromagny*, are now abandoned; but it is hoped that those of the first two localities will be resumed ere long.

In the mountains of the Black Forest, separated from the Vosges by the valley of the Rhine, but composed of the same rocks, there occur at *Badenweiler* and near *Hochberg*, not far from Freiberg, mines which have at times been actively worked. In the Fürstenberg district, near *Wolfach*, particularly at *Wittichen* and *Schapbach*, there are mines of copper, cobalt and silver. The mines of Wittichen produced, some years ago, 1,600 marcs, or near 880 lbs. avoird. of silver per annum. They supply a manufacture of smalt, and one of arsenical products. A few other inconsiderable mines of the same kind exist in the grand-duchy of Baden, and in Wurtemberg.

Several important iron mines are explored in the Vosges; the principal are those of *Framont*, whose ores are red oxide of iron, with crystalline specular ore, which appear to form veins of great thickness, much ramified, and very irregular, in a district composed of greenstone, limestone and clay-slates. The subterranean workings, opened on these deposits, have been hitherto very irregular. There has been discovered lately in these mines, an extremely rich vein of sulphuret of copper. At *Rothau*, a little to the east of Framont, thin veins of red oxide of iron are worked; sometimes magnetic, owing probably to an admixture of protoxide of iron. These veins run through a granite, that passes into syenite. At Saulnot near Belfort, there are iron mines, analogous to those of Framont.

In the neighbourhood of Ihann and Massovaux, near the sources of the Moselle, veins are worked of an iron ore, that traverse formations of greywacke, clay-slate, and porphyry. Lastly, in the north of the Vosges, near Bergzabern, Erlenbach, and Schenau, several mines have been opened on very powerful veins of brown hæmatite and compact bog ore, accompanied with a little calamine, and a great deal of sand and *débris*. In some points of these veins, the iron ore is replaced by various ores of lead, the most abundant being the phosphate, which are explored at *Erlenbach* and *Katzenthal*. These veins traverse the sandstone of the Vosges: a formation whose geological position is not altogether well known, but which contains iron mines analogous to the preceding at *Langenthal*, at the foot of Mount Tonnerre, and in the Palatinate. Many analogies seem to approximate to the sandstone of the Vosges, the sandstone of the environs of Saint Avold (Moselle), which include the mine of brown hæmatite of *Creutzwald*, and the lead mine of *Bleiberg*, analogous to that of Bleiberg, near Aix-la-Chapelle.

At *Cruttnich* and *Tholey*, to the north of Sarrbrück, mines of manganese are worked, famous for the good quality of their products. The deposit exploited at Cruttnich, seems to be inclosed in the sandstone of the Vosges, and to constitute a vein in it analogous to the iron veins mentioned above.

There has been also opened a manganese mine at *Lavelline* near *La Croix-aux-Mines*, in a district of gneiss with porphyry.

In the *Vosges* and the *Black Forest* there are several deposits of anthracite (stone-coal), of which two are actually worked, the one at Zunswir near Offenbourg, in the territory of Baden, and the other at Uvoltz, near Cernay, in the department of the Upper Rhine. There are also several deposits of the true coal formation on the flanks of the Vosges.

Mines situated in the Schistose Formations of the Banks of the Rhine, and in the Ardennes.

The transition lands, which form, in the N.W. of Germany and in Flanders, an extensive range of hilly country, and culminate in the Hündsruck, the Taunus, the Eifel, and the Westerwald mountains, include several famous mines of iron, zinc, lead, and copper. The latter lie on the right bank of the Rhine, in the territories of Nassau and Berg, at Baden, Augstbach, Rheinbreitbach, and near Dillenburg. That of Rheinbreitbach yielded formerly 110,000 lbs. avoird. of copper per annum, and those of the environs of Dillenburg have more recently furnished annually 176,000 lbs. There are also some mines of argentiferous lead in the same regions. The most remarkable are in the territory of Nassau, such as those of Holzappel, Pfingstwiese, Löwenburg, and Augstbach on the Wied, and Ehrenthal on the banks of the Rhine, which altogether produce 600 tons of lead and 3,500 marcs of silver. To the above, we must add those of the environs of Siegen and Dillenburg, situated in the slaty rock and greywacke of the Devonian system, to which the greater part of the area in question belongs. A little cobalt is explored in the neighbourhood of Siegen, and some mines of the same nature are mentioned in the grand-duchy of Hesse-Darmstadt, and in the duchy of Nassau Usingen.

But iron is the most important product of the mines on the right bank of the Rhine. Veins of hydrous oxide, or brown hæmatite, are explored in a great many points of Hessia, and of the territory of Nassau, Berg, Marck, Tecklenburg, and Siegen, along with veins or masses of sparry iron, and beds of red oxide of iron. We may note particularly: 1. The enormous mass of sparry iron, known under the name of Stahlberg, mined since the beginning of the 14th century in the mountain of Martinshardt, near Müsen; and the numerous lodes of hæmatite, brown oxide and sparry iron, in the same district; 2. The abundant and beautiful mines of hydrous oxide and sparry iron on the banks of the Lahn and the Sayn, and among them the mine of Bendorf; 3. The mine of Hohenkirchen in Hessia, where a powerful bank of manganesiferous ore is worked, and where the mines are kept dry by a gallery more than one thousand yards long, walled over its whole extent. These several mines supply a great many iron works, celebrated for their steel, and for the objects of hardware, scythes, &c., manufactured there. Nassau produces a considerable quantity of first-rate ore annually, most of which is exported.

The Prussian provinces of the left bank of the Rhine, the duchy of Luxembourg and the Low Countries, include also many iron furnaces, of which a great number are supplied, in whole or in part, by ores of hydrous oxide of iron, occasionally zinciferous, extracted from the transition rocks, where they form sometimes veins, and sometimes also very irregular deposits. A portion is explored by open quarrying, and a portion by underground workings. Great activity has within the last few years been imparted to these operations, by the rapid development of the Westphalian coal-field, and the increased manufacture of coke-made iron.

The *Eifel* formerly possessed important lead mines. Some still exist, which are feebly worked at Berncastle, 8 leagues below Trèves, on the banks of the Moselle. Those of Trarbach, situated two leagues lower, are now completely abandoned. The same holds with those of Bleialf, which were opened on veins incased in the greywacke-slate, 3 leagues W.N.W. of Prüm, not far from the line of separation of the waters of the Moselle and the Meuse, in a district from which manufactures and comfort have disappeared since the mines were given up which sustained them. The mine Wohlfahrt, near Rehscheid, produces annually 500 tons of a fine galena, suitable for 'potter's ore.'

More to the north a great many deposits of calamine occur. The most considerable, and the one which for many years past has given the Company working it the command of the zinc trade of the world, is called the *Vieille Montagne* (Altenberg), at Moresnet, between Aix-la-Chapelle and Herbesthal. The mass upon which the works are opened, and in which the calamine is very irregularly intermixed with clay and ochre, is about 450 yards in length and 150 in width: it is situated at the junction of the carboniferous limestones and the slate termed the *schiste anthraxifère*, upon which geological horizon a number of other deposits of a similar character have been found at intervals, with a thickness and richness equally variable. The minerals, brown iron ore, galena, zinc-blende, and iron pyrites occur with the calamine, and the former especially sometimes overpowers it. Among such deposits, many of them largely worked, are Herrenberg near Holberg, Engis, Huy, Verviers, Corphalie, Membach, and some which reappear, after dipping beneath the alluvial valley of the Rhine, in the same geological position, in Westphalia.

The *Vieille Montagne* Company possess other sources of zinc ore in the Prussian and in the Baden territory; and, employing about 7.000 men in all, produce no less than 16,000 tons of zinc from their own mines, besides manufacturing a large quantity purchased from other producers. The *Nouvelle Montagne* Company, Verviers, also work their deposits on a large scale, and increasing success appears to attend the works established more recently on the right bank of the Rhine.

Of the mines in this border district which produce lead, the most important are those of the Stolberg Westphalia Company, yielding annually 5;000 tons of lead, and those of the *Eschweiler* and the *Alliance* Company, also of Stolberg.

A lead mine is opened at Vedrin, N. of Namur, on a vein of galena, nearly vertical, which courses from N. to S. in a limestone in nearly vertical strata. The vein is from 4 to 15 ft. thick, and is recognised through a length of half a league. The mine, worked for two centuries, presents very extensive excavations; particularly a fine Adit Level. From its former annual production of 900 tons of lead it has now sunk to a very small amount.

Mines of the Centre of France.

The ancient formations, principally granitic, which constitute the basis of several departments of the centre and south of France, are hardly any richer in explorations than the districts mentioned at the end of the Black Forest. Many metalliferous veins have been observed in the mountains of the Auvergne, Forez, Cevènnes and Lozère, but very few of the workings have attained to any importance. Most of the mining trials have been made near the eastern border of the mass of primary formations, in a zone characterised by a great abundance of schistose rocks.

At Villefort and Vialas, in the department of the Lozère, and in some places adjoining, several veins of argentiferous galena are worked which traverse the gneiss and the granite. These mines, remarkable at present for the regularity of their workings, employ 300 persons, and produce annually about 1,000 quintals of lead, and about 2,000 marcs of silver.

Pontgibaud has been for some years the centre of mines of argentiferous lead, opened upon a group of north and south lodes intersecting a rock of gneissose granitic character. Explorations have been commenced mostly where these lodes were discovered in the valleys, as at Roure, Rosier, Mioch, Pranal, and Barbecot; and since 1853, by the joint exertions of an English and French proprietary, the mines have been raised to an important position, employing about 1,200 workpeople. An unusual source of difficulty has been presented, in the form of strong emanations of carbonic acid gas from the lode and the fissures of the country, and which renders it necessary to employ powerful ventilating machines, driven by water-wheels. The presence of this gas is evidently connected with the volcanic phenomena of the adjacent district, where streams of recent lava overlie the metalliferous granite, and are not penetrated by the lodes. The Pontgibaud mines yield annually about 1,500 tons of lead, and 145,000 ozs. of silver.

In the department of the Loire, the lead mines of *St.-Martin-la-Sauveté* south of Roanne have been extensively opened on veins running N.W. and S.E.; they are now in English hands.

The mountains of Ambert, on the west of the valley of the Dore, Saint-Amand-Roche-Savine and Giroux, as well as the mountains above Jumeaux, exhibit veins of somewhat analogous character.

At Malbosc and Bordezac (Ardèche), small lodes of antimony are seen in the slaty rocks.

The city of Vienne, in Dauphiny, is built on a hill of gneiss, separated by the Rhône from the main body of the primitive formations, and in which veins of galena occur, which are now imperfectly mined. Other lead mines of less importance are observed at *St. Julien-Molin-Molette*, department of the Loire, and at *Joux*, dep. of the Rhône.

At *Chessy*, seven leagues N.W. of Lyons, mines, now worked out, were opened upon an irregular deposit of copper ore, occurring at the contact of granite with the lower sandy beds of the lias. The carbonates of copper were especially abundant, and the azurite, or blue carbonate, from this mine is noted for the beauty of its crystallisation. At Sainte-Bel, two leagues S. of Chessy, a very similar deposit of copper pyrites, has also, after many years of activity, been abandoned.

An abundant deposit of manganese ore, very irregularly worked, at Romanèche (Saône-et-Loire) occurs in an analogous geological position; as do also smaller bodies of galena, calamine, and zinc-blende at Figeac, Villefranche, and Lardin.

At Ecouchets, near Couches, the oxide of chromium disseminated in the sandstones termed *arkoses*, has been occasionally worked. Some important veins of zinc-blende have been traced at Clairac, in the department du Gard, for above 1,000 yards from N. to S. in the beds of metamorphic lias. Iron ores of oolitic texture are largely worked in the Jurassic and Neocomian rocks in various parts of France.

Lastly, tin ore, accompanied by wolfram, has been found to occur in small lodes in the district of Limoges, so well known for its china-clay, especially at Vaulry, a few leagues NN.E. of that town; and bismuth has recently been worked at Meymac, in the department of Corrèze.

Mines of Brittany.

In its geological conformation Brittany has a great analogy to its opposite neighbour, Cornwall; but notwithstanding the resemblance of its granites, ancient schists (killas), and porphyries, it bears no comparison in the importance of its mineral repositories. Tin ore has been found at two places, Piriac, a few miles to the N.E. of the mouth of the Loire, where small quartzose veins, containing that mineral, occur at the junction of the granite and schists, and appear to have given rise to the alluvial deposits of tin found near the mouth of the Vilaine; and at Villeder, department of

Morbihan, where a quartzose tin-bearing vein intersects the granite, in the direction E.N.E. and W.S.W., and contains also mispickel, topaz, and beryl. These localities have afforded very fine specimens of tin ore, excellent examples of which appeared at the Paris Exposition in 1855; but although frequent trials have been made upon them, they have not yet led to an extensive and systematic working.

The most important exploitations in this district are the lead mines of *Poullaouen* and *Huelgoat*, situated near Carhaix. The mine of Huelgoat, celebrated for the *plomb-gomme* (hydro-aluminate of lead) discovered in it, is opened on a vein of galena, which traverses clay-slate rocks. The workings have subsisted for about three centuries, and have attained to a depth of 270 meters.

The lode has been followed over a horizontal distance of about 1,000 meters, and contains, besides argentiferous galena, ochreous substances yielding about $\frac{1}{1000}$th of silver in the native state, or as chloride.

The vein of Poullaouen, called the New Mine, was discovered in 1741. It was powerful and very rich near the surface; but it became subdivided and impoverished with its depth, notwithstanding which the workings have been sunk to upwards of 250 meters below the surface. In these mines there are fine hydraulic machines for the drainage of the waters, with wheels from 14 to 15 yards in diameter; and water-pressure machines have been some years since constructed there.

The vein courses through greywacke in a direction N. 22° E., and, including five branches, has in some places reached the width of 60 feet.

The annual produce of these mines is 300 tons of lead and 1,400 kilograms of silver. Several veins of galena exist at *Châtelaudren*, near Saint-Brieuc, but they are not worked at present. There is also one at Pontpéan, near Rennes, which has been worked to a depth of 140 yards, but has in like manner been abandoned. It affords, besides the galena, a very large quantity of blende (sulphuret of zinc), considerable amounts of which, of a very crystalline character, have, during the last few years, been exported. This is also a N.S. lode.

There occurs, moreover, a lead mine at Pierreville, department of the Channel, opened on a vein which traverses limestone. The same department presents a deposit of sulphuret of mercury at Ménildot. A mine of antimony was worked at La Ramée, department of La Vendée.

At Melles (Deux Sèvres), ancient works on argentiferous galena are traceable, of which the date is unknown.

It is, however, evident that these metals are only in part the production of the mines of France proper.

Mines of Great Britain and Ireland.

The mines comprehended in this section are situated, 1. in Cornwall, Devonshire, and Somersetshire; 2. in the S.E. of Ireland; 3. in the island of Anglesey and the adjoining part of Wales; 4. in Cumberland, Westmoreland, the north of Lancashire, Yorkshire and Derbyshire, Durham and Northumberland, and the Isle of Man; 5. in the south and west of Scotland.

It will be observed that the metalliferous rocks, analogous to those of the N.W. of France last described, present themselves in the West of England, Wales, and Scotland, striking in a direction of E.N.E. or N.E.; whilst in Ireland, although the same general direction is usually apparent, similar rocks form the surface in many portions of the island.

Cornwall and Devonshire present four principal mining districts: viz. that of the West, including St. Just, St. Ives, Marazion, and St. Erth; secondly, that of the West centre, including Gwennap, Redruth, Camborne, St. Agnes, and Wendron; thirdly, the East centre of St. Austell and Lostwithiel; fourthly, the eastern district, from Liskeard to Tavistock. Again, in Devonshire, there are the mines between Newton and Exeter, and those near North Molton.

The first two of these districts are the most important of the four in the number and richness of their mines of copper and tin. The ores of copper, which consist almost entirely of copper pyrites and vitreous sulphuret of copper, constitute very regular veins, running nearly from east to west, and incased most frequently in a clay-slate locally termed *killas*, and belonging to the Devonian system of modern geologists; but frequently also in the granite, which forms a series of protuberances rising through clay-slates, in an E.N.E. direction from the Land's End to Dartmoor. The tin, besides being found in alluvial deposits or 'stream-works,' which are nearly all worked out, also occurs in veins or lodes which have a general east and west direction, the same held by numerous dykes of granitic porphyry ('elvan'), which appear to have a close relation to the metalliferous veins. The tin ore in a few mines forms also irregular masses (termed *tin-floors* and *carbonas*) which appear most usually attached to the veins by one of their points. Some of the veins present the copper and tin ores together; a mixture which occurs often near the points of intersection of the two metallic veins. Certain mines furnish alternately both copper and tin; but the most part produce only one of these metals, especially Dolcoath and the surrounding mines.

Among the more important mines of the above metals in the western districts may be noticed: Huel Basset, North and West Basset, South Francis, United Mines, Huel Buller, Alfred Consols, Carn Brea, Levant, and Botallack; for tin more especially, Huel Vor, Dolcoath, and Polberro.

In the environs of St. Austell the more remarkable mines were those of Fowey Consols, which was once the deepest-worked mine in Britain, Par Consols, Crinnis, the tin mine of Polgooth, abandoned, and the singular open-cast of Carclaze, worked on numerous small strings of tin, coursing through a granite so decomposed as to be in great part available for china-clay.

North of Liskeard, the Phœnix and Caradon mines have attained, since 1838, a great degree of prosperity; whilst still further east the neighbourhood of Callington is marked by several productive copper mines on a smaller scale, and the large ancient tin mine of Drake Walls. The Tavistock district has been rendered famous by the long-continued successful working of Huel Friendship, and the enormous wealth extracted since 1845 from the series of mines on one great lode, entitled the Devon Great Consols.

There exists also in Cornwall veins running more or less N. and S.; these are lead lodes generally. The 'cross-courses,' which intersect and often dislocate these lodes, sometimes containing only clay (*flucan*) or quartz (*spar*), at other times particular metallic minerals. Thus, near Helston several such veins have been worked for silver-lead ore; at Restormel near Lostwithiel, and in the St. Austell granite, for red and brown oxides of iron: east of Liskeard, at Herodsfoot, Huel Mary Anne, Redmoor, and the Tamar mines, for lead ores containing from 30 to 80 ounces of silver to the ton.

In some few instances, and chiefly in connection with these cross veins, ores of silver, cobalt, and nickel, have been raised; whilst very rich silver ores were obtained some years ago from E. and W. veins, at Huel Vincent, Huel Brothers, &c., near Callington.

Antimony has been raised from mines near Endellion, and at Huel Boys; and manganese is now worked from shallow irregular deposits in the slates at many points in the east of Cornwall, and in Devonshire.

The tin and copper ores of Cornwall are accompanied with arsenical pyrites, which is turned to some account by the production of white arsenic (arsenious acid).

The tin ores are treated at several works situated in Cornwall. All the copper ores are sent to Swansea in South Wales to be smelted; and a part of the lead ores only is reduced at smelting-works near Truro, at Par, and on the Tamar.

In consequence of the great influx of subterranean waters, the mines of Cornwall and Devonshire are worked upon principles somewhat differing from those of many other mining districts, expedition being regarded as one great source of economy. Especially in the application of steam-power to pumping-purposes have the inventive powers of the engineers, in modifying the engines and boilers, and the skill of the miners, in placing the pit-work and pumps, attained a high degree of perfection. For this purpose engines having a cylinder of 80, 90, and even 100 inches in diameter have been erected, employing high-pressure steam expansively.

Many of the mines are explored to a depth of between 1,200 and 2,000 feet; and some are celebrated for the boldness of their workings. Thus several mines, especially Botallack and Levant, in the parish of St. Just, near Cape Cornwall, have their shafts placed close to the edge of the cliffs, and extend several hundred fathoms under the sea, and to depths of from 120 to 240 fathoms beneath its level. At Huel Cock so small a thickness of rock has been left to support the weight of the waters that the rolling of pebbles on the bottom is distinctly heard by miners during a storm. The mine of Huel Werry, near Penzance, was worked by means of a single shaft opened on a reef of rock in a space left dry by the sea only for a few hours at every ebb. A small wooden tower was built over the mouth of the shaft, which, being carefully caulked, kept out the waters of the ocean when the tide rose, and served to support the machines for raising the ore and water. A vessel driven by a storm overturned it during the night, and put an end to this hazardous mode of mining, which has not been resumed.

An important group of veins of lead, often argentiferous, is opened in the slaty rocks of Cardiganshire and Montgomeryshire, all of which have an E. and W. direction, although so far from parallel that they often meet, and frequently form at such points of intersection 'courses' of ore. The galena is accompanied generally by quartz and blende, more rarely by iron pyrites and calcspar. Some of these mines were very profitably worked in the 17th century, and during the last forty years several of them, as Goginan, Cwm Ystwyth, Logylas, and Frongoch, have been highly productive. In 1873 these counties yielded 10,061 tons of metallic lead and 94,826 ounces of silver.

The more complicated geological formations of Carnarvonshire and Merionethshire present, chiefly among the slaty rocks, a number of veins bearing copper, lead, and zinc ores, in which a special point of interest is the occurrence of gold. This metal has been found within the last few years in rich specimens, mostly associated with quartz and blende; but it has not hitherto been remuneratively raised. The veins occur chiefly in two groups, the one to the NN.W. of the town of Dolgelly, the other in the hills around the Bala Lake. Flintshire and Denbighshire produced in 1873 3,712 tons of lead, yielding 23,676 ounces of silver.

The adjacent isle of Anglesey is celebrated for the copper mines of Mona, and the Parys mountain. The ore is copper pyrites, intercalated among slaty rocks and felstone, and near the surface it occurred in enormous mass. The workings have thence been carried on as open casts; but beneath these, again, regular subterranean operations have been conducted, although the veins there show themselves small, and comparatively poor. Large quantities of copper are here obtained by precipitation from the mine-water, and the various ores are treated at furnaces situate at Amlwch. The Isle of Man has two important lead mines, the Foxdale and Laxey; the former remarkable for the great size of its main lode, and the occasional high percentage of silver; the latter for its crystalline blende. Ten mines produced lead in 1873, three copper, and four zinc ore.

The slates of Cumberland and Westmoreland yield lead ores, and a small quantity of copper ore. At Borrowdale, near Keswick, a mine of graphite (plumbago) has been worked for a long period. It furnishes the black-lead of the English pencils, so celebrated over the world. The mineral occurs in irregular lumps and nests, in a variety of greenstone rock. Coniston copper mine in Lancashire is specially notable. The lead mines of Durham and Northumberland are also very productive; the total produce of those countries in 1873 being 16,864 tons of lead. The lead mines of Yorkshire produced in the same year 3,704 tons.

There are famous lead mines in the south of Scotland, at Wanlock-head, in Dumfriesshire and Leadhills in Lanarkshire, the veins of which occur in Silurian rocks. At Cally, in Kirkcudbrightshire, copper ore has been discovered; and a mine of antimony has been known in Dumfriesshire; but neither has been turned to good account.

In the middle part of Scotland the lead mines of Strontian in Argyleshire deserve to be noticed. A lead mine in schist has been also worked by the Marquis of Breadalbane at Tyndrum. In the Isle of Islay lead is being worked.

The produce of the Scotch lead mines in 1873 was 2,150 tons of lead.

In Ireland the Berehaven and the Knockmahon mines have, with great profits to the adventurers, for many years past produced large quantities of copper ore. In 1873 7,003 tons of ore were sold. Copper ores are also worked at the Ballycummisk mine, Co. Cork, and at Connorree and four other mines.

Among the other mines of Ireland are those of Ballygahan and Tigrony, and of Ballymurtagh, situated 3 leagues S.W. of Wicklow. Their object is to work pyrites, accompanied with some poor ores of copper, galena, sulphide of antimony. Iron pyrites, since 1840, has been a large article of export, amounting in some years to from 60,000 to 100,000 tons. In 1873 the ores of Wicklow amounted to 40,063 tons only.

The granite of Wicklow also contains some lead mines. Luganure and Glendalough were the only mines worked in 1873.

In the south-west of Ireland indications of copper and lead ores have been met with at many other points, but no important mines have yet been opened upon them.

An Irish correspondent, writing on the iron ores which are now largely worked in the north of Ireland, states that at Carrlough immense quantities of iron ore and limestone are shipped. The former, which is not of the best quality, is carried to Seaham, there to meet the coal from the mines on Lord Londonderry's estate. A railway is being constructed from Red Bog to the top of Glenariff. This undertaking, which will cost 50,000*l.* to 60,000*l.*, is entirely in the hands of an English company, and will be used only for the transit of iron ore. Close to Red Bog is a wire tramway, the property of the Antrim Iron Ore Company. It has four stationary engines along its route to work it, and extends a distance of 6 miles. At Red Bog three distinct companies are employed shipping iron ore, which is of a very superior quality, and contains over 50 per cent. of pure iron. The bleak moorland at Glenravel is now varied by the numerous mouths of tunnels driven into hills, which appear as if they were composed of iron ore in inexhaustible abundance. A great part of the iron mountains belong to Lord Antrim. The companies pay large sums annually for their leases, besides royalties of 6*d.* a ton on all ore shipped. The miners' wages are by no means high; at Red Bog the English company gives 14*s.* and the Antrim Iron Ore Company, 15*s.* per week. In 1873 these iron mines produced 138,765 tons of iron ores.

Mines of the Pyrenees.

The Pyrenees and the mountains of Biscay, of the Asturias, and the north of Galicia, which are their prolongation, are not very rich in deposits of ores. The most important mines that occur there are of iron, which are widely spread throughout the whole chain, except in its western extremity. We may mention particularly in Biscay the mine of *Sommorostro*, opened on a bed of red oxide of iron; and in the province of Guipuscoa, the mines of Mondragon, Oyarzun, and Berha, situated on deposits of sparry iron. There are several analogous mines in Aragon and Catalonia. In the French part of the Pyrenees veins of sparry iron are worked, which traverse the red sandstone of the mountain Ustelleguy, near Baygorry, department of the Basses-Pyrenees. The same department affords in the valley of Asson the mine of Haugaron, which consists of a bed of hydrate of iron, subordinate to transition limestone. The deposit of hydrate of iron, worked for an immemorial time at *Rancié*, in the valley at Vicdessos, department of the Arriège, and averaging 60 feet in thickness, occurs in a limestone now regarded as of the age of the lias. The ancient workings have been very irregular and very extensive; but the deposit is still far from being exhausted. There are also considerable mines of sparry iron at *Lapinouse*, at the tower of Batera, at Escaron, and at Fillols, at the foot of the *Canigou*, in the department of the Oriental Pyrenees. The iron mines of the Pyrenees keep in activity 200 Catalonian forges. Although there exists in these mountains, especially in the part formed of transition rocks, a very great number of veins of lead, copper, cobalt, antimony, &c., one can hardly mention any workings of these metals; and among the abandoned mines, the only ones which merit notice are, the mine of argentiferous copper of *Baygorry*, in the department of the Low Pyrenees, the lead and copper mines of *Aulus*, in the valley of the Erce, department of the Arriège, and the mine of cobalt, of the valley of Gistain, situated in Aragon, on the southern slope of the Pyrenees. The mines of plumbago opened at Sahun in Aragon should not be forgotten. Analogous deposits are known to exist in the department of the Arriège, but they are not mined.

Previous to the discovery of America, considerable workings were carried on in auriferous sands at various points in this department. A gold mine has also been wrought, but without success, near Cabo de Creua, on the Spanish side.

Mines of Spain and Portugal.

The granite, gneiss, and slaty formations of the Iberian Peninsula, noted in early times for their mineral wealth, have during the last 40 years again become the scene of important mining operations. The region of the Sierra-Morena, comprising parts of the provinces of Andalusia, Estremadura, and La Mancha, forms one of those primary districts which offer close analogies with some of the mining localities already described; and exhibits numerous mines now in activity, and the traces of former extensive operations.

The noted quicksilver mines of Almaden, producing about 2,000 tons per annum, are worked on three parallel veins of from 6 to 12 meters in width, lying conformably with highly-inclined Silurian strata.

The silver mines of Guadalcanal and Cazalla, north of Seville, in mica slate, were very rich in the time of the Counts Fugger, but are now inconsiderable; this territory presented formerly important mines at Villa-Guttier, not far from Seville. At the beginning of the 17th century they are said to have been worked with such activity that they furnished daily 170 marcs of silver.

In the limestones near Santander were very important mines of calamine, but these have not been worked recently (1874).

More to the east there exists in the mountains of La Mancha a mine of antimony at Santa-Crux-de-Mudela. On the southern slope of the Sierra-Morena very important lead mines occur, particularly at Linares, 12 leagues N. of Jaèn. The veins are very rich near the surface, whence the ground is riddled, as it were, with shafts. More than 5,000 old and new pits may be counted; the greater part of which is ascribed to the Moors.

Systematic workings have been for some years carried on by English companies at some of these mines, with excellent results; and, with the aid of steam-engines, a depth of 80 or 90 fathoms has now been attained.

The lodes, which have a medium width of 3 or 4 feet, course generally NN.E.

dipping towards the N.W., and traverse a granite, which on the outskirts of the district is overlaid by clay-slates and sandstone, also penetrated by the veins. The galena is accompanied by barytes in large quantity, and, in greater depth, by calc-spar. A single mine, that of Pozo Ancho, raises 500 tons of lead ore per month.

At Rio Tinto, near Seville, a massive deposit of iron pyrites, 50 *varas* in width, has been worked, chiefly for the copper pyrites which is mingled with it. The cupriferous iron pyrites, which occurs in large deposits in the south-west of Spain and in Portugal, is now very largely worked; the pyrites being first burnt for its sulphur, and then treated by the wet way for extraction of copper. See Pyrites.

Abundant mines of zinc ores occur near Alcaraz, 15 leagues N.E. of Linares; which supply materials to a brass manufactory established in that town. There are also lead mines in the provinces of Murcia and Grenada. Very productive ores have been worked for some time in the Sierra de Gador near Almeria, a harbour situated some leagues to the W. of the Cape de Gata, and also near Cartagena. A fine silver lode has been worked to a depth of 110 fathoms, at Almagrera.

In Murcia, Grenada, and Cordova, there are also several iron mines, and near Marbella and Ronda, in Grenada, mines of plumbago are explored.

Among the most remarkable mines of Spain are those of silver at Hiendelencina, in the district of Guadalaxara, discovered only a few years since, and worked on regular lodes in gneiss, and stated to have yielded enormous profits.

Lastly, near Ferrol in Galicia, and Zamora in Leon, tin ores occur in granite, and at the latter place are worked in several mines, not far distant from others, which produce argentiferous lead and antimony ores. The Carthaginians appear to have worked tin mines in this part of the Peninsula.

Within the Portuguese frontier very similar tin ores occur near the river Douro; and other localities in that kingdom are indicated as exhibiting ores of copper, antimony, and lead. Among the latter, the Palhal, and Carvalhal mines are working by an English (the 'Lusitanian') mining company.

Ores of iron occur at very numerous places in the Peninsula, but have hitherto been worked on a comparatively small scale. Those of Sommorostro near Bilbao, and of Marbella, are among the best known. The impulse given to iron-mining in Spain a few years ago has been checked by the present disturbed state of the country (1874).

Two ancient iron-works exist in Portuguese Estremadura, the one in the district of Thomar, and the other in that of Figueiro dos Vinhoss: they are supplied by mines of red oxide of iron, situated on the frontiers of this province and of Beira. One deposit of quicksilver ore occurs at Couna, in Portugal.

Mines of the North of Europe.

These mines are situated for the most part in the south of Norway, towards the middle of Sweden, and in the south of Finland, a little way from the shortest line drawn from the Lake Onega to the south-west angle of Norway. A few mines occur in the northern districts of Norway and Sweden. The main products of these several mines are iron, copper, and silver.

The iron mines of Norway lie on the coasts of the Gulf of Christiania, and on the side facing Jutland, principally at Arendal, at Krageroe, and the neighbourhood. The ores consist almost solely of black oxide of iron, which forms beds or veins of from 4 to 60 feet thick, incased in gneiss, which is accompanied with pyroxene (augite), epidote, garnets, &c. These iron ores are reduced in a great many smelting-furnaces situated on the same coast, and particularly in the county of Laurwig. Their annual product is about 16,500,000 lbs. avoird. of iron, in the form of cast iron, bar iron, sheet iron, nails, &c.; of which one-half is exported.

Norway possesses rich copper mines, some of which lie towards the south and the centre of the country; but the most considerable occur in the north, at *Quikkne*, *Læken*, *Selboe*, and *Rœraas*, near Drontheim. The mine of Rœraas, 16 miles from Drontheim, to the S.E. of the city, is opened on a very considerable mass of copper pyrites, and has been worked as an open-cast since 1664. It has poured into the market, from that time till 1701, 77,000,000 lbs. avoird. of copper. In 1805 its annual production was 864,600 lbs. Not far from the North Cape, copper mines have been for some years past actively worked by an English (the Alten) mining company, on irregular veins at Kaafiord and Raipas.

Norway comprehends also some celebrated silver mines. They are situated from 15 to 20 leagues S.W. of Christiania, in a mountainous country near the city of Kongsberg, which owes to them its population. Their discovery goes back to the year 1623, and their objects are veins of carbonate of lime, accompanied with asbestos and other substances in which native silver occurs, usually in small threads or network, and sometimes in considerable masses, along with sulphuret of silver. These veins are very numerous, and run through a considerable space, divided into four districts (arrondissements), each of which contains more than 15 distinct explorations. When a new mine is opened, it is generally as an open-cast, which embraces several veins, and they then prosecute by subterranean workings only those that appear to be of consequence. The workings are about 200 fathoms deep. Fire is employed for attacking the ore. In 1782 the formation of a new adit-level was commenced, destined to have a length of 10,000 yards, and to cost 60,000*l.* These mines, since their discovery till 1792, have afforded a quantity of silver equivalent to above 4,000,000*l.* sterling. The year 1768 was the most productive, having yielded 38,000 marcs of silver. Twice during the present century they have been threatened with abandonment, but have again become profitable, yielding from 1,300 to 1,400 kilograms of silver per annum.

Cobalt mines may be noticed at *Modum* or Fossum, 8 leagues W. of Christiania; they are extensive, but of little depth.

Lastly, graphite is explored at *Englidal*; and chromate of iron deposits have been noticed in some parts of Norway.

The irons of Sweden enjoy a merited reputation, and form one of the chief objects of the commerce of that kingdom. Few countries, indeed, combine so many valuable advantages for this species of manufacture. Inexhaustible deposits of iron ore are placed amid immense forests of birches and resinous trees, whose charcoal is probably the best for the reduction of iron. The different groups of iron mines and forges form small districts of wealth and animation in the midst of these desolate regions.

The province of Wermeland, including the north bank of the lake Wener, is one of the richest of Sweden in iron mines. The two most important are those of Nordmarck, 3 leagues north of Filipstadt, and those of Perseberg, 2½ leagues east from the same city. Filipstadt is about 50 leagues W. ¼ N.W. from Stockholm. Both mines are opened on veins or beds of magnetic oxide of iron several yards thick, directed from N. to S. in a ground composed of hornblende, talcose and granite rocks. These masses are nearly vertical, and are explored in the open air to a depth of 130 yards.

The principal iron mines of Rosslagen (part of the province of Upland), are those of Dannemora, situated 11 leagues from Upsal. They stand in the first rank of those of Sweden, and even of Europe. The masses worked upon are somewhat lenticular, and vertical, running from N.E. to S.W., and are incased in a ground formed of primary rocks, among which gneiss, petrosilex and granite are most conspicuous. They amount to three in number, very distinct, and parallel to each other; and are explored through a length of more than 1,500 yards, and to a depth of above 80, by the employment of fire, and blasting with gunpowder. The explorations are mere quarries, each presenting an open chasm 65 yards wide, by a much more considerable length and an appalling depth. Magnetic iron ore is extracted thence, which furnishes the best iron of Sweden and Europe; an iron admirably qualified for conversion into steel.

Of the works which prepare bar iron from the Dannemora ores, may be mentioned in the first class Löfsta, Osterby, Simö, and Ranäs.

The island of Utoe, situated near the coast of the province of Upland, presents also rich iron mines. The magnetic ore there forms a thick bed in the gneiss. It is worked in trenches far below the level of the sea. The ore cannot be smelted in the island itself; but is transported in great quantities to the continent.

The province of Smoland includes also very remarkable mines. Near Jönköping, a hill called the *Taberg* occurs, formed in a great measure of magnetic oxide of iron, contained in a greenstone in the midst of the gneiss.

In several parts of Lapland, the magnetic oxide of iron occurs in great beds or immense masses. At Gellivara, 200 leagues N. of Stockholm, towards the 67th degree of latitude, it constitutes a considerable mountain, into which an exploitation has been opened. The iron is despatched on small sledges drawn by rein-deer to streams which fall into the Lulea; and thence by water-carriage to the port of Lulea, where it is embarked for Stockholm.

There are a great many iron works in Dalecarlia, but a portion of the ores are got from alluvial deposits. Similar deposits exist also in the provinces of Wermeland and Smoland.

The annual production of the iron mines and furnaces of Sweden and Norway has increased but little of late years, the chief attention being devoted to the quality, and not to the quantity. At present it amounts to above 150,000 tons of pig iron, of which probably two-thirds are exported as bar iron, steel, &c.

The copper mines of Sweden are scarcely less celebrated than its iron mines. The principal is that of Falun or Kopparberg, situated in Dalecarlia, near the town of Falun, 40 leagues N.W. of Stockholm. It is excavated in an irregular and very powerful mass of pyrites, which in a great many points is almost entirely iron pyrites, but in others, particularly near the circumference, includes a greater or less portion of copper. This mass is enveloped in talcose or hornblende rocks. More to the west, there are three other masses almost contiguous to each other, which seem to bend in an arc of a circle around the principal mass. They are explored as well as the last. This was at first worked in the open air; but imprudent operations having caused the walls to crumble and fall in, since 1647 the excavation presents near the surface nothing but frightful precipices. The workings are now prosecuted by shafts and galleries into the lower part of the deposit, and have arrived at a depth of 194 fannars (nearly 430 yards). They display excavations spacious enough to admit the employment of horses, and the establishment of forges for repairing the miners' tools. It is asserted that the exploration of this mine goes back to a period anterior to the Christian era. During its greatest prosperity, it is said to have produced 11 millions of pounds avoird. of copper per annum, or about 5,000 tons. It furnishes now about the seventh part of that quantity; yielding at the same time about 70,000 lbs. of lead, with 50 marcs of silver, and 3 or 4 of gold. The ores smelted at Falun produce from 2 to 2½ of copper per cent. But the extraction of the metal is not the sole process; sulphur is also saved; and with it, or the pyrites itself, sulphuric acid and other chemical products are made. Round Falun, within the space of a league, 70 furnaces or factories of different kinds may be seen. The black copper obtained at Falun is converted into rose copper, in the refining hearths of the small town of *Ofwostad.*

In the copper mine of *Garpenberg*, situated 18 leagues from Falun, there occur 14 masses of ore quite vertical, and parallel to each other, and to the beds of mica-slate or talc-slate, amid which they stand. This mine has been worked for more than six hundred years.

The mine of *Nyakopparberg*, in Nericia, 20 leagues W. of Stockholm, presents masses of ores parallel to each other, the form and arrangement of which are very singular. It is worked by open quarrying, and with the aid of fire.

We may notice also the copper mines of Atvidaberg, in Ostrogothia, which furnish annually about a sixth part of the whole copper of Sweden.

There are several other copper mines in Sweden. Their whole number is ten; but it was formerly more considerable. They yield at the present day in all, about 2,000 tons of metallic copper.

The number of the silver mines of Sweden has in like manner diminished. In 1767, only 3 were reckoned under exploration, viz. that of *Hellefors*, in the province of Wermeland; that of *Segersfors*, in Nericia; and that of *Sala* or *Sahlberg*, in Westmannia, about 23 leagues N.W. of Stockholm. The last is the only one of any importance. It is very ancient, and passes for having been formerly very productive; though at present it yields only from 4 to 5,000 marcs of silver *per annum*. Lead very rich in silver is its principal product. It is explored to a depth of more than 200 yards. The soundness of the rock has allowed of vast excavations being made in it, and of even the galleries having great dimensions; so that in the interior of the workings there are winding machines, and carriages drawn by horses for the transport of the ores.

At Sala, there are deposits of sulphuret of antimony.

For the last 30 or 40 years, mines of cobalt have been opened in Sweden, principally at Tunaberg and Los, near Nyköping, and at Otward in Ostrogothia. The first are worked upon veins of little power, which become thicker and thinner successively; whence they have been called *bead-veins.* It appears that the products of these mines, though of good quality, are inconsiderable in quantity.

Lastly, there is a gold mine in Sweden; it is situated at Adelfors, in the parish of Alsfeda, and province of Smoland. It has been under exploration since 1737, on veins of auriferous iron pyrites, which traverse schistose rocks; presenting but a few inches of ore. It formerly yielded from 30 to 40 marcs of gold *per annum*, but for the last few years it has furnished only from 3 to 4.

The south of Finland and the bordering parts of Russia contain some mines, but they are far from having any such importance as those of Sweden.

At Orfjerwy near Helsingfors, a mine of copper occurs whose gangue is carbonate of lime, employed as a limestone.

Near Cerdopol, a town situated at the N.W. extremity of the Ladoga Lake, veins of copper pyrites were formerly mined.

Under the reign of Peter the Great, an auriferous vein was discovered in the granitic mountains which border the eastern bank of the Lake Ladoga, near Olonetz. It was rich only near the surface; and its working was soon abandoned.

Latterly, an attempt has been made to mine copper and iron ores near Eno, above and to the N.W. of Cerdopol, but with little success.

Some time ago, rich ores of iron, lying in veins, were worked near the Lake Shuyna, N.W. from Cerdopol; but this mine has also been relinquished.

The transition limestone which constitutes the body of Esthonia contains lead ore at *Arossaar* near *Fellin.* These ores were worked when these provinces belonged to the Swedes. It was attempted in 1806 to resume the exploitation, but without success.

MINES OF THE URAL MOUNTAINS.

This chain of mountains, which begins on the coasts of the icy sea, and terminates in the 50th degree of latitude amidst the steppes of the *Kirghiz*, after having formed, through an extent of more than 40 leagues, the natural limit between Europe and Asia, contains very rich and very remarkable deposits of metallic ores, which have given rise to important mines of iron, copper, and gold. These explorations are situated on the two slopes, but chiefly on the one that looks to Asia, from the environs of Ekaterinbourg to about 120 or 130 leagues north of that city. They constitute the department of the mines of Ekaterinbourg, one of the three belonging to Siberia.

The copper mines are pretty numerous, and lie almost wholly on the oriental slope of the chain. They are opened upon veins of a very peculiar nature, and which, although very powerful at the surface, do not extend to any considerable depth. These veins are in general filled with argillaceous matters, penetrated with red oxide of copper, and mingled with green and blue carbonates of copper, sulphuret of copper, and native copper. The most important workings are those of *Tourinsk* and *Nijni-Taguil.*

The first are situated 120 leagues north of Ekaterinbourg, towards the 60th degree of N. latitude, at the eastern base of the Uralian mountains, near the banks of the *Touria.* They amount to three, opened in the same vein, which turns round an angle presented by the chain in this place. The rock consists of a porphyry with a hornstone basis, of clay-slate, and of a white or greyish limestone, which form the roof and floor of the vein. The ore yields from 18 to 20 per cent., and these mines produced annually in 1786, 10,000 metric quintals (2,200,000 lbs. avoird.) of copper.

The mine of Nijni-Taguil is remarkable for the fine masses of malachite which it has produced.

At Bogoslowsk copper ores have also been largely worked from a contact-deposit between greenstone and limestone.

The beds of iron ore occur generally at a certain distance from the axis of the central chain. Those of the western slope lie sometimes in a grey compact limestone, which contains encrinites and other fossils, and appears to be much more modern than the rocks of the central chain. Both the one and the other seem to form large veins, which extend little in depth, or rather fill irregular and shallow cavities. The most common ore is the hydrous oxide of iron, hæmatite, or compact iron ore, sometimes mixed or accompanied with oxide of manganese, and occasionally with ores of zinc, copper, and lead. Black oxide of iron, possessing magnetic polarity, likewise frequently occurs, particularly in the mines of the eastern slope, on which, in fact, entire mountains of loadstone repose. All these ores, mixed with a greater or less quantity of clay differently coloured, are worked by open quarries, and most usually without using gunpowder. They yield rarely less than 50 or 60 per cent., and keep in action numerous smelting-houses situated on two flanks of the chain; the oldest of them have been established since 1628, but the greater number date only from the middle of the 18th century. The most celebrated mines are those of *Blagodat* and *Keskanar*, situated on the eastern slope from 30 to 50 leagues north of *Ekaterinbourg.* In the foundries of the eastern slope, anchors, guns, shot and shell, &c. are manufactured; and in the whole a considerable quantity of bar iron. The products of the works on the western side are directly embarked on the different feeders of the Volga, from which they are at no great distance. Those of the eastern slope are transported during winter on sledges to the same feeder streams, after crossing the least elevated passes of the Urals.

The quantity of materials manufactured by the iron works of both slopes, amounted annually, as far back as the year 1790, to more than 11,000,000 lbs. avoird. This country is peculiarly favoured by nature for this species of industry; for vast deposits of excellent iron ores occur surrounded by immense forests of firs, pines, and birches; woods, whose charcoal is excellently adapted to the manufacture of iron.

The copper mines of the Uralian mountains, and the greater part of the iron mines and foundries, form a portion of the properties of some individuals, who may be instanced as among the richest in Europe. The Russian Government has neglected no opportunity of promoting these enterprises. It has established at Tourinsk a considerable colony, and at Irbitz a fair, which has become celebrated.

There is only one gold mine in the Ural mountains, that of *Berezof*, situated three leagues N.E. of Ekaterinbourg, at the foot of the Urals, on the Asiatic side. It is famous for the chromate of lead, or red lead ore, discovered there in 1776, and worked in the following years, as also for some rare varieties of minerals. The ore of Berezof is a cavernous hydrate of iron, presenting here and there some small striated cubes of hepatic iron, and occasionally some pyrites. It contains five parts of gold in 100,000. This deposit appears to have a great analogy with the deposits of iron ore of the same region. It constitutes a large vein, running from N. to S., encased in a formation of gneiss, hornblende schists, and serpentine. It becomes poor in proportion to its distance from the surface. The exploitation, which is in the open air, has attained but a small depth, although carried on since the year 1726. The gold is extracted from the ore by stamping and washing. In 1786, 500 marcs were collected; but the preceding years had furnished only 200, because they then worked further from the surface. German miners were called in to direct the operations. Since that period, however, great attention has been bestowed on the education of the mining engineer officers, who now form a corps pre-eminent in attainments.

The auriferous sands, or 'stream' deposits of the Ural were discovered in 1814, and since 1823 have become very important. They extend over a district of some hundreds of miles in length, although with interruptions; the continuous portions of gold-bearing detritus, being generally from 50 to 600 yards in length and 10 to 60 in breadth. In some few places platinum has been similarly found. The form in which these precious metals occur, is generally in minute scales or grains, more rarely as lumps or *pepites*, which have, in the case of gold, attained in one instance the weight of 100 lbs., in that of platinum 23 lbs.

The Russian miners have observed that these deposits rarely overlie the granite or syenite; but generally the slaty rocks of the chain, near the outburst of serpentine or hornblendic rocks.

The beautiful plates of mica, well known in mineral cabinets, and even in commerce, under the name of *Muscovy talc*, or Russian mica, come from the Urals. There are explorations for them near the lake Tschebarkoul, on the eastern flank of this chain. From the same canton there is exported a very white clay, apparently a *kaolin*.

Twenty-five leagues north of Ekaterinbourg, near the town of Mourzinsk, there occur in a graphic granite, numerous veins, containing amethysts, several varieties of beryl, emeralds, topazes, &c.

It is difficult to obtain any reliable return of the production of minerals in Russia. The following Table of the production of the Russian mines during the years 1830, 1831, 1832, 1833, and 1834, by M. Teploff, one of their officers, exhibits very fairly the annual average production of the Russian mines even at the present time.

Substances	1830	1831	1832	1833	1834
	kil.	kil.	kil.	kil.	kil.
Gold	6,260	6,582	6,916	6,706	6,626
Platinum	1,742	1,767	1,907	1,919	1,695
Auriferous silver	20,974	21,563	21,454	20,552 (3)	20,666
Copper	8,860,696	3,904,533	3,620,201	3,387,252	?
Lead	698,478	792,935	688,351	716,500 (3)	?
Cast iron	182,721,274	180,043,730 (2)	162,480,224	159,118,372	?
Salt	342,240,893	282,821,358	372,776,283	491,862,299	?
Coal	7,863,642	9,774,998	6,596,034	8,227,528	?
Naphtha	4,253,000	4,253,000	4,253,000	4,253,000	?

Mines of the Altaï Mountains.

At the western extremity of the chain of the Altaï mountains, which separate Siberia from Chinese Tartary, there exists a number of metalliferous veins, in which several important workings have been established since the year 1742. They constitute the locality of the mines of Kolywan; the richest in the precious metals of the three districts of this kind existing in Siberia.

These mines are opened up in the schistose formations which surround to the N. and W. and to the S.W. the western declivity of the high granitic chain, from which they are separated by formations consisting of other primary rocks. These schists alternate in some points with quartzose rocks, called by M. Renovantz hornstone, and with limestone. They are covered by a limestone, containing ammonites. The metalliferous region forms a semicircle, of which the first lofty mountains occupy the centre.

The most important exploration of this country is the silver mine of Zméof, or Zméinogorsk, in German *Schlangenberg*, situated to the N.W. of the high mountains in 51° 9′ 25″ N. L. and 79° 49′ 50″ long. east of Paris. It is opened on a great vein, which contains argentiferous native gold, auriferous native silver, sulphuret of silver, hornsilver, grey copper, sulphuret of copper, green and blue carbonated copper, red oxide of copper, copper pyrites, sulphuret of lead, and great masses of arsenic slightly argentiferous. There occur likewise sulphuret of zinc, or blende, iron pyrites, and sometimes arsenical pyrites. The gangues (vein-stones) of these different ores are sulphate of baryta, carbonate of lime, quartz, but rarely fluor-spar. The principal vein, which is of great power, has been traced through a length of several hundred fathoms, and to a depth of no less than 96 fathoms. In its upper portion, it has an inclination of about 50 degrees; but lower down it becomes nearly vertical. Its roof is always formed of clay-slate. On the foot-wall of the vein the slate alternates with hornstone. This vein pushes out branches in several directions; it is intersected by barren veins, and presents successive stages of different richness. The first years were the most productive.

The most important of the other silver mines of this department are those of Tcherepanofsk, 3 leagues S.E. of Zméof; those of Semenofsk, 10 leagues S.E.; those of Nicolaiefsk, 20 leagues to the SS.W.; and of Philipofsk, 90 leagues S.E. of the same place. The last mine lies on the extreme frontier of Chinese Tartary.

The mine of Zyrianofsk is opened amid talco-chloristic schists; and from workings about 180 yards in length yields about 800 tons of lead, 500 tons of copper, and 700 kilograms of silver per annum.

About 36,000 lbs. weight of silver, at the most, are furnished by the whole of the Altaï mines.

Since the year 1830 the gold workings of Siberia have attained a high degree of value; and, although the average proportion of gold is but 1 to 250,000 parts of refuse, a total quantity of 75,000 Russian lbs. of gold is given as the produce of the Siberian works in the best years. Those on the Yenisei and the Lena are the most productive.

The precious metals are not the sole product of this mineral district. There is an important copper mine 15 leagues W. of Zméof, in a chain of hills formed of granitic rocks, schists, porphyries, and shell-limestone, graduating into the plain. The vein presents copper pyrites, sulphide of copper, and native copper, disseminated in argillaceous substances, more or less ferruginous, and of different degrees of hardness. This mine, which bears the name of Loktiefsk, furnished annually, at the date of 1782, 330,000 lbs. avoirdupois of copper. At present, it and the neighbouring mine of Solotoushinsk yield little more than 120,000 lbs. per annum each. At Tchakirskoy, on the banks of the Tscharisch, towards the northern extremity of the metalliferous semicircle mentioned above, there is a mine of argentiferous copper and lead, opened in a very large but extremely short vein. Besides the lead and copper ores, including a little silver, this mine affords a great quantity of calamine (carbonate of zinc), which affords occasionally fine stalactites of a white or green colour.

The northern flank of the Altaï mountains presents few mines. Some veins of copper exist 200 leagues E. of Zméof, near the spot where the river Yenisei issues from the Saïansk mountains, which are a prolongation of the Altaïan chain.

The Altaï produces but little lead; but the Crown works, in this and the Nertschinsk district, together produce about 1,680,000 lbs. annually.

The first smelting-house erected in this district was in the middle of the metalliferous region at *Kolywan*, the place from which it takes its name. It has been suppressed on account of the dearth of wood in the neighbourhood of the mines. The principal existing foundry is that of Barnaoul on the Obi, 50 leagues N. of Zméof. Plumbago has been largely worked by M. Alibert at Irkutsk, near Lake Baikal.

Mines of Daouria.

The name Daouria is given to a great region, wholly mountainous, which extends from the Baikal Lake to the Eastern Ocean. Its chief mining district is beyond the Jablonnoï chain, which divides the waters of the Saghalien or Amour from the streams which flow to the icy sea. The mines opened here constitute the third arrondissement of the Siberian mines, called that of Nertschinsk, from the name of its capital, which lies more than 1,800 leagues E. of St. Petersburg.

The country of the metalliferous portion of Daouria is formed of granite, hornschiefer, and schists, on which reposes a grey limestone, sometimes siliceous and argillaceous, rarely fossiliferous, and in which the repositories of lead occur. The plains of these regions, often salt-deserts, exhibit remarkable sandstones and pudding-stones; as also vesicular rocks of a volcanic aspect. It appears that the metalliferous limestone is much dislocated, and the lead-veins are subject to several irregularities, which render their exploitation difficult and uncertain. The mines lie chiefly near the banks of the Schilca and the Argoun, in several cantons, at a considerable distance from one another; wherefore it was requisite to build a great number of smelting-furnaces. The want of wood has placed difficulties in the working of some of them. The ores are principally oxides and carbonates of lead, with brown oxide of iron, calamine, and a varying proportion of native silver, occurring seldom in regular bodies, but generally in cavernous openings, more or less united by narrow veins.

The silver extracted from the mines of Daouria, contains a very small proportion of gold. M. Patrin says that their annual product was, towards the year 1784, from 30,000 to 35,000 marcs of silver. Since that time it has diminished. The exploitation of some of the mines of Daouria goes back to the end of the 17th century. It had been commenced in some points by the Chinese, who were not entirely expelled from this territory till the beginning of the following century. Many of the mines are reputed to be exhausted: among the best of the now existing works are those of Akatouiefsk, Algatchinsk, and Ivanofsk.

Besides the lead mines, there are some unimportant mines of copper in Daouria, and in different explorations of this region, arsenical pyrites, from which arsenious acid is sublimed in factories established at Jutlack and at Tchalbutchinsky.

About 45 leagues to the S. of Nertschinsk the mountain of Odon-Tchelon occurs, celebrated for the different gems or precious stones extracted from it. It is formed of a friable granite, including harder nodules or balls which inclose topazes: it is very analogous to the topaz-rock of Saxony. In this granite there are veins containing cavities filled with a ferruginous clay, in which are found emeralds, aqua-marines, topazes, crystals of smoked quartz, &c. Multitudes of these minerals have been extracted by means of some very irregular workings. The mountain of Toutt-Kaltoui, situated near the preceding, offers analogous deposits. The presence of wolfram had excited hopes that tin might be found in these mountains; hopes which have been realised by its discovery on the Onone. There are some unworked deposits of sulphide of antimony in this country.

Considerable attention has of late years been directed to the tributaries of the Amour river, many of which have yielded large quantities of gold, and some districts on the northern borders of the sea of Okotsk, are reported as being rich in ores of silver.

Mines of Hungary.

It must be premised of this country, that many of the metalliferous formations which used some years ago to be considered of high geological antiquity, have been proved to belong to the secondary, and even to the tertiary period; whence it is only as a matter of convenience rendered the more needful by a number of undetermined questions, that all the mines are here classed together.

The metallic mines of this kingdom, including those of Transylvania, and the Bannat of Temeschwar, form four principal groups, which we shall denote by the group of the N.W., group of the N.E., group of the E., and group of the S.E.

The group of the North-West embraces the districts of Schemnitz, Kremnitz, Kœnigsberg, Neusohl, and the environs of Schmœlnitz, Bethler, Rosenau, &c.

Schemnitz, a royal free city of mines, and the principal centre of the mines of Hungary, lies 25 leagues to the N. of Buda, 560 yards above the sea, in the midst of a small group of mountains covered with forests. The most part of these mountains, the highest of which reaches an elevation of 1,130 yards above the ocean, are formed of barren trachytes (rough trap-rocks); but, within their ambit, a formation is observed, consisting of greenstone porphyries, connected with syenites, passing into granite and gneiss, and including subordinate beds of mica-slate and limestone. It is in this formation that all the mines occur.

It has been long known that the greenstone porphyries of Schemnitz have intimate relations with the metalliferous porphyries of South America. M. Beudant, on comparing them with those brought by Von Humboldt from Guanaxuato, Real del Monte, &c., has recognised an identity in the minutest details of colour, structure, composition, respective situation of the different varieties, and even in the empirical character of effervescence with acids.

The metalliferous rocks of Schemnitz appear in a tract of a few miles in extent, and are traversed by a principal group of five master-lodes coursing N.E. and S.W., besides a great number of less important veins, which occur on the north side of the ridge of the Paradise mountain. The most powerful of the first of these, the *Spitaler Gang*, attains occasionally a width of from 10 to 20 fathoms; and is traceable for upwards of 4 miles in length. The lodes seldom exhibit distinct walls, but a portion of the greenstone porphyry (*saxum metalliferum* of the older miners) is often decomposed, and impregnated with iron pyrites for some distance from the plane of contact. Intersections and dislocations are of rare occurrence.

The substances which constitute the body of these veins, are fragments of the adjoining rock, often decomposed to clay, drusy quartz, ferriferous carbonate of lime and sulphate of baryta, with which occur sulphuret of silver mixed with native silver containing more or less gold, which is rarely in visible scales; ruby-silver ore, argentiferous galena, blende, copper, and iron pyrites, &c. The sulphuret of silver and the galena are the most important ores. Sometimes these two substances are isolated, sometimes they are mixed in different ratios, so as to furnish ores of every degree of richness, from such as yield 60 per cent. of silver down to the poorest galena. The gold seldom occurs alone; it generally accompanies the silver in variable proportion, which has undoubtedly diminished in depth. The galena appears to occur in comparatively larger quantity in the greatest depths attained.

The ores of Schemnitz are all treated by fusion; the poor galenas at the smelting work near Schemnitz (Bleihütte), and the resulting lead is sent as *work lead* to the smelting-houses of Kremnitz, Neusohl, and Scharnowitz, whither all the silver ores prepared in the different spots of the country are transported in order to be smelted.

The mines of Schemnitz, opened 800 years ago, have been worked to a depth of more than 200 fathoms. The explorations are in general well conducted. Excellent galleries of efflux have been excavated; the waters for driving the machinery are collected and applied with skill. It may be remarked, however, that these mines have declined from the state of prosperity in which they stood a century ago. Maria Theresa, established in 1760, at Schemnitz, a school of mines. This acquired at its origin, throughout Europe, a great celebrity, but will probably not recover from the blow which it received in the civil war of 1848–9. After numbering before those events 300 or 400 students, it has seen a great proportion of them pass to the rival schools of Gratz and Przibram.

Kremnitz lies about five leagues NN.W. of Schemnitz, in a valley flanked on the right by a range of hills formed of rocks quite analogous to the metalliferous rocks of Schemnitz. In the midst of these rocks, veins are worked nearly similar to those of Schemnitz; but the quartz which forms their principal mass is more abundant, and contains more native gold. Here is also found comparatively a great abundance of sulphide of antimony. The metalliferous district is of very moderate extent, and is surrounded by the trachytic formation which geologically overlies it, forming to the east and west considerable mountains.

The city of Kremnitz is one of the most ancient free royal cities of mines in Hungary. It is said that mines were worked there even in the times of the Romans; but it is the Germans who, since the middle ages, have given a great development to these exploitations. There exists at Kremnitz a Mint-office, to which all the gold and silver of the mines of Hungary are carried in order to be parted, and where all the chemical processes, such as the fabrication of acids, &c., are carried on in the large way.

About six leagues NN.E. from Schemnitz, on the banks of the Gran, lies the town of Neusohl, founded by a colony of Saxon miners. The mountains surrounding it include mines very different from those of which we have been treating. At Herrengrund, two leagues from Neusohl, greywacke forms pretty lofty mountains; this rock is covered by transition limestone, and is supported by mica-slate. The lower beds contain bands of copper ores, chiefly copper pyrites. The mica-slate includes likewise masses of ore, apparently constituting veins in it. These ores have been worked since the thirteenth century. The copper ore is argentiferous, and these mines produce annually about 2,137 cwts. of copper and 1,345 marcs of silver.

In the higher ridge which adjoins this range, and worked in a region of snows and bears, is the interesting mine of Magurka, on an E. and W. lode in granite, yielding gold, antimony, and a little galena.

The mines of Lower Hungary (Nieder-Ungarn), employ 15,500 workmen, and yield metals of the annual value of 360,000*l.*

Eighteen or twenty leagues to the east of Neusohl, we meet with a country very rich in iron and copper mines, situated chiefly in the neighbourhood of Bethler, Schmœlnitz, Einsiedel, Roseneau, &c. Talcose and clay-slates form the principal body of the mountains here, along with hornblende rocks. The veins appear to lie generally conformably to the strata. The ores of iron are sparry ore, and especially hydrous oxide of iron, compact and in concretions, accompanied with specular iron ore. They give employment to many large smelting-houses, mostly in the counties of Gömor and Zips. The copper mines lie chiefly in the neighbourhood of Schmœlnitz and Gœlnitz. The copper extracted contains about 6 or 7 ounces of silver in the hundredweight, and the *fahlerz* has been proved to contain a considerable percentage of mercury, which is now extracted. This group of mines, belonging almost entirely to private persons, and chiefly worked by a company called the *Waldbürgerschaft*, produces annually 17,000 cwts. of copper, 4,650 marcs of silver, and 7,967 lbs. of quicksilver. In the neighbourhood of Dobschau, large quantities of the ores of cobalt and nickel are obtained.

To conclude our enumeration of the mineral wealth of this country, it remains merely to state that there are *opal* mines in the environs of Czervenitza, situate in the trachytic conglomerate, which in several localities contains *opalised* wood.

Group of the North-East, or of Nagybanya.—The mines of this group lie in a somewhat considerable chain of mountains, which, proceeding from the frontiers of Buckowina, where it is united to the Carpathians, finally disappears amidst the saliferous sandstones between the *Theiss*, *Lapos*, and *Nagy Szamos*, on the northern frontiers of Transylvania. These mountains are partly composed of rocks analogous to those of Schemnitz, traversed by veins which have much resemblance to the veins of this celebrated spot. Into these veins a great many mines have been opened, the most important of which are those of Nagybanya, Kapnik, Felsobanya, Veresviz, Miszbanya, and Laposbanya. All these mines produce gold. Those of Laposbanya furnish, likewise, argentiferous galena, and those of Kapnik copper, especially as silver-fahlerz. Realgar occurs in the mines of Felsobanya; and orpiment in those of Ohlalapos. Several of them produce manganese and sulphuret of antimony. Lastly, towards the north, in the county of Marmarosh, lies the important copper mine of *Borscha*, and near the frontiers of Buckowina the lead mine of *Rodnau*, in which also much zinc ore occurs.

The mines composing the group of the East, or of Abrudbanya, occur almost all in the mountains which rise in the western part of Transylvania, between the *Lapos* and *Maros*, in the environs of *Abrudbanya*. There may be noticed in this region, limestones, sandstones, trachytes, basalts, and porphyries, very analogous to the greenstone porphyries of Schemnitz. It seems to be principally in the latter rocks that the mines forming the wealth of this country occurs, but some of them exist also in the mica-slate, the greywacke, and even in the limestone. The principal veins are at Nagyag, Körösbanya, Offenbanya, Vöröspatak, Boitza, Csertesch, Fatzbay, Füzes, Vulkoj, Porkura, Butschum, and Toplitza. There are very numerous mines, the whole of which produce auriferous ores smelted at the works of Zalathna. These mines contain also silver, copper, antimony, and manganese. They are celebrated for their *tellurium* ores, which were peculiar to them prior to the discovery of this metal a few years back in Norway. The auriferous deposits contained in the greenstone porphyry are often very irregular. The mines of Nagyag are the richest and best worked. The numerons veins of the district occur partly in the porphyry, and partly in a sandstone which used to be termed greywacke, and considered a transition rock, but is now ascribed to the upper secondary period. The gold is accompanied by galena, realgar, ores of manganese, iron, zinc, and rarely of silver.

At Rezbanya ores of copper and lead are worked in small veins, which intersect crystalline schists and marble.

Large deposits of iron ore are worked near Vayda Hunyad, and south-west of Rezbanya on the borders of porphyry and limestone.

The group of the South-East, or of the Bannat of Temeschwar, occurs in the mountains which block up the valley of the Danube at Orschova, through a narrow gorge of which the river escapes. The principal mines are at Oravitza, Moldawa, Szaszka, and Dognaczka. They produce chiefly argentiferous copper, yielding a marc of silver (nearly ½ lb.) in the hundredweight, with occasionally a little gold. Ores of lead, zinc, and iron, are also met with. The mines are famous for their beautiful specimens of blue carbonate of copper, and various other minerals. The mine of Moldawa affords likewise orpiment. These metallic deposits lie in flats and veins; the former occurring particularly between the mica-slate and the limestone, or sometimes between the limestone and the syenite porphyry. Well-defined veins also are known to exist in the syenite and the mica-slate. The Bannat possesses, moreover, important iron mines at Moravitza and Ruskberg. Cobalt ores occur likewise in these regions. The mines of the Bannat have been leased, together with the railroads, to a French company.

The mines constituting the four groups now described are not the sole metallic mines possessed by Hungary. A few others, but generally of little importance, are scattered over different parts of this kingdom. Several have been noticed in the portion of the Carpathians which separates Transylvania from Moldavia and Wallachia. Their principal object is the exploration of some singular deposits of galena.

Besides the mines just noticed, Hungary contains some coal and lignite mines, numerous mines of rock-salt, and several deposits of golden sands situated chiefly on the banks of the Danube, the Marosch, and the Nera.

Mines of South America.

Few regions are so celebrated for their mineral wealth as the great chain which, under the name of the Cordillera of the Andes, skirts the shores of the Pacific Ocean from the land of the Patagonians to near the north-west point of the American Continent. Who has not heard of the mines of Mexico and Potosi? The mineral wealth of Peru has passed into a proverb. More recently the gold of California has thrown half the world into a fever of excitement.

The most important mines of the Cordilleras have been those of silver; but several of gold, mercury, copper, and lead, have likewise been opened. These mountains are not equally metalliferous in their whole extent. The workings occur in a small number of districts, far distant from each other.

In the Andes of Chili, particularly in the district of Copiapo, silver mines are explored, which afford chiefly ores of an earthy or ferruginous nature, mingled with small particles of ore with a silver base, known there under the name of *pacos*. Sulphide, chloride, and chloro-bromide of silver are also found, and an alloy of silver and mercury called *arquerite*. The same province presents also copper mines of considerable importance, especially in Coquimbo and Huasco, from which are extracted native copper, red oxide, carbonate of copper (malachite), and copper pyrites, associated with some chloride of copper. In a few mines, masses of native copper of extraordinary magnitude have been found.

The second metalliferous region of the Andes occurs between the 21st and 15th degrees of south latitude. It includes the celebrated mountains of Potosi, situated in nearly the 20th degree of south latitude, on the eastern slope of the chain, and several other districts likewise very rich, which extend principally towards the north-west, as far as the banks of the lake Titicaca, and even beyond it, through a total length of nearly 150 leagues. All these districts, which formerly depended on Peru, were united in 1778, to the government of Buenos Ayres, and are now included in Bolivia. The mines of Potosi were discovered in 1545, and have furnished since that period till our days, a body of silver which Von Humboldt values at 230,000,000*l* sterling. The first years were the most productive. At that time ores were often found which afforded from 40 to 45 per cent. of silver. Since the beginning of the eighteenth century, the average richness of the ores does not exceed above from 3 to 4 parts in 10,000. These ores are therefore very poor at the present day; they have diminished in richness in proportion as the excavations have become deeper. But the total product of the mines has not diminished in the same proportion; abundance of ore having made up for its poverty. Hence, if the mountain of Potosi is not, as formerly, the richest deposit of ore in the world, it may, however, be still placed immediately after the famous vein of Guanaxuato. The present yield is estimated at about 50,000 lbs. troy. The ore lies in veins in a primary clay-slate, which composes the principal mass of the mountain, and is covered by a bed of clay-porphyry. This rock crowns the summit, giving it the form of a basaltic hill. The veins are very numerous; several, near their outcrop, were almost wholly composed of sulphuret of silver, antimoniated sulphuret of silver, and native silver. In 1790, seven copper mines were known in the vice-royalty of Buenos Ayres, seven of lead, and two of tin; the last being merely washings of sands found near the river Oraro.

On the opposite flank of the chain, in a low, desert plain, entirely destitute of water, which adjoins the harbour of Iquique, and forms a part of Peru, occur the silver mines of Huantajaya, celebrated for the immense masses of native silver which have been sometimes found in them. In 1758 one was discovered weighing eight cwts.

Baron Humboldt quotes 40 cantons of Peru as being at the time of his journey most famous for their subterranean explorations of silver and gold. Those of gold are found in the provinces of Huaailas and Pataz; the silver is chiefly furnished by the districts of Huantajaya, Pasco, and Chota, which far surpass the others in the abundance of their ores.

The silver mines of the district of Pasco are situated about 30 or 40 leagues north of Lima, in 10½ degrees of south latitude, 4,400 yards above the sea-level, on the eastern slope of the Cordilleras, and near the sources of the river Amazon. They were discovered in 1630. These mines, and especially those of the Cero of Yauricocha, are actually the richest in all Peru. Their annual produce is above 400,000*l*. The ore is an earthy mass of a red colour, containing much iron, mingled with particles of native silver, hornsilver, &c., constituting what they call *pacos*. At first nothing but these *pacos* were collected; and much grey copper and antimoniated sulphuret of silver were thrown amongst the rubbish. The mean produce of all the ores is $\frac{1}{1250}$;

or an ounce and $\frac{28}{100}$ per cwt.; although some occur which yield 30 or 40 per cent These rich deposits do not seem to be extended to a great depth; they have not been pursued farther than 130 yards, and in the greater part of the workings only to from 85 to 45. Forty years ago, these mines, which produced nearly 2,000,000 of piastres annually, were the worst worked in all South America. The soil seems as if riddled with an immense number of pits, placed without any order. The drainage of the waters was effected by the manual labour of men, and was extremely expensive. In 1816, some Europeans, among whom were several miners from Cornwall, erected, under the direction of the celebrated Richard Trevithick, several high-pressure steam-engines, imported from England, and introduced a considerable improvement in the workings.

The total yield of Peru is estimated at about 300,000 lbs. troy per annum.

The mines of the province of Chota are situated in about seven degrees of south latitude. The principal ores are those of Gualcayoc, near Mecuicampa, discovered in 1771; their outcrop occurs at the height of 4,500 yards above the sea; the city of Mecuicampa itself has 4,000 yards of elevation, that is, higher than the highest summits of the Pyrenees. The climate is hence very cold and uncomfortable. The ore is a mixture of sulphuret of silver and antimoniated sulphuret, with native silver. It constitutes veins of which the upper portion is formed of *pacos*, and they sometimes traverse a limestone and sometimes a hornstone, which occurs in subordinate beds. The annual produce of the mines is 67,000 marcs of silver, according to Von Humboldt.

In the districts of Huaailas and Pataz, which are at a little distance from the former two, gold mines are worked. This metal is extracted chiefly from the veins of quartz, which run across the primary schistose mountains. The district of Huaailas contains also lead mines. Peru possesses, moreover, some mines of copper.

The quicksilver mine of Huancavelica, long the only important mine of this species which was worked in the New World, occurs on the eastern flank of the Andes of Peru, in 13 degrees of south latitude, at upwards of 6,000 yards above the level of the sea. It does not seem referrible to the same class of deposits with the mines hitherto mentioned, but occurs in sandstones and shales, apparently of the carboniferous period. Indications of mercurial ores have been observed in several other points of the Andes of Northern Peru, and the south of New Granada.

Deposits of rock salt are known to exist in Peru, especially near the silver mines of Huantajaya; and nitrate of soda is found in large quantity in the desert of Tarapaca.

On receding from the district of Chota, the Cordilleras are less abundantly stored with metallic wealth, to the isthmus of Panama, and even far beyond it. The kingdom of New Granada offers but a very small number of silver mines. There are some auriferous veins in the province of Antioquia, and in the mountains of Guamoco. The province of Caracas, the mountains of which may be considered as a ramification of the Cordilleras, presents at Aroa a copper mine which furnishes annually from 700 to 800 metric quintals (1,400 to 1,600 cwts.) of this metal. Finally, we may state in passing, that there is a very abundant salt mine at Zipaquira, in the province of Santa-Fé, and that between this point and the province of Santa-Fé-de-Bogotà, a coal-field occurs at the extraordinary height of 2,700 yards. Emeralds are worked at Muzo.

Although Mexico presents a great variety of localities of ores, almost the only ones worked are those of silver. Nearly the whole of these mines are situated on the back or the flanks of the Cordilleras, especially to the west of the chain, at the height of the great table-land which traverses this region of the globe, or a little below its level in the chains which divide it. They lie in general between 2,000 and 3,000 yards above the sea; a very considerable elevation, which is favourable to their prosperity, because in this latitude there exists at that height a mean temperature mild, salubrious, and most propitious to agriculture. There were at the time of Humboldt's visit, from 4,000 to 5,000 deposits of ore exploited. The workings constituted 3,000 distinct mines, which were distributed round 500 head-quarters or *Reales*. These mines are not, however, uniformly spread over the whole extent of the Cordilleras. They may be considered as forming eight groups, which altogether do not include a greater space than 12,000 square leagues; viz. hardly more than the tenth part of the surface of Mexico.

These eight groups are, in proceeding from south to north,—

1. The group of *Oaxuaca*, situated in the province of this name at the southern extremity of Mexico properly so called, towards the 17th degree of north latitude. Besides silver mines, it contains the only veins of gold explored in Mexico. These veins traverse gneiss and mica-slate.

2. The group of *Tasco*. The most part of the mines which compose it are situated 20 or 25 leagues to the south-west of Mexico, towards the western slope of the great *plateau*.

3. The group of *Biscania*, about 20 leagues north-east of Mexico. It is of moderate

extent, but it comprehends the rich workings of Pachuca, Real del Monte, and Moram. The district of Real del Monte contains only a single principal vein, named *Veta Bezicana* of Real del Monte, in which there are several workings; it is, however, reckoned among the richest of Mexico.

4. The group of *Zimapan*. It is very near the preceding, about 40 leagues north of Mexico, towards the eastern slope of the plateau. Besides numerous silver mines, it includes abundant deposits of lead, and some mines of yellow sulphuret of arsenic.

5. The *Central group*, of which the principal point is *Guanaxuato*, a city of 70,000 inhabitants, placed at its southern extremity, and 60 leagues NN.W. of Mexico. It comprises among others the famous mine districts of *Guanaxuato, Catorce, Zacatecas,* and *Sombrerete*; the richest in Mexico, which alone furnish more than half of all the silver which this kingdom brings into circulation.

The district of Guanaxuato presents only one main vein, called the *Veta Madre*. This vein is enclosed principally in clay-slate, to whose beds it runs parallel, but occasionally it issues out of them to intersect more modern rocks. The vein is composed of quartz, carbonate of lime, fragments of clay-slate, &c.; and includes the sulphurets of iron, of lead, and of zinc in great quantities, some native silver, sulphide of silver, and red silver; its power (thickness of the vein) is from 43 to 48 yards. It is recognised and worked throughout a length of upwards of three leagues, though the principal workings are within 2,000 yards; and contains 19 exploitations, which produced annually nearly 1,200,000*l*. in silver. One of the explorations, that of Valenciana, produces 320,000*l*.; being equal to about one-fifteenth of the total product of the 3,000 mines of Mexico. Since 1764, the period of its discovery, its nett annual product has never been less than from two to three millions of francs (80,000*l*. to 120,000*l*.); and its proprietors, at first men of little fortune, became, in ten years, the richest individuals in Mexico, and perhaps in the whole globe.

The workings of this mine are very extensive, and penetrate to a depth of 2,000 feet.

The district of Zacatecas presents in like manner only a single vein in greywacke; which, however, is the seat of several workings.

The deposits mined at Catorce are in limestone; the mine called *Purissima de Catorce* has been explored to about 650 yards in depth; and yielded in 1796 nearly 220,000*l*. There are also mines of antimony in the district of Catorce.

Since the year 1824, several English companies, on a large scale, have undertaken the working of some of the Mexican silver mines. Of late years many of them have been fairly successful.

Towards the western part of the group of which we are now speaking, copper mines are worked in the provinces of Valladolid and Guadalaxara; the ores being chiefly composed of suboxide of copper (ruby copper), sulphide of copper, and native copper. These mines produce about 2,000 metric quintals of copper annually (440,000 lbs. English). In the same district, ores of tin are collected in the alluvial soils, particularly near Mount Gigante. The concretionary oxide of tin, so rare in Europe, is here the most common variety. This metal occurs also in veins.

The central part of Mexico contains many indications of sulphide of mercury (cinnabar); but in 1804 it was worked only in two places, and to an inconsiderable extent.

6. The group of *Neu Gallicia* is situated in the province of this name, about 100 leagues N.W. from Mexico. It comprises the mines of Bolanos, one of the richest districts.

7. The group of *Durango* and *Soaora*, in the intendancies of the same name. It is very extensive. The mines are situated in part on the table-land, and in part on the western slope. Durango is 140 leagues NN.W. of Mexico. Tin ore is found here.

8. The group of *Chihuahua*. It takes its name from the town of Chihuahua, situated 100 leagues N. of Durango. It is exceedingly extensive, but of little value; and terminates at 29° 10′ of north latitude.

Mexico possesses, besides, several mines which are not included in the eight preceding groups. Thus the provinces of New Leon and of New Santander present abundant ores of lead. New Mexico contains copper mines and many others.

Lastly, rock-salt is mined in several points of New Spain; and coal seems to occur in New Mexico.

The richness of the different districts of the *silver mines* or *reales* is extremely unequal. Nineteen-twentieths of these *reales* do not furnish altogether more than one-twelfth of the total product. This inequality is owing to the excessive richness of some deposits. The ores of Mexico are principally in veins; beds and masses are rare. The veins traverse chiefly, and perhaps only, igneous and transition rocks, among which certain porphyries are remarked as very rich in deposits of gold and silver. The silver ores are mostly sulphide of silver, black antimoniated sulphide of silver (stephanite and polybasite), muriate of silver (horn silver), and grey copper. Many explorations are carried on in certain earthy ores, called *colorados*, similar to the *pacos* of Peru. Lastly, there are ores of other metals, which are worked principally, and sometimes exclusively, for the silver which they contain; such are the argentiferous sulphides of lead, of copper, and of iron.

Ores of very great richness occur in Mexico; but the average is only from 3 to 4 ounces per cwt., or from 18 to 25 in 10,000. There are some, indeed, whose estimate does not exceed $2\frac{1}{8}$ ounces. Almost all the argentiferous veins afford a little gold; the silver of Guanaxuato, for example, contains $\frac{1}{360}$. The enormous product of the Mexican mines is to be ascribed rather to the great facility of working them, and the abundance of ores, than to their intrinsic richness. The present yield is estimated at above 5,000,000*l.* for silver, and 62,000*l.* for gold.

The art of mining was little advanced in this country at the period of Humboldt's journey; the workings presented a combination of small mines, each of which had only one aperture above, without any lateral communications between the different shafts.

The form of these explorations was too irregular to admit of their being called *regular stopes.* The shafts and the galleries were much too wide. The interior transport of the ores is generally effected on the backs of men; rarely by mules. The machines for raising the ore and drawing the water are in general ill-combined, and the horse-whims for setting them in motion ill-constructed. The timbering of the shafts is very imperfectly executed; the walled portions alone are well done. There are some adit-levels, but they are too few, and ill directed. The efforts of the English companies have produced but little change either in the mining or subsequent treatment of the ores.

The silver ores of Spanish America are treated partly by fusion and partly by amalgamation, but more frequently by the latter mode; hence the importation of mercury forms there an object of the highest importance, especially since the quicksilver mine of *Huancavelica* fell in, and ceased to be worked on the same scale as previously.

Gold mining is carried on in Nicaragua, and some gold is also yielded by Costa Rica, and the Island of Aruba.

The most important of these gold-sands are washed on the western slope of the Cordilleras, viz.: in New Granada, from the province of Barbacoas to the Isthmus of Panama, and to Chili. There are likewise some on the eastern slope of the Cordilleras, in the high valley of the river Amazons. The washings of New Granada produce, also, some platinum.

The mines, properly so called, and the washings of South America, furnish, altogether, 42,575 marcs, or 10,418 kilogrammes (22,920 lbs. Eng.) of gold, worth 1,435,720*l.*

Besides the extensive washings of the sands that produce the diamonds and other precious stones, the platinum, and a great part of the gold of Brazil, mines of gold, lead, and iron are opened in what appear to be ancient geological formations, very different from those of the Cordilleras. There are no silver mines, and this, again, indicates a great difference between the deposits of Brazil and those of Spanish America. The province of Minas-Geraes in Brazil is that most remarkable for its mineral productions. The slaty strata of the country contain intercalated portions of quartzose rock, among which a micaceous one, called *Itacolumite*, and one largely charged with scales of specular iron, termed *Jacotinga*, are regarded as constant accompaniments of the gold.

Several English companies have for years worked gold mines in this region; among which that of St. John d'El Rey still yields a considerable profit, due in a great measure to the steady skill and economy with which the underground works, as well as the stamping and dressing of the auriferous 'stone' is conducted: this is an auriferous pyrites. Among the most noted of the mines are the Bahu, Gongo Soco, and Morro Velho, which although yielding only from two to three oitavas (or eighths of an ounce) per ton, are worked on a large scale. The Morro Velho, which was the largest gold mine in Brazil, is now suffering from the effects of a most disastrous fire which occurred there a few years ago. Among other interesting minerals, the rare metal palladium is found mingled with some of the Brazilian gold, and it was owing to the liberality of the well-known assayer, Percival Johnson, F.R.S., that the Geological Society of London was for years enabled to bestow an annual 'Wollaston' medal struck in palladium, of which that chemist was the discoverer.

Mines of North America.

Within the last few years a stupendous activity in the production of certain metals has succeeded to the unimportant trials which at intervals used to be made. It was especially the discovery of gold in California in 1848, which invited the attention of the world to the metallic riches of the Pacific side of this continent, or to the western flank of the continuation of the great chain of mountains which we have traced upwards from South America.

Almost the entire quantity of the gold produced in California is obtained from stream-works, washings, or 'diggings,' but the precious metal itself has evidently been derived from veins in the granitic and the ancient slaty rocks which constitute the range of the Sierra Nevada. The alluvial deposits occupying ancient river-courses are termed 'deep placers,' whilst those which have been re-distributed, and lie near the surface, are called 'shallow placers.' The gold-bearing gravels are usually worked by a process known as 'hydraulic mining.' See Gold. Platinum and osmiridium have also been found here.

The auriferous tracts extend northward far into the British territory, and are worked in British Columbia.

In one of the side valleys of San José, a mine of quicksilver, 'New Almaden,' has for some years been opened upon irregular and contorted deposits of cinnabar, associated with clay-slates highly inclined and similarly contorted. It is said that above 10,000 cwts. of mercury are produced here annually.

On the eastern or Atlantic side of the North American continent, the existence of gold has long been known, as well in alluvium in Virginia, Carolina, Georgia, and Canada, as in veins which occur at intervals in the schist rocks of the Appalachian chain, and which have given rise to numerous explorations.

The veins appear generally to course NN.E. and SS.W., and to consist mainly of quartz, often extending to a great thickness. Few, however, of these mines have been followed down to a depth of more than 100 feet, or have been developed on a continuously large scale.

Lead mines have been worked in distinct veins at Rossie, St. Lawrence County, N.Y., at Shelburne in New Hampshire, Southampton and Northampton, in Massachusetts, Middleton, Connecticut, Chester County, and Wheatley mines, Pennsylvania; but the most important are those opened in irregular deposits sometimes vertical, at others horizontal, which distinguish the Silurian limestones of the Upper Mississippi. The lead-bearing region is 87 miles long from east to west, and 54 miles broad from north to south, the chief centres being Galena, Mineral Point, and Dubuque. The ore, generally pure galena, occurs with great irregularity. It occupies only one zone, about 100 feet in thickness, of the 'galena' limestone, and hence the mines have been but shallow. In Missouri an analogous state of things occurs. Copper has been worked at several mines in the Atlantic States, in Maryland; in New Jersey; several localities in Tennessee; and Perkiomen in Pennsylvania, where the veins occur in new red sandstone and shale.

In 1841 Mr. Doughton, state geologist for Michigan, first drew public attention to the native copper of Lake Superior, which has been the object of very numerous workings, and has been produced in steadily increasing quantity.

The copper occurs in a district of bedded augitic trap, amygdaloid, and sandstone, with conglomerate of the lower Silurian period, and the rocks are especially remarkable for bearing native copper with but little of the ordinary ores of that metal.

Ores of zinc are associated with lead ores at several of the above-mentioned localities, especially in the Wisconsin district, where the calamine is known among the miners by the name of 'dry-bone.' But one of the most peculiar mineral deposits in the United States is that of the red oxide of zinc, and of Franklinite, which occur in Sussex County, New Jersey, at Sparta and Stirling. They are intercalated among the beds of a crystalline limestone, with a total thickness of above 30 feet, and are the scene of very successful undertakings.

Lastly, iron ores of various species, particularly the magnetic oxide and hæmatite, occur in numerous localities, Missouri is remarkable for large masses, and Lake Superior offers even a greater abundance.

A bed of magnetic oxide of iron occurs in gneiss near Franconia in New Hampshire. It has a width of from 5 to 8 feet; and has been mined through a length of 200 feet, and to a depth of 90 feet. The same ore is found in veins in Massachusets and Vermont, accompanied by copper and iron pyrites. It is met with in immense quantities on the western bank of the lake Champlain, forming beds of from 1 to 20 feet in thickness, almost without mixture, encased in granite. It is also found in the mountains of that territory. These deposits appear to extend without interruption from Canada to the neighbourhood of New York, where an exploration on them may be seen at Crown-Point. The ore there extracted is in much esteem. Several mines of the same species exist in New Jersey. The primary mountains which rise in the north of this state near the Delaware, include beds almost vertical of black oxide of iron, which have been worked to 100 feet in depth. In the county of Sussex the same ore occurs, accompanied with Franklinite. At Roxbury, in Connecticut, a good sized lode of sparry iron occurs; the only one of the kind known in the Alleghanies.

Although the mineral resources of Canada are remarkably rich and varied, mining operations have not yet been adequately carried out. Iron ores of great value, chiefly magnetic oxide and red hæmatite, are abundant in the Laurentian rocks at several points on the Ottawa, along the Rideau Canal, and near Marmora; but the want of coal has prevented their due development. Good iron ore is also found in many of the eastern townships, and bog ore has been smelted at the Radnor Forges, Batiscan. Copper ores are worked in Huronian rocks on the north-eastern shore of Lake Huron, and the ores of the eastern townships have been worked at Harvey's Hill, in Leeds, and at the Acton mine, now exhausted. Gold workings have been established on the Chaudière and its tributaries, whilst the metal was at one time worked at the Richardson mine, Hastings Co., where it was found curiously associated with lignite. Veins of galena are found in the Laurentian rocks, but are not worked. Among the non-metallic minerals of the Dominion may be mentioned the fine deposits of phosphate of lime, or apatite, and mica. Petroleum is widely distributed in certain localities.

Coal seams of great value are actively worked in the provinces of New Brunswick and Nova Scotia; whilst gold is yielded by the quartz-veins of Waverley and other districts in Nova Scotia.

Before quitting America, it should be mentioned that the West India Islands offer indications of mineral. Many cupriferous veins have been explored in Jamaica. Copper ore and molybdenite occur at Virgin Gorda; and Cuba has for years been remarkable for the richness and abundance of its copper ores. The principal mine is the Cobre, worked on an extensive scale. The lodes, which have been very large at shallow depths, course E. and W. through greenstone and conglomeritic rock. The Santiago mines have also yielded a large amount of ore.

To R. W. Raymond, Ph.D., we are indebted for the following:—

Professor W. P. Blake, in a note to his 'Catalogue of California Minerals,' pointed out that the mining districts of the Pacific slope are arranged in parallel zones, following the prevailing direction of the mountain ranges. This interesting generalization has been more fully illustrated and connected with the geological history of the country by Mr. Clarence King, who sums up the observed phenomena as follows:—

'The Pacific coast-ranges upon the west carry quicksilver, tin, and chromic iron. The next belt is that of the Sierra Nevada and Oregon Cascades, which, upon their west slope, bear two zones, a foot-hill chain of copper mines, and a middle line of gold deposits. These gold-veins, and the resultant placer mines, extend far into Alaska, characterised by the occurrence of gold in quartz, by a small amount of that metal which is entangled in iron sulphurets, and by occupying splits in the upturned metamorphic strata of the Jurassic age. Lying to the east of this zone, along the east base of the Sierras, and stretching southward into Mexico, is a chain of silver mines, containing comparatively little base metal, and frequently included in volcanic rocks. Through Middle Mexico, Arizona, Middle Nevada, and Central Idaho is another line of silver mines, mineralised with complicated association of the base metals, and more often occurring in older rocks. Through New Mexico, Utah, and Western Montana, lies another zone of argentiferous galena lodes. To the east, again, the New Mexico, Colorado, Wyoming, and Montana gold-belt is an extremely well-defined and continuous chain of deposits.'

These seven longitudinal zones or chains of mineral deposits must not, in my opinion, be held to constitute a complete classification. The belts of the coast-range and the west slope of the Sierra are well defined, both geologically and topographically; but it is not so easy to separate into distinct groups the occurrences of gold and silver of the Sierra. For instance, the gold of Eastern Oregon, Idaho, and Western Montana, together with such occurrences in Nevada as those of the Silver Peak and New Pass districts, and numerous instances of sporadic occurrence of particular ores of silver or argentiferous base metals, cannot be brought within the classification above given. Either more zones must be recognised, or a greater mineralogical variety must be acknowledged in those already laid down. The latter alternative is, I think, the more reasonable. According to the principles set forth in a discussion of mineral deposits in my report for 1870,[1] it appears evident that the agencies which affect the general constitution of geological formations are far wider in their operation than those which cause the formation of fissures; and that the causes influencing the filling of fissures are still more local in their peculiarities than those which form the fissures themselves. Thus, of the area covered by rocks of a given epoch, more or less uniform in lithological character, only a small portion may have been exposed to conditions allowing deposits of useful minerals, even when such deposits are contemporaneous, as in the case of coal. Still more

[1] 'Statistics of Mines and Mining in the States and Territories west of the Rocky Mountains,' by R. W. Raymond, U. S. Commissioner of Mining Statistics.

limited is the field for the formation of fissures; but it must be freely confessed that, in the case before us the corrugation of half the continent into parallel ranges offers good grounds for the expectation of vast longitudinal systems of fissures. When we come to consider the filling of these fissures, however, it is evident that the mineralogical character of the vein-material must vary, to some extent, as to the gangue, but to a still greater extent as to the nature of the ores. Even single mines, in the course of extensive exploitation, have produced ores differing as widely as do those of the different zones enumerated by Mr. King. I am, in fact, strongly inclined to consider freedom from base metals, for instance, a peculiarity due in many cases to secondary processes, and not to be relied upon as characteristic for single veins even, to say nothing of whole groups, districts, and continental zones.

Nevertheless, the generalisations of Professor Blake and Mr. King on this subject are highly interesting and valuable. The criticism here made is not in opposition to their views so much as in qualification of a possible rash application on the part of the general public. The zonal parallelism does exist, though in a somewhat irregular way; and it is clearly referrible, as these writers have shown, to the structural features of the country, the leading feature of which is the longitudinal trend of the mountain ranges.

Subordinate to this trend (or, more strictly, resulting from the same causes as produced it) appear the predominant longitudinal strike of the great outcrops of sedimentary rocks, the longitudinal axes of granite outbursts, and, finally, the longitudinal vents of lava-overflows and the arrangement of volcanos in similar lines. It is evident that in crossing the country from east to west we traverse a series of different formations; while, by following routes parallel with the main mountain ranges, we travel upon the continuous outcrops of the same general age.

Mr. King distinguishes in the history of the entire Cordillera two periods of disturbance, which have been accompanied by the rending of mountain chains, and the ejection of igneous rocks. Such periods would afford the conditions of solfataric action, thermal springs, and the generation of acid gases and metallic sublimates and solutions, and thus favour the formation of metalliferous deposits. The first of these periods, he says, culminated in the Jurassic, produced over the entire system a profound disturbance, and is, in all probability, the dating-point of a large class of lodes. To the second, or tertiary period, he assigns the mineral-veins which traverse the early volcanic rocks.

The expression 'culminated in the Jurassic' merely refers, no doubt, to the fact that the cretaceous strata of California repose unconformably upon the upturned and metamorphosed Jurassic slates, having been themselves neither tilted nor highly metamorphosed. Perhaps it is well to remember, however, that the cretaceous is a weak point in the California series, at least, as determined by leading fossils; and perhaps the results of more complete stratigraphical surveys will indicate that there are gaps of no little significance, dynamically and chronologically, in this part of the geological record. At all events, the period of the folding of the Sierra Nevada (presumably that of the formation of many metalliferous deposits) was in some sense post-Jurassic rather than Jurassic; and probably this is the meaning of Mr. King, who speaks of it in another passage as 'late Jurassic.'

The lodes which are referred to this period are of two types: first, those wholly inclosed in the granites, the outburst of which accompanied the upheaval of the earlier stratified group, or in the metamorphosed Jurassic or sub-Jurassic strata; secondly, those which occupy planes of stratification or jointure, thus following in general the dip and strike of the country-rock, while they present in other respects the indications of fissure-veins. The veins of the Reese-river granite are examples of the first type; many gold-veins of California, the Humboldt mines, &c., are given as illustrations of the second. The White Pine district, the mineral deposits of which are said to be inclosed conformably between strata of Devonian limestone, is declared to be a 'prominent example of the groups comprised wholly within the ancient rocks.'

We have hitherto supposed the strata immediately overlying the argentiferous limestone at White Pine to be deep-water Carboniferous; but their Devonian character seems to be demonstrated by Mr. Arnold Hague.[1] More practically important is the assignment of these deposits to the earlier period of geological disturbance.

Mr. King appears here to include in one group *all* the White Pine deposits, the 'Base Range,' as well as 'Treasury Hill'; yet the striking distinction in mineralogical character is worthy of regard. The deposits of Treasury Hill are notably free from base metals; and it seems to me that in their present form they must be due to a secondary action, which has concentrated and recombined the metallic elements of

[1] See volume on 'Mining Industry of the United States Geological Exploration of the Fortieth Parallel.'

older deposits. It should be added, however, that although the chlorides of Treasury Hill are as pure as those of Lander Hill, they do not appear, like the latter, to yield in depth to such silver ores as characterize the fissure-veins of Reese-river district —ruby-silver, for instance. Nor are they fissure-veins, so far as we can now decide.

To the tertiary period of orographical disturbance are referred the volcanic overflows and the veins wholly or partly inclosed in volcanic rocks. Under this head Mr. King classes many important veins of Mexico, several of those which border the Colorado river in the United States, and, in general, that zone which lies along the eastern base of the Sierra Nevada. The Comstock lode is adduced as the most prominent example of this type, and the Owyhee district in Idaho is also referred to it, because, although in granite, it presents a series of volcanic dykes, which appear to prove, by the manner of their intersections with the quartz lodes, that the latter are of tertiary origin. It will be seen that although the extent and number of the deposits of this class are inferior to those of the earlier period, they include some of the most brilliant instances in the history of mining. As Mr. King, however, points out, many of the veins which are wholly inclosed in the older rocks may nevertheless be due to this later period of disturbance. Nor does he ignore the bearing of this thought on his determination of the early period as Jurassic. He confesses that in more recent strata, formed from *débris* of Jurassic rocks, ore-bearing pebbles have not been found; but he regards this fact as a piece of negative evidence merely.

The distribution of mineral deposits east of the Rocky mountains follows somewhat different laws. Here we have but one longitudinal range, that of the Alleghanies, which is accompanied by a gold-bearing zone of irregular extent and value. In the Southern States the strata flanking this range present a remarkable variety of mineral deposits. On the eastern slope of the Rocky mountains, again, occurs what may perhaps be denominated a zone or longitudinal series of coal-fields. But between these mountain boundaries the geological formations of the country cluster, as it were, around centres or basins. We have such a group in Michigan, another in the Middle States, and a third in the South-west.

The deposits of the different metals, ores, and useful minerals, in the country east of the Rocky mountains, vary widely in age. The ores of gold, copper, and iron, in the pre-Silurian schists of the south; the galena and cobalt ores of the south-west, and the copper ores of Lake Superior, in the lower Silurian rocks; the argillaceous iron ores of New York, and other States west of New York, in the upper Silurian, and the salines of the same group; the bitumen, salt, coal, and iron ores of the Subcarboniferous; the coal and iron of the Carboniferous; the coal, copper, and barytes of the Triassic; the lignites of the Cretaceous; and the fossil phosphates of the Tertiary period; are instances which may serve to show how great is this variety. It is not within the province of this paper to discuss the mineral deposits of the Mississippi basin, the Appalachian chain, or the Atlantic coast. I shall content myself with brief mention of two points. The first is the greater relative age of the metalliferous deposits as compared with those of the inland basin and the Pacific slope. On this side the period of greatest activity in such formations was over before it began in the west. The great gold and silver deposits beyond the Rocky mountains appear to be post-Devonian, post-Jurassic, and even Tertiary in their origin. The vast volcanic activity which affected so wide an area in California, Oregon, Washington, Idaho, and Nevada, is not represented in the east.

The other point is the peculiar relative position of our coal and iron deposits. This was eloquently described by Mr. Abrams Hewitt, United States Commissioner to the Paris Exposition, in his admirable review of the iron and steel industry of the world. I cannot do better than quote his forcible words:—

'The position of the coal-measures of the United States suggests the idea of a gigantic bowl filled with treasure, the outer rim of which skirts along the Atlantic to the Gulf of Mexico, and thence, returning by the plains which lie at the eastern base of the Rocky mountains, passes by the great lakes to the place of beginning, on the borders of Pennsylvania and New York. The rim of the basin is filled with exhaustless stores of iron ores of every variety, and of the best quality. In seeking the natural channels of water-communication, whether on the north, east, south, or west, the coal must cut this metalliferous rim; and, in its turn, the iron ore may be carried back to the coal, to be used in conjunction with the carboniferous ores, which are quite as abundant in the United States as they are in England, but hitherto have been left unwrought, in consequence of the cheaper rate of procuring the richer ores from the rim of the basin. Along the Atlantic slope, in the highland range, from the borders of the Hudson river to the state of Georgia, a distance of 1,000 miles, is found the great magnetic range, traversing seven entire States in its length and course. Parallel with this, in the great limestone valley which lies along the margin of the coal-field, are the brown hæmatites, in such quantities at some points, especially in Virginia, Tennessee, and Alabama, as to fairly stagger the imagination.

And, finally, in the coal-basin is a stratum of red fossiliferous ore, beginning in a comparatively thin seam in the state of New York, and terminating in the state of Alabama in a bed 15 feet in thickness, over which the horseman may ride for more than 100 miles. Westward, in Arkansas and Missouri, is reached that wonderful range of red oxide of iron, which, in mountains rising hundreds of feet above the surface, or in beds beneath the soil, culminates at Lake Superior in deposits of ore which excite the wonder of all beholders; and returning thence to the Atlantic slope, in the Adirondacks of New York, is a vast, undeveloped region, watered by rivers whose beds are of iron, and traversed by mountains whose foundations are laid upon the same material. In and among the coal-beds themselves are found scattered deposits of hæmatite and fossiliferous ores, which, by their proximity to the coal, have inaugurated the iron industry of our day.'

Mines of Australia.

Victoria is essentially a gold-producing colony, extensive mining operations having for many years been systematically carried on not only in the alluvial drifts and deep 'leads,' but also in the auriferous quartz-reefs which course through lower Silurian rocks. Silver ores have been worked by the St. Arnaud Silver Mines Company. Stream-tin, in the form of 'black-sand,' is frequently found in connection with the alluvial gold, and veins of tin ore have also been discovered. Copper and lead, though found in the colony, are not abundant; nor is the iron worked, although in the form of titaniferous iron-sand it enjoys a wide distribution. Mining for coal has been attempted at Western Port, Cape Otway, and at some other localities; but a Board recently appointed to enquire into the coal-producing resources of the colony have reported unfavourably. A thick deposit of lignite has been worked at Lal Lal.

South Australia is remarkably rich in copper, the Burra Burra mines being celebrated for their production of malachite, or green carbonate. Several copper mines are also established on Yorke's Peninsula, and are notable for yielding the oxychloride of copper, or *atacamite*. Among the principal copper mines may be mentioned the Wallaroo, the Kapunda and Moonta mines. The colony also possesses magnificent iron ores in the form of magnetite and red and brown hæmatite, but they are not yet worked to any extent. Gold, silver, and bismuth, are to be mentioned among the useful minerals of South Australia.

In New South Wales coal-measures are worked at Newcastle, Wollongang, and Hartley. Oil-shales are also wrought at some of these localities, and distilled for sake of the kerosine oil which they yield. The iron of the colony is not yet largely worked. Copper mines are opened up to a limited extent, and gold mining is not neglected. Valuable deposits of tin ore were discovered in the Northern districts of the colony in 1870, and are being actively developed. The tin extends into the adjacent colony of Queensland.

Queensland is rich in coal, some of which appears to be of palæozoic and some of mesozoic age. Gold is worked both in reefs and in alluvial deposits. Copper ores are mined at Peaks Down and Mount Perry; and the iron ores have recently received attention, whilst the discovery of tin is being eagerly followed up by the miner. Agates, chrysoprase, and opal must also be enumerated among the mineral products of this colony,

In Tasmania tin ore has recently been worked in the neighbourhood of Mount Bischoff. Coal occurs on the Mersey river and elsewhere; some of the Tasmanian coal is bituminous, and some anthracitic, whilst other varieties are merely lignite. A peculiar bituminous substance, known as *Tasmanite*, occurs on the Mersey.

New Zealand is rich in mineral wealth. Gold has been successfully worked in some parts of the colony, as at the Thames gold-fields. Bituminous coal occurs in the Pukawan coal-field, whilst lignite is widely distributed in the North and Middle Islands, and is often associated with a fossil gum or *retinite*. Copper ores occur in the serpentine of the Dunn Mountain, and titaniferous iron-sand skirts the shore of Taranaki. Among the other mineral products may be mentioned chrome iron ore, arsenic, graphite, and jade.

On some other less known Mine Countries.

The islands of Cyprus and Negropont, in the Mediterranean, were celebrated, in former times, for their copper mines; and several islands of the Archipelago presented gold mines, now abandoned. The same thing may be said of Macedonia and Thrace. The mountains of Servia and Albania contain iron mines; and lead mines occur in Servia, and the adjacent provinces of European Turkey. The silver mines of Laurium, in Attica, used in early times to form a most important source of revenue to Athens. These are now being partially reworked. Mines of silver ore, with galena, are still worked at Keban Maden and Ghumush Khaneh in Asia Minor; whilst that of copper at Arghaneh Maden, in the Taurus, yields a large supply of the ores of that metal, which are refined at Tocat. Some also occur in Arabia and in Persia; and in the territories round the Caucasus. Persia has mines of argentiferous lead a few leagues from Ispahan; and Natolia, or Asia Minor, furnishes orpiment and chrome iron ore.

Thibet passes for being rich in gold and silver mines. China produces a great quantity of iron and mercury. The copper mines of this empire lie principally in the province of Yu-Nan and the island Formosa. Japan, likewise, possesses copper mines in the provinces of Kijunack and Sarunga. They seem to be abundant; and are now being explored. Japan presents, moreover, mines of quicksilver, also mines of gold, silver, tin, red sulphide of arsenic, &c. But in China, as in Europe, coal is the most important of the mining products. This combustible is explored, especially in the environs of Pekin, and in the northern parts of the empire. See Coal.

Iron mines exist in several points of the Burman empire, and of Hindostan. Near Madras, there exist excellent ores of sparry iron, and black oxide, analogous to the Swedish ores. The islands of Macassar, Borneo, and Timor, include copper mines. The tin obtained from the islands of Banca and Billiton, and from the peninsula of Malacca, and several other points of Southern Asia, proceeds entirely from the washing of sands. The same is undoubtedly true of the gold furnished by the Philippine Isles, Borneo, &c. It appears, however, that mines of gold and silver are worked in the island of Sumatra.

In Africa, large quantities of gold are washed by the natives from the alluvium. Some interest has recently been excited by the discovery of gold-fields in South Africa, near the frontier of the Transvaal Republic.

Near the Cape of Good Hope, in Namaqualand, numerous indications of copper ore are met with, which, in a few instances only, have led to the opening of remunerative mines. At Bembi, near Ambriz, a powerful vein of malachite has been rudely worked by the negro chiefs, and is now leased to an English company by the Portuguese Government. It is asserted that a great deal of copper exists in Abyssinia. On the banks of the Senegal, the Moors and the Pouls fabricate iron in travelling forges. They employ as the ore the richest portions of a ferruginous sandstone, which seems to be a very modern formation. Morocco appears to contain ores of various metals; and Algeria, since it has been in the hands of the French, has given rise to active explorations, among which may especially be mentioned the copper mines of Tenes.

For a description of the South African diamond mines, see Diamond.

Mines of the Calcareous Mountains of England.

The limestone formation immediately subjacent to the coal-measures, or the carboniferous limestone, constitutes almost alone several mountainous regions of England and Wales; in which three districts very rich in lead mines deserve to be noted.

The first of these districts, Alston Moor, comprehends the upper parts of the valleys of the Tyne, the Wear, and the Tees, in the counties of Cumberland, Durham, and York. Its principal mines are situated near the small town of Alston, in Cumberland. The veins of galena which form the object of the workings, traverse alternate beds of limestone, shale, and sandstone; and are very remarkable for their becoming suddenly thin and impoverished on passing from the limestone into the shale or sandstone; and for resuming their richness, and usual size, on returning into the limestone. The exploitations are situated in the flanks of considerably high hills, bare of wood, and almost wholly covered with marshy heaths. The waters are drawn off by long adit-levels; and the ores are dragged out by horses to the day. The galena extracted from these mines is smelted by means of coal and a little peat, in furnaces of Scotch construction. The lead is very poor in silver; but most of it is now treated by the Pattinson process. The mines of this district produce annually about 25,000 tons of lead. Copper ores have been raised, although not in large quantity, from a very strong vein, containing chiefly iron pyrites and some galena, about six miles south-west of Alston.

This region is bounded by the Cross Fell range on the west, and extends southward to the Yorkshire valleys of Swaledale, Arkendale, &c., to Grassington, where numerous lead mines are worked under very similar circumstances. The Yorkshire mines yielded in 1856, 8,986 tons of lead.

The second metalliferous district lies in the northern part of Derbyshire, and in the conterminous parts of the neighbouring counties. The districts called the Peak and King's-Field are the richest in workable deposits. The mines of Derbyshire are getting exhausted; they are very numerous, but in general inconsiderable. The galena extracted from them is treated with coal in reverberatory furnaces; but the silver is very small in quantity. They yield annually 5,000 tons of lead; with a certain quantity of calamine, and a little copper ore. At Ecton, in North Staffordshire, a remarkably rich copper mine was worked in the last century, at the intersection of several veins, in the midst of very contorted beds of grey and black limestone.

The veins of both the above districts are noted for the beauty of the fluor, calc-spar, and other crystallised minerals accompanying the galena; and those of Derbyshire, also, for the thinning or partial interruption which they suffer in crossing the 'toadstone,' a rock of igneous origin, which is interstratified with the limestone. Besides the lodes or 'rake-veins,' the less normal forms of repository termed 'flats' and 'pipe-veins' yield in both these districts large amounts of ore.

The third metalliferous district is situated in Flintshire and Denbighshire, counties forming the N.E. part of Wales. Next to Alston Moor this is the most productive; furnishing annually nearly 6,000 tons of lead, and a certain quantity of calamine. The galena is smelted in reverberatory furnaces, and affords a lead far from rich in silver, which was therefore seldom subjected to cupellation, until the introduction of Pattinson's process of desilverising. The lodes, coursing E. and W., are intersected by several great cross veins, which may be traced for many miles, and only exceptionally yield ore. None of the lead veins appear to be prolonged into the subjacent slate rocks. At the Orme's Head, cupriferous veins have also been worked in the limestone.

Mines of galena and calamine have, from a very early period, been worked in the Mendip Hills, to the south of Bristol, but are now almost entirely idle.

Besides the metallic mines just enumerated, the formation of the metalliferous limestone presents, in England, especially in the counties of Northumberland and Cumberland, seams of coal, generally very thin and anthracitic. Far more important are the red and brown oxides of iron, which this formation yields in vast quantity; the brown ore in beds and veins in Alston Moor; hæmatite of the richest kind, in irregular deposits, near Whitehaven, Cumberland, and at Ulverstone, Lancashire; in less important repositories in Derbyshire, Flintshire, and on the flanks of the Mendip Hills; and, lastly, excellent brown peroxide in the upper limestone environing the Forest of Dean, where it occupies a series of devious caverns and holes lying more or less in the same plane. Appearances of the same kind, but on a smaller scale, fringe the southern side of the South Welsh coal-field.

Mines of the later Rock Formations.

The most important mines of what used to be termed, in the earlier days of geology, the Secondary rocks, and perhaps of all mineral formations whatsoever, are those worked in the most ancient strata of that division, in the coal-measures. Since, however, the organic contents of the rocks have been more fully studied and compared, the coal-measures have been classed with the Palæozoic systems, and that supposed line of demarcation between them and the older strata already treated of, can only be retained as a matter of convenience, and as marking in most countries a great change in the character of the mineral contents as we ascend in the geological scale.

The British islands, France and Germany, frequently present ranges of the older rocks, upon the flanks of which, sometimes unconformably, repose the deposits of coal. The principal of these have become great centres of manufacture; for Newcastle, Birmingham, Glasgow, Sheffield, St. Etienne, &c., owe their prosperity and their rapid enlargement to the coal raised as it were at their gates in enormous quantities. Lancashire, Wales, Belgium, and Silesia, owe equally to their extensive collieries a great portion of their activity, their wealth, and their population. Other coal districts, less rich, or mined on a less extensive scale, have procured for their inhabitants less distinguished, but by no means inconsiderable, advantages; such, for example, in Great Britain, are Derbyshire, Cheshire, Shropshire, Warwickshire, the environs of Bristol, &c.; some parts of Ireland; in France, Litry, department of Calvados, Comanteric, Alais, le Creuzot, &c.; in Rhine Prussia, Saarbrück, and Westphalia; and several localities in Saxony, Bohemia, Spain, Portugal, the United States, &c.

We need not enter here into ampler details on coal mines; these particulars are given in the article Coal.

Nature has frequently deposited close to the coal, an ore, whose intrinsic value alone is very small, but whose abundance in the neighbourhood of fuel becomes extremely precious to man; we allude to the clay-ironstone of the coal-measures. It is extracted in enormous quantities from the coal-fields of Scotland, Yorkshire, Staffordshire, Shropshire, and South Wales. Much of it is also raised from the coal-strata of Silesia and of Westphalia, but few coal-fields appear to be entirely deficient of it. The iron works of England, which are supplied in great part from this ironstone reduced with coke or coal, pour annually into commerce six millions and a half tons of pig iron.

The shale, or slate-clay, of the coal-measures contains sometimes a very large quantity of pyrites, which decomposing by the action of the air, with or without artificial heat, produces sulphate of iron, and sulphate of alumina, whence copperas and alum are manufactured in great abundance.

The calcareous formation which surmounts the coal-measures, called by geologists *Zechstein*, magnesian limestone, and older Alpine limestone, contains different deposits of metallic ores; the most celebrated being the cupreous schist of Mansfeld, a stratum of slightly calcareous slate, from a few inches to 2 feet thick, containing copper pyrites in sufficient quantity to afford 2 per cent. of the weight of the ore of an argentiferous copper. This thin layer displays itself in the north of Germany over a length of eighty leagues, from the shores of the Elbe to the banks of the Rhine. Notwithstanding its thinness and relative poverty, skilful miners have contrived to establish, on different points of this slate, a number of important explorations, the most considerable being in the territory of Mansfeld, particularly near Rothenburg. They produce annually 2,000 tons of copper, and 20,000 marcs of silver. We may also mention those of Hessia, situated near Frankenberg, Bieber, and Riegelsdorf. In the latter, the cupreous schist and its accompanying strata are traversed by veins of cobalt, mined by the same system of underground workings as the schist. These operations are considerable; they extend, in the direction of the strata, through a length of 8,700 yards, and penetrate downwards to a very great depth. Three galleries of efflux are to be observed; two of which pour their waters into the Fulde, and the third into the Verra. These mines have been in activity since the year 1530. Analogous mines exist near Saalfeld in Thuringia.

A very remarkable deposit of the same period, whence geologists have given this formation the name of Permian, occurs in the Russian government of Perm, the sandstones containing disseminated particles of copper ore, chiefly in the form of carbonate, to the distance of 400 or 500 wersts from the chain of the Oural. Some of the thick flaggy grey grits contain as much as 2½ per cent. of copper, and the imperial zavods near Perm are stated to yield 260 tons annually from this source.

To the same geological formation must probably be referred the limestone which contains the sparry iron mine of Schmalkalden at the western foot of Thuringerwald, where there has been explored from time immemorial a considerable mass of this ore, known by the name of *Stahlberg*. The working has been executed in the most irregular manner, and has opened up enormous excavations; whence disastrous 'runs' have taken place in the mines.

At Tarnowitz, 14 leagues S.E. of Oppeln in Siberia, the zechstein contains, in some of its strata, considerable quantities of galena and calamine; into which mines have been opened, that yield annually from 600 to 700 tons of lead, 1,000 to 1,100 marcs of silver, and much calamine. Mines of argentiferous lead are noticed at Olkutch and Jaworno in Gallicia, about 6 leagues N.E. of Cracow, and 15 leagues E.N.E. of Tarnowitz. From their position these have been referred to the same period. The important lead mines of Villach and Bleiberg in Carinthia have been shown by the Austrian geologists to belong to a rather more recent formation, whilst several minor lead-bearing localities of the same province occur in the Hallstadt limestone (Upper Trias), and Gailthal limestone (carboniferous).

There has been discovered near *Confolens* in the department of *la Charente*, in a secondary limestone, calcareous beds, and particularly subordinate beds of quartz, which contain considerable quantities of galena. At *Figeac* also, in the department of *le Lot*, deposits of galena, blende, and calamine occur in a secondary limestone. At *la Voulte*, on the banks of the Rhône, there is mined, in the lower courses of the limestones that constitute a great portion of the department of the Ardèche, a powerful bed of iron ore.

It used to be supposed that it is in the zechstein, or in the sandstones and trap rocks of nearly the same age, that the four great deposits of the sulphuret of mercury, of *Idria*, the *Palatinate*, *Almaden*, and *Huancavelica* are mined, but more recent observations would place some of them, at least, in rocks contemporaneous with the coal-measures. See Mercury.

The formation which separates the *Zechstein* from the *lias* (*calcaire à gryphites*), called New Red Sandstone and Red Marl in England, and *Bunter-sandstein*, *Muschelkalk*, and *Keuper* in Germany, presents hardly any important mines except those of rock-salt; which enrich it in Cheshire, and in many parts of continental Europe. The mines of Salzburg belong to a formation somewhat higher, and those of Wieliczka, Bochnia and of Transylvania, as well as of Cardona in Spain, are of Tertiary date. The copper-bearing sandstones of *Alderley Edge*, in Cheshire, are of Triassic age, and at *Mechernich*, in Rhenish Prussia, galena is worked in a conglomerate belonging to the Bunter series.

The lias often contains very pyritous lignites and shales, which are mined in many places, and particularly at Whitby and Guisborough in Yorkshire, for the manufacture of alum and copperas.

Within the last few years, most important beds of stratified iron ore have been worked in the marlstone, or middle lias in Cleveland, in the north of Yorkshire.

Strata of iron ore also occur in the overlying oolitic limestones, in Yorkshire, Northamptonshire, and other parts of England. The same formations have in France long been noted for the supply of large quantities of iron ore.

The Lower Greensand beneath the chalk formation is often so strongly imbued with iron as to have led in former times to extensive mining operations and iron smelting in the south-eastern part of England. Since the general introduction of railways, attempts have again been made to utilise those iron deposits.

The lowest beds of the chalk contain iron pyrites, which has become the object of an important exploration at *Vissans*, on the southern coast of the *Pas-de-Calais*, where it is converted into sulphate of iron. The waves turn the nodules out of their bed, and roll them on the shore, where they are picked up.

If the chalk be poor in useful minerals, this is not the case with the tertiary formation above it; for it contains important mines. In it are explored numerous beds of lignite (wood-coal), and from some of these lignite deposits, also, yellow amber is extracted. The iron mines of the north-east of Ireland, previously noticed, are in deposits of basalt of miocene age.

The other tertiary formations present merely a few mines of sulphur, of iron and bitumen; but it must here again be remarked, that many of the secondary, and even of the tertiary strata have in certain countries been subjected to metamorphic action, of such a nature as to have led to their being classed with the older rocks; and thus some of the metalliferous formations of the east of Europe and of South America, although still somewhat obscure, ought without doubt in strictness to be classified with these more recent deposits.

Several of the secondary or tertiary strata contain deposits of sulphur, which are mined in various countries.

The formations of a decidedly volcanic origin afford but few mining materials, if we except sulphur, alum, and opals.

Mines of the Alluvial Strata.

This formation contains very important mines, since from it are extracted all the diamonds, and almost all the precious stones, the platinum, and the greatest part of the gold, with a considerable portion of the tin. The diamond mines are confined nearly to Brazil, and to the kingdoms of Golconda and Visapour in the East Indies. The South-African diamonds are found partly in river-beds, and partly in 'dry diggings.' See Diamond.

The tin-stream works of Cornwall, Bohemia, and the East Indies, and the gold-washings, placers, or 'diggings' of Siberia, Borneo, California, and Australia, belong to beds of alluvium or drift, irregularly deposited over the older formations. See Gold; Tin.

MINING. As the operations of mining vary with the conditions of the rock-formations, in which the minerals sought for by the miner occur, it is necessary to give a brief description of the more especially marked distinctions which are seen in our geological formations.

Geologists divide rocks into *stratified* and *unstratified*. Those mineral systems, which consist of parallel, or nearly parallel planes, whose length and breadth greatly exceed their thickness, are called *stratified* rocks; while to those which occur in thick blocks, and which do not exhibit those parallel planes, the term of *unstratified* rocks is applied. These formations have been divided into two other classes, namely, the *primary* and the *secondary*. The advances of geological science, however, and more accurate information, have materially modified the views which gave rise to those divisions; and when men have learned to look on great natural phenomena without the interposition of the medium of some favourite theory, there is but little doubt the interpretation will be somewhat different from even that which is now received.

A certain set of rocks may be classed as of truly igneous origin. These are the traps, basalt, and the like. These have often been termed primary rocks. Yet we have rocks of this class, not merely forcing their way through the superincumbent and more recent rocks, but actually overflowing them; they in many cases, therefore, are much more recent than the secondary rocks. Granite has commonly been classed as a truly igneous rock; but facts have lately been developed which show, at all events, the combined action of water. See Granite.

Granite is usually classed with the unstratified rocks; but the section of any granite quarry will exhibit very distinct lines, conforming, more or less, to the horizontal—known to the quarrymen as the *bedway*—which would appear almost sufficient to place those rocks for certain purposes amongst the stratified ones.

It is commonly stated that the unstratified rocks possess a nearly vertical position, the stratified rocks assuming more nearly a horizontal one. There are numerous examples adverse to this view; indeed, it must be regarded as a hasty generalisation —the bedway of the granite approaching very nearly to the horizontal, while we often find the truly stratified rocks in a vertical position.

Where the older rocks graduate down into the plains, rocks of an intermediate character appear, which, though possessing a nearly vertical position, like the unstratified and non-fossiliferous rocks, contain a few vestiges of animal beings. These were formerly called *transition*, to indicate their being the passing links between the first and second systems of ancient deposits; some of them are distinguished by their fractured and cemented texture, for which reason they are sometimes called *conglomerate*. These transition rocks form part of the *Palæozoic* series of modern geologists.

Between the older and the secondary rocks, another very valuable series is interposed in certain districts of the globe; namely, the coal-measures, the paramount formation of Great Britain. The coal-strata are frequently disposed in a basin-form, and alternate with parallel beds of sandstone, slate-clay, ironstone, and occasionally of limestone.

As a practical rule it may be here stated that, in every mineral formation, the inclination and direction are to be noted; the former being the angle which it forms with the horizon, the latter the point of the azimuth or horizon towards which it dips, as west, north-east, south, &c. The direction of a bed is that of a horizontal line drawn in its plane; and which is also denoted by the point of the compass. Since the lines of direction and inclination are at right angles to each other, the first may always be inferred from the second; for when a stratum is said to dip to the east or west, this implies that its direction is north and south.

The following terms have been used to express dissimilar conditions in mineral deposits, well known to the practical miner.

Masses are mineral deposits, not extensively spread in parallel planes, but irregular heaps, rounded, oval, or angular, enveloped in whole or in a great measure by rocks of a different kind. Lenticular masses, being frequently placed between two horizontal or inclined strata, have been sometimes supposed to be stratiform themselves, and have been accordingly denominated by the Germans *liegende Stocke*, *lying-heaps*, or *blocks*.

The orbicular masses often occur in the interior of unstratified mountains, or in the bosom of one bed. These frequently indicate pre-existing cavernous spaces, which have been filled in with metalliferous or mineral matter.

Nests, *Concretions*, or *Nodules*, are small masses found in the middle of strata; the first being commonly in a friable state; the second often kidney-shaped, or tuberous; the third nearly round and encrusted. like the kernel of an almond.

Lodes, or *Veins*, are flattened masses, with their opposite surfaces not always parallel. These sometimes terminate like a wedge, at a greater or less distance, and do not run parallel with the rocky strata in which they lie, but cross them in a direction not far from the perpendicular; often traversing several different mineral planes. The *lodes* are sometimes deranged in their course, so as to pursue for a little way the space between two contiguous strata; at other times they divide into several branches. The matter which fills the lodes is for the most part entirely different from the rocks they pass through, or at least it possesses peculiar features.

This mode of occurrence suggests the idea of clefts or rents having been made in the stratum posterior to its consolidation, and of the vacuities having been filled with foreign matter, either immediately or after a certain interval. There can be no doubt as to the justice of the first part of the proposition, for there may be observed round many lodes undeniable proofs of the movement or dislocation of the rock; for example, upon each side of the rent, the same strata are no longer situated in the same plane as before, but make greater or smaller angles with it; or the stratum upon one side of the lode is raised considerably above, or depressed considerably below, its counterpart upon the other side. With regard to the manner in which the rent has been filled, different opinions may be entertained. In the lodes which are widest near the surface of the ground, and graduate into a thin wedge below, the foreign matter would seem to have been introduced as into a funnel at the top, and to have carried along with it portions of rounded gravel, and sometimes, though rarely, organic remains. In other, but very exceptional, cases, lodes are largest at their under part, and become progressively narrower as they approach the surface. From this circumstance, it has been inferred that the rent has been caused by an expansive force acting from within the earth; and that the foreign matter, having been in a fluid state, has afterwards slowly crystallised. Accurate observation shows that in the large majority of cases the metalliferous deposits are of aqueous, and not of igneous origin.

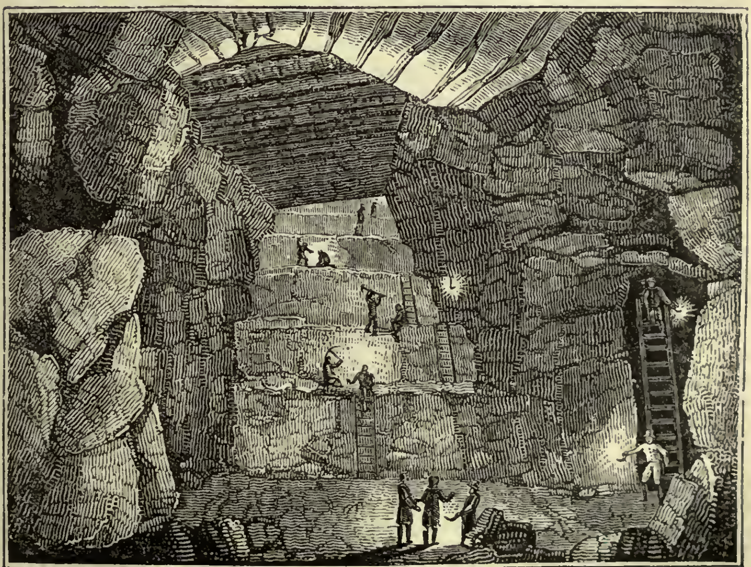
In the lodes, the principal matters which fill them are to be distinguished from the accessory substances; the latter being distributed irregularly, amidst the mass of the first, in crystals, nodules, grains, seams, &c. The non-metalliferous portion, which is often the largest, is called *gangue*, from the German *Gang*, vein. The position of a vein is denoted, like that of the stratum, by the angle of inclination, and the point of the horizon towards which it dips, whence the direction is deduced. In popular language a *lode* may be described to be a crack or fissure, such as is formed in the drying of a pasty mass, extending over a considerable extent of country, and penetrating to a great depth into the earth.

A metalliferous substance is said to be *disseminated* when it is dispersed in crystals, spangles, scales, globules, &c., through a large mineral mass. Tin is not unfrequently thus disseminated through granite and clay-slate rocks.

Certain ores which contain the metals most indispensable to human necessities, have been treasured up by the Creator in very bountiful deposits; constituting either great masses in rocks of different kinds, or distributed in lodes, veins, nests, concretions, or beds with stony and earthy admixtures; the whole of which become the objects of mineral exploration. These stores occur in different stages of the geological formations; but their main portion, after having existed abundantly in the several orders of the older strata, cease to be found towards the middle of the secondary rocks. Iron ores are, with a few exceptional cases, the only ones which continue among the more modern deposits, even so high as the beds immediately beneath the chalk, when they exist almost entirely as colouring-matters of the tertiary beds.

Granite, gneiss, mica, and clay-slate, constitute in Europe the grand metallic domain. There is hardly any kind of ore which does not occur in these in sufficient abundance to become the object of mining operations, and many are found in no

1446



A general view of mining operations as given in Ville-Fosse's 'Sur la Richesse Minérale.'

other rocks. The transition rocks, and the lower part of the secondary ones, are not so rich, neither do they contain the same variety of ores. But this order of things, which is presented by Great Britain, Germany, France, Sweden, and Norway, is far from forming a general law; since in equinoctial America the gneiss is but little metalliferous; while the superior strata, such as the clay-schists, the syenitic porphyries, the limestones, which complete the transition series, as also several secondary deposits, include the greater portion of the immense mineral wealth of that region of the globe.

All the substances of which the ordinary metals form the basis, are not equally abundant in nature; a great proportion of the numerous mineral species which figure in our classifications are mere varieties scattered up and down in the cavities of the great masses or lodes. The workable ores are few in number, being mostly sulphides, oxides, and carbonates. These occasionally form of themselves very large masses, but more frequently they are blended with lumps of quartz, felspar, and carbonate of lime, which form the main body of the deposit. The ores in that case are arranged in small layers parallel to the strata, or in small veins which traverse the rock in all directions, or in nests or concretions stationed irregularly, or finally disseminated in hardly-visible particles. These deposits sometimes contain only one species of ore, sometimes several, which must be mined together, as they seem to be of contemporaneous formation; whilst in other cases they are separable, having been probably formed at different epochs.

In mining, as in architecture, the best method of imparting instruction is to display the master-pieces of the respective arts. It is not so easy, however, to represent at once the general effect of a mine as it is of an edifice; because there is no point of sight from which the former can be sketched at once, like the latter. The subterranean explorations certainly afford some of the finest examples of the useful labours of man; but, however curious and grand in themselves, they cannot become objects of a panoramic view. It is only by the lights of geometry and geology that mines can be contemplated and surveyed, either as a whole or in their details; and, therefore, these marvellous subterranean regions, in which roads are cut which, with their sinuosities, extend at different levels over many hundred miles, are altogether unknown or disregarded by men of the world. Should any of them, perchance, from curiosity or interest, descend into these dark recesses of the earth, they are prepared to discover only a few insulated objects, which they may think strange or possibly hideous; but they cannot recognise either the symmetrical disposition of mineral bodies, or the laws which govern geological phenomena, and serve as sure guides to the skilful miner in his adventurous search. It is only by exact plans and sections of subterraneous workings, that a knowledge of the nature, extent, and distribution of mineral wealth can be acquired.

General Observations on the Localities of Ores, and on the Indications of Metallic Mines.

1. *Tin* exists in the primary rocks, appearing either in interlaced veins, in beds, as a constituent part of the rock itself, or in distinct veins. Tin ore is found in alluvial land, filling up low situations between lofty mountains; but this tin (stream-tin) has been derived from the older rocks of the neighbourhood. See TIN.

2. *Gold* occurs either in beds, or in veins, frequently in primary rocks; though in other formations, and particularly in alluvial deposits, it is also found. When this metal exists in the bosom of primitive rocks it is particularly in schists; it is not found in serpentine, but it is met with in greywacke in Transylvania. The gold of alluvial districts, called stream-gold or placer-gold, occurs, as well as alluvial tin, among the *débris* of the more ancient rocks. See GOLD.

3. *Silver* is found, particularly in veins and beds, in primitive and transition formations; though some veins of this metal occur in secondary strata. The rocks richest in it are gneiss, mica-slate, clay-slate, greywacke, and old alpine limestone. Localities of silver ore itself are not numerous, at least in Europe, among secondary formations; but silver occurs in combination with the ores of copper or of lead. See SILVER.

4. *Copper* exists in the three mineral epochs: 1, in primary rocks, principally in the state of copper pyrites, in lodes or veins; 2, in transition districts, sometimes in masses, usually in veins of copper pyrites; 3, in secondary strata, especially in beds of cupreous schist. The *Kupferschiefer* is, however, of palæozoic age, but copper ores are also found in true secondary strata, as at Alderley Edge. See COPPER.

5. *Lead* occurs, also, in each of the three mineral epochs; abounding particularly in primary and transition grounds, where it usually constitutes lodes, and occasionally beds of sulphide of lead (galena). The same ore is found in strata or in veins among secondary rocks, associated now and then with ochreous iron-oxide and calamine (carbonate of zinc); and it is sometimes disseminated in grains through more recent strata. See LEAD.

6. *Iron* is met with in four different mineral eras, but in different ores. Among primary rocks magnetic iron ore and specular iron ore occur chiefly in beds, sometimes of enormous size; the ores of red or brown oxide of iron (hæmatite) are found

sometimes in veins, but occasionally in very large masses, both in primitive and transition rocks; as also sometimes in secondary strata; but more frequently in the coal-measure strata, as beds of clay-ironstone, or globular iron oxide, and carbonate of iron. In alluvial districts we find ores of clay-ironstone, granular iron ore, bog-ore, swamp ore, and meadow ore. The iron ores which belong to the primitive period have almost always the metallic aspect, with a richness amounting to 75 per cent. of iron, while the ores in the posterior formations become, in general more and more earthy, down to those in alluvial soils, some of which present the appearance of a common stone, and afford not more than 20 per cent. of metal, though its quality is often excellent. See IRON.

7. *Mercury* occurs principally among secondary strata, in disseminated masses, along with combustible substances; though the metal is met with occasionally in primitive countries. See MERCURY.

8. *Cobalt* belongs to the three mineral epochs; its most abundant deposits are veins in primary rocks; small veins containing this metal are found, however, in secondary strata.

9. *Antimony* occurs in lodes among the older and transition rocks.

10, 11. *Bismuth* and *Nickel* do not often constitute the predominating substance of any mineral deposits; but they commonly accompany cobalt.

12. *Zinc* occurs in three several formations, namely: as sulphide or blende, particularly in primary and transition rocks; as calamine, in secondary strata, usually along with oxide of iron, and sometimes with sulphide of lead.

The study of the mineral substances, called *gangues* or vein-stones, which usually accompany the different ores, is indispensable in the investigation and working of mines. These *gangues*, such as quartz, calcareous spar, fluor spar, heavy spar, &c., and a great number of smaller substances, although of small value in themselves, become of great consequence to the miner, either in pointing out by their presence that of certain useful minerals, or by characterising in their several associations different deposits of ores of which it may be possible to follow the traces, and to discriminate the relations, often of a complicated kind, provided we observe assiduously the accompanying *gangues*.

Among the indications of mineral deposits, some are proximate, and others remote. The proximate are an efflorescence, so to speak, of the subjacent metallic masses; the frequent occurrence of fragments of particular ores, &c. The remote indications consist in the geological character, and in the nature of the rocks. From the examples previously adduced, marks of this kind acquire new importance when, in a district susceptible of including deposits of workable ores, the *gangues* or vein-stones are met with which usually accompany any particular metal. The general aspect of mountains whose flanks present gentle and continuous slopes, the frequency of sterile veins, the presence of metalliferous sands, the neighbourhood of some known locality of an ore; but when ferruginous or cupreous waters issue from sands or clays, such characters merit in general little attention, because the waters may flow from a great distance. No greater importance can be attached to metalliferous sands and saline springs.

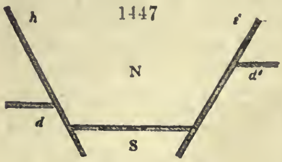
In speaking of remote indications, we may remark that in several places, and particularly near Clausthal in the Hartz, a certain ore of oxide of iron occurs above the most abundant deposits of the ores of lead and silver; whence it has been named by the Germans the *iron-hat*. It appears that the iron ore rich in silver, which is worked in America under the name of *pacos*, has some analogy with this substance; but iron ore is in general so plentifully diffused on the surface of the soil that its presence can be regarded as only a remote indication relative to other mineral substances, except in the case of clay-ironstone with coal. The *gossans* of Cornwall, occurring in the upper portions of lodes, are analogous formations to the *eiserne Hut* of the German miners.

Mineral veins are subject to derangements in their course, which are called shifts or *faults*. Thus, when a transverse vein throws out, or intercepts, a longitudinal one, we must commonly look for the rejected vein on the side of the obtuse angle which the direction of the latter makes with that of the former. When a bed of ore is deranged by a fault, we must observe whether the slip of the strata be upwards or downwards; for, in either circumstance, it is only by pursuing the direction of the fault that we can recover the ore; in the former case by mounting, in the latter by descending beyond the dislocation.

When two veins intersect each other, the direction of the *offcast* is a subject of interest both to the miner and the geologist. In Saxony it is considered as a general fact that the portion thrown out is always upon the side of the obtuse angle, a circumstance which holds also in Cornwall; and the more obtuse the angle, the outthrow is the more considerable. A vein may be thrown out on meeting another vein, in a line which approaches either towards its inclination or its direction. The Cornish miners use two different terms to denote these two modes of rejection; for the first case they say the vein is *heaved*, for the second it is *started*.

The great copper lode of Carharack (*d*, *fig.* 1447), in the parish of Gwennap, is an instructive example of intersection. The thickness of this vein is 8 feet; its direction is nearly east and west, and it dips towards the north at an inclination of 2 feet per fathom; its upper part being in the *killas* (a greenish clay-slate), its lower part in the granite. The lode has suffered two intersections: the first produced by meeting the vein *h*, called *Stevens's fluckan*, which runs from north-west to south-east, and which throws the lode several fathoms out; the second vein is produced by another vein, *i*, almost at right angles with the first, and which occasions another out-throw of 20 fathoms to the right side. The fall of the vein occurs therefore in the one case to the right, and in the other to the left; but in both it is towards the side of the obtuse angle. This distribution is very singular, for one part of the vein appears to have mounted while the other has descended. N, S, denotes north and south. *d* is the copper lode running east and west; *h*, *i*, are systems of clay-slate veins called *fluckans*; the line over S represents the downthrow, and *d′* the up-throw.

1447



There is a great want of exactness of expression in the terms used to describe the phenomena of dislocations. The foregoing paragraphs are strictly according to the technical language of the miner, who usually regards the cross-courses, here called *fluckans*, as being the *cause* of the alteration in the mineral veins, whereas they are themselves merely the effect of the general movement of the rock masses. The singularity alluded to disappears if the woodcut be regarded as a cross-section representing the result of two distinct movements in a direction from the observer. See Faults.

In different districts in this country the terms used to distinguish mineral veins vary considerably. The following terms prevail in Derbyshire and the north of England.

Lodes or mineral veins are usually distinguished by the miners of these districts into at least four species: 1. The rake vein; 2. The pipe vein; 3. The flat or dilated vein; and 4. The interlaced mass (*Stock-werke*), indicating the union of a multitude of small veins mixed in every possible direction with each other, and with the rock.

1. The *rake* vein is a mineral fissure; and is the form best known among practical miners. It commonly runs in a straight line, beginning at the superfices of the strata, and cutting them downwards, generally further than can be reached. This vein sometimes stands quite perpendicular; but it more usually inclines or hangs over at a greater or smaller angle, or slope, which is called by the miners the *hade* or *hading* of the vein. The line of direction in which the fissure runs, is called the *bearing of the vein*.

2. The *pipe* vein resembles in many respects a huge irregular cavern, pushing forward into the body of the earth in a sloping direction, under various inclinations, from an angle of a few degrees to the horizon, to a dip of 45°, or more. The pipe does not in general cut the strata across like the rake vein, but insinuates itself between them; so that if the plane of the strata be nearly horizontal, the bearing of the pipe vein will be conformable; but if the strata stand up at a high angle, the pipe shoots down nearly headlong like a shaft. Some pipes are very wide and high, others are very low and narrow, sometimes not larger than a common mine or drift.

3. The *flat* or *dilated* vein, is a space or opening between two strata or beds of stone, the one of which lies above, and the other below this vein, like a stratum of coal between its roof and pavement: so that the vein and the strata are placed in the same plane of inclination. These veins are subject, like coal, to be interrupted, broken, and thrown up or down by slips, dykes, or other interruptions of the regular strata. In the case of a metallic vein, a slip often increases the chance of finding more treasure. Such veins do not preserve the parallelism of their beds, characteristic of coal seams; but vary excessively in thickness within a moderate space. Flat veins occur frequently in limestone, either in a horizontal or declining direction. The flat or strata-veins open and close, as the rake veins also do.

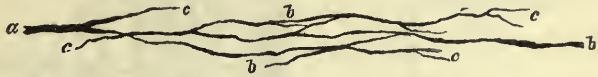
4. The interlaced mass has been already defined. The interlaced strings are more frequent in primitive formations, than in the others.

To these may be added the *accumulated* vein, or irregular mass (*Butzenwerke*), a grave deposit placed without any order in the bosom of the rocks, apparently filling up cavernous spaces.

In Cornwall and Devonshire, where different conditions prevail, other terms are employed.

The *lode*, or mineral vein, is, as in the former instances, a great line of dislocation, accompanied by minor lines of fracture. Of these Sir H. De la Beche says, 'It could scarcely be supposed that the great lines of fracture would be unaccompanied by smaller dislocations, running from them in various directions according to modifying resistances, which would depend upon the kinds of rock traversed by the great fractures, the direction in which they are carried through them as regards the bearing of their strata should they be stratified, and other obvious causes.' The great fractures would often also tend to split in various directions, and reunite into main lines, as in the annexed sketch (*fig.* 1448), in which *a b* represents the line of principal fracture,

1448



splitting at *b b* from local causes, and uniting, both towards *a* and *b*, minor cracks running into the adjoining rocks at *c*, *c*, *c*, *c*. These are known as *side-lodes*, *strings*, *feeders*, and *branches*.

These *strings* are sometimes very curiously developed, and illustrate the peculiar force of crystalline action, and all the phenomena of *heaves* and faults. The following figure (1449) furnishes a good illustration.

1449

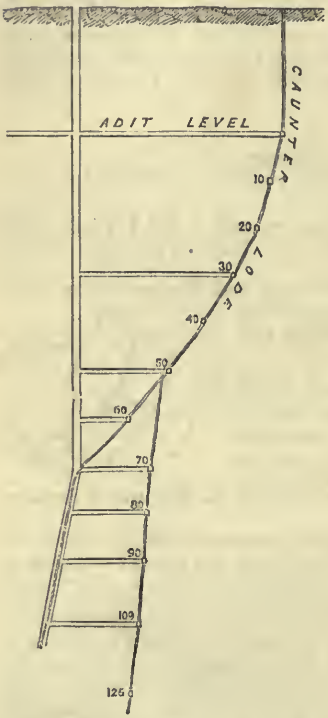
It represents a specimen of strings of oxide of tin in slate from St. Agnes, Cornwall, *h h* illustrating the *heaves* alluded to. Sir Henry de la Beche is disposed to refer these to the fact of oxide of tin recementing fractured masses of slate. We think we have sufficient evidence for referring the action to the crystallogenic force enlarging a fissure, or small crack, producing those lateral cracks, which again, by the operation of the same force, dislocate or heave the original fissure.

In these lodes we find peculiar mechanical arrangements, which are known by various names; a lode is said to be *comby* when we have the crystals of quartz or other mineral dovetailing, as it were, with the metalliferous masses. *Bunches* are isolated masses of ore found in the lode surrounded by earthy minerals. The upper part of a lode is known as its *back*, and the accumulations of ferruginous matter which very commonly occur in the *backs* and near the surface are known as *gossans*. These are to the experienced miner important guides as indicating the characters of the lode at a greater depth. *The country* signifies, with the Cornish miner, the rock through which the mineral vein runs, and accordingly as he is pleased with the indications he speaks of its being *kindly* or the contrary. The softer rocks, whether of clay-slate or granite, are spoken of as *plumb*, and a *plumb granite*, or *elvan*, is greatly preferred to the harder varieties, and spoken of as being more kindly.

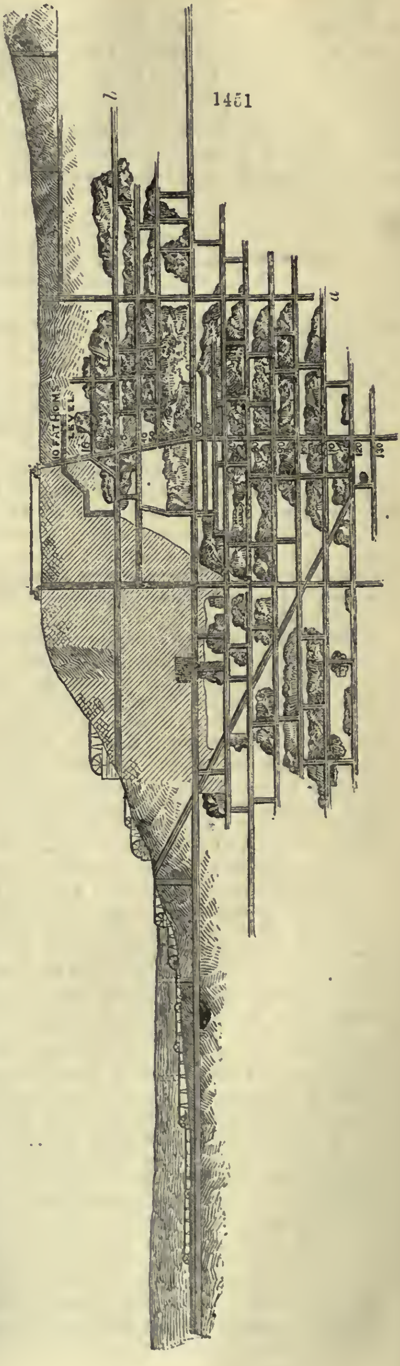
The rock forming the sides of a lode are known as its *walls* or *cheeks*. The latter term we have heard of late years in Cornwall, but we believe it to be imported by miners who have worked in the north of England. As all mineral veins incline more or less, the sides are spoken of as the upper and under walls, the upper being usually termed the *hanging wall*, and the lower the *foot-wall*.

The following woodcuts, *figs.* 1450, 1451, will serve to assist the reader in understanding the peculiarities of mining operations in our metalliferous mines. In *fig.* 1451, which is a section of one of the lead mines of Cardiganshire, the shafts, which have been sunk on the lode are shown, at varied angles from the vertical and the several horizontal levels. In this instance these *levels* or *galleries* have been worked at irregular distances. In Cornwall they are usually ten fathoms apart. The smaller shafts connecting the levels one with the other are called *winzes*. They serve for exploring the lode, or for purposes of ventilation, when the excavations are going forward. When these smaller connected shafts are worked upwards, as they sometimes are, they are called '*risings*,' and the miner is said to be working on the '*rise*.' In this woodcut the lightest shading is to indicate a portion of this particular mine which was worked out by the Romans. The darker shaded masses indicate portions of the lode which have been very productive of metalliferous matter, and which have consequently been removed. The term *counter* or *caunter lode* is given to such lodes as dip at a considerable angle with the direction of the other lodes in its vicinity. Such a lode is shown, *fig.* 1450, which is, however, inserted principally to explain that where the 'underlie' of the lode is great, a vertical shaft is sunk at some distance from it on the surface, so as to 'cut' (intersect) the lode at some depth, in this instance at 70 fathoms below the adit-level. As the inclination of the lode then alters, the shaft is continued on the lodes. Another fissure or lode, sometimes called a '*dropper*,' is seen to take nearly a

1450



1451



vertical direction from the 50-fathom level, and from the shafts levels are driven into this lode, at about every 10 fathoms.

Fig. 1452 represents in plan the underground workings of a Cornish mine. Those who are not familiar with mining are requested to suppose that the earth is transparent so as to enable us to see the *levels* worked at various depths, from the *adit-level*—through which the water pumped from the mine is discharged—to the 125-fathom level below it. These levels are numbered in the plan. They are not worked immediately under one another; but, as the lode inclines, in the same way as is shown in the *Caunter lode* (*fig.* 1450), they follow in position this *underlie* of the lode. The dark lines and the dotted lines crossing the numbered lodes, are workings upon lodes, running in a contrary direction to the lode principally shown. This plan shows the junction of the granite with the killas or clay-slate of Cornwall, and the occurrence of *elvan* courses is shown at the different levels. By studying the plan, with the horizontal and transverse section, the operations of metalliferous mining will be understood.

1452

OF MINING IN PARTICULAR.

The mode of working mines is two-fold; by *open excavations*, and *subterranean* exploitation.

Workings in the open air present few difficulties, and occasion little expense, unless when pushed to a great depth. They are always preferred for working deposits little distant from the surface; where, in fact, other methods cannot be resorted to, if the substance to be raised be covered with incoherent matters. The only rules to be observed are, to arrange the workings in terraces, so as to facilitate the cutting down of the earth; to transport the ores and the rubbish to their destination at the least possible expense: and to guard against the crumbling down of the sides. With the latter view, they ought to have a suitable slope, or to be propped by timbers whenever they are not quite solid.

Open workings are employed for valuable clays, sands, as also for the alluvial soils of diamonds, gold, and oxide of tin, iron ores, &c., limestones, gypsums, building stones, roofing slates, masses of rock salt in some situations, and certain deposits of ores, particularly the specular iron of the island of Elba; the masses of stanniferous granite of Geyer, Altenberg, and Seyffen, in the Erzgebirge, a chain of mountains between Saxony and Bohemia; the thick veins or masses of magnetic oxide of iron of Nordmarch, Dannemora, &c., in Sweden; the mass of cupreous pyrites of Ræraas, near Drontheim, in Norway; several mines of iron, copper, and gold in the Ural mountains. Some of the iron mines near Whitehaven, and Carclase tin mine in Cornwall, may also be quoted.

Subterranean workings may be conveniently divided into five classes, viz. :—

1. Veins, or beds, much inclined to the horizon, varying much in thickness.
2. Beds of slight inclination, or nearly horizontal, the power or thickness of which does not exceed two yards.
3. Beds of great thickness, but slightly inclined.
4. Veins, or beds highly inclined, of great thickness.
5. Masses of considerable magnitude in all their dimensions.

Subterranean mining requires two very distinct classes of workings: the *preparatory*, and those for *extraction*.

The *preparatory* consist in galleries, or in pits (shafts) and levels destined to conduct the miner to the point most proper for attacking the deposit of ore, for tracing it from this point, for preparing chambers of excavation, and for concerting measures with a view to the circulation of air, the discharge of waters, and the transport of the extracted minerals.

If the vein or bed in question be placed in a mountain, and if its direction forms a very obtuse angle with the line of the slope, the miner begins by opening in its side, at the lowest possible level, a gallery (level) of elongation, which serves at once to give issue to the waters, to explore the deposit through a considerable extent, and then to follow it in another direction; but to commence the real mining operations, he pierces either shafts or galleries, according to the slope of the deposit, across the first gallery.

For a stratum but little inclined to the horizon, placed beneath a plain, the first thing is to pierce two vertical shafts, which are usually made to arrive at two points in the same line of slope, and a gallery is driven to unite them. It is, in the first place, for the sake of circulation of air that these two pits are sunk; one of them, which is also destined for the drainage of the waters, should reach the lowest point of the intended workings. If a vein is intersected by transverse ones, the shafts are placed so as to follow, or, at least, to cut through the intersections. When the mineral ores lie in nearly vertical masses, it is right to avoid, as far as possible, sinking pits into their interior. These should rather be perforated at one side of their floor, even at some considerable distance, to avoid all risk of crumbling the ores into a heap of rubbish, and overwhelming the workmen.

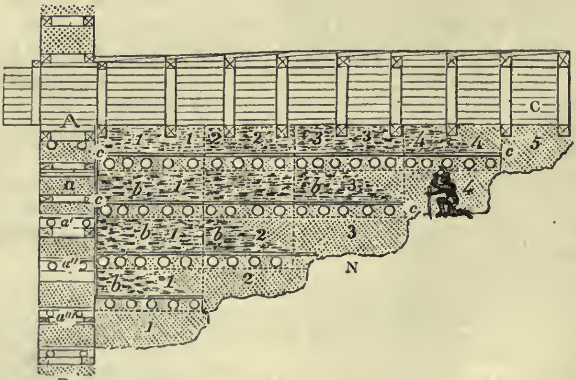
With a vein of moderate width, as soon as the preparatory labours have brought the miners to the point of the vein from which the ulterior workings are to ramify, whenever a circulation of air has been secured, and an outlet to the water and the matters mined, the first object is to divide the mass of ore into large parallelopipeds, by means of oblong galleries, pierced ten fathoms below one another, with pits of communication opened up, 30, 40, or 50 yards asunder, which follow the slope of the vein. These galleries and shafts are usually of the same breadth as the vein, unless when it is very narrow, in which case it is requisite to cut out a portion of the roof or the floor. Such workings serve at once the purposes of mining, by affording a portion of ore, and the complete investigation of the nature and riches of the vein, a certain extent of which is thus prepared before removing the cubical masses. It is proper to advance first of all, in this manner, to the greatest distance from the central point which can be mined with economy, and afterwards to remove the parallelopiped blocks, in working back to that point.

This latter operation may be carried on in two different ways; of which one consists in attacking the ore from above, and another from below. In either case, the excavations are disposed in steps similar to a stair upon their upper or under side. The first is styled a *working* in *direct* or descending steps; and the second a *working* in *reverse*, or ascending steps.

The descriptions given by Dr. Ure relate chiefly to the processes carried forward in the German mines. In very many respects they resemble our own processes of mining; and, for the general information these give to the English reader, Dr. Ure's description has been retained.

1. Suppose, for example, that the post N, *fig.* 1453, included between the horizontal gallery A C and the shaft A B, is to be excavated by direct steps, a workman stationed

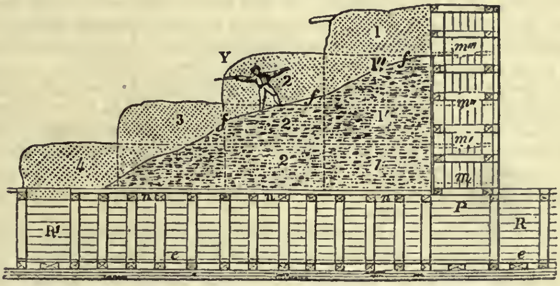
1453



upon a scaffold at the point a, which forms the angle between the shaft and the elongated drift, attacks the rock in front of him and beneath his feet. Whenever he has cut out a parallelopiped (a rectangular mass), of from four to six yards broad, and two yards high, a second miner is set to work upon a scaffold at a', two yards beneath the first, who, in like manner, excavates the rock under his feet and before him. As soon as the second miner has removed a post of four or six yards in width, by two in height, a third begins upon a scaffold at a'' to work out a third step. Thus, as many workmen are employed as there are steps to be made between the two oblong horizontal galleries which extend above and below the mass to be excavated; and since they all proceed simultaneously, they continue working in similar positions, in floors, over each other, as upon a stair with very long wide steps. As they advance, the miners construct before them wooden floors *c c c c*, for the purpose of supporting the rubbish which each workman extracts from his own step. This floor, which should be very solid, serves also for wheeling out his barrow filled with ore. The round billets which support the planks sustain the roof or the wall of the mineral vein or bed under operation. If the rubbish be very considerable, as is commonly the case, the floor planks are lost. However strongly they may be made, as they cannot be repaired, they sooner or later give way under the enormous pressure of the rubbish; and as all the weight is borne by the roof of the oblong gallery underneath, this must be sufficiently timbered. By this ingenious plan, a great many miners may go to work together upon a vein without mutual interference; as the portions which they detach have always two faces at least free, they are consequently more easily separable, either with gunpowder or with the pick. Should the vein be more than a yard thick, or if its substance be very refractory, two miners are set upon each step. *b b b b* indicate the quadrangular masses that are cut out successively downwards; and 1 1, 2 2, 3 3, forwards; the lines of small circles are the sections of the ends of the billets which support the floors.

2. To attack a mass Y, *fig.* 1454, a scaffold *m*, is erected in one of its terminal pits P, at the level of the ceiling of the gallery R R′, where it terminates below. A miner

1454



placed on this scaffold, cuts off at the angle of this mass a parallelopiped 1, from one to two yards high, by six or eight long. When he has advanced thus far, there is placed in the same pit upon another scaffold *m′*, a second miner, who attacks the vein above the roof of the first cutting, and hews down, above the parallelopiped 1, a parallelopiped of the same dimensions 1′, while the first is taking out another, 2, in advance of 1. When the second miner has gone forward 6 or 8 yards, a third is placed also in the same pit. He commences the third step, while the first two miners are pushing forward theirs, and so in succession.

In this mode of working, as well as in the preceding, it is requisite to support the rubbish and the walls of the vein. For the first object, a single floor, *n n n*, may be sufficient, constructed above the lower gallery, substantial enough to bear all the rubbish, as well as the miners. In certain cases, an arched roof may be substituted; and in others, several floors are laid at different heights. The sides of the vein are supported by means of pieces of wood fixed between them perpendicularly to their planes. Sometimes, in the middle of the rubbish, small pits are left at regular distances apart, through which the workmen throw the ore coarsely picked, down into the lower gallery. The rubbish occasionally forms a slope *f f f*, so high that miners placed upon it can work conveniently. When the rich portions are so abundant as to leave too little rubbish to make such a sloping platform, the miners plant themselves upon moveable floors, which they carry forward along with the excavations.

These two modes of working in the *step-form* have peculiar advantages and disadvantages; and each is preferred to the other, according to circumstances.

In the *descending workings*, or in *direct steps*, *fig*. 1453, the miner is placed on the very mass or substance of the vein; he works commodiously before him; he is not exposed to the splinters which may fly off from the roof; but by this plan he is obliged to employ a great deal of timber to sustain the rubbish; and the wood is fixed for ever

In the *ascending workings*, or in *reversed steps*, *fig*. 1454, the miner is compelled to work in the re-entering angle formed between the roof and the front wall of his excavation, a posture sometimes oppressive; but the weight of the ore conspires with his efforts to make it fall. He employs less timber than in the *workings* with *direct steps*. The *sorting* of the ore is more difficult than in the *descending working*, because the rich ore is sometimes confounded with the heap of rubbish on which it falls.

When seams of diluvium or gravel-mud occur on one of the sides of the vein or on both, they render the quarrying of the ore more easy, by affording the means of uncovering the mass to be cut down, upon an additional face.

Should the vein be very narrow, it is necessary to remove a portion of the sterile rock which encloses it, in order to give the work a sufficient width to enable the miner to advance. If, in this case, the vein be quite distinct from the rock, the labour may be facilitated, as well as the separation of the ore, by disengaging the vein, on one of its faces through a certain extent, the rock being attacked separately. This operation is called *stripping the vein*. When it is thus uncovered, a shot of gunpowder is sufficient to detach a great mass of it, unmixed with sterile stones.

By the methods now described, only those parallelopipeds are cut out, either in whole or in part, which present indications of richness adequate to yield a prospect of benefit. In other cases, it is enough to follow out the threads of ore which occur, by workings made in their direction.

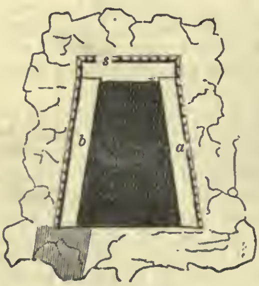
The miner, in searching within the crust of the earth for the riches which it conceals, is exposed to many dangers. The rocks amidst which he digs are seldom or never entire, but are almost always traversed by clefts in various directions, so that impending fragments threaten to fall and crush him at every instant. He is even obliged at times to cut through rotten friable rocks or alluvial loams. Fresh atmospheric air follows him with difficulty in the narrow channels which he lays open before him; and the waters which circulate in the subterranean seams and fissures filter incessantly into his excavation, and tend to fill it. Let us now take a view of the means he employs to escape from these three classes of dangers.

1. *Of the timbering of excavations.*—The excavations of mines are divisible into three principal species: *shafts*, *galleries*, and *chambers*. When the width of these excavations is inconsiderable, as is commonly the case with shafts and galleries, their sides can sometimes stand upright of themselves; but more frequently they require to be propped or stayed by billets of wood, or by walls built with bricks or stones; or even by stuffing the space with rubbish. These three kinds of *support* are called *timbering*, *walling*, and *filling up*.

Timbering is most used. It varies in form for the three species of excavations, according to the solidity of the walls which it is destined to sustain.

In a gallery, for example, it may be sufficient to support merely the roof, by means of joists placed across, bearing at their two ends in the rock; or the roof and the tow walls by means of an upper joist, s, *fig.* 1455, which is then called a *cap* or *cornice beam*, resting on two lateral upright posts or *stanchions*, *a b*, to which a slight inclination towards each other is given, so that they approach a little at the top, and rest entirely upon the floor. At times, only one of the walls and the roof need support. This case is of frequent occurrence in pipe veins. Pillars are then set up only on one side, and on the other the joists rest in holes of the rock. It may happen that the floor of the gallery shall not be sufficiently firm to afford a sure foundation to the standards; and it may be necessary to make them rest on a horizontal piece called the *sole*. This is timbering with *complete frames*. The upright posts are usually set directly on the sole; but the extremities of the *cap* or ceiling, and the upper ends of the *standards*, are mortised in such a manner that these cannot come nearer, whereby the cap shall possess its whole force of resistance. In friable and shivery rocks there is put behind these beams, both upon the ceiling and the sides, *facing boards*, which are planks placed horizontally, or spars of cleft wood, set so close together as to leave no interval. They are called *fascines* in French. In ordinary ground, the miner puts up these *planks* in proportion as he goes forwards; but in a loose soil, such as sand or gravel, he must mount them a little in advance. He then drives into the mass behind the wooden framework thick but sharp-pointed planks or stakes, and which, in fact, form the sides of the cavity, which he proceeds to excavate. Their one extremity is thus supported by the earth in which it is thrust, and their other end by the last framing. Whenever the miner gets sufficiently on, he sustains the walls by a new frame. The size of the timber, as well as the distance between the frames or *stanchions*, depends on the degree of pressure to be resisted.

1455



When a gallery is to serve at once for several distinct purposes, a greater height is given to it; and a flooring is laid on it at a certain level. If, for example, a gallery is to be employed, both for the transport of the ores and the discharge of the waters, a floor, *e e*, *fig.* 1454 is constructed above the bottom, over which the carriages are wheeled, and under which the waters are discharged.

The timbering of shafts varies in form, as well as that of galleries, according to the nature and the locality of the ground which they traverse, and the purposes which they are meant to serve. The shafts intended to be stayed with timber are usually square or rectangular, because this form, in itself more convenient for the miner, renders the execution of the timbering more easy. The woodwork consists generally of rectangular frames, the spars of which are about eight inches in diameter, and placed at a distance asunder of from a yard to a yard and a half. The spars are never placed in contact, except when the pressure of the earth and the water is very great. The pieces composing the frames are commonly united by a half-check, and the longer of the two pieces extends often beyond the angles, to be rested in the rock. Whether the shaft is vertical or inclined, the framework is always placed so that its plane may be perpendicular to the axis of the pit. It happens sometimes in inclined shafts that there are only two sides, or even a single one, which need to be propped. These are stayed by means of cross beams, which rest at their two ends in the rock. When the frames do not touch one another strong planks or stakes are fastened behind them to sustain the ground. To these planks the frames are firmly connected, so that they cannot slide. In this case the whole timbering will be supported, when the lower frame is solidly fixed, or when the pieces from above pass by its angles to be abutted upon the ground.

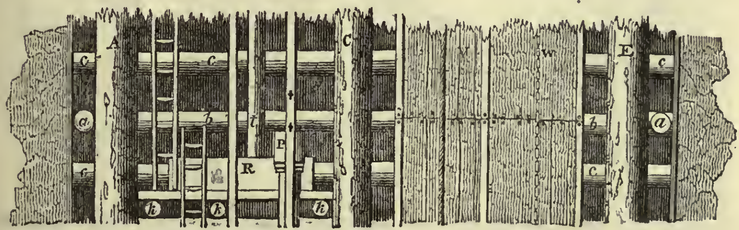
In the large rectangular shafts, which serve at once for extracting the ores, for the discharge of the waters, and the descent of the workmen, the spaces destined for these several purposes are in general separated by partitions, which also serve to increase the strength of the timberings, by acting as buttresses to the planks in the long sides of the framework. Occasionally a partition separates the ascending from the descending basket, to prevent their jostling. Lastly, particular passages are left for ventilation.

As it is desirable that the wood shall retain its whole force, only those pieces are squared which absolutely require it. The spars of the frames in shafts and galleries are deprived merely of their bark, which, by holding moisture, would accelerate the decomposition of the wood. The alburnum of oak is also removed.

Resinous woods, like the pine, last much shorter than the oak, the beech, and the cherry-tree; though the larch is used with advantage. The oak has been known to last upwards of 40 years; while the resinous woods decay frequently in 10. The fresher the air in mines, the more durable is the timbering.

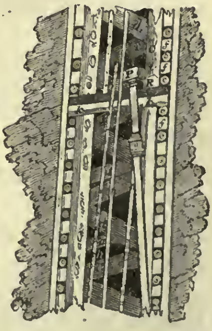
The *figs.* 1456, 1457 represent two vertical sections of a shaft, the one at right

1456



angles to the other, with the view of showing the mode of sustaining the walls of the excavation by timbering. It is copied from an actual mine in the Hartz. There we may observe the spaces allotted to the descent of the miners by ladders, to the drainage of the waters by pumps P, and rods *t*, and to the extraction of the mineral substances by baskets. *a*, *b*, *c*, *f*, *h*, *k*, are various cross timbers; A, C, E, upright do.; R, pump cistern; V, W, corve-ways. The shafts here shown, are excavated in the line of the vein itself,—the rock enclosing it being seen in the second figure.

1457



In a great many mines it is found advantageous to support the excavations by brick or stone buildings, constructed either with or without mortar. These constructions are often more costly than wooden ones, but they last much longer, and need fewer repairs. They are employed instead of timberings, to support the walls and roof of galleries, to line the sides of shafts, and to bear up the roofs of excavations.

Sometimes the two sides of a gallery are lined with vertical walls, and its roof is supported by an ogee vault, or an arch. If the sides of the mine are solid, a simple arch is sufficient to sustain the roof, and at other times the whole surface of a gallery is formed of a single elliptic vault, the great axis of which is vertical; and the bottom is surmounted by a wooden plank, under which the waters run off: see *fig.* 1458.

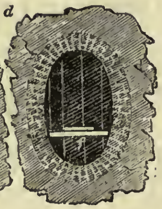
Walled shafts also are sometimes constructed in a circular or elliptic form, which is better adapted to resist the pressure of the earth and waters. Rectangular shafts of all dimensions, however, are frequently walled.

The sides of an excavation may also be supported by filling it completely with rubbish. Whenever the sides need to be supported for some time without the necessity of passing along them, it is often more economical to stuff them up with rubbish, than to keep up their supports. In the territory of Liège, for example, there have been shafts thus filled up for several centuries; and which are found to be quite entire when they are emptied. The rubbish is also useful for forming roads among steep strata, for closing air-holes, and forming canals of ventilation.

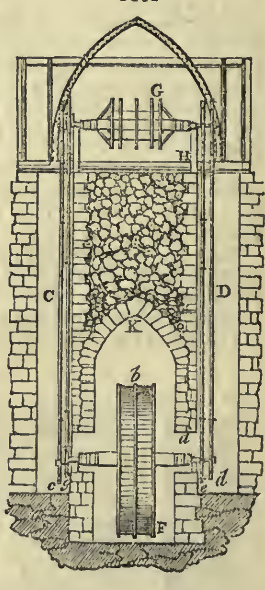
Figs. 1458, 1459, 1460, represent the principal kinds of mason-work employed in the galleries and shafts of mines. *Fig.* 1461 exhibits the walling in of the cage of an

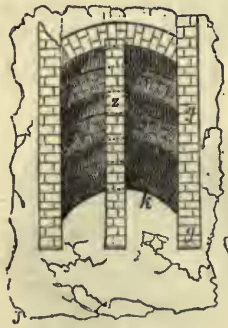
1459

1458



1461





overshot water-wheel, as mounted within a mine. Before beginning to build, an excavation large enough must be made in the gallery to leave a space three feet and a half high for the workman to stand in, after the brick-work is completed. Between the two opposite sides, cross beams of wood must be fixed at certain distances as chords of the vault, over which the rock must be hollowed out to receive the arch-stones, and the centring must then be placed covered with deals to receive the *voussoirs*, beginning at the flanks and ending with the keystone. When the vault is finished through a certain extent, the interval between the arch and the rock must be rammed full of rubbish, leaving passages if necessary through it and the arch, for currents of water.

In walling galleries, attention must be paid to the direction of the pressure, and to build vertically or with a slope accordingly. Should the pressure be equal in all directions, a closed vault, like *fig.* 1458, should be formed. For walls not far from the vertical, salient or buttressed arches are employed, as shown in *fig.* 1460, called in German *überspringende Bogen*; for other cases, twin-arches are preferred, with an upright wall between.

Fig. 1459 is a transverse section of a walled drain-gallery, from the grand gallery of the Hartz; see also *fig.* 1461. *a* is the rock which needs to be supported only at the sides and top; *b*, the masonwork, a curve formed of the three circular arcs upon one level; *c*, the floor for the water-course. *Fig.* 1458 is a cross-section of a walled gallery, as at Schneeberg, Rothenburg, Idria, &c.; *d* is the rock, which is not solid either at the flanks, roof, or floor; *e*, the elliptic masonwork; *f*, the wooden floor for the waggons, which is sometimes, however, arched in brick to allow of a water-course beneath it.

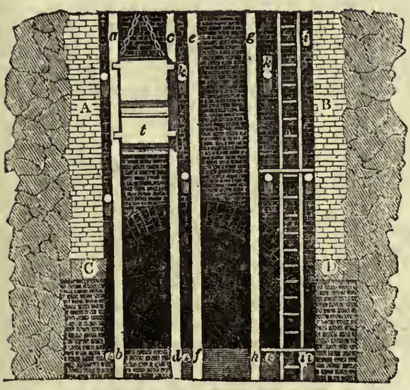
Fig. 1460 shows two vertical projections of a portion of a walled shaft with buttresses, as built at the mine *Vater Abraham*, near Marienberg. J is a section in the direction of the vein *g h*, to show the roof of the shaft. I, a section exhibiting the slope of the vein *g h*, into which the shaft is sunk; *m* is the wall of the vein; *k* is the roof of the same vein; *n*, buttresses resting upon the flanks of the shaft; *g*, great arcs on which the buttresses bear; *y*, vertical masonwork; *z*, a wall which divides the shaft into two compartments, of which the larger *p* is that for extracting the ore, and the smaller for the draining and for the descent of the miners.

Fig. 1461. C D is the shaft in which the vertical crank-rods *c*, *g*, *e*, *d*, move up and down. F, is a double hydraulic wheel, which can be stopped at pleasure by a brake mounted upon the machine of extraction. G, is the drum of the gig or whim for raising the *corves* or tubs (*tonnes*); H, is the level of the ground, with the carpentry which supports the whim and its roof. K, is the keystone of the *ogee* arch which covers the water-wheel; *a*, is the opening or window, traversed by the extremity of the driving shaft, upon each side of the water-wheel, through which a workman may enter to adjust or repair it; *b*, line of conduits for the streams of water which fall upon the hydraulic wheel; *c*, *g*, double crank with rods, whose motion is taken off the left side of the wheel; *e*, *d*, the same upon the right side. The distance from H to F is about 22 yards.

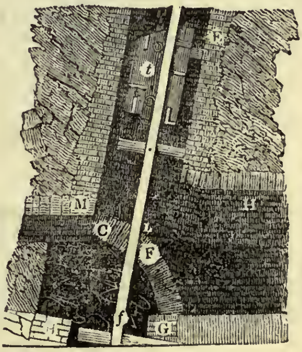
Figs. 1462, 1463, present two vertical sections of the shaft of a mine walled, like the roof of a cavern, communicating with the galleries of the roof and the wall of the vein, and well arranged for both the extraction of the ore, and the descent of the miners. The vertical partition of the shaft for separating the passage for the corves or tubs from the ladders is omitted in the figure, for the sake of clearness.

In *fig.* 1462, A B are the side-walls supported upon the buttresses C and D; in *fig.* 1463, E is the masonry of the wall, borne upon the arch F at the entrance to a gallery, the continuation being at G, which is sustained by a similar arch built lower.

1462



1463



L, is the vault arch of the roof, supported upon another vault M, which presents a double curvature, at the entrance of a gallery; at H is the continuation of the arch or vault L, which underneath is supported in like manner at the entrance of a lower gallery.

a, *b*, *c*, *d*, *fig.* 1462, are small upright guide-bars or rods for one of the corves, or kibbles.

e, *f*, *g*, *h*, are similar guide-bars for the other corf.

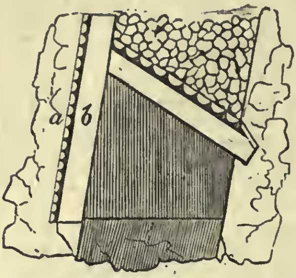
i i, are cross-bars of wood, which support the stays of the ladders of descent.

k k, are also cross-bars by which the guide-rods are secured.

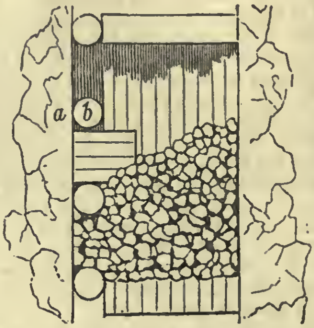
t, a *corf*, or extraction-kibble, furnished with friction rollers; the other corf is supposed to be drawn up to a higher level, in the other vertical passage.

Figs. 1464, 1465 represent in a vertical section the mode of timbering the galleries of the silver and lead mines at Andreasberg in the Hartz. *Fig.* 1464 shows the plan viewed from above. Upon the roof of the timbering, the workman throws the waste rubbish, and in the empty space below, which is shaded black, he transports in his waggons or wheel-barrows the ores towards the mouth of the mine. *Fig.* 1465 is the cross-section of the gallery. In the two figures, *a* represents the rock, and *b* the timbering; round which there is a garniture of small spars or lathes for the purpose of drainage and ventilation, with the view of promoting the durability of the wood-work.

1464



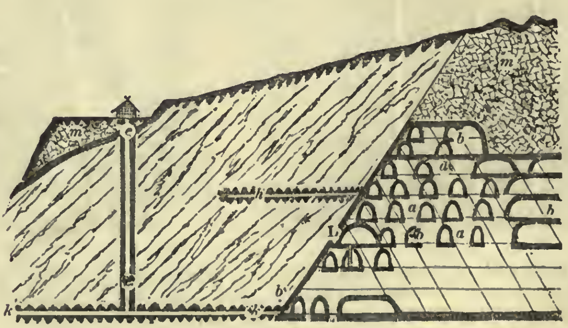
465



The working of minerals by the *mass* is well exemplified a few leagues to the north of Siegen, near Müsen (Rhenish Prussia), in a mine of iron and other metals, called Stahlberg, which forms the main wealth of the country. The plan of working is termed *the excavation of a direct or transverse mass.* It shows in its upper part the danger of bad mining, and in its inferior portion, the regular workings, by whose means art has eventually prevented the destruction of a precious mineral deposit.

Fig. 1466 is a vertical section of the bed of ore, which is a *direct* mass of spathose iron, contained in Devonian clay-slate. *a, a, a,* are pillars of the sparry ore reserved to support the successive stages or floors, which are numbered 1, 2, 3, &c. *b, b, b,* are excavations worked in the ore; which exhibit at the present day several floors of arches, of greater or less magnitude, according to the localities. It may be remarked, that where the metallic deposit forms one entire mass, rich in spathose iron ore of good quality, there is generally given to the vaults a height of 3 fathoms; leaving a thickness over the roof of 2 fathoms, on account of the numerous fissures

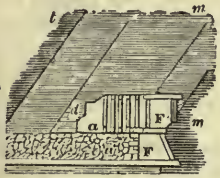
1466



which pervade the mass. But where this mass is divided into three principal branches, the roof of the vault has only 1½ fathom of thickness, while the excavation is 3½ fathoms high. In the actual state of the workings, it may be estimated that from all this direct mass, there is obtained no more out of every floor than one-third of the mineral. Two-thirds remain as labours of reserve, which may be resumed at some future day, in consequence of the regularity and the continuation of the subterranean workings. *e* is a shaft for extraction, communicating below with the gallery of efflux, *k*; *h* is an upper gallery of drainage, which runs in different directions (one only being visible in this section) over a length of 400 fathoms; the lower gallery, *k*, runs 646 fathoms in a straight line; *m m,* represents the mass of sparry iron.

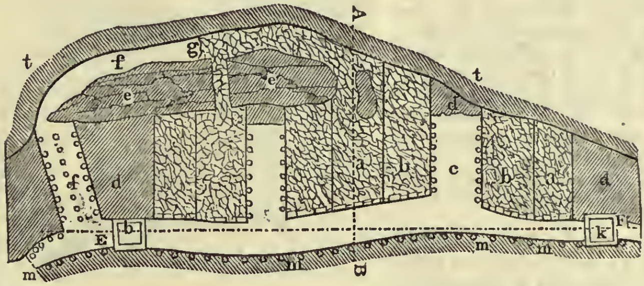
Figs. 1467, 1468, 1469, represent the cross system of mining, which consists in forming galleries through a mineral deposit, from its wall or floor towards its roof, and not, as usual, in the direction of its length. This mode was contrived towards the middle of the 18th century, for working the very thick veins of the Schemnitz mine in Hungary; and it is now employed with advantage in many places, particularly at Idria in Carniola. In the two sections, *figs.* 1467, 1469, as well as in the ground-plan, *fig.* 1468, the wall is denoted by *m m*, and the roof by *t t*. A first gallery of prolongation, E F, *fig.* 1468, being formed to the wall, transverse cuts, *a a*, are next established at right angles to this gallery, so that between every two there may be room enough to place three others, *b*, *c*, *b*, *fig.* 1468. From each of the cuts, *a*, ore is procured by advancing with the help of timbering, till the roof, *t*, be reached. When this is done, these first cuts, *a*, are filled up with rubbish, laid upon pieces of timber with which the ground is covered, so that if, eventually, it should be wished to mine underneath, no downfall of detritus is to be feared. These heaps of rubbish rise only to within a few inches of the top of the cuts, *a*, in order that the working of the upper story may be easier, the bed of ore being there already laid open upon its lower face.

1467



In proportion as the cuts, *a*, of the first story, E F, are thus filled up, the greater part of the timbering is withdrawn, and made use of elsewhere. The intermediate cuts, *b*, *c*, *b*, are next mined in like manner, either beginning with the cuts *c*, or the cuts *b*, according to the localities. From *fig.* 1468 it appears that the working may be so arranged that, in case of necessity, there may be always between two cuts in

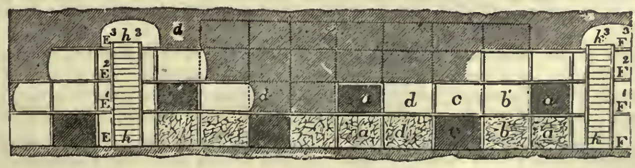
1468



activity the distance of three cuts, either not made, or filled up with rubbish. Hence, all the portion of the bed of ore may be removed which corresponds to a first story, E F, *fig.* 1469, and this portion is replaced by rubbish.

The exploration of the upper stories E′ F′, E² F², E³ F³, is now prepared in a similar manner; with which view shafts *h h*³, *k k*³, are formed from below upwards in the wall, *m*, of the deposit, and from these shafts oblong galleries proceed, established

1469



successively on a level with the stories thus raised over one another. See *fig.* 1469. The following objects may be specified in the figures:—

a a, the first cuts filled up with rubbish, upon the first story E F, *fig.* 1468.
b b, other cuts subsequently filled up, upon the same story.
c, the cut actually working.
d, the front of the cut, or place of actual excavation of the mineral deposit.
e, masses of the barren rock, reserved in the cutting, for pillars of safety.

f, galleries, by means of which the workmen may turn round the mass *e*, in order to form in the roof, *t*, an excavation in the direction of the deposit.

g, rubbish behind the mass *e*.

h h, two shafts leading from the first story, E F, to the upper stories of the workings, as already stated.

m, the wall, and *t* the roof, of the mineral-bed.

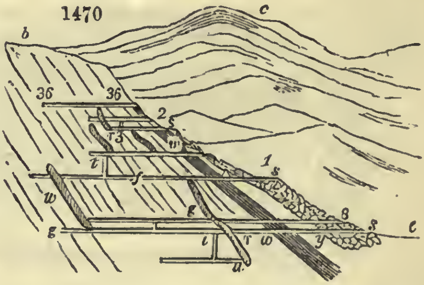
In the second story, E′ F′, the gallery of prolongation, F′, *figs.* 1467, 1469, is not entirely perforated; but it is further advanced than that of the third story, which, in its turn, is more than the gallery of the fourth.

From this arrangement there is produced upon *fig.* 1469 the general aspect of a working by reversed steps.

Whenever the workings of the cuts, *c*, in the first story are finished, those of the second, *a′ a′*, may be begun in the second; and thus, by mounting from story to story, the whole deposit of ore may be taken out and replaced with rubbish. One great advantage of this method is, that nothing is lost; but it is not the only one. The facilities offered by the system of *cross-workings* for disposing of the rubbish, most frequently a nuisance to the miner, and expensive to get rid of, the solidity which it procures by the banking up, the consequent economy of timbering, and saving of expense in the excavation of the rock, reckoning from the second story, are so many important circumstances which recommend this mode of mining. Sometimes, indeed, rubbish may be wanted to fill up, but this may always be procured by a few accessory perforations; it being easy to establish in the vicinity of the workings a vast excavation in the form of a vault, or kind of subterraneous quarry, which may be allowed to fall in, with proper precautions, and where rubbish will thus accumulate in a short time, at little cost.

Fig. 1470 represents a section of the celebrated lead mines of Bleiberg in Carinthia, not far from Villach.

1470



b, *c*, is the ridge of the mountains of compact limestone, in whose bosom the workings are carried on.

e, is the metalliferous valley, running from east to west, between the two parallel valleys of the Gail and the Drave, but at a level considerably above the waters of these rivers.

f, *g*, is the direction of a great many vertical beds of metalliferous limestone.

On considering the direction and dip of the marly schist and metalliferous limestone, in the space *w w*, to the west of the line 1, *s*, it would appear that a great portion of this system of mountains has suffered a slip between 1, *s*, and a parallel one towards the east; whereby, probably, that vertical position of the strata has been produced which exists through a considerable extent. The metalliferous limestone is covered to a certain thickness with a marly schist, and other more recent rocks. It is in this schist that the 'fire-marble,' known under the name of the *lumachella of Bleiberg*, is quarried. This appears to be of Liassic age.

The galena occurs at the bottom of this rock in flattened masses, or blocks of a considerable volume, which are not separated from the rest of the calcareous beds by any seam. It is accompanied by zinc ore (*calamine*), especially in the upper parts of the mountain.

Several of the workable masses are indicated by r, r^3; each presents itself as a solid analogous to a very elongated ellipse, whose axis dips, not according to the inclination of the surrounding rock, but to an oblique or intermediate line between this inclination and the direction of the beds of limestone; as shown by *r w*, *r′ w′*.

The faults, called *kluft* (*rent*), at Bleiberg are visible on the surface of the ground. Experienced miners have remarked that the rich masses occur more frequently in the direction of these faults than elsewhere.

It is in general by galleries cut horizontally in the body of the mountain, and at different levels, *s g*, *s f*, that the miner advances towards the masses of ore r, r^3. Many of these galleries are 500 fathoms long before they reach a workable mass. The several galleries are placed in communication by a few shafts, such as *t*; but few of these are sunk deeper than the level of the valley, *e*.

The total length of the mines of Bleiberg is about 10,000 yards, parallel to the valley *e*; in which space there are 500 concessions granted by the Government to various individuals or joint-stock companies, either by themselves, or associated with the Government.

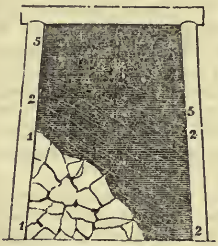
The metalliferous valley contains 5,000 inhabitants, all deriving subsistence from the mines; 300 of whom are occupied in the government works.

Each concession has a number and a name: as Antoni, Christoph, Matthæus, Oswaldi, 2, 8, 36, &c.

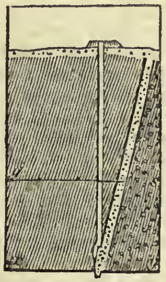
Fig. 1471 is a section of the quicksilver mine of Idria. 1, is the grey limestone; 2, is a blackish slate; 5, is a greyish slate. Immediately above these transition rocks lies the bed containing the ores, called *Corallcnerz*, which consist of an intimate mixture of sulphuret of mercury and argillaceous limestone; in which four men can cut out in a month 2½ toises cube of rock.

Fig. 1472 represents a section of part of one of the copper mines of Mansfeld; containing the cellular limestone, called *Rauchwacke*, always with the magnesian limestone, called *Zechstein*; the cupreous schist, or *Kupferschiefer*; the wall of greyish-white sandstone, called the *weisse Liegende*; and the wall of red sandstone, or the *rothe Licgende.* The thin dotted stratum at top is vegetable mould; the large dotted portion to the right of the figure is oolite; the vein at its side is sand; next is *Rauchwacke*; and lastly, the main body of fetid limestone, or *Stinkstein.*

1471



1472



1473

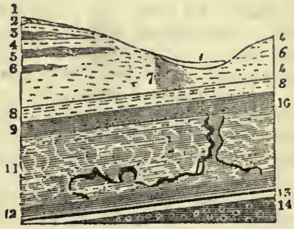


Fig. 1473 represents a section of one of the Mansfeld copper-schist mines in the district called Burgoerner, or Preusshoheit: 1. Vegetable mould, with siliceous gravel. 2. Ferruginous clay or loam. 3. Sand, with fragments of quartz. 4. Red clay, a bed of variable thickness as well as the lower strata, according as the cupreous schist is nearer or farther from the surface. 5. Oolite (*Rogenstein*). 6. Newer variegated sandstone (*bunter Sandstein*). 7. Newer gypsum; below which, there is 8. A bluish marly clay. 9. Stinkstone, or lucullite. 10. Friable greyish marl.

11. Older gypsum: a rock totally wanting in the other districts of the mines of Rothenberg; but abounding in Saxon Mansfeld, where it includes vast caverns known among the miners by the name of *Schlotten*, as indicated in the figure (1473).

12. The calcareous rock, called *Zechstein.* The lower part of this stratum shows symptoms of the cupriferous schist that lies underneath. It presents three thin bands, differently modified, which the miner distinguishes as he descends by the names of the sterile or rotten (*faüle*) rock; the roof (*Dachklotz*); and the main rock (*oberberg*).

13. Is a bed of cupriferous schist (*Kupferschiefer*), also called the *bitumino-marly* schist, in which may be noted, in going down, but not marked in the figure—

a, the *Lochberg*, a seam 4 inches thick.
b, the *Kammschale*, ¼ of an inch thick.
c, the *Kopfschale*, 1 inch thick.

These seams are not worth smelting; the following, however, are:—

d, the *Schiefer-kopf*, the main copper-schist, 2 inches thick.
e, a layer called *Lochen*, 1 inch thick.

14. The wall of sandstone, resting upon a porphyry.

Fig. 1474 is a section of the mines of Kiegelsdorf in Hessia, presenting—

1. Vegetable mould.

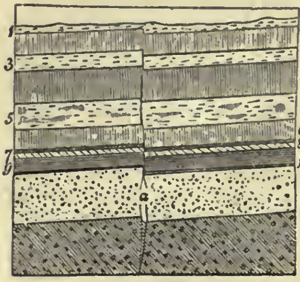
2. Limestone distinctly stratified, frequently of a yellowish colour, called *lagerhafter Kalkstein.*

3. Clay, sometimes red, sometime blue, sometimes a mixture of red, blue, and yellow.

4. The cellular limestone (*Rauhkalk*). This rock differs both in nature and position from the rock of the same name at Mansfeld.

5. Clay, usually red, containing veins of white gypsum, and fine crystals of selenite.
6. Massive gypsum of recent formation.

1474



7. Fetid limestone, compact and blackish grey, or cellular and yellowish grey.

8. Pulverulent limestone, with solid fragments interspersed.

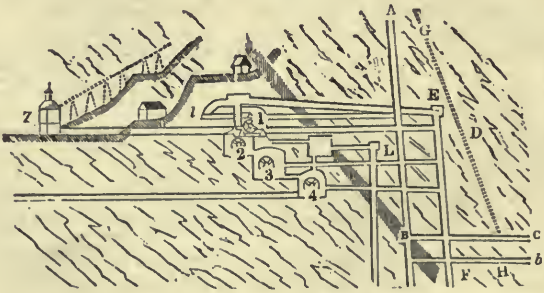
9. Compact marl-limestone, or *Zechstein*, which changes from a brownish colour above to a blackish schist below, as it comes nearer the cupreous schist, which seems to form a part of it.

10. Cupreous schist (*Kuperschiefer*), of which the bottom portion, from 4 to 6 inches thick, is that selected for metallurgic operations. Beneath it is found the usual wall or bed of sandstone. A vein of cobalt ore, *a*, which is rich only in the greyish-white sandstone (*weisse Liegende*), traverses and deranges the beds wherever it comes.

Of working Mines by Fire.—The celebrated mine worked since the 10th century in the mountain called Rammelsberg, in the Hartz, to the south of Goslar, presents a stratified mass of ores, among the beds of the rock which constitute that mountain. The mineral deposit is situated in the earth like an enormous inverted wedge, so that its thickness (power), inconsiderable near the surface of the ground, increases as it descends. At about 100 yards from its outcrop, reckoning in the direction of the slope of the deposit, it is divided into two portions or branches, which are separated from each other, throughout the whole known depth, by a mass of very hard clay-slate, which passes into flinty slate. The substances composing the workable mass are copper and iron pyrites, with sulphuret of lead (galena), accompanied by quartz, carbonate of lime, compact sulphate of baryta, and sometimes grey copper ore, sulphuret of zinc, and arsenical pyrites. The ores of lead and copper contain silver and gold, but in small proportion, particularly as to the last.

A mine so ancient as that of Rammelsberg, and which was formerly divided among several adventurous companies, cannot fail to present a great many shafts and excavations; but, out of the 15 pits, only two are employed for the present workings, namely, those marked A B and E F in *fig.* 1475, by which the whole extraction and

1475



drainage are executed. The general system of exploitation by fire, as practised in this mine, consists of the following operations:—

1. An advance is made towards the deposits of ore, successively at different levels, by transverse galleries, which proceed from the shaft of extraction, and terminate at the walls of the stratiform mass.

2. There are formed in the level to be worked large vaults in the heart of the ore, by means of fire, as we shall presently describe.

3. The floor of these vaults is raised up by means of terraces, formed from the rubbish in proportion as the roof is scooped out.

4. The ores detached by the fire from their bed are picked and gathered; sometimes the larger blocks are blasted with gunpowder.

5. Lastly, the ores thus obtained are wheeled towards the shaft of extraction, and turned out to the day.

Let us now see how the excavation by fire is practised; and, in that view, let us consider the state of the workings in the mines of Rammelsberg. We may remark in *fig.* 1475 the regularity of the vaults previously scooped out above the level B C, and the other vaults which are in full activity of operation. It is, therefore, towards the lower levels that the new workings must be directed. For this purpose, the transverse gallery being already completed, there is prepared on the first of these floors a vault of exploitation at *b*, which eventually is to become similar to those of the superior levels. At the same time there is commenced, at the starting-point below it, reached by a small well dug in the line of the mineral deposit, a transverse gallery in the rock, by means of blasting with gunpowder. The rock is also attacked at the starting-point by a similar *cut*, which advances to meet the first perforation. In this way, whenever the vaults of the level C are exhausted of ore, and terraced up with rubbish, those of the level beneath it will be in full activity.

Others will then be prepared at a lower level; and the exploitation may afterwards be driven below this level by pursuing the same plan, by which the actual depth of excavation has been gained.

In workings by fire we must distinguish: 1, the case where it is necessary to open a vault immediately from the floor; 2, the case where, the vault having already a certain elevation, it is necessary to heighten its roof. In the former case, the wall or floor of the mineral deposit is first penetrated by blasting with gunpowder. As soon as this penetration is effected over a certain length, parallel to the direction of the future vault, as happens at *b*, there is arranged on the bottom a horizontal layer of billets of firewood, over which other billets are piled in nearly a vertical position, which rests upon the ore, so that the flame in its expansion comes to play against the mineral mass to be detached. When, after some similar operations, the flame of the pile can no longer reach the ore of the roof on account of its height, a small terrace of rubbish must be raised on the floor of the deposit; and over this terrace a new pile of faggots is to be heaped up as above described. The ancient miners committed the fault of constantly placing such terraces close to the roof, and consequently arranging the faggots against this portion of the ore, so that the flame circulated from the roof down to the floor. The result of such procedure was the weakening of the roof, and the loss of much of the ore which could not be extracted from so unstable a fabric; and, besides, much more wood was burned than at the present day, because the action of the flame was dissipated in part against the whole mass of the roof, instead of being concentred on the portion of the ore which it was desired to dislodge. Now, the flame is usually made to circulate from the floor to the roof, in commencing a new vault.

When the vault has already a certain height, care is always taken that between the roof of the vault and the rubbish on which the pile is arranged, no more than two yards of space should intervene, in order that the flame may embrace equally the whole concavity of the vault, and produce an uniform effect on all its parts. Here, the pile is formed of horizontal beds, disposed crosswise above one another, and presents four free vertical faces, whence it has been called a *chest* by the miners.

It is usually on Saturday that the fire is applied to all the piles of faggots distributed through the course of the week. Those in the upper floors of exploitation are first burned, in order that the inferior piles may not obstruct, by their vitiated air, the combustion of the former. Thus, at 4 o'clock in the morning, the fires are kindled in the upper ranges; from pile to pile the fireman and his assistant descend towards the lower floors, which occupies them till 3 o'clock in the afternoon.

When the flame has beat for a few instants on the beds of ore, a strong odour of sulphur, and sometimes of arsenic, is perceived; and soon afterwards loud detonations are heard in the vaults. Suddenly the flame is seen to assume a blue colour, or even a white; and at this period, after a slight explosion, flakes of the ore, of greater or less magnitude, usually fall down on the fire, but the chief portion of the heated mineral still remains fixed to the vault. The ores pass now into a shattered and divided condition, which allows them afterwards to be detached by long forks of iron. In this manner the fire, volatilising entirely some constituents, such as sulphur, zinc, arsenic, and water, changing the aggregation of the constituent parts of the ore, and causing fissures by their unequal expansibilities, facilitates the excavation of such materials as resist by their tenacity the action of gunpowder.

The combustion goes on, without any person entering the mine, from Saturday evening till Monday morning, on which day the fireman and his assistants proceed to extinguish the remains of the bonfires. On Monday, also, some piles are constructed in the parts where the effect of the former ones has been incomplete; and they are kindled after the workmen have quitted the mines. On Tuesday all hands are employed in detaching the ores, in sorting them, taking them out, and preparing new piles against the next Saturday.

The labour of a week consists, for every man, of five posts during the day, each of 8 hours, and of one post of 4 hours for Saturday. Moreover, an extra allowance is made to such workmen as employ themselves some posts during the night.

The labour of one compartment, or *atelier*, of the mine consists, therefore, in arranging the faggots, in detaching the ore which has already experienced the action of the fire; in breaking the blocks obtained; in separating the ore from the *débris* of the pile; and, whenever it may be practicable or useful, in boring holes for blasting with gunpowder. The heat is so great in this kind of mine that the men are obliged to work in it without clothing.

We have already remarked that, besides the working by fire, which is chiefly used here, recourse is sometimes had to blasting by gunpowder. This is done in order either to recover the bottom part or ground of the vaults on which the fire can act but imperfectly, to clear away some projections which would interfere with the effect of the pile, or, lastly, to strip the surrounding rock from the mass of the ore, and thence to obtain schist proper for the construction of the rubbish-terraces.

The blasting-process is employed when the foreman of the workshop or mine-chamber judges that a hole well placed may separate enough of ore to pay the time, the repair of tools, and the gunpowder expended. But this indemnification is rarely obtained. The following statement will give an idea of the tenacity which the mineral deposit often presents:—

In a portion of the Rammelsberg mine, the ore, consisting of extremely compact iron and copper pyrites, was attacked by a single man, who bored a mining-hole. After 11 posts of obstinate labour, occupying altogether 88 hours, the workman, being vigilantly superintended, had been able to advance the hole to a depth of no more than 4 inches; in doing which he had rendered entirely unserviceable 126 punches or borers, besides 26 others which had been re-tipped with steel, and 201 which had been sharpened; 6¼ lbs. of oil had been consumed in giving him light; and ½ lb. of gunpowder was required for blasting the bore. It was found from a calculation made upon these facts by the administration of mines, that every inch deep of this hole cost, at their low price of labour, nearly a florin, value two shillings and sixpence.

It is therefore evident that, though the timber, of which the consumption is prodigiously great, were much less abundant and dearer than it still is at Rammelsberg, mining by fire would be preferable to every other mode of exploitation. It is even certain that, on any supposition, the employment of gunpowder would not be practicable for every part of the mine; and if fuel came to fail, it would be requisite to renounce the workings at Rammelsberg, although this mountain still contains a large quantity of metals.

If in all mines the free circulation of air be an object of the highest importance, we must perceive how indispensable it must be in every part of a mine where the mode of exploitation maintains the temperature of the air at 112° Fahr., when the workmen return into it after the combustion of the piles, and in which, besides, it is necessary that this combustion be effected with activity in their absence. But, in consequence of the extent and mutual ramifications of the workings, the number of the shafts, galleries, and their differences of level, the ventilation of the mine is in a manner spontaneously maintained. The high temperature is peculiarly favourable to it. The aid of art consists merely in placing some doors judiciously, which may be opened or shut at pleasure, to carry on the circulation of the air.

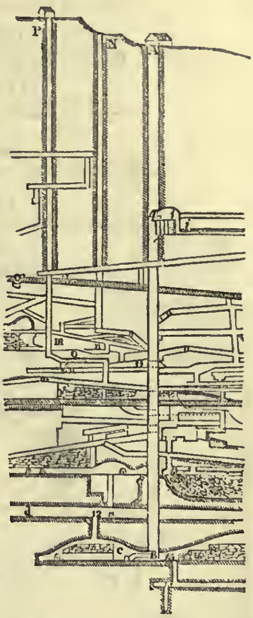
In considering the Rammelsberg from its summit, which rises about 400 yards above the town of Goslar, we observe, first, beds of slaty sandstone, which become the more horizontal, the nearer they approach to the surface. At about 160 yards below the top level there occurs, in the bosom of the slaty greywacke, a powerful stratum of shells embedded in a ferruginous limestone. In descending towards the face of the ore, the parallel stratification of the clay-slate, which forms its walls and roof, grows more and more manifest. Here the slate is black, compact, and thinly foliated. The inclination of the different beds of rock is considerable.

The ores are argentifereus and auriferous, but very slightly so, especially as to the gold. It is the ores of lead and copper which contain the silver, and in the latter the gold is found, but without its being well ascertained in what mineral it is deposited. Sometimes the ore occurs in the native state, or as copper of cementation. Beautiful crystals of sulphate of lime are found in the old workings.

In *figs.* 1475, 1476, A B is the shaft of extraction, called the *Kahnenkuhler*; N is the ventilation-shaft, called *Breïtlingerwetterschacht*; P is the extraction-shaft, called *Innier-schacht.*

E F is a new extraction-shaft, called *Neuertreibschacht*, by which also the water is pumped up; by A B and E F the whole extraction are carried on. The ores are raised in these shafts to the level of the waggon-gallery (*galerie de roulage*) *i*, by the whims 1, *q*, provided with ropes and buckets. 1, 2, 3, 4, *fig.* 1475, represent the positions of four water-wheels for working the whims; the first two being employed in extracting the ores, the last two in draining. The driving-stream is led to the wheel 1, along the drift *l*; whence it falls in succession upon the wheels 2, 3, 4. The general system of working consists of the following operations:—

1476



1. The bed of ore is got at by the transverse galleries *m*, *n*, *o*, *q*, *r*, *s*, which branch off from the extraction-shaft, and terminate at the wall of the main bed;
2. Great faults are scooped out at the level of the workings, by means of fire;
3. The roofs of these vaults are progressively propped with mounds of rubbish;
4. The ores thus detached, or by blasting with gunpowder, are then collected;
5. Lastly, they are brought out to the day, and washed near z.

Of the Instruments and Operations of Subterranean Mining.—It is by the aid of geometry, in the first place, that the miner studies the situation of the mineral deposits on the surface and in the interior of the ground; determines the several relations of the veins and the rocks; and becomes capable of directing the perforations towards a suitable end.

The instruments are:—

1. The magnetic compass, which is employed to indicate the direction of a metallic lode.
2. The graduated semicircle, which serves to measure the inclination or dip; this instrument is also called the clinometer.
3. The chain or cord for measuring the distance of one point from another.
4. When the neighbourhood of iron makes the use of the magnet uncertain, a plate or plane table is employed.

In order to penetrate into the interior of the earth, and to extract from it the objects of his toils, the miner has at his disposal several means, which may be divided into three classes:—1, *manual tools;* 2, *gunpowder;* 3, *fire.*

The tools used by the miners of Cornwall and Devonshire are the following:—

Fig. 1477. The *Pick.* It is a light tool, and somewhat varied in shape according to circumstances. One side used as a hammer is called the *poll*, and is employed to drive in the *gads*, or to loosen and detach prominences. The *point* is of steel, carefully tempered, and drawn under the hammer to the proper form. The French call it *pointerolle.*

Fig. 1478. The *Gad.* It is a wedge of steel, driven into crevices of rocks, or into small openings made with the point of the pick.

Fig. 1479. The *Miner's Shovel.* It has a pointed form, to enable it to penetrate among the coarse and hard fragments of the mine-rubbish. Its handle being somewhat bent, a man's power may be conveniently applied without bending his body.

The *blasting-* or *shooting*-tools are:—a *sledge* or *mallet*, *fig.* 1480; *borer*, *fig.* 1481; *claying-bar*, *fig.* 1482; *needle* or *nail*, *fig.* 1483; *scraper*, *fig.* 1484; *tamping-bar*, *fig.* 1485.

Besides these tools, the miner requires a powder-horn; he is supplied with safety-fuse (see Safety-Fuse); tin cartridges for occasional use in wet ground; now more frequently is he supplied with cartridges made with well pitched paper.

The *borer*, *fig.* 1481, is an iron bar tipped with steel, formed like a thick chisel, and is used by one man holding it straight in the hole, with constant rotation on its axis, while another strikes the head of it with the iron sledge or mallet, *fig.* 1480. The hole is cleared out from time to time by the scraper, *fig.* 1484, which is a flat iron rod turned up at one end. If the ground be very wet, and the hole gets full of mud, it is cleaned out by a stick bent at the end into a fibrous brush, called a *swab-stick.*

Fig. 1486 represents the plan of blasting the rock, and a section of a hole ready for firing. The hole must be rendered as dry as possible, which is effected very simply by filling it partly with tenacious clay, and then driving into it a tapering iron rod, which nearly fills its calibre, called the *claying-bar* (*fig.* 1482). This being forced in

1480

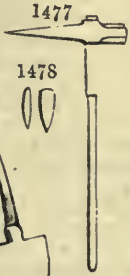
1484
1485

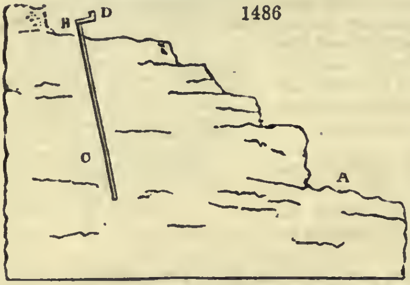
1479

1477


1478

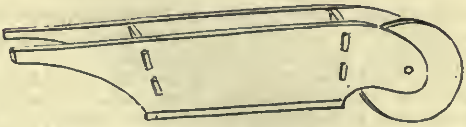
with great violence, condenses the clay into all the crevices of the rock, and secures the dryness of the hole. When the hole is dry, and the charge of powder introduced, the *nail*, a small taper rod of copper, is inserted so as to reach the bottom of the hole, which is now ready for *tamping*. Different substances are employed for *tamping*, or cramming the hole, the most usual one being any soft species of rock free from siliceous or flinty particles. Small quantities of it only are introduced at a time, and rammed very hard by the *tamping-bar*, which is held steadily by one man, and struck with a sledge by another. The hole being thus filled, the nail is withdrawn by putting a bar through its eye, and striking it upwards. Thus a small perforation or vent is left for the safety-fuse which communicates the fire.

1486



For conveying the fire, the large and long green rushes which grow in marshy ground were formerly used in our mines, and are still used in some quarries. A slit is made in one side of the rush, along which the sharp end of a bit of stick is drawn, so as to extract the pith, when the skin of the rush closes again by its own elasticity. This tube is filled up with gunpowder, dropped into the vent-hole, and made ready with a bit of clay. A paper *smift*, adjusted to burn a proper time, is then fixed to the top of the rush-tube, and kindled, when the men of the quarry retire to a safe distance. The 'safety-fuse' is now, however, almost universally employed.

In *fig.* 1486 the portion of the rock which would be dislodged by the explosion is that included between A and B. The charge of powder is included in that part

1488


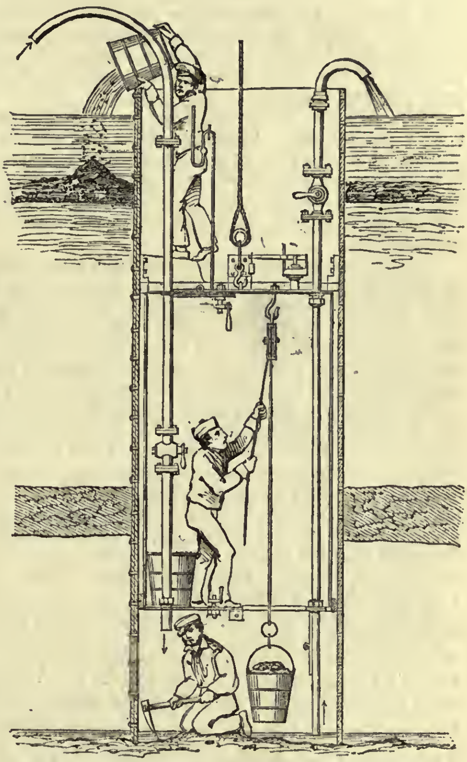
1487

which fills the hole up to C; from which point to the top, the hole is filled with *tamping*. The old *smift* is shown at D.

Fig. 1487 is an iron bucket, or, as it is called in Cornwall, a *kibble*, in which the ore is raised in the shafts, by machines called *whims* or *whimseys*, sometimes worked by horses, and frequently by steam-power. The best kibbles are made of sheet iron, and hold each about three hundred weight of ore: 120 kibbles are supposed to clear a cubic fathom of rock. In place of the kibble, *skips* running in guides fixed on the sides of the shafts are now used in the large and well-conducted mines.

Fig. 1488 represents the wheel-barrow used underground for conveying ore and waste to the foot of the shafts. It is made of light deal, except the wheel, which has a narrow rim of iron.

1489



In all mines, to a greater or a less extent, there will be found accumulations of water; it is necessary, therefore, to adopt measures to ensure its removal. The mineral treasures, being brought to the surface, necessarily undergo a process of 'dressing,' that is, the separation of the richer from the poorer portion. For a full account of dressing machinery, &c., see DRESSING OF ORES.

It sometimes happens that the necessities of mining demand the construction of shafts in places covered with water. Some years since a very extraordinary case of this kind was carried out at the Wherry Mine, near Penzance, where a cylinder of wood, rising through the sea, formed the entrance to a shaft sunk into the mine. In a storm a ship ran against this wooden structure and destroyed it.

M. Triger, engineer in the department of Maine and Loire, had the idea of making a well in the very bed of the Loire by means of compressed air. A cylinder of thin iron, *fig.* 1489, serving as a cutting machine, was sunk into the alluvium; it was separated into three compartments by horizontal partitions. The upper compartment remained always open, the lower compartment was the workshop, and between them was the middle one, which served as the chamber of equilibrium, designed to be put in communication with either the compartment above or the one below. The things being so disposed, they forced into the bottom compartment, air compressed by a vapour-machine without intermission. This air drove the water up a tube, of which the lower part was buried in the bottom of the excavation, and of which the upper part was raised above the cylinder. The workmen were then able to penetrate the first apartment and open the second, which was afterwards hermetically closed, and in which the air of ordinary pressure was put in communication with the compressed air in the third. Having arrived in the third compartment, they excavated the sands, and caused the machine to descend. As they accumulated, the sands excavated in the middle compartment, they had only to remove them by shutting the communication with the bottom and opening that of the top. A pressure sufficient to balance the exterior waters was maintained during the work, without sensibly incommoding the workmen.

It is evident that wells dug in the water-saturated earths must immediately be cased, that is to say, covered with a casing of wood, of masonry, or of iron, solid and impermeable, which is able to resist the infiltration and pressure of the waters at the same time.

For a description of the machine employed for facilitating the ascent and descent of miners, see MAN ENGINE.

MINING FOR COAL. The processes of boring, by which it is usual to begin for the purpose of determining the existence and depth of any bed or beds of coal, have been already described. See BORING.

Of Winning a Coal-field.—In sinking a shaft for working coal, the great obstacle to be encountered is water, particularly in the first opening of a field, which proceeds from the surface of the adjacent country; for every coal-stratum, however deep it may lie in one part of the basin, always rises till it meets the alluvial cover, or *crops out*, unless it be met by a slip or dyke. When the basset-edge of the strata is covered with gravel or sand, any body or stream of water will readily percolate downwards through it, and fill up the porous interstices between the coal-measures, till arrested by the face of a slip, which acts as a natural dam, and confines the water to one compartment of the basin, which may, however, be of considerable area, and require a great power of drainage.

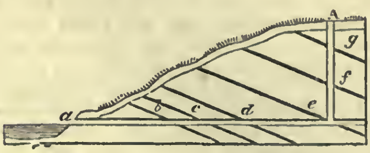
In reference to water, coal-fields are divided into two kinds: 1, level free coal; 2, coal not level free. In the practice of mining, if a coal-field, or portion of it, is so situated above the surface of the ocean that a level can be carried from that plane till it intersects the coal, all the coal above the plane of intersection is said to be level free; but if a coal-field, though placed above the surface of the ocean, cannot, on account of the expense, be drained by a level or gallery, such a coal-field is said to be not level free.

Besides these general levels of drainage, there are subsidiary levels, called off-takes or drifts, which discharge the water of a mine, not at the mouth of a pit, but at some depth beneath the surface, where, from the form of the country, it may be run off level free. From 20 to 30 fathoms off-take is an object of considerable economy in pumping; but even less is often had recourse to; and when judiciously contrived, may serve to intercept much of the crop water, and prevent it from getting down to the dip part of the coal, where it would become a heavy load on a hydraulic or pumping engine.

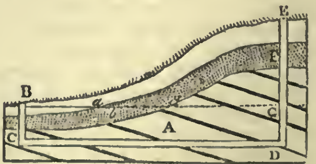
Day-levels were an object of primary importance with the early miners, who had not the gigantic pumping power of the steam-engine at their command. Levels ought to be no less than 4 feet wide, and from 5 feet and a half to 6 feet high: which is large enough for carrying off water, and admitting workmen to make repairs and clear out depositions. When a day-level, however, is to serve the double purpose of drainage, and an outlet for coals, it should be at least 5 feet wide, with its bottom gutter for drainage either covered over or open. In other instances a level not only carries off the water from the colliery, but is converted into a canal for bearing boats loaded with coals for the market. Some subterranean canals are 9 feet wide, and 12 feet high, with 5 feet depth of water.

If, in the progress of driving a level, workable coals are intersected before reaching the seam which is the main object of the mining adventure, an air-pit may be sunk, of such dimension as to serve for raising the coals. These air-pits do not in general exceed 9 feet in diameter; and they ought to be always cylindrical. *Fig.* 1490 represents a coal-field where the winning is made by a day-level; *a* is the mouth of the gallery on a level with the sea; *b*, *c*, *d*, *e*, are intersected coal-seams, to be drained by the gallery. But the coals beneath this level must obviously be drained by pumping. A represents a coal-pit sunk on the coal *e*; and if the gallery be pushed forward the coal-seams, *f*, *g*, and any others which lie in that direction, will also be drained, and then worked by the pit A. The chief obstacle to the execution of day-levels, is presented by quicksands in the alluvial cover, near the entrance of the gallery. The

1490



1491



best expedient to be adopted amid this difficulty is the following:—*Fig.* 1491 represents the strata of a coal-field A, with the alluvial earth *a*, *b*, containing the bed of quicksand *b*. The lower part, from which the gallery is required to be carried, is shown by the line B G. But the quicksand makes it impossible to push forward this day-level directly. The pit B C must therefore be sunk through the quicksand by means of *tubbing* (to be presently described), and when the pit has descended a few yards into the rock, the gallery or drift may then be pushed forward to the point D, when the shaft E D is put down, after it has been ascertained by boring that the rock-head or bottom of the quicksand at F is a few yards higher than the mouth of the small pit B. During this operation, all the water and mine-stuff are drawn off by the pit D; but whenever the shaft E D is brought into communication with the gallery, the water is allowed to fill it from C to D, and rise up both shafts till it overflows at the orifice B. From the surface of the water in the deep shaft at G, a gallery is begun of the common dimensions, and pushed onwards till the coal sought after is intersected. In this way no drainage-level is lost. This kind of drainage-gallery, in the form of an inserted syphon, is called a drowned or a blind level.

When a coal-basin is so situated that it cannot be rendered level free, the winning must be made by the aid of machinery. The engines at present employed in the drainage of coal mines are:—the water-wheel, the water-pressure engine, and the steam-engine. See Hydraulic Machinery.

The depth at which the coal is to be won, or to be drained of water, regulates the power of the engine to be applied, taking into account the probable quantity of water which may be found, a circumstance which governs the diameter of the working barrels of the pumps. Experience has proved, that in opening collieries, even in new fields, the water may generally be drawn off by pumps of from 10 to 20 inches diameter; excepting where the strata are connected with rivers, sand-beds filled with water, or marsh-lands. As feeders of water from rivers or sand-beds may be hindered from descending coal-pits, the water proceeding from these sources need not be taken into account; and it is observed, in sinking shafts, that though the influx which cannot be cut off from the mine may be at first very great, even beyond the power of the engine for a little while, yet as this excessive flow of water is frequently derived from the drainage of fissures, it eventually becomes manageable. The pumping machinery of a new colliery should be adequate to pump the water in 8 or 10 hours out of the 24. In the course of years many water-logged fissures come to be cut by the workings, and the coal-seams get excavated towards the outcrop, so that a constant increase of water ensues, and thus a colliery which has been long in operation, frequently becomes heavily loaded with water, and requires the action of its hydraulic machinery both night and day.

Of Engine-pits.—In every winning of coal, the shape of the engine-pit deserves much consideration. For shafts of moderate depth, many forms are in use; as circular, oval, square, octagonal, oblong-rectangular, and oblong-elliptical. In pits of inconsiderable depth, and where the earthy cover is firm and dry, any shape deemed most convenient may be preferred; but in all deep shafts, no shape but the circular should be admitted. Indeed, when the water-run requires to be stopped by tubbing or cribbing, the circular is the only shape which presents a uniform resistance in every point to the equable circumambient pressure. The elliptical form is the next best, when it deviates little from the circle; but even it has almost always given way to a considerable pressure of water. The circular shape has the advantage, moreover, of strengthening the shaft walls, and is less likely to suffer injury than other figures, should any failure of the pillars left in working out the coal cause the shaft to be shaken by subsidence of the strata. The smallest engine-pit should be ten feet in diameter, to admit of the pumps being placed in the lesser segment, and the coals to be raised in the larger one, as shown in *fig.* 1492, which is called a double pit. If much work is contemplated in drawing coals, particularly if their masses be large, it would be advantageous to make the pit more than 10 feet wide. When the area of a shaft is to be divided into three compartments, one for the engine-pumps, and two for raising coals, as in *fig.* 1493, which is denominated a triple pit, it should be 12 feet in diameter. If it is to be divided into four compartments, and made a quadrant shaft, as in *fig.* 1494, with one space for the pumps, and three for ventilation and coal-drawing, the total circle should be 15 feet in diameter. These dimensions are, however, governed by local circumstances, and by the daily discharge of coals.

1492

1493

1494

If there is a large quantity of water to pump, it is most desirable to appropriate a shaft exclusively for the purpose. Another shaft being used for raising coal, and as an upcast for the ventilation of the mine.

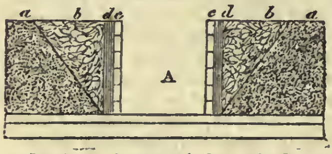
When only one shaft is sunk, and divided by wood or stone partitions, the ventilation of the mine is dependent upon these slight divisions of the shaft. If the partitions of a shaft become injured or burnt, which has been the case with wood partitions, the ventilation of the mine may suddenly be destroyed. Many lives have been placed in great jeopardy by the burning of wood partitions, which has destroyed the ventilation and prevented escape up the shaft.

The most approved arrangement of shafts for a large colliery yielding explosive gas, and where water has to be pumped, is to sink a shaft for pumping, another for raising coals, and a third for ventilation or upcast; at the bottom of which is kept burning a large furnace.

The shaft, as it passes through the earthy cover, should be securely faced with masonry of jointed ashlar, having its joints accurately bevelled to the centre of the circle.

When the alluvial cover is a soft mud, recourse must be had to the operation of tubbing. A circular tub, of the requisite diameter, is made of planks from 2 to 3 inches thick, with the joints bevelled by the radius of the shaft, inside of which are cribs of hard wood, placed from 2 to 4 feet asunder, as circumstances may require. These cribs are constructed of the best heart of oak, sawn out of the natural curvature of the wood, adapted to the radius, in segments from 4 to 6 feet long, from 8 to 10 inches in the bed, and 5 or 6 inches thick. The length of the tub is from 9 to 12 feet, if the layer of mud have that thickness; but a succession of such tubs must be set on each other, provided the body of mud be thicker. The first tub must have its lower edge thinned all round, and shod with sharp iron. If the pit be previously secured to a certain depth, the tub is made to pass within the cradling, and is lowered down with tackles till it rests fair among the soft alluvium. It is then loaded with iron weights at top, to cause it to sink down progressively as the mud is removed from its interior. Should a single tub not reach the solid rock (sandstone or basalt), then another of like construction is set on, and the gravitating force is transferred to the top. *Fig.* 1495, represents a bed of quicksand resting on a bed of impervious clay, that immediately covers the rock. A is a finished shaft; *a a*, the quicksand; *b b*, the excavation necessarily sloping much outwards; *c c*, the lining of masonry; *d d*, the moating or puddle of clay, hard rammed in behind the stone-work, to render the latter water-tight. In this case, the quicksand being thin in body, has been kept under for a short period, by the hands of many men scooping it rapidly away as it filled in. But the most effectual method of passing through beds of quicksand, is by means of cast-iron cylinders; called therefore, cast-iron tubbing. When the pit has a small diameter, these tubs are made about 4 feet high, with strong flanges and bolt holes inside of the cylinder, and a counterfort ring at the neck of the flange, with brackets: the first tub, however, has no flange at its lower edge, but is rounded to facilitate its descent through the mud. Should the pit be of large diameter, then the cylinders must be cast in segments of 3, 4, or more pieces, joined together with inside vertical flanges, well jointed with oakum and white-lead. When the sand-bed is thick, eighty feet, for instance, it is customary to divide that length into three sets of cylinders, each thirty feet long, and so sized as to slide within each other, like the eye-tubes of a telescope. These cylinders are pressed down by heavy weights, taking care to keep the lower part always further down than the top of the quicksand, where the men are at work with their shovels, and where the bottom of the pumps hangs for withdrawing the surface water.

1495



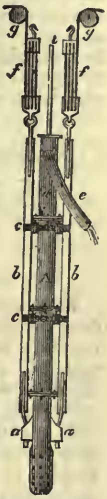
The engine-pit being secured, the process of sinking through the rock is ready to be commenced, as soon as the divisions of the pit formed of carpentry, called brattices, are made. In common practice, and where great tightness of joining is not required, for ventilating inflammable air, bars of wood called buntons, about 6 inches thick and 9 deep, are fixed in a horizontal position across the pit, at distances from each other of 10, 20, or 30 feet, according to circumstances. Being all ranged in the same vertical plane, deals an inch and a half thick are nailed to them, with their joints perfectly close; one half of the breadth of a bunton being covered by the ends of the deals. In deep pits, where the ventilation is to be conducted through the brattice, the side of the buntons next the pumps is covered with deals in the same way, and the joints are rendered secure by being caulked with oakum. Fillets of wood are also fixed all the way down on each side of the brattice, constituting what is called a double pit.

When a shaft is to have 3 compartments, it requires more care to form the brattice, as none of the buntons stretch across the whole space, but merely meet near the middle, and join at certain angles with each other. As the buntons must therefore sustain each other, on the principle of the arch, they are not laid in a horizontal plane, but have a rise from the sides towards the place of junction of 1 or 9 inches, and are bound together by a three-tongued iron strap. Fillets of wood are carried down the whole depth, not merely at the joinings of the brattice with the sides of the pit, but also at their central place of union; while wooden pillars connect the centre of each set of buntons with those above and below. Thus the carpentry work acquires sufficient strength and stiffness.

In quadrant shafts the buntons cross each other towards the middle of the pit, and are generally let into each other about an inch, instead of being half-checked. *Fig.* 1492 is a double shaft: A, the pump pit; B, the pit for raising coal. *Fig.* 1493 is a triple shaft; in which A is the pump compartment; B and C are coal pits. *Fig.* 1494 is a quadrant shaft: A, the pump pit; B, pit for ventilation or upcast for the smoke; C and D, pits for raising coals.

Whenever the shaft is sunk so low that the engine is needed to remove the water, the first set of pumps may be let down, by the method represented in *fig.* 1496; where A is the pump; *a a*, strong ears through which pass the iron rods connected with the spears *b b*; *c c*, are the lashings; *d*, the hoggar pump; *e*, the hoggar; *f f*, the tackles; *g g*, the single pulleys; and *i*, the pump-spears. By this mechanical arrangement the pumps are sunk in the most gradual manner, and of their own accord, so to speak, as the pit descends. To the arms of the capstans, sledges are fastened with ropes or chains; the sledges are loaded with weights, as counterpoises to the weight of the column of pumps, and when additional pumps are joined in, more weight is laid on the sledges. As the sinking set of pumps is constantly descending, and the point for the delivery of the water above always varying, a pipe, of equal diameter with the pumps, and about 11 feet long, but much lighter in metal, is attached to *e*, and is terminated by a hose of leather, of sufficient length to reach the cistern where the water is delivered. This is called the hoggar-pipe. In sinking, a vast quantity of air enters with the water, at every stroke of the engine; and therefore the lifting stroke should be very slow, and a momentary stop should take place before the returning stroke, to suffer all the air to escape. As the working barrels are generally 9 or 10 feet long, and the full stroke of the engine from 7 to 8 feet, when at regular work, it is customary to diminish the length of stroke, in sinking, to about 6 feet; because, while the pumps are constantly getting lower, the bucket in the working barrel has its working range progressively higher.

1496



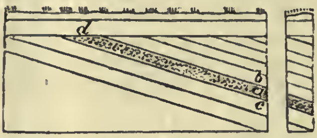
Another method of suspending the pumps in the sinking shaft, in the place of the ropes and blocks, is by two powerful iron screws about 15 feet in length, which are supported at the top of the shaft by strong beams of timber. As the shaft is sunk, the pumps are lowered by the screws; when lowered sufficient for a pump 9 feet in length, the pumps are securely fastened, while the screws are detached and screwed up ready for again lowering the pumps as the shaft is sunk.

The water obtained in sinking through the successive strata is, in ordinary cases, conducted down the walls of the shaft; and if the strata are compact, a spiral groove is cut down the sides of the shaft, and when it can hold no more, the water is drawn off in a spout to the nearest pump-cistern; or a perpendicular groove is cut in the side of the shaft, and a square box-pipe either sunk in it, flush with the sides of the pit, or it is covered with deal boards well fitted over the cavity. Similar spiral rings are formed in succession downwards, which collect the trickling streams, and conduct them into the nearest cistern; or rings made of wood or cast iron, are inserted flush with the sides of the pipe; and the water is led from one ring to another, through perpendicular pipes, until the undermost ring is full, when it delivers its waters into the nearest pump-cistern. Keeping the shaft dry is very important to the comfort of the miners, and the durability of the work.

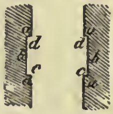
When an engine shaft happens to pass through a great many beds of coal, a gallery a few yards long is sometimes driven into each coal-seam, and a bore then put down from one coal-seam to another, so that the water of each may pass down through these bores to the pump-cisterns. The water is more frequently taken down the shaft in pipes to the nearest cistern.

While a deep pit is sinking, a register is kept of every part of the excavations, and each feeder of water is measured daily, to ascertain its rate of discharge, and whether it increases or abates. The mode of measurement is by noting the time, with a seconds watch, in which a cistern of 40 or 50 gallons gets filled. There are modes of keeping back or stopping up these feeders, by plank tubbing, iron tubbing, and by oak cribs. Let *fig.* 1497 represent the sinking of a shaft through a variety of strata, having a top cover of sand, with much water resting on the rock summit. Each plane of the coal-measure rises in a certain direction till it meets the alluvial cover. Hence the pressure of the water at the bottom of the tubbing that rests on the summit of the rock is as the depth of water in the superficial alluvium; and if a stratum *a* affords a great body of water, while the superjacent stratum *b*, and the subjacent *c*, are impervious to water; if the porous bed *a* be 12 feet thick, while no water occurs in the strata passed through from the rock-head, until the depth (supposed to be 50 fathoms from the surface of the water in the cover); in this case, the tubbing or cribbing must sustain the sum of the two water-pressures, or 62 fathoms; since the stratum *a* meets the alluvial cover at *d*, the fountain-head of all the water that occurs in sinking. Thus we perceive, that though no water-feeder of any magnitude should present itself till the shaft had been sunk 100 fathoms; if this water required to be stopped up or tubbed off through the breadth of a stratum only 3 feet thick, the tubbing would need to have a strength to resist 100 fathoms of water-pressure. For though the water at first oozes merely in discontinuous particles through the open pores of the sands and sandstones, yet it soon fills them up, like a myriad of tubes, which transfer to the bottom the total weight of the hydrostatic column of 100 fathoms; and experience shows, as we have already stated, that whatever water occurs in coal-pits, or in mines, generally speaking, proceeds from the surface of the ground. Hence, if the cover be an impervious bed of clay, very little water will be met with among the strata, in comparison with what would be found under sand.

1497



1498



1499

When several fathoms of the strata must be tubbed, in order to stop up the water-flow, the shaft must be widened regularly to admit the kind of tubbing that is to be inserted; the greatest width being needed for plank-tubbing, and the least for iron-tubbing. *Fig.* 1498 represents a shaft excavated for plank-tubbing, where *a*, *a*, *a*, *a* are the impervious strata, *b*, *b* the porous beds water-logged, and *c*, *c* the bottom of the excavation, made level and perfectly smooth with mason chisels. The same precautions are taken in working off the upper part of the excavation *d*, *d*. In this operation, three kinds of cribs are employed; called wedging, spiking, and main cribs. Besides the stout plank for making the tub, a quantity of well-seasoned and clean reeded deal is required for forming the joints; called sheeting deal by the workmen. This sheeting deal is always applied in pieces laid endwise, with the end of the fibres towards the area of the pit. Since much of the security from water depends on the tightness of the tub at its jointing with the rock, several plans have been contrived to effect this object; the most approved being represented in *fig.* 1499. To make room for the lower wedging crib, the recess is excavated a few inches wider, as at *c*; and from *b* to *c*, sheeting deals are laid all round the circle, or a thin stratum of oakum is introduced. On this the wedging crib *d* is applied, and neatly jointed in the radius-line of the pit, each segment being drawn exactly to the circle: and at each of its elements sheeting deal is inserted. This wedging crib must be 10 inches in the bed, and 6 inches deep. The vacuity *e*, at the back of the crib, about 2 and a half inches wide, is filled with pieces of dry clean reeded deal, inserted endwise; which is regularly wedged with one set of wedges all round, and then with a second and a third set of wedges, in the same regular style, to keep the crib in a truly circular posture. By this process, well executed, no water can pass downwards by the back of the crib. The next operation is to fix spiking cribs *f*, to the rock, about 10 or 12 feet from the lower crib, according to the length of the planks to be used for the tubs. They must be set fair to the sweep of the shaft, as on them its true circular figure depends. The tubbing deals, *k*, must now be fixed. They are 3 inches thick, 6 broad, and planed on all sides, with the joints accurately worked to the proper bevel for the circle of the pit. The main cribs, *g g*, are then to be placed as counterforts, for the support and strength of the tubbing. The upper ends of the first set of tub-planks being cut square and level all round, the second spiking crib, *l*, is fixed, and another set of tubbing deals put round like the former, having sheeting deal inserted betwixt the ends of the two sets at *f*. When this is wedged, the cribs, *h h*, are placed.

Oak cribbing is made with pieces of the best oak, from 3 to 4 feet long, 10 inches in the bed, and 7 or 8 inches deep.

The third mode of tubbing, by means of iron cylinders cast in segments, now supersedes the wooden tubbing, from the great reduction in the price of iron, and its superior strength and durability. Each segment is adjusted piece to piece in the circular recess of the pit cut out for their reception. The flange for the wedging joint is best turned inwards. In late improvements of this plan, executed by Mr. Buddle, where the pressure amounted to several hundred feet, the segments were 6 feet long, 2 feet broad, and an inch thick, counterforted with ribs or raised work on the back; the lip of the flange was strong, and supported by brackets.

These segments of the iron cylinder are set true to the radius of the pit; and every horizontal and perpendicular joint is made tight with a layer of sheeting deal. A wedging crib is fixed at the bottom, and the segments are built up regularly with joints like ashlar-work. This kind of tubbing can be carried to any height, till the water finds an outlet at the surface, or till strata containing water can be tubbed off, as by the modes of tubbing already described. A shaft finished in this manner presents a smooth lining-wall of iron, the flanges being turned towards the outside of the cylinders. In this iron tubbing, no screw bolts are needed for joining the segments together; as they are packed hard within the pit, like the staves of a cask.

The weight of the hydrostatic column is not the only pressure to which the tubbing is exposed. There is the pressure from accumulated carburetted hydrogen gas, which considerably exceeds the water-pressure. If the tubbing in deep shafts was put in without pressure pipes, it would be liable to be fractured by great pressure from gas. The pressure pipes are usually fixed to each length of tubbing; strong taps or cocks are first screwed into the tubbing, and malleable iron pipes of from 1 to 2 inches in diameter are fixed to the tops and carried up to the surface; and in many cases a continual overflow of gas and water issues. By these means the tubbing is only subject to the pressure due to the hydrostatic column.

Before tubbing a shaft, it is necessary to ascertain whether the strata containing water is likely to be dislocated, so as to let down the water by working the coal away; in such a case, tubbing the shaft is unnecessary. The judgment of the mining engineer must decide about this.

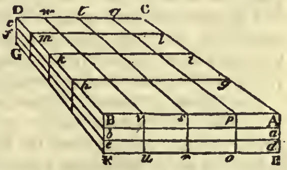
When a porous thin bed or parting betwixt two impervious strata gives out much water, or when the fissures of the strata, called cutters, are very leaky, the water can be completely stopped up by the improved process of wedging. The fissure is cut open with chisels, to a width of 2, and a depth of 7 inches, as represented in *fig.* 1500. The lips being rounded off about an inch and a half, pieces of clean deal are then driven in, whose face projects no further than the contour of the lips, when the whole is firmly wedged, till the water is entirely stopped. By sloping back the edges of the fissures, and wedging back from the face of the stone, it is not liable to burst or crack off in the operation, as took place in the old way, of driving in the wedge directly.

1500

Messrs. Kind and Chaudron's improved methods of sinking shafts through water-bearing strata and beds of quicksand, successfully practised in many of the continental coal-fields, are fully described in the article Boring.

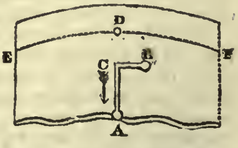
Working of Coal.—A stratum, bed, or seam of coal, is not a solid mass, of uniform texture, nor always of homogeneous quality. It is often divided and intersected, with its concomitant strata, by what are named partings, backs, cutters, reeds, or ends. Besides the chief partings at the roof and pavement of the coal-seam, there are subordinate lines of parting in the coal mass, parallel to these, of variable dimensions. These divisions are delineated in *fig.* 1501, where A, B, C, D, E, F, G, represent a portion of a bed of coal; the parallelogram A B D C the parting at the roof, and E F G the parting at the pavement; *a b*, *b c*, *d e*, and *e f*, are the subordinate or intermediate partings; *g h*, *i k*, *l m*, the backs; *o p*, *p q*, *r s*, *s t*, *u v*, and *v w*, the cutters. It is thus manifest that a bed of coal, according to the number of these natural divisions, is subdivided into solid figures of various dimensions, and of a cubical or rhomboidal shape.

1501



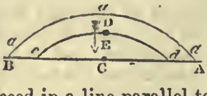
When the engine-pit is sunk, and the lodgement formed, a heading or drift is then made in the coal to the rise of the field, or a cropping from the engine-pit to the second pit. This heading may be 6 or 8 feet wide, and carried either in a line directly to the pit bottom, or at right angles to the backs or web of the coal, until it is on a line with the pit, where the heading is set off, upon one side, to the pit bottom. This heading is carried as nearly parallel to the backs as possible, till the pit is gained. *Fig.* 1502 represents this mining operation. A, is the engine-pit. B, the second or bye-pit, A C, the gallery or heading driven at right angles to the backs. C B, the gallery set off to the right hand, parallel to the backs. The next step is to drive the main levels from the engine-pit bottom. In this business the best colliers are always employed, as the object is to drive the gallery in a truly level direction, independently of all sinkings or risings of the pavement. For coal-seams of ordinary thickness, this gallery is usually not more than 6 feet wide; observing to have on the dip side of the level a small quantity of water, like that of a gutter, so as to guide the workmen in

1502



driving the level. When the level is driven correctly, with the proper depth of water, it is said to have dead water at the face. In this operation, therefore, the miner pays no regard to the backs or cutters of the coal; but is guided in his line of direction entirely by the water-level, which he must attend to solely, without regard to slips or dislocations of the strata throwing the coal up or down. In the last figure, the coal-field is a portion of a basin; so that if the shape be uniform and unbroken, and if any point be assumed on the dip of the crop, as D, the level lines from that point will be parallel to the line of crop, as D E, D F, and the levels from any point, whatever the dip or inclination of strata, will be also parallel to these; and hence, were the coal-field an entire elliptical basin, the dip-head levels carried from any point would be elliptical, and parallel to the crop. If, as is more commonly the case, the coal-field be merely a portion of a basin, formed by a slip of the strata, as represented in *fig.* 1503, where *a, a, a* is the crop and A B, a slip of great magnitude, forming another coal-field on the side C, then the crop not only meets the alluvial cover, but is cut off by the slip at A and at B. Should any point, therefore, be assigned for an engine-pit, the levels from it will proceed in a line parallel to the crop, as D *d*, D *c*; and the level on both sides of the engine-pit will be also cut off by the slip A B. In this figure, the part included between the two curve lines is the breadth or breast of coal-field won by the engine-pit D; what is not included is termed the under-dip coal, and can be worked only by one or more new winnings towards the dip, according to circumstances.

1503



In British practice, there are four different systems of working coal-mines.

1. Working with pillars and rooms or boards, styled post and stall, where the pillars left bear such proportion to the coal excavated as is just adequate to the support of the incumbent strata.

2. Working with post and stall, where the pillars are left of an extra size, and stronger than may be requisite for bearing the superior strata, with the intention of removing a considerable portion of each massive pillar, whenever the regular working of post and stall has been finished in the colliery.

3. Working with post and stall, or with comparatively narrow rooms or boards, whereby an uncommonly large proportion of coal is left, with the view of working back towards the pits, whenever the colliery is worked in this manner to the extent of the coal-field, and then taking away every pillar completely, if possible, and allowing the whole superincumbent strata to crush down, and follow the miners in their retreat.

4. Working the long way, being the Shropshire and Derbyshire method; which leaves no pillars, but takes out all the coal progressively as the workings advance. On this plan the incumbent strata crush down, creeping very close to the heads of the miners.

The post-and-stall system is practised with coals of every thickness. The long-work method is adopted generally with thin coals; for when the thickness exceeds 6 or 7 feet, and there is only little refuse made in excavating the coal to cart into the excavated part, this mode has been found impracticable.

The following considerations must be had in view in establishing a coal-mine:—

1. The lowest coal stratum of the winning should be worked in such a manner as not to injure the working or the value of the upper coals of the field; but, if this cannot be done, the upper coals should be worked in the first place. There are, however, cases where an upper seam of coal can be worked more advantageously by working a lower seam first on the long-wall method.

2. The coals must be examined as to texture, hardness, softness, the number and openness of the backs and cutters.

3. The nature of the pavement of the coal-seam, particularly as to hardness and softness; and if soft, to what depth it may be so.

4. The nature of the roof of the coal-seam, whether compact, firm, and strong; or weak, and liable to fall; as also the nature of the superincumbent strata.

5. The nature of the alluvial cover of the ground, as to water, quicksands, &c.

6. The situation of rivers, lakes, or marshes; particularly if any be near the outcrop of the coal-strata.

7. The situation of towns, villages, and mansion-houses, upon a coal-field as to the chance of their being injured by any particular mode of mining the coal.

Mr. Bald gives the following general rules for determining the best mode of working coal by post and stall:—

'1. If the coal, pavement, and roof, are of ordinary hardness, the pillars and rooms may be proportioned to each other, corresponding to the depth of the superincumbent strata, providing all the coal proposed to be wrought is taken away by the first working, as in the first system; but, if the pillars are to be winged, or partially worked afterwards, they must be left of an extra strength, as in the second system.

'2. If the pavement is soft, and the coal and roof strong, pillars of an extra size must be left, to prevent the pillars sinking into the pavement, and producing a creep.

'3. If the coal is very soft, or has numerous open backs and cutters, the pillars must be left of an extra size, otherwise the pressure of the superincumbent strata will make the pillars fly or break off at the backs and cutters, the result of which would be a total destruction of the pillars, termed a crush or sit, in which the roof sinks to the pavement, and closes up the work.

'4. If the roof is very bad, and of a soft texture, pillars of an extra size are required, and the rooms or boards comparatively very narrow.

'In short, keeping in view all the circumstances, it may be stated generally, that when the coal, pavement, and roof, are good, any of the systems before mentioned may be pursued in the working; but if they are soft, the plan is to work with rooms of a moderate width, and with pillars of great extra strength, by which the greater part of the coal may be got out at the last of the work, when the miners retreat to the pit bottom, and there finish the workings of a pit.'

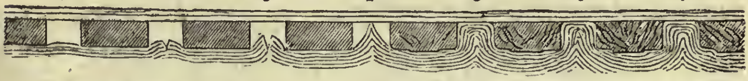
1504

1505

Fig. 1504 represents the effect of pillars sinking into the pavement, and producing a creep; and *fig.* 1505 exhibits large pillars and a room, with the roof stratum bending down before it falls at *a*. Thus the roads will be shut up, the air-courses destroyed, and the whole economy of the mining operations deranged.

In the 'Report from the Select Committee of the House of Lords, appointed to take into consideration the state of the Coal Trade in the United Kingdom,' printed in June 1829, under the head of Mr. Buddle's evidence, we have an excellent description of the nature and progress of creeps, which we have adverted to in the preceding account. The annexed figure (1506) exhibits the creep in all its progressive stages,

1506



1. First stage of active creep.
2. Second do.
3. Third do.
4. Fourth do.
5. The metal ridge closed, and the creep beginning to settle.
6 and 7. The creep settled, the metal ridges being closely compressed, and supporting the roof.

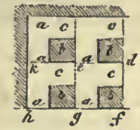
from its commencement until it has completely closed all the workings, and crushed the pillars of coal. The section of the figures supposes us standing on the level of the different galleries which are opened in the seam. The black is the coal pillars between each gallery; when these are weakened too much, or, in other words, when their bases become too narrow for the pavement below, by the pressure of the incumbent strata, they sink down into the pavement, and the first appearance of creep is a little curvature in the bottom of each gallery: that is, the first symptom obvious to sight; but it may generally be heard before it is seen. The next stage is when the pavement begins to open with a crack longitudinally. The succeeding stage is when that crack is completed, and it assumes the shape of a metal ridge. The next is when the metal ridge reaches the roof. The following stage is when the peak of the metal ridge becomes flattened by pressure, and forced into a horizontal direction, and becomes quite close; just at this moment the coal pillars begin to sustain part of the pressure. The next is when the coal pillars take part of the pressure. The last stage is when it is dead and settled, that is, when the metal or factitious ridge, formed by the sinking of the pillar into the pavement, bears, in common with the pillars of coal on each side, the full pressure, and the coal becomes crushed or cracked, and can be no longer worked, except by a very expensive and dangerous process.

The proportion of coal worked out, to that left in the pillars, when all the coal intended to be removed is taken out at the first working, varies from four-fifths to two-thirds; but, as the loss of even one-third of the whole area of coal is far too much, the better mode of working, suggested in the third system, ought to be adopted.

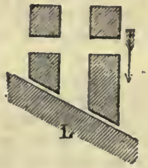
The proportion of a winning to be worked may be thus calculated:—Let *fig.* 1507 be a small portion of the pillars, rooms, and thirlings, formed in a coal-field; *a*, *a*, are two rooms; *b*, the pillars; *c*, the thirlings (or area worked out). Suppose the rooms to be 12 feet wide, the thirlings to be the same, and the pillars 12 feet on each side; adding the face of the pillar to the width of the room, the sum is 24; and also the end of the pillar to the width of the thirling, the sum is likewise 24; then $24 \times 24 = 576$; and the area of the pillar is $12 \times 12 = 144$; and as 576 divided by 144 gives 4 for a quotient, the result is, that one-fourth of the coal is left in pillars, and three-fourths extracted. Let *d*, *e*, *f*, *g*, be one winning, and *g*, *e*, *k*, *h*, another. By inspecting the figure, we perceive the workings of a coal-field are resolved into quadrangular areas, having a pillar situated in one of the angles.

In forming the pillars and carrying forwards the boards with regularity, especially where the backs and cutters are very distinct and numerous, it is of importance to

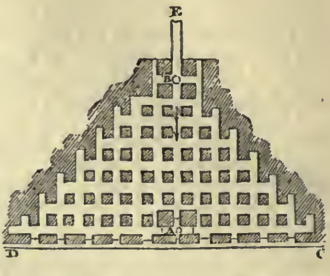
1507



1508



1509



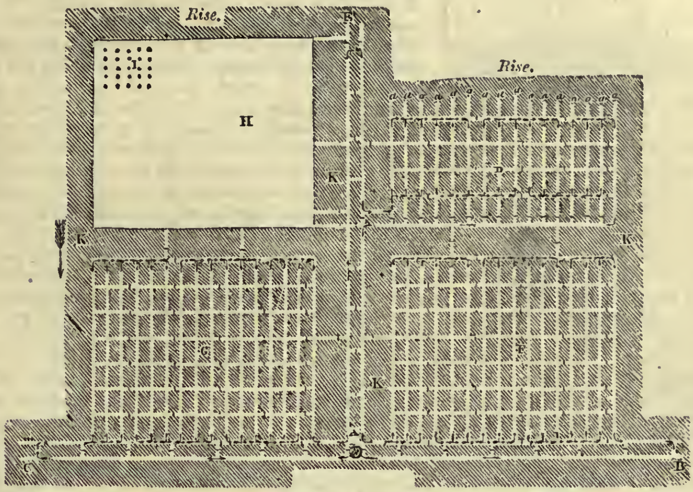
work the rooms at right angles to the backs, and the thirlings in the direction of the cutters, however oblique these may be to the backs, as the rooms are by this means conducted with the greatest regularity with regard to each other, kept equidistant, and the pillars are strongest under a given area. At the same time, however, it seldom happens that a back or cutter occurs exactly at the place where a pillar is formed; but this is of no consequence, as the shearing or cutting made by the miner ought to be in a line parallel to the backs and cutters. It frequently happens that the dip-head level intersects the cutters in its progress at a very oblique angle. In this case, when rooms and pillars are set off, the face of the pillar and width of the room must be measured off an exact breadth in proportion to the obliquity, as in *fig.* 1508. By neglect of this rule much confusion and irregular work is often produced. It is, moreover, proper to make the first set of pillars next the dip-head level much stronger, even where there is no obliquity, in order to protect that level from being injured by any accidental crush of the strata.

We shall now explain the different systems of working: one of the simplest of which is shown in *fig.* 1509: where A represents the engine-pit; B, the bye-pit; C, D, the dip-head levels, always carried in advance of the rooms; and E, the rise- or crop-gallery, also carried in advance. These galleries not only open out the work for the miners in the coal-bed, but, being in advance, afford sufficient time for any requisite operation, should the mines be obstructed by dykes or hitches. In the example before us, the room or boards are worked from the dip to the crop; the leading rooms, or those most in advance, are on each side of the crop-gallery E; all the other rooms follow in succession, as shown in the figure: consequently, as the rooms advance to the crop, additional rooms are begun at the dip-head level, towards C and D. Should the coal work better in a level-course direction, then the level rooms are next the dip-head level, and the other rooms follow in succession. Hence the rooms are carried to the crop or rise in the one case, till the coal is cropped out, or is no longer workable; and in the other, they are extended as far as the extremity of the dip-head level, which is finally cut off, either by a dyke or slip, or by the boundary of the coal-field.

Fig. 1510 represents a part of a colliery laid out in four panels, according to the improved method of the north of England. To render it as distinct as possible, the line of the boards is at right angles with the dip-head level, or level course of the coal. A is the engine-shaft, divided into three compartments, an engine-pit and two coal-pits, like *fig.* 1493. One of the coal-pits is the down-cast, by which the atmospheric air is drawn down to ventilate the works; the other coal-pit is the up-cast shaft, at whose bottom the furnace for rarefying the air is placed. B C, is the dip-head level; A E, the rise- or crop-gallery; K, K, the panel-walls; F, G, are two panels completed as to the first work; D, is a panel, with the rooms *a*, *a*, *a*, in regular progress to the rise; H, is a panel fully worked out, whence nearly all the coal has been extracted: the loss amounting in general to no more than a tenth, instead of a third, or even a half, by the old method. By this plan of Mr. Buddle's also, the pillars of a panel may be worked out at any time most suitable for the economy of the mining operation.

In Mr. Buddle's system the pillars are very large, and the rooms or boards narrow; the pillars being in general 12 yards broad, and 24 yards long; the boards 4 yards wide; and the walls or thirlings cut through the pillars from one board to another, only 5 feet wide, for the purpose of ventilation. In the figure, the rooms are represented as proceeding from the dip to the crop, and the panel-walls act as barriers thrown round the area of the panel to prevent the weight of the superincumbent strata from over-running the adjoining panels. Again, when the *pillars* of a panel are to be worked, one range of pillars, as at I (in H), is first attacked; and, as the workmen cut away the furthest pillars, columns of prop-wood are erected betwixt the pavement and the roof, within a few feet of each other (as shown by the dots), till an area of above 100 yards square is cleared of pillars, presenting a body of strata perhaps 130 fathoms thick, suspended clear and without support, except at the line of the surrounding pillars. This operation is termed working the *goaf*. The only use of the prop-wood is to prevent the stratum, which forms the ceiling over the workmen's heads, from falling down and killing them by its splintery fragments. Experience has proved that before proceeding to take away another set of pillars, it is necessary to allow the last-made goaf to fall. The workmen then begin to draw out the props, which is a most hazardous employment. They begin at the more remote props, and knock them down one after another, retreating quickly under the protection of the remaining props. Meanwhile the roof-stratum begins to break by the sides of the

1510



pillars, and falls down in immense pieces; while the workmen still persevere, boldly drawing and retreating till every prop is removed. Nay, should any props be so firmly fixed by the top pressure that they will not give way to the blows of heavy mauls, they are cut through with axes; the workmen making a point of honour to leave not a single prop in the goaf. If any props are left in the goaf it causes an irregular subsidence of the strata, and throws more pressure on the adjacent pillars. The miners next proceed to cut away the pillars nearest to the sides of the goaf, setting prop-wood, then drawing it, and retiring as before, until every panel is removed, excepting small portions of pillars which require to be left under dangerous stones to protect the retreat of the workmen. While this operation is going forward, and the goaf extending, the superincumbent strata, being exposed without support over a large area, break progressively higher up; and when strong beds of sandstone are thus giving way, the noise of the rending rocks is very peculiar and terrific; at one time loud and sharp, at another hollow and deep.

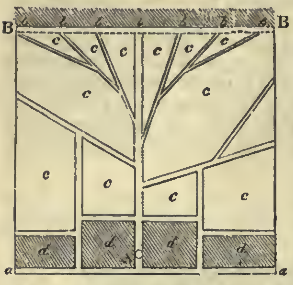
As the pillars of the panels are taken away, the panel-walls are also worked progressively backwards to the pit-bottom; so that only a very small proportion of coal is eventually lost.

The fourth system of working coal is called the *long way*, the long-wall, or the Shropshire and Derbyshire method.

The object of this system is, to begin at the pit-bottom, and to cut away at once every inch of coal progressively forward, and to allow the whole superincumbent strata to crush down behind and over the heads of the workmen. This plan is pursued chiefly with coals that are thin, from 4 to 5 feet being reckoned the most favourable thickness for proceeding with comfort, amidst ordinary circumstances, as to roof, pavement, &c. When a pit is opened on a coal to be treated by this method, the position of the coals above the lowest seam sunk to must first be considered; if the coal-beds be contiguous it will be proper to work the upper one first, and the rest in succession downwards; but if they are 8 fathoms or more apart, with strata of strong texture betwixt them, the working of the lower coals in the first place will do no injury to that of the upper coals, except breaking them, perhaps, a little. In many instances, indeed, by this operation on a lower coal, upper coals are rendered more easily worked.

When the operation is commenced by working on the long-wall plan, the dip-head levels are driven in the usual manner, and very large bottom-pillars are formed, as represented in *fig.* 1511. Along the rise-side of the dip-head level, chains of wall, or long pillars, are also made, from 8 to 10 yards and upwards in breadth, and only mined through occasionally, for the sake of ventilation, or of forming new roads. In other cases no pillars are left upon the rise-side of the level; but, instead of them, buildings of stone are reared, 4 feet broad at the base, and 9 or 10 feet from the deep side of the level. Though the roads are made 9 feet wide at first, they are reduced to half that width after the full pressure of the strata is upon them. Whenever these points are secured, the operation of cutting away the whole body of the coal begins. The place where the coal is removed, is named the *gobb* or waste; and *gobbin*, or gobb-stuff, is stones or rubbish taken away from the coal, pavement, or roof, to fill up that excavation as much as possible, in order to prevent the crush of superincumbent strata from causing heavy falls, or following the workmen too fast in their descent. Coals mined in this manner work most easily according to the way in which the widest backs and cutters are; and therefore, in the Shropshire mode, the walls stand sometimes in one direction, and sometimes in another; the mine always turning out the best coals when the open backs and cutters face the workmen. As roads must be maintained through the gobb or goaf to the working face, pillars of stone, called packs, are formed along each side of the road of several feet in width; and the rock over head along this road is blasted down of sufficient height, so that when the superincumbent strata have sunk, there may be ample height to convey the coals with ponies. In many cases these roads are 6 to 7 feet high, and seldom less than 4 feet. In some coal-fields stone cannot be got in the mine to build the road pillars or packs; but a substitute is found in cord wood, which is formed into a pillar on each side of the road by building it up, and making it as solid as possible with small coal and other small refuse. The pressure of the strata soon makes this a very compact pillar. This method is common in the Leicestershire coal-field.

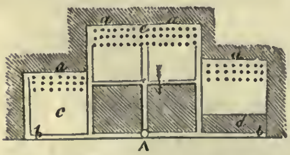
1511



There are two principal modifications of the long-wall plan. The first, or the original system, was to open out the wall round the pit-bottom; and, as the wall face extended, to set off main roads and branches, very like the branches of a tree. These roads were so distributed, that between the ends of any two branches there should be a distance of 30 or 40 yards, as might be most convenient (see *fig.* 1511). Each space of coal betwixt the roads is called a wall; and one half of the coals produced from each wall is carried to the one road, and the other half to the other road. This is a great convenience when the roof is bad; and hence a distance of only 20 yards betwixt the roads is in many instances preferred. In *fig.* 1511, A represents the shaft; B B, the wall-face; *a*, the dip-head level; *b*, the roads, from 20 to 40 yards asunder; *c*, the *gobb* or waste, with buildings along the sides of the roads; and *d*, the pillars.

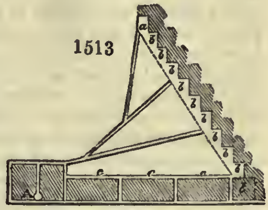
The other plan is represented in *fig.* 1512, where A shows the pit, with the bottom pillars; *b*, the dip-head levels; *c*, the off-break from the level, where no pillars are left; *d*, the off-break, where pillars remain to secure the level. All roads are protected in the sides by stone buildings, if they can be had, laid off 9 feet wide. After the crush settles, the roads generally remain permanently good, and can, in many cases, be travelled through as easily 50 years after they have been made as at the first. Should stones not be forthcoming, coals must be substituted, which are built about 20 inches in the base. In this method, the roads are likewise from 20 to 40 yards apart; but instead of ramifying, they are arranged parallel to each other. The miners secure the waste by gobbing; and three rows of props are carried forwards next the wall faces *a*, with pillars of stone or of coal reared betwixt them. This mode has a more regular appearance than the other; though it is not so generally practised in Shropshire as in Derbyshire.

1512



In the post-and-stall system, each man has his own room, and performs all the labour of it; but in that of Shropshire, there is a division of labour among the workmen, who are generally divided into three companies. The first set curves, holes, or pools the coal along the whole line of walls. laying in or pooling at least 3 feet, and frequently 45 inches, or 5 quarters, as it is called. These men are named *holers*. As the crush is constantly following them, and impending over their heads, causing frequent falls of coal, they plant props of wood for their protection at regular distances in an oblique direction between the pavement and wall face, called *spragging*. Indeed, as a further precaution, staples of coal, about 10 inches square, are left at every 6 or 8 yards, till the line of holing or curving is completed. The walls are then marked off into spaces of from 6 to 8 yards in length; and at each space a shearing or vertical cut is made, as deep as the holing; and when this is done, the holer's work is finished. The set who succeed the holers are called getters. These commence their operations at the centre of the wall divisions, and drive out the *gibbs*, or sprags, and staples. They next set wedges along the roof, and bring down progressively each division of coal; or, if the roof be hard-bound, the coal is blown down with gunpowder. When the roof has a good parting, the coals will frequently fall down the moment the gibbs are struck; which makes the work very easy. The getters are relieved in their turn by the third set, named butty-men, who break down the coals into pieces of a proper size for sending up the shaft, and take charge of turning out the coal from the wall face to the ends of the roads. This being done, they build up the stone pillars, fill up the gobb, set the trees, or props, clear the wall faces of all obstructions, set the gibbs, and make everything clear and open for the holers to resume their work. If the roads are to be heightened by taking down the roof, or removing the pavement, these butty-men do this work also, building forwards the sides of the roads, and securing them with the requisite props. When a coal has a following or roof stone, which regularly separates with the coal, this facilitates the labour, and saves much of the coal; and should a soft bed of fire-clay occur a foot or two beneath the coal-seam, the holing is made in it, instead of into the coal, and the stone betwixt the holing and the coal benched down, which serves for pillars and gobbing. In this way all the vendible coal becomes available.

1513



Another form of the Shropshire system is, for each miner to have from 6 to 12 feet of coal before him, with a leading-hand man; and for the several workmen to follow in succession like the steps of a stair. When the coal has open backs and cutters this work goes on very regularly, as represented in *fig.* 1513, where the leading miner is at *a*, next to the outcrop, and *b b*, &c. are the wall faces of each workman; A being the shaft, and B the dip-head level. In this case the roads are carried either progressively through the gobb, or the gobb is entirely shut up; and the whole of the coals are brought down the wall-faces, either to the dip-head level or the road *c c*. This method may be varied by making the walls broad enough to hold two, three, or four men, when each set of miners performs the whole work of holing, getting, breaking down, and carrying off the coals.

It is estimated that from one-eighth to one-twelfth part only of the coals remains underground by the long-wall plan; nay, in favourable circumstances, almost every inch of coal may be taken out, as its principle is to leave no solid pillars nor any coal below, except what may be indispensable for securing the gobb. Indeed, this system might be applied to coal-seams of almost any ordinary thickness, providing stuff to fill up the gobb could be conveniently procured.

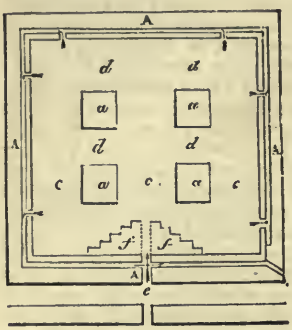
When coals do not exceed 20 feet in thickness, and have good roofs, they are sometimes worked as one bed of coal; but if the coal be tender or free, it is worked as two beds. One-half of such thick coal, however, is in general lost in pillars; and it is very seldom that less than one-third can be left. When the coal is free and ready to crumble by the incumbent pressure, as well as by the action of the air, the upper portion of the coal is first worked, then a scaffolding of coal is left, 2 or 3 feet thick, according to the compactness of the coal; and the lower part of the coal is now worked, as shown in *fig.* 1514. As soon as the workings are completed to the proposed extent, the coal scaffoldings are worked away, and as much of the pillars as can be removed with safety. As propwood is of no use in coal-seams of such a height, and as falls from the roof would frequently prove fatal to the miners, it is customary with tender roofs to leave a ceiling of coal from 2 to 3 feet thick. This makes an excellent roof; and should it break, gives warning beforehand, by a peculiar crackling noise, very different from that of roof-stone crushing down.

1514

One of the thickest coals in Great Britain, worked as one bed from roof to pavement, is the very remarkable seam near the town of Dudley, known by the name of the Ten-yard coal, about 7 miles long and 4 broad. No similar coal has been found in the island; and the mode of working it is quite peculiar, being a species of panel work, totally different from the modern Newcastle system. A compartment, or panel, formed in working the coal, is called a side of work; and as the whole operation is exhibited in one of these compartments, it will be proper to describe the mode of taking the coal from one of them, before describing the wholeextent of the workings of a mine.

Let *fig.* 1515 represent a side of work: A, the ribs or walls of coal left standing, round, constituting the side of work; *a*, the pillars, 8 yards square; *c*, the stalls, 11 yards wide; *d*, the cross openings, or through puts, also 11 yards wide; *e*, the bolt-hole, cut through the rib from the main road, by which bolt-hole the side of work is opened up, and all the coals removed. Two, three, or even four bolt-holes open into a side of work, according to its extent; they are about 8 feet wide and 9 feet high. The working is in a great measure regulated by the natural fissures and joints of the coal-seam; and though it is 30 feet thick, the lower band, of 2 feet 3 inches, is worked first; the miners choosing to confine themselves within this narrow opening, in order to gain the greater advantage afterwards, in working the superjacent coal. Whenever the bolt-hole is cut through, the work is opened up by driving a gallery forward, 4 feet wide, as shown by the dotted lines. At the sides of this gallery next the bolt-hole, each miner breaks off in succession a breast of coal, two yards broad, as at *f f*, by means of which the sides of the rib-walls A, are formed, and the area of the pillars. In this way each collier follows another, as in one of the systems of the Shropshire plan. When the side of work is laid open along the rib-walls, and the faces and sides of the pillars have been formed, the upper coals are then begun to be worked, next the rib-wall. This is done by shearing up to a bed next the bolt-hole, and on each side, whereby the head coals are brought regularly down in large cubical masses, of such thickness as suits with the free partings or subordinate divisions of the coals and bands. Props of wood, or even stone pillars, are placed at convenient distances for the security of the miners.

1515



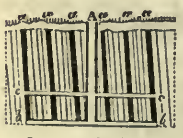
In working the ten-yard coal, a very large proportion of it is left underground, not merely in pillars and rib-walls, but in the state of small coal produced in breaking out the coal. Hence from four-tenths to a half of the total amount is lost for ever.

The thick or ten-yard coal has, however, been worked on the long-wall method by Mr. Gibbons, near Dudley, with great advantage in the yield. He works 12 to 14 feet of the upper part of the seam first; and after allowing the strata to become somewhat consolidated, the lower part is worked, leaving 2 to 3 feet of coal for a roof, some portion of which is picked out of the gobb. About 12 per cent. of the coal is left by this method.

Edge coals, which are nearly perpendicular, are worked in a peculiar manner; for, the collier stands upon the coal, having the roof on the one hand, and the floor on the other, like two vertical walls. The engine-pit is sunk in the most powerful stratum. In some instances the same stratum is so vertical as to be sunk through for the whole depth of the shaft.

Whenever the shaft has descended to the required depth, galleries are driven across the strata from its bottom, till the coals are intersected, as is shown in *fig.* 1516, where we see the edge coals at *a, a*; A, the engine-pit; *b, b*, the transverse galleries from the bottom of the shaft; and *c, c*, upper transverse galleries, for the greater conveniency of working the coal. The principal edge-coal works in Great Britain lie in the neighbourhood of Edinburgh.

1516



The modes of carrying coals from the point where they are excavated to the pit-bottom, are nearly as diversified as the systems of working.

One method employs hutches, or baskets, having slips or cradle feet shod with iron, containing from 2 to 3 hundred weight of coals. These baskets are dragged along the floor by ropes or leather harness attached to the shoulders of the workmen, who are either the colliers or persons hired on purpose. This method is used in several small collieries; but it is extremely injudicious, exercising the muscular action of a man in the most unprofitable manner. Instead of men, horses are sometimes yoked to these basket-hurdles, which are then made to contain from 4 to 6 hundred weight of coals; but from the magnitude of the friction this plan cannot be commended. This method is now almost entirely extinct.

An improvement on this system, where men draw the coals, is to place the basket or corve on a small four-wheeled carriage, called a tram, or to attach wheels to the corve itself. Thus much more work is performed, provided the floor be hard; but not on a soft pavement, unless some kind of wooden railway be laid.

The transport of coals from the wall-face to the bottom of the shaft was greatly facilitated by the introduction of cast-iron railways, in place of wooden roads, first brought into practice by Mr. John Carr of Sheffield. The rails are called tram-rails, or plate-rails, consisting of a plate from 3 to 4 inches broad, with an edge at right angles to it about two inches and a half high. Each rail is from 3 to 4 feet long, and is fixed either to cross-bearers of iron, called sleepers, or more usually to wooden bearers. In some collieries, the miners, after working out the coals, drag them along these railways to the pit-bottom; but in others, two persons called trammers are employed to transport the coals; the one of whom, in front of the corve, draws with harness; and the other, called the putter, pushes behind. The instant each corve arrives from the wall-face, at a central spot in the system of the railways, it is lifted from the tram by a crane placed there, and placed on a carriage called a rolley, which generally holds two corves. Whenever three or four rolleys are loaded, they are hooked together, and the rolley driver, with his horse, takes them to the bottom of the engine-shaft. The rolley horses have a peculiar kind of shafts, commonly made of iron, named *libers*, the purpose of which is to prevent the carriage from overrunning them. One of these shafts is represented in *fig.* 1517. The hole shown at *a*, passes over an iron peg or stud in front of the rolley, so that the horse may be quickly attached or disengaged. By these arrangements the work is carried on with surprising regularity and despatch. Where the roads are well constructed, a horse will convey a load of 7 to 8 tons on the level.

1517

We shall now describe briefly the modes of working coal dip of or on the deep of the engine-pit bottom. Headings are driven either on the full dip of the mine, or any convenient angle to it, the requisite distance. The water is pumped up these dip headings by the pumping-engine on the surface. A pump-rod or spear passes down the side of the shaft, and is attached to a quadrant at the bottom of the shaft, which quadrant transfers the perpendicular motion of the spears in the shaft to the spears or pump-rods in the dip headings. The quadrant is constructed so that the stroke of the pump in the dip headings can be lengthened or shortened as required.

In level free coals, these pumps may be worked by a water-wheel stationed near the bottom of the pit, impelled by water falling down the shaft, to be discharged by the level to the day (day level).

When the above arrangements are applied for pumping, the coals are drawn from the deep either by horses or an engine placed on the surface.

Where operations are very extensive, some mining engineers place the engine underground for working the dip coal; and it both pumps the water and draws the coal to the bottom of the shaft.

High-pressure engines are employed for this purpose, working at a pressure of from 30 to 50 lbs. per square inch. These machines are quite under command, and, producing much power in little space, they are the most applicable for underground work. An excavation is made for them in the strata and isolated from the coal, and the air used for the furnace under the boiler is the returned air of the mine ventilation if the mine is free from explosive gas. If the mine yields explosive gas, the boiler furnace is supplied with fresh air. In the dip road a double tram-road is laid; so that while a number of loaded corves are ascending, an equal number of empty ones are going down. Although this improved method has been introduced only a few years back, dip workings have been already executed more than an English mile to the dip of the engine-pit bottom in the Newcastle coal-fields. It may hence be inferred, that this mode of working is susceptible of most extensive application; and in place of sinking pits of excessive depth upon the dip of the coal, at an almost ruinous expense, much of the dip coal will in future be worked by means of the pits sunk on the rise. In the Newcastle district, coals are now working in an engine-pit 115 fathoms deep, and dip of the engine-pit bottom, above 1,600 yards, and fully 80 fathoms of perpendicular depth more than the bottom of the pit.

The deep pit in Dukinfield is 2,004 feet below the surface to the point where it intersects the Black Mine coal-seam, which is 4 feet 6 inches thick, and of the best quality for domestic and manufacturing purposes—and a further depth of 500 feet has been attained by means of an engine-plane in the bed of coal, which dips at an angle of 27°, so that a great portion of the coal is now worked there at the depth of 2,504 feet below the surface.

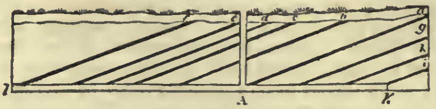
The shafts at Pendleton are 1,635 feet deep, and in like manner a further depth has been reached of about 500 feet, amounting in the aggregate to 2,135 feet, at which point a large quantity of coal is daily worked.

The Rose Bridge Pits near Wigan intersect the cannel at 1,773 feet below the surface—which varies in thickness from 2 feet 8 inches to 3 feet, and is of excellent quality.

At the most extensive collieries in the north of England, engine-power is not only applied for the transit of coals from the dip, but along the main level roads of the mine, by means of endless wire ropes. The economy of steam-power has superseded horses at many collieries. Steam-power can only be applied with advantage where large quantities of coal have to be removed.

If an engine-pit be sunk to a given coal at a certain depth, all the other coals of the coal-field, both above and below the coal sunk to, can be drained and worked to the same depth by driving a level cross-cut mine, both to the dip and rise, till all the coals are intersected, as represented in *fig.* 1518, where A is the engine-pit bottom

1518



reaching to the coal *a*; and *b*, *c*, *d*, *e*, *f*, coals lying above the coal *a*; the coals which lie below it, *g*, *h*, *i*; *k* is the forehead of the cross-cut mine, intersecting all the lower coals; and *l*, the other forehead of the mine, intersecting all the upper coals.

MINIUM. Red oxide of lead, obtained by roasting metallic lead or its carbonate.

MINT (Saxon *mynet*, money or stamped coin; Danish *munt*, *mint*, coin. The word 'mint' is doubtless a derivative from *mine*, or, Latin, *moneta*, from the same root). The place where money is coined by public authority.

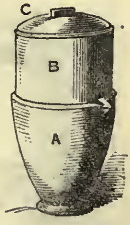
Minting or coining is the term applied to the processes employed in the manufacture of money. It is proposed to describe the present mode of manufacture; but it may be as well to state, that in remote periods money was made by cutting out a piece of metal somewhat of the form of the intended coin, and imparting the device to it by the blow of a sledge-hammer. For this purpose the blank piece of metal was laid upon a die, say the obverse, fixed into a block of wood or stone, supposed to have been so large as to absorb the vibration caused by the blow, and to a great extent prevent the quivering which would naturally arise, and cause unsteadiness. The workman then took the other die, say the reverse, and passing it through a folded sheet of lead, in order to avoid the shock to the hand, he placed the engraved part on the blank, which was resting on the lower die, and held it firmly while another workman struck it with a sledge-hammer. It is worthy of remark that a piece of lead such as that described is in the Museum of Dies at the Royal Mint; and although its surface, by the action of the atmosphere and other causes, is now converted into carbonate of lead, indentations caused by the tips of the workman's fingers are evident. This piece is believed to have been used with a die of Edward IV. At a later period the upper die was held in a twisted hazel stick. After each blow the dies were what is technically termed locked together; that is, the lower and upper dies were made to fit into the partly-formed coin, so that neither die could turn without turning the whole mass, and then a second or third blow was given, till the coin was completed. An improvement on this method was effected by fitting the two dies into rods of iron, which may be represented as a pair of tongs; the flat parts which are used to take a coal would then show the position occupied by the dies. This plan saved the operator some risk of bruised fingers, but the process was essentially the same as the original one; and to money produced by either means was applied the term *hammered* money, in contradistinction to *milled* money; that is, money which was made from blanks obtained from fillets which had been rolled in a very rough kind of rolling mill, driven by horse-power—the germ from which sprang the present machinery. On this point it is perhaps of interest to quote a passage from the Report made to the Lords of the Treasury in 1695 by Mr. William Lowndes, who says:—'All the moneys we have now in England, both gold and silver, are reducible to two sorts, one stamped with the hammer, and the other pressed with an engine called the mill. The gold or silver of the hammered money is first cast from the melting-pot into long bars, those bars are cut with shears into several square pieces of exact weight for sovereigns, angels, crowns, half-crowns, shillings, &c. Then with tongs and hammer they are forged into a round shape, after which they are blanched (that is, made white or refulgent by nealing or boiling), and afterwards stampt or impressed with an hammer to make them perfect money. This method of making money with the hammer (as appears in the said red book) was practised in the reign of King Edward the First' [the book referred to is in the Exchequer] . . . 'and this kind of hammered money continued through all the reigns of succeeding Kings and Queens till about the year of our Lord 1663, when by several warrants and command of the King, Charles the Second: to wit, by one warrant, dated the fifth of November 1662; one warrant, dated the eighth of April 1663; and a third warrant, dated the twenty-fourth of December 1663; the other sort, called *milled money*, was first fabricated to be current in England in this manner: first, the gold or silver is cast out of the melting-pot into long flat bars, which bars are drawn through a mill (wrought by a horse), to produce the just thickness of guineas, half-guineas, crowns, half-crowns, shillings, &c. Then with forcible engines called *cutters*, which answer exactly to the respective sizes or dimensions of the money to be made, the round pieces are cut out from the flat bar, shaped as aforesaid (the residue whereof, called sizel, is melted again), and then every piece is weighed and made to agree exactly with the intended weight, and afterwards carried to other engines (wrought secretly), which put the letters upon the edges of the larger silver pieces, and mark the edges of the rest with a graining. The next thing is the blanching, performed as above; and at last every piece is brought to the press, which is called the *mill* (wrought of the strength of men), and there receives the impression, which makes it perfect *milled* money.'

The processes now used are as elaborate as the old methods were simple; but considering the requirements of the present day, and the enormous quantity of money produced, it must not be expected that our coins will, for depth of engraving, bear comparison with those of the Romans, who, though succeeding in producing finished works of art, seem to have forgotten the wear and tear to which they would be subjected, and so left them, as a rule, free from a protecting edge; hence they would lose their image and superscription at a far earlier date from their birth or manufacture than would well-made coins of the present period.

It was formerly believed that gold could be sent to the Mint to be coined free of charge to the importer; such, however, was not the case. By the Act 33 Vict. cap. 10, several Acts relating to the coinage were repealed, and all persons obtained the right to send gold to the Mint on certain specified conditions. The standard for gold coin is fixed, by the Act now referred to, at 'twenty-two carats fine and two carats of alloy in the pound weight Troy.' The same that has obtained since 18th Charles II. Silver is also maintained at the former standard, 'eleven ounces two pennyweights fine silver and eighteen pennyweights of alloy in every pound weight Troy.' The Bank of England is practically the only 'importer' of bullion to the Mint, and by coinage makes a considerable profit merely from its exceptional circumstances; but for full details, we refer the reader to Ansell's 'Royal Mint,' (3rd edition, Effingham Wilson), where will be found elaborate discussions upon the various modes of proceeding, as well as on the loss and gain in the different operations: subjects which are manifestly unfitted for this work.

When the authorities of the Bank of England desire to coin gold they send at stated intervals 'importations' of 200 or 300 ingots, each weighing about 180 ounces Troy, and previously assayed. Upon arrival at the Mint these ingots are again weighed and assayed, and in accordance with the amount of gold they contain they are alloyed with copper or enriched by the addition of fine gold, to bring them to the fineness of standard or crown gold, so that each coin when formed shall contain 22 parts of pure gold and 2 parts of alloy. The ingots having been thus 'potted' or rated are taken to the melting-house, where their individuality is finally lost, for it is here that they are formed into bars for coining.

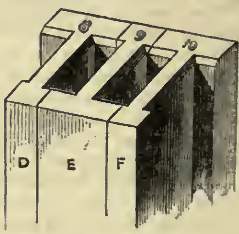
1519



In the Mint there are many furnaces; each furnace being 12 inches square, and 24 inches deep to the top of the bars. The melting of the gold is effected in a plumbago crucible, A, shown in *fig.* 1519. It is 9½ inches deep, and 7 inches across the top of the inside. The pot previously annealed is placed on a bottom which stands upon the two centre fire-bars. The bottom is intended to protect the base of the pot A from the stream of air which is necessary to the combustion of the fuel, but which would destroy the pot. The pot is then covered by its muffle, B, and lid C, and surrounded by fuel, which, as it burns up, warms and then heats the pot to redness, but so gradually that there is no great risk of breaking the pot. When the pot has become of a full red heat the ingots are carefully placed in it, and the alloy added by means of a funnel to prevent any being thrown on one side; the pot is then covered up and allowed to remain till the whole mass of metal has liquefied. The foreman then stirs it with a rod made of the same substance as the pot, which is a compound of blacklead and Stourbridge clay, and is fully described under CRUCIBLE. The fluid metal is allowed to remain in the furnace till it has acquired a peculiar appearance, known by experience as indicating the temperature to be such that the metal when poured into the moulds will produce solid and workable bars. At this point the firing is removed, and the lid and muffle taken from the pot, which is lifted from the furnace by an assistant by a hand crane. The foreman then conveys the pot with its contents by means of a pair of tongs, which clamp it to the frame of moulds, when his assistant brings forward a loop of iron, suspended by a chain and cord from the ceiling, and passing the loop of iron over a button on the end of the tongs, as shown at A, *fig.* 1520, supports the weight of the pot, and regulates its height, while the foreman pours the metal into the moulds, B, fixed in the frame, C, which runs on wheels in a tramway. Three pieces of planed iron form two moulds, as shown in *fig.* 1521, where D^8,E^9,F^{10}, show the form

1520

1521

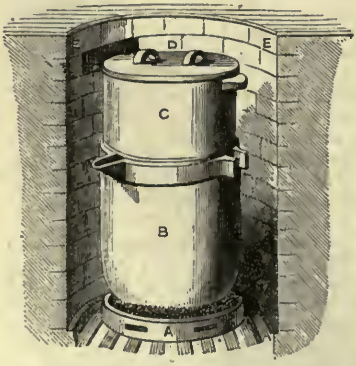


of these planed pieces, and the manner of placing them together. The bars are solidified immediately, and when all the moulds have been filled, they are taken to pieces, and the bars plunged into cold water, as in the case of silver, to be described. From the bars obtained from each pot, two pieces are cut off for assaying, by the assayers, the bars being numbered according to the pot from which they were poured, and lettered distinctively, according to the day on which they were melted. Should the assay prove unsatisfactory, the metal is adjusted and re-melted. If the assays are satisfactory, the bars are forwarded to the coining department.

Previously to melting, pieces of charcoal are placed at the bottom of the pot for the purpose of reducing any oxide that may be present in the alloy, because oxide of copper renders some kinds of gold perfectly brittle and unworkable. In order to prevent this charcoal from falling into the moulds with the gold the assistant holds a piece of stick at the mouth of the pot, thus allowing the gold to flow while he detains the charcoal.

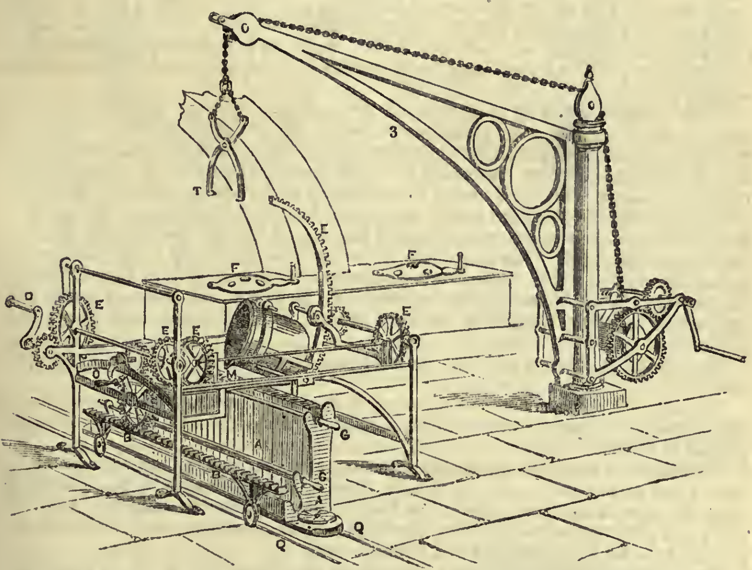
Silver is bought, through the brokers, by the Master of the Mint, either in the form of foreign coin (5-franc pieces are preferred) or ingots; and to the silver so obtained is added so much copper or pure silver as shall bring the whole mass up to the standard silver of the realm, which consists of 220 parts of silver and 18 parts of copper. The metal so arranged is weighed out into charges of about 4,000 ounces for the wrought-iron (plumbago is now used) melting-pot, which is represented in *fig.* 1522, as seen in the furnace E, standing on the 'bottom,' A, which rests on the fire-bars, and is made partially cup-shaped, and filled with powdered coke, that the bottom of the pot, B, may be perfectly supported, while at the same time it is protected from the current of air which is supplied to the furnace. Powdered coke, being a bad conductor, prevents the free passage of heat from the base of the pot to the 'bottom,' and the consequent probable fusion of the two through the agency of the oxide of iron, which forms and accumulates whenever iron is repeatedly heated. D is the lid of the pot; and C, the muffle or funnel, against the sides of which the metal rests during the process of fusion, to prevent its falling over into the burning coke. The pot, when

1522



charged, is allowed to remain in the furnace till the metal has fused, and the temperature has risen to a point little short of that which would so far soften the wrought-iron pot as to cause it to lose its shape. The pot is lifted by the tongs, T, of the crane, 3, from the furnace, F, *fig.* 1523, (after the fire has been removed by displacing some of the fire-bars), swung round and dropped into the cradle, M, when it is secured by a screw, which draws tight the band at the top. The melted silver is then thoroughly stirred with an iron rod; and, all being ready, the frame of moulds, A, is run under the cradle-stand so far as to allow the rack, B, to work into the wheel N. The foreman then, by means of the handle D, which communicates by E with the cradle in which the pot is fixed, raises the pot, and tilts it so much as is necessary to pour the fluid silver into the mould until it is filled; he then lowers the pot, and waits while an assistant by the handle O, connected with the cogwheel N, moves the moulds forward as they are required to be filled. The moulds are ranged side by side in the frame, and pressed firmly together by screws at the ends of the mould-frames, and secured in front by two bars of iron, G, which fit into wedge-shaped grooves, slanting forwards.

1523



The metal solidifies immediately, and the pot having been emptied, the carriage of moulds is run on its wheels, Q, from under the cradle-frame, and the screws having been loosened, the moulds are caused to fall to pieces, and each bar as it is exposed is taken by tongs and plunged into cold water, as much to save time as to soften and case-harden the bar by sudden cooling. The bars produced from the whole pot of metal are numbered with a distinctive figure to designate the pot, and with two letters to indicate the day's melting; assay-pieces are then cut from the first, middle, and last bars of the set.

The bars for different denominations of coins are proportioned in width so as to admit of two rows of blanks being cut from the fillets produced from them. Space, however, hardly admits of our giving detailed measurements; but it may be expected that a uniform thickness of $\frac{1}{2}$ an inch will at last be adopted by the Mint authorities for all bars, both of gold and silver, as they now admit the advantage of using $\frac{1}{2}$-inch bars for the gold coinage.

The 'assay-pieces' are assayed to determine that they contain the proportion of gold or of silver required by law, and it is assumed that these pieces give a fair average of the bars; hence, that the coin produced will be accurate. For a full description of the processes adopted, see GOLD; but it should be here noticed that the operation has been much simplified by the improvements to which we now invite attention.

Messrs. Johnson, Matthey, and Co. have invented a tray of platinum capsules or thimbles, into which the assay-pieces are placed for treatment with acid, instead of into the ordinary glass vessels over gas-burners. The advantages of this invention are too manifest to require elaboration; but saving of acid, gas, labour, and risk of error are amongst the chief of them; and, besides, the plan has been in successful operation in their own assay offices in Hatton Garden, as well as in other important assay offices, for several years past. The first cost would seem to be the principal objection to this plan of Messrs. Johnson, Matthey, and Co.; but this is really a small matter, for the apparatus becomes stock-in-trade, and its cost should be viewed simply as so much capital, whose interest is paid by the saving effected in glass, but more especially by the smaller amount of acid actually employed, while the platinum can at all times be sold, for nearly its original cost, as old metal.

The mode of operation is as follows:—A stand of slate is so arranged that a means of heating is made to rest on its base. For this purpose a jet of gas is preferred; where, however, gas cannot be obtained, an ordinary oil lamp or a charcoal fire may be used. On a shelf over the source of heat are placed two or three receptacles of platinum, each communicating with a vessel made of porcelain, provided with three necks and an overflow-pipe. There is a kind of sieve or tray of platinum, so arranged as to carry from 16 to 100 thimbles of platinum, and provided with a handle, so that this tray, with its charge, can be manipulated at pleasure. The thimbles vary in size according to taste, but each one is slit or cut at the bottom, so that the solution of silver as it is formed may by its density fall out, and allow the clean acid to take its place.

When an operation is to be performed, the tray filled with the charged thimbles—that is, containing the assay-pieces—is placed in one of the platinum receptacles or boilers, and heated to a fitting temperature; when the desired effect is produced, the tray is lifted into another receptacle, and again heated; this may be carried to three times if necessary. The products of decomposition of the acid go, with the acid which evaporates, into the porcelain vessel, where the free acid falls through the overflow-pipe into a proper chamber, while the acid fumes pass into the flue through the third neck before spoken of. The parted assays having been washed by several immersions in boiling distilled water, without removal from their thimbles, have now to be dried and annealed in a platinum muffle, so formed as to fit into an ordinary muffle, and, after annealing, to be weighed in the usual manner, having saved at least 75 per cent. of the usual trouble.

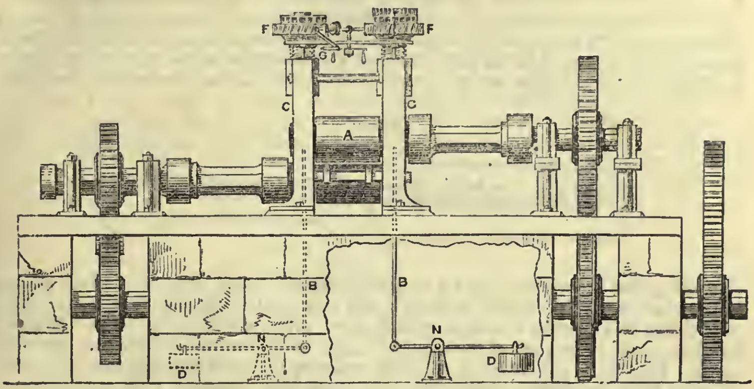
It is almost needless to add that the system of *proofs* must be used with this process.

The assay for silver is not so tedious, as it is finished at the point where it leaves the muffle on the cupel; but up to this point it passes through precisely the same process as the gold.

The Master of the Mint, on receipt of the assay reports, determines if the metal has been found within the limits, or remedy allowed for error; and, if he be satisfied, signs the reports, and thus enables the bars to be forwarded for coining. And from this point gold and silver undergo nearly the same operations; to follow, then, the practice used for sovereign-bars will suffice for all.

The sovereign-bars having been weighed by the officer, and given by him to his men, are wrought in sets of twenty; each set is called a *batch*, and each bar in the batch undergoes precisely the same process. The bar is passed into an opening of the breaking-down mill, *fig.* 1524, where it receives a considerable compression, for the rollers A, seizing its end, drag it forward, while they roll back and retard the progress of that part of the bar which is not between them. The result is that the bar is lengthened, but not widened materially, so that length is gained at the expense of the thickness, which is regulated by the distance between the rollers. The rollers are driven by shafts and adjusting-couplings, which are themselves driven by the geared wheels. The distance between the rollers is determined by the action of the lever G, which, by the endless wheels on its axle fitting into geared wheels, gives motion to powerful screws shown at F, which terminate in cups on the upper part of the upper brasses of the rollers A, as may be seen at C. The upper brasses are kept always against the ends of the screws by weights, D, which are beneath the mill, but from which levers and rods, B, terminate at the lower part of the upper brasses, at about the position indicated by dotted lines, so that the upper roller has motion either upwards or downwards at pleasure, but the motion upwards is arrested by the powerful screw F, and this point once determined by the reading of a scale, is fixed by the clamp near G. The thickness, therefore, of each bar in a batch is determined within certain limits; and, when each bar in the batch has been rolled, the mill is altered, refixed, and again the rolling goes on till each bar has passed several times, at varying pinches, through these rollers. Owing to the wear of the moulds in which the bars are cast—and which is largely due to the presence of minute portions of antimony in the gold—the bars are never of uniform thickness; hence bars of every denomination are passed through the rollers on their edge, so as

1524



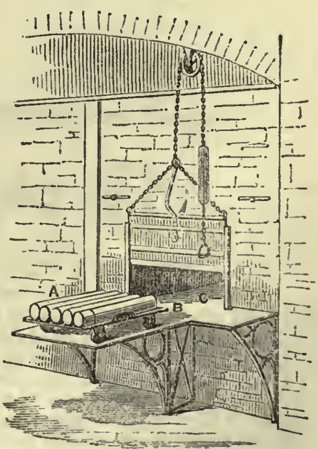
to reduce them to one uniform thickness, otherwise the fillets resulting would be ragged, and of unequal widths, which defect would cause them to produce blanks out of *remedy* as to weight.

When the metal is poured into the moulds, it almost immediately solidifies, and while solidification is going on contracts in volume, leaving a kind of cup of metal, or hollow part, on the top of the bar. In the act of rolling, the bar maintains an equable width until this hollow part is reached, when it suddenly expands, and at this point the workman shears off the defective part of the bar, because it would ultimately cause dumb works. This operation is now performed in the melting-house, before the bar is rolled, thus saving labour and loss of metal.

The shears may be regarded as large scissors, driven by a drum on the same shaft that carries the driving-wheel for D. The drum is excentric, so that at each revolution the shears are caused to open and shut.

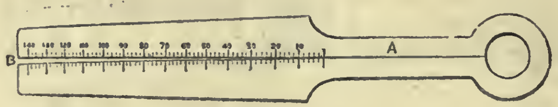
The sheared bars for half-sovereigns are placed in copper tubes, the tops of which are luted on with clay. It is imperative that the copper tubes should be made without solder, because this fuses at a temperature below that which is required to anneal the gold; if present it would run down upon the hot gold, and cause it to fuse and alloy with the solder, thus spoiling the work and entailing expense upon the coiner. The tubes which were used in the Royal Mint were made by Messrs. Benhams and Froud, of Chandos Street, Strand, who, after considerable pains, arrived at a method of making the tubes in such a manner as to entirely satisfy the requirements of the Mint. The tubes, A, are placed on an iron carriage, B, which is then run into the furnace, as shown in *fig.* 1525. The door of the furnace, C, is closed by raising the counterpoise; the heat of the furnace is regulated by a damper. After remaining in this furnace for twenty minutes, the carriage is withdrawn, and the tubes, taken with tongs, are plunged into cold water, to cool the gold as rapidly as possible. The rapid cooling of gold and silver gives to each metal a peculiar character, which is of value in the after processes, and prevents the access of the atmosphere, which, in prolonged cooling, would cause the oxidation and consequent removal of so much copper that the alloyed metal would become too rich in gold for circulation as coin. After annealing, the bars, which are now called *fillets*, go again to the breaking-down mill, through which they are

1525



passed twice, and are then submitted to another pinch without altering the scale at all; so that what is called a *spring-pinch* is given, with the intention of effecting the reduction of the fillet to one uniform thickness, for the breaking down and subsequent rolling cause the fillets to become much thicker in their middle than at their sides. The widening of the fillet is very trifling; but width may be gained to any desired extent at the will of the workman if the bars be submitted to a heavy pinch instead of a series of light ones. The fillet having been submitted to the fourth spring-pinch, is gauged on its side by a steel instrument, of which *fig.* 1526 is a representation. It is a hollow wedge, which is graduated to the thousandth of an inch.

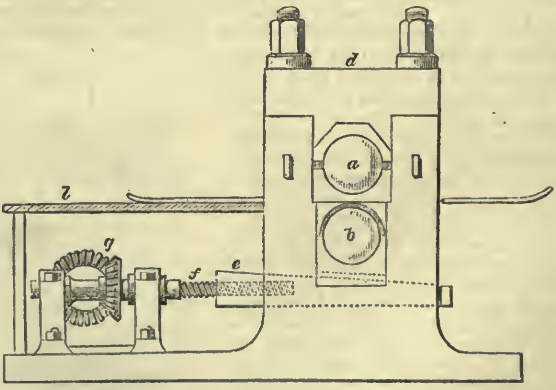
1526



Supposing that the opening from A to B were extended until it were one inch wide at A, the space would be divided between it and B into 1,000 parts, and then every fillet passed into this opening would stop at a given point, say for instance, at 140; such being the case, every part of the same fillet should be arrested precisely at the same point. The fillets are reduced till they measure 117 on this gauge, and are consequently 0·117 inch thick. They are then passed to the next mill, and then to a third mill, where they receive very light pinches. They then pass to another mill, still finer than any of the preceding, and here are submitted to very light pinches, by which they are reduced to 0·058 inch, and are finally finished at the sixth or gauging mill, where they receive three pinches, and are then 0·053 inch thick.

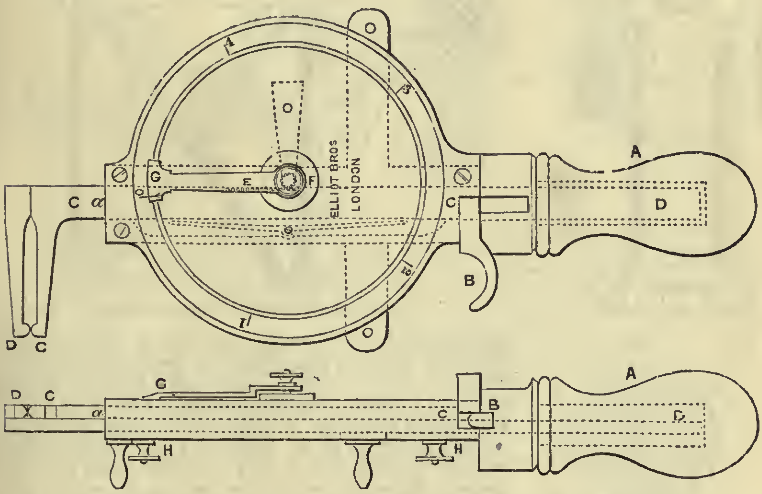
The gauging mill is of different construction from the other mills, as may be seen by reference to *fig.* 1527, where the rollers, *a*, *b*, are seen in the act of reducing a fillet. The upper roller is fixed in brasses loosely clamped together; the upper brass, B, being firmly bolted to the main frame of the mill by screws, while the lower one, which carries the weight of the roller when it is running empty, is supported by spiral springs not shown. The lower roller works on a brass, which rests on a wedge shown at *e*; the brass being cut to fit the wedge, so that it may become similar to a solid mass, irrespective of any motion given to the wedge. By this mode of adjusting, a difference of

1527



the 0·001 of an inch may be made with ease between the distance of the rollers, and consequently in the thickness of fillets which may pass between them. The wedge *e* is moved forward and backward by the screw *f*, which itself has motion from the gear work, *g*. Directly a fillet is passed between the rollers, the topmost one is forced against its upper brasses, and further upward motion becomes impossible. As the gauger of fillets requires other tests besides that of the thickness of the edge of the fillet, he punches out a blank from an occasional fillet by a hand-press; the blank falling through the bolster of the cutter is caught, and is then weighed in the hand scales against a standard weight, from which it must not vary more than 0·50 grain. He has, in addition to the gauge represented by *fig.* 1526, one of great accuracy, by which to measure the fillets at any point, as to width and thickness. This gauge will be more intelligible by reference to *fig.* 1528. A is the handle, which is hollow; B is a lever attached to the flat rod of copper C, which at E is cut with a rack, into which a pinion, F, is made to work. The pinion, F, works on a shaft, the upper end of which carries a hand provided with a vernier, G. If now the handle, A, be firmly held by the hand, while the thumb be made to press the lever, B, towards the end of the handle, the rod, C, is set in motion, and causes the vernier, G, to travel over the dial-plate. The rod, C, rests on another rod, D, made of steel, and so long as to pass into the handle of the instrument. The ends of the rods, C and D, are fitted at *a* with steel shoulders, and are then continued, as represented. If it be desired to measure the thickness of a fillet, the points are caused to open by pressure applied to B, and the fillet is placed between them, when a spring brings back the rod, C, as soon as B is gently released, and encloses the fillet. The separation of the points by the fillet causes the hand or indicator, G, to stand at a point from zero, which is then read. The

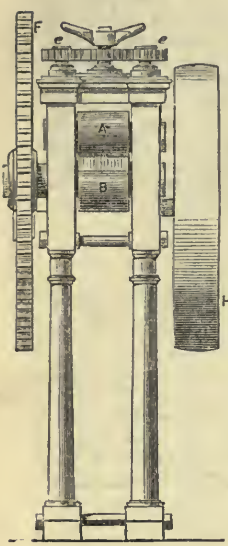
1528



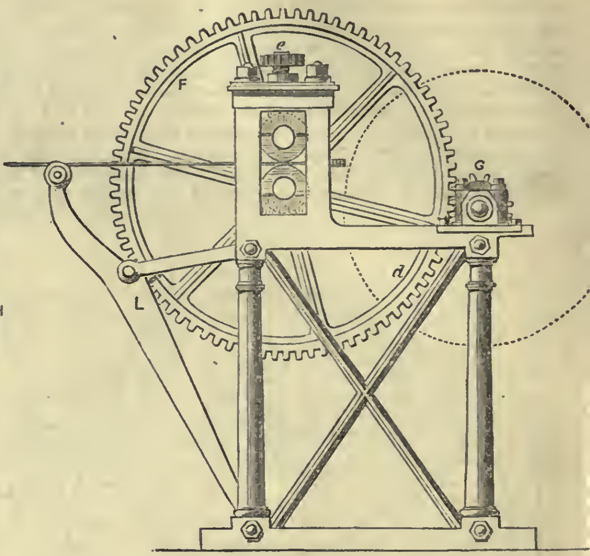
scale is divided into 500 parts; and if the points be opened 0·50 inch, the hand makes one revolution; so that the ·001 of an inch is gained by one reading. But each 0·001 is subdivided by the vernier into ten, so that a ten-thousandth part of an inch is read without trouble. To measure the diameter of a blank coin, or the width of a fillet, it must be placed between the points; but since the extreme graduation of this gauge is 0·50 inch, it is necessary if it be desired to measure a larger diameter, to press back the lever, B, till the zero of the vernier, G, reaches 0·500 on the scale, and hold it there while a clamp is made fast at the spot indicated by *a*, to prevent the motion of C without D. When the clamp is fixed, the rod, D, must be drawn out till the zero of the vernier reaches that of the scale, when the screws, H, must be tightened to retain D in its new position, with half an inch permanent opening between the points. In a new measurement, that permanent 0·500 must be added to the reading. This arrangement admits of measuring up to 3·5000 inches, to which limit the gauge is extremely accurate. The instrument was invented by Mr. G. F. Ansell, because he found it difficult to convince the men that the fillet was thickest in its middle, and consequently heavier there than it should be; and the production of this instrument at once overcame all those difficulties.

The fillets are weighed from the rolling-room to the drag-room, where they are finally adjusted; for with every energy, discretion, and skill, *fillets cannot be obtained of uniform thickness by simple rolling.* In the drag-room the fillets are taken to the small shears, by which one end of each fillet is trimmed so as to render it square. The fillets having been trimmed so as to render their ends square, are next passed to the extent of about two inches between the rollers of a flatting mill, shown in *figs.* 1529, 1530, 1531, which reduce that part of the fillet to about two-thirds its thickness. A B represent a pair of small rollers, the upper one of which is cut with three flat faces, so that it has three rounding and three flat surfaces; hence, when both rollers are revolving, there are spaces with openings between them; but when the rounding faces come down, those openings are much narrowed, so that any fillet placed between them becomes thinned to just such an extent as may be deemed necessary.

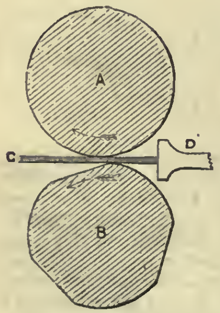
1529



1530



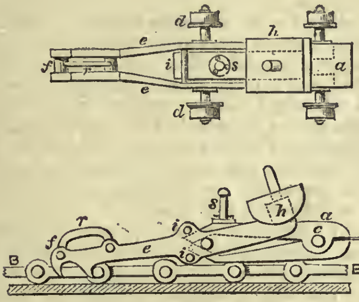
1531



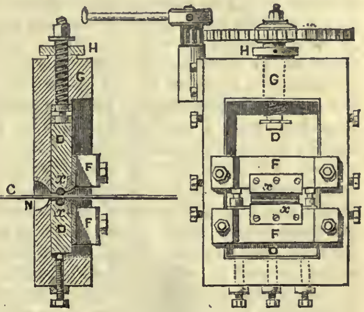
The rollers travel in opposite directions, so as to cause the expulsion of a fillet placed between them. The fillets are rested on L while being *flatted*, and are, after flatting, placed in a trough, from which they are taken to a rolling-mill in the drag-room, of precisely the same construction as that exhibited at *fig.* 1527, to be passed twice through at equal pinches, with a view to render them still more accurate than they were when leaving the rolling-room, as well as to reduce them to the exact thickness at which the tryer has found they will produce the best work at the draw-bench, to which they are now taken for final adjustment. The rolling-mill in the drag-room was provided with steel rollers, which have been wisely abandoned.

Figs. 1532, 1533, represent the head of the *draw-bench*, the name of which is retained, as being in fact its only appropriate one. The *flatted* end of each fillet is passed into the opening shown. The *dog*, *fig.* 1532, is then run up till its teeth seize the fillet. The lever is depressed until one of the hooks, *f*, catches a bar of the circulating chain, B, which in its onward motion drags the dog, and causes it to bite the fillet and *draw* it through the opening at which it has been entered. B gets its motion from a notched cam, the axle of which is shown at O. There are two distinct chains to each draw-bench, and there are two distinct draw-benches, so that one description does for both double ones. C is a cogged wheel, the shaft of which, O, carries two notched drums, and each drum gives motion to a chain, so that both chains travel at the same pace. C is set in motion by the pinion, D, on the shaft which is driven by the wheel E, *fig.* 1534. E is driven by H, which is on the shaft driven by the strap and drums G. *Fig.* 1533 is a representation of the head of the draw-bench, and in studying this engraving it will be well to refer at the same time to *fig.* 1532. The dog takes its name from its resemblance to the head of a bull-dog. It consists of a pair of levers, whose long arms extend beyond the axle-tree of the wheels *d*, and whose shortest arms are formed by the passing of the other axle-tree through the lever. The teeth are set at the front of the short arms. The axle-tree near *d* is fixed to the bars forming *e*, *f*, and runs loosely between the long arms of the lever, so that when *e*, *f* is pulled forcibly it causes the axle-tree to open the long end of the levers, and thereby to close the short end or teeth of the dog, the more rigidly in proportion to the pressure exerted. Directly the fillet has passed through the cylinders, the dog springs slightly by the elasticity of the fillet, and thus releases itself from the chain B; at the instant of release the weight, *h*, over the foremost wheels falls, and by its fall lifts the hooks *f* so high as to admit of their escaping contact with the circulating chain B. The position of the teeth of the dog is shown between *x*, *x*, in *fig.* 1533.

1532

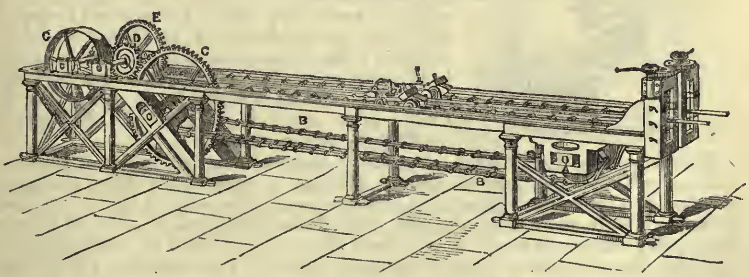


1533



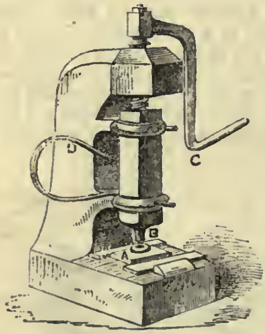
The flatted part of the fillet is just so thin as to admit of its passing easily between the cylinders until seized by the dog, but the part which is not thinned comes against the cylinders, X, and requires considerable force to drag it between them. The cylinders do not rotate; in fact, they may be considered as forming part of a solid mass. As the cylinder wears, the screws of F may be loosened to permit the shifting of the abraded part, so that the whole circumference of the cylinder may be used. The lower cylinder is laid on the bed D, and is clamped there by a cheek fastened on to F by three screws, the holes for which are shown on *x*; the upper cylinder is fixed to the mass, D, by a precisely similar arrangement. The beds C, D, are held perpendicularly by the points of the screws E; and we may now view the cylinders as secured to, and forming part of, their beds. The distance between the cylinders is regulated by the capstans, H, which separate the beds of the cylinders, and so separate the cylinders.

1534



The accuracy of this adjustment is all-important, because the distance between the cylinders determines the thickness of the fillet which passes between them. The bed, D, of the upper cylinder is required to be moveable at pleasure; it is therefore provided with four wedges, two of which, *c*, *c*, are cut so that if looked upon from the top a round hole shows itself, and through this hole the end of the screw G, which at this point, L, is plain, and has a neck turned in it, passes, with its head beneath the wedges and against the upper D. So soon as this is effected the wedges A, B, are pressed into their places, and these holding *c c* together, cause them to secure G by its neck; if, therefore, G be now caused to rise, the block D must rise with it, but the head of this screw rests on the solid block D, while its neck is just so long as to admit of this without itself being pressed against the wedges *c*, *c*. G is a very fine-cut screw, which fits into a female-screw cut in the frame of the head of the draw-bench; it is moved to any distance varying from the 100,000th part of an inch (0·00001) and upwards by the wheel H, which receives a very minute motion from the pinion P by means of a lever, O, fitting into the capstan-head H. K was originally intended to be used to set or fix the screw G when it had been brought to its proper position, but it is not used; for, in fact, the cylinders wear away appreciably by the passage of the fillets, so that they constantly require to be brought nearer together to make up for this wear. With some species of gold the friction is so great that, although oil is used, the cylinders become so hot as to render the gold pasty; in such case a kind of welding takes place, which causes the tearing of the fillet. If this extreme point be not reached, as indeed it seldom is, the cylinders become of varying temperatures, and so great is the effect of this that, in order to compensate for it, the upper cylinder has to be continually raised or depressed. The beds which carry the cylinders become worn by the strain and fret, and require grinding out at intervals; therefore, to allow for the difference which this would make, screws, N, are provided, by which the cylinder in the lower bed can always be raised to its proper position. We cannot but admire the ingenious productions of inventive minds; and surely, if ever there were a marvellous machine for assisting the coiner, it is this; indeed, it may be doubted whether a more admirable instrument for its purpose can be contrived. Sir John Barton, who invented and directed the making of it, took into consideration every circumstance which could possibly arise, but he never saw practically the full advantage of his conception. There are some persons who smile at the draw-bench, but it is one of those inventions which will outlive its detractors, at least so long as economy and perfection are points to be studied in coining. Foreign mints are said to have found no advantage in the use of the draw-bench. It is to be regretted that this instrument has not yet been efficiently used. Mr. J. Martin, of the Paris Mint, has recently made some very accurate experiments with the draw-bench, and has produced results every way in accordance with those obtained by Mr. Ansell in the Royal Mint, and is convinced that the draw-bench may be considered as the coiner's right hand.

1535



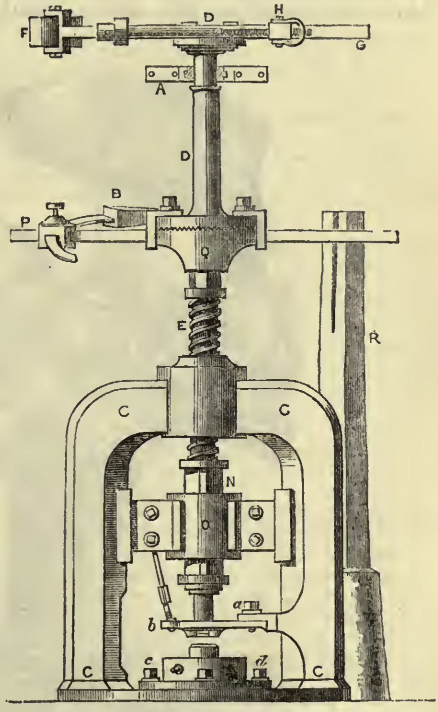
When the fillets have passed between the cylinders of the draw-bench, they are sheared into four lengths by a pair of hand-shears affixed to the bench, and the pieces passed on to the tryer who, by a hand cutting-out press, shown at *fig.* 1535, punches out one or more blanks from each piece of fillet, and weighs it in a delicate balance, placed close beside him, that he may judge if the fillet be likely to produce good blanks. The fillet is placed for this purpose on the bolster, A, and is held in the left hand, while with the right he seizes the handle, C, and pulls it suddenly towards him, when its motion causes a screw with which it is provided to depress the cutter, B, which cuts a blank and pushes it through A, the tryer at the same moment placing his hand under the bench to catch the blank as it falls. The spring, D, is so powerful as to carry back the handle to its original position while the tryer is catching the falling blank.

The fillets, notwithstanding the draw-bench, cannot be brought to perfect accuracy; and, to meet such variations as arise, a difference is made in two of the cutting-out punches, by altering their diameters to such an extent, that a blank cut by them from a standard fillet would vary in weight from a blank cut by them from an ordinary fillet. One cutting-out punch is so altered that a blank would be 0·125 grain, and the other that a blank would be 0·250 grain heavier. This admits of a fillet otherwise too thin being used; but if the fillet be found to err on the other side, it is passed once more either through the draw-bench, or through the mill at a spring-pinch. The tryer should be selected as a peculiarly steady man, possessing a calm judgment, with considerable energy, as upon him depends the accuracy of the whole process of coining; he has not unfrequently so to manage his work that, upon 5,000,000 of sovereigns coined, he should arrive to within one sovereign of the calculated value.

The fillets, having been thrown by the tryer into the receptacles which indicate the particular cutting-out punches to which they are to be taken, are fetched by a man, who wipes off the oil, and then carries them to the cutting-out room, where the fillets are cut into blanks and scissel. The cutting-out presses used in the Royal Mint are very cumbersome, and when in operation are terribly noisy; it is therefore hoped that at no distant period they may be replaced by some of a far more simple construction;

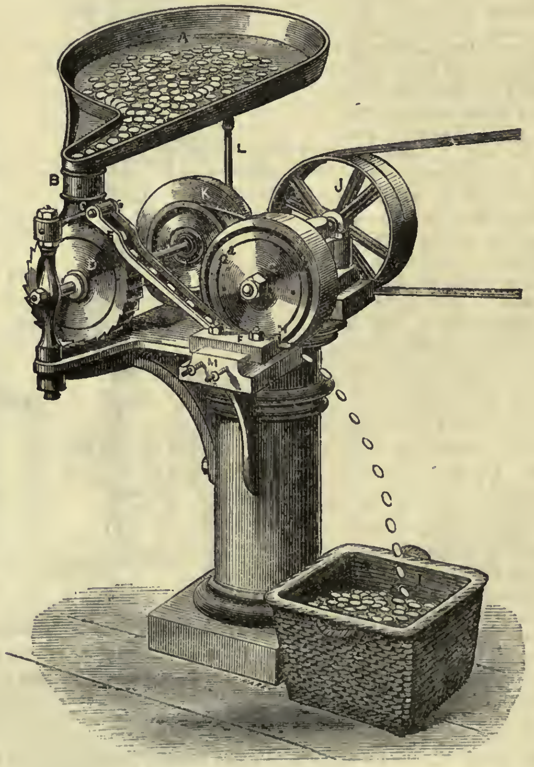
but it is believed that under all circumstances it will be found wise to adhere to the plan of cutting out a single blank at each descent of the punch. For bronze it is well to obtain five or more blanks at each blow, but the limited variation of weight allowed by law on blanks of the precious metals would render this false economy. *Fig.* 1536 represents one of the twelve cutting-out presses, which are all driven by a wheel provided with a series of cams on its outer rim; one of these cams is in the act of striking the friction-roller, F, which is attached to, and forms part of, the lever D. D is fixed to an upright shaft, which at E is cut with a screw-thread working into a female-screw fitted into the main-shoulder of the press at C. If now the cam strikes F, and throws it outwards, it causes the shaft D to take a part of a revolution, and in so doing the screw E makes it rise and carry with it the block N, whose tendency to circular motion is prevented by a plug fitting into its groove, and fixed in the guide O. The lower end of N carries a screwed cap, which supports the cutting-out punch, so that when E rises it carries the cutting-out punch through just the same distance that itself travels upwards. The cutting-out punch is now ready for action, and is released by the continued revolution of the wheel; but, as it could not fall with sufficient force of itself, assistance is rendered by the pressure of the atmosphere, as will be seen by the following arrangement. The lever D is provided at H with a loop of iron travelling on a screw, so that it may be moved farther from, or nearer to, the centre of action, and thus admit of the increase of power. This loop of iron is represented by H, and is continued by a rod of iron across the upper part of the room, and through a hole in the wall to a system of levers, from which a rod is suspended, the lower end being connected with a piston working in a chamber. The chamber is an hermetically-closed vessel secured to a stone firmly fixed in the floor. The piston works in this chamber, and is covered with about 2 inches of oil, which prevents the access of the atmosphere by leaks to any part beneath the piston. If the piston, therefore, be raised from the base of the chamber, a vacuum is produced in that portion from which the piston is removed, and consequently the atmosphere presses on the surface of the oil, which in its turn presses on the piston, and carries it down; in its fall the piston pulls down the cutter, which has been raised; for the same blow which raises the cutter also raises this piston; therefore, when the cutter is raised the workman places the fillet from which blanks are to be cut on the bolster, shown beneath O, and holds it firmly while the cutter descends and punches out a blank, which falls through the bolster into a drawer. By the time that the down-stroke of the cutting-out punch is complete, the wedge B has entered a slit in the spring R, and strikes the spring, thus throwing the machine back, and preparing it to start when the cam shall strike the friction-roller F. The point at which B may strike R is determined by a screw near the left hand P. The upright shaft D, which is partly hollow, terminates at a flat cogged wheel, and the upper part of E is made to pass into D; while at S is an arrangement which serves to detach or connect these pieces, that the cutter may upon occasion be used by the hand by means of the lever T, as well as to admit of the necessary alterations, as the punches, by regrinding, become shorter. The cutting-out punch, when it rises, carries with it the fillet from which the blank has been punched, until the fillet comes against the guard *b*, which detaches it.

1536



The fillets from which the blanks have been punched have the appearance of ribbons perforated with round holes, and are now called *scissel* (from the Latin *scindo*, to cut). These are taken at intervals, and bound up by strips of the same into bundles of 180 ounces—in the case of silver 360 ounces—ready for re-melting. The cutting-out press is set at liberty to start by the workman pressing his foot on a lever in connection with the line and spring; and so long as he keeps this lever down, the press is worked continuously, but when he releases it the spring catches the extreme end of D at G, and motion is arrested. The blanks which accumulate in the box are collected at frequent intervals and examined, to see that their edges are smooth; if they be ragged, as may happen from the wear or fracture of the edge of either the cutter or bolster, a loss of weight would be entailed subsequently which would cause the coin to be outside the prescribed limit, and to pass at an illegal weight into circulation, as the rough edges would be removed after the coining of the blanks had been effected. According to the quality of the work—the character of the gold—under operation, the tryer tests more or less frequently the variations of weight in a given number of blanks. This process is called *pounding*, and is, next to the *trying*, the most important of his

1537



duties; if such an expression can be admitted, he has, by *trying*, fired his shot, and here determines if he has hit the bull's-eye, all depending on his own unaided judgment. The gauge, *fig.* 1528, is found of great service in detecting irregularities as to diameter and thickness, which would not be, and are not, detected by weight, for the weight may remain equal, although both diameter and thickness may vary. All these points require considerable care on the part of those whose duty it is to attend to them; for the quality of a coinage is determined in this room: blanks which once leave it cannot be afterwards altered. The subsequent operations, being purely mechanical, would be quite as well performed by automaton machines.

The completing processes form undoubtedly the prettiest and most interesting part of the operation of coining; nevertheless the processes already described constitute its most essential features. The blanks are weighed from this room in drafts of about

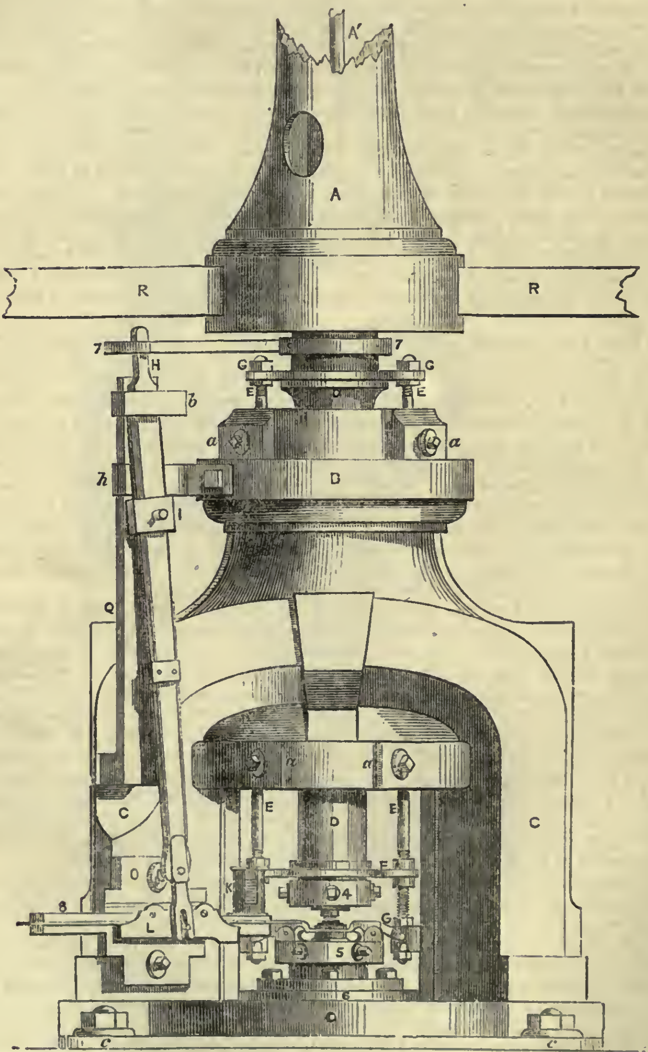
720 ounces, and placed in bags; each bag, therefore, contains four *journeys* of about 180 ounces each. These bags are placed on trucks and taken into the marking-room, where they are emptied, and the blanks submitted to the action of a machine whose operations reduce the diameter of each blank by compressing its edge. It is called Jones's Edge Compressor. *Fig.* 1537 represents Mr. Jones's machine. The blanks are placed in the hopper A, and fall by an incline into a tube B until they rest at C, on a notched wheel D. As D revolves each of its notches carries away the bottom blank of the pile from the tube B, and leaves it to slide down the tube E till it reaches the block F. The block F is cut with a narrow groove, which exactly corresponds with the groove G* on the plate or disc G. The disc G revolves, and as the blank slides down and comes with some little impetus against the groove in the block F, the groove G* catches it, and causes it to take two revolutions between the disc G and the block F, finally permitting its escape at H, when it falls into I, being now reduced in diameter and thicker on the edge, but its centre remaining as it was before. The machine is driven by J, the shaft of which carries a reduced rigger for the driving of K. The hopper is supported by the rod L. The distance between F and G represents the diameter of the blank after its edge is compressed, this distance being determined by the screws seen at M. Blanks of all diameters may be compressed at this machine if the block F and the plate or disc G be removed and replaced by others, neither operation taking many minutes. The edges of the blanks are compressed at the rate of 700 per minute. A boy of fourteen could work this perfectly well, and with more convenience now that the hopper is replaced by such an one as is used to supply Mr. Cotton's weighing machine. The edge of the blank is compressed with a view to prepare it for the *crenating* to be given by the collar in the after process of conversion into a coin.

The blanks are conveyed from the edge-compressor to the annealing-room, where they are freed from oil and placed in copper tubes, some charcoal being sprinkled on them to prevent the action of atmospheric oxygen on the alloy so far as possible. The tubes are then placed on iron carriages, and run into reverberatory furnaces, heated by Juckse's smoke-consuming apparatus, where they remain for an indefinite period. The furnaces are like that represented in the rolling-room for annealing the fillets in copper-tubes. To anneal the blanks, the temperature should be raised rapidly until the tubes attain a full red heat; and the time allowed for the operation should be from twenty to twenty-five minutes at the utmost. After the heating, the tubes are withdrawn from the furnace and placed on the floor of the room, till the blanks are assumed to have become cool. The charcoal is then sifted away, and the blanks cleaned and taken to the press-room to be coined. There are, nevertheless, some soiled blanks, which are blanched in dilute sulphuric acid.

The blanks taken from the annealing-room are each by a single blow of the coining press converted into coins possessing the obverse and reverse impressions, as well as the *crenated* edge, which is one of the means employed to protect the coin from the peculations of the clippers, those enemies to coin of all ages and all countries, but whose business has departed, not so much from the crenated edge as from the better balances placed in the hands of almost every man—certainly within reach of every man. The crenated edge is known to be no protection against the plan called 'sweating,' and which is effected by shaking the new coins in bags, when perhaps an ounce of gold may be obtained from 1,000 new sovereigns. The sovereigns thus treated are passed, and the operator makes his profit, but the light gold is detected by the balance, not by the eye. This is not the place to discuss such a question, so that we pass on to a description of the machine which is used to give the image and superscription to coins which will be current in accordance with the law.

The engraving illustrates Mr. Boulton's screw coining press, which alone we describe, although there are also lever presses in the Mint. The blank is laid by the automaton hand L, on the lower die; L, retires, and the collar then rises and encloses the blank, while the upper die, fixed to the main screw of the press by the securing apparatus 4, comes down with a blow estimated to be about forty tons, and, striking the blank, causes its particles to re-arrange themselves, and to assume the form given by the engraving on the dies and the crenated collar which surround them; in other words, the plain blank becomes by one blow a coin in every way complete. The following description will convey to the reader an explanation of the processes as they arise. The press having been set at rest, with the fullest space between the dies, is called *up*—that is to say, the upper die has been raised from the lower die, and in this position the automaton hand L has conveyed a blank from the tube K to, and holds it over, the lower die; upon the first motion of the press downwards, the eccentric wheel or cam 7 causes the lever H, which works on the pivot 1, to withdraw. The lever H may be lengthened or shortened at pleasure by an arrangement at the lower end. The first motion towards the withdrawal of L causes its finger or hand to open, and to release the blank, which falls upon the face of the lower die. The opening of the finger, or hand, is effected by a pin which works in a slit in the moveable finger of L. The continuation of the motion which draws back L, causes the rods E, which are carried by the main screw D, to release the collar by the levers G. The collar being thus relieved from downward pressure, rises by the elasticity of the springs until it wholly encloses the blank which has been left on the lower die. The rods E pass through the shoulder of the frame of the press, and are destined for

1538



another service besides that just described; for the main screw D, which travels through a female-screw fixed in the frame of the press, thereby receives its power to rise or fall upon each part of a revolution, whereas the upper die must strike the blank a blow just such as would be struck by a hammer, and without a twisting motion; therefore that motion of D is lost just below the lower D, where D fits into a cup suspended rigidly on, and is prevented from twisting by, the rods I, as shown at F.

To the lower part of the cup is fastened 4, which carries the upper die. So that, just at the moment that the levers G have permitted the collar to enclose the blank, the upper die reaches the full force of its blow, and comes upon the blank. The force of the blow, by converting the blank into a coin, causes an instantaneous recoil of the screw D, which is assisted in its rise by a kind of balance just equal to its weight. The nature of this arrangement will be better understood by reference to *fig.* 1538, where the funnel-shaped tube A is seen to be traversed by a rod A′, which terminates in the head of the screw D; the opening in the funnel being for the convenience of fixing this rod to D. At the top is a swivel, where the twisting motion is lost. It is connected at its upper end with a balanced beam, the other end of which is in communication with a partially-exhausted chamber: an arrangement which, while it becomes a counterpoise to the weight of the press, is used as a regulator of the blow to be given, so that it is quite possible to coin blanks of differing denominations by the agency of this chamber without altering the vacuum in the large vessel; for it must be explained that the motive power of the press, that which brings down the die with force, is gained by the pressure of the atmosphere.

As the coined money issues from the press it is collected in trays and examined; all imperfect coins, curiously termed 'brockages,' are picked out; and the good coins weighed into drafts of 701 sovereigns, equal in weight to about 180 ounces; these are at present sent to the weighing-room, where they are examined for imperfect coins, by passing over a kind of blanket, so arranged on a series of rollers that each coin lying on its surface can be seen as the blanket revolves.

1539

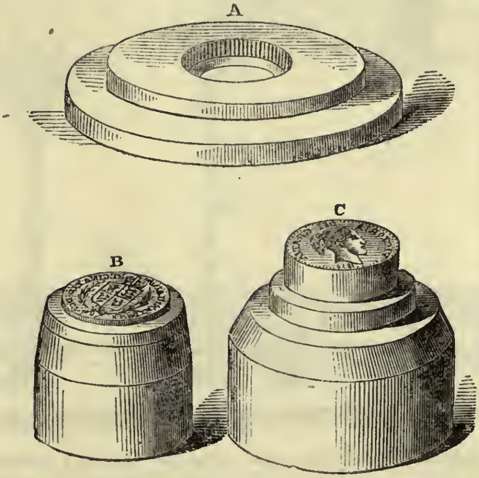


Fig. 1539 gives a view of the milled collar A. B being a representation of the lower die, with its long neck which fits nicely into the milled collar A. C, the upper die, also passes to a small distance into the collar, so that at the moment of the blow the blank is absolutely enclosed. The blow, which is estimated at 40 tons, forces the metal into every engraved part of the collar and dies. The press, which has been described with as few technical terms as possible, coins from 60 to 80 blanks per minute, finishing by one blow the obverse and reverse impressions, and adding the milled edge. (For the manufacture of dies, see DIES.)

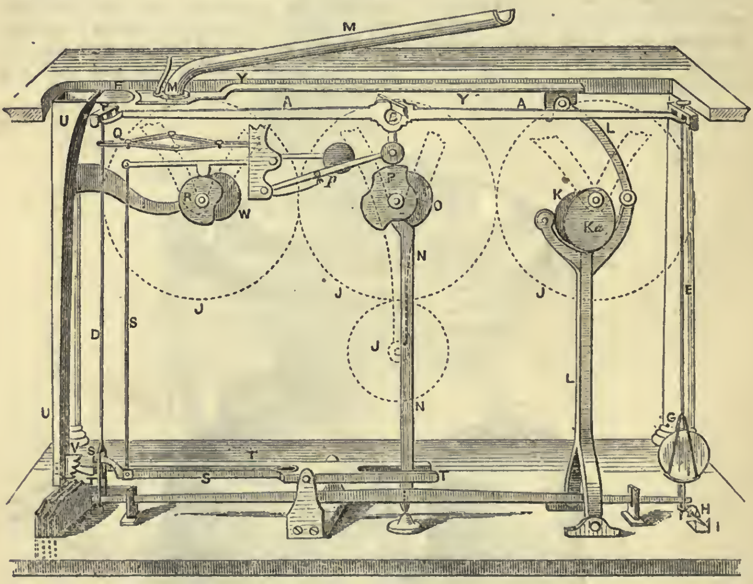
The coins when struck are collected at frequent intervals and carefully overlooked to find any which may be defective, for with all the beauty of the mechanism of the press, accidents cannot be avoided, and it is found that about one coin in 200 is imperfect in its finish whatever its size or value. The imperfect coins are returned, with the ends cut from the bars, the scissel, and the imperfect and out-of-remedy blanks, to the melting-house every morning. The coins are weighed into bags, each containing 701 sovereigns, and at intervals, depending on the requirements of the Bank, sent to the weighing-room, where each coin is weighed separately in Mr. Cotton's balance.

Mr. Cotton's weighing-machines form perhaps the most elegant and clever invention of modern times. They effect the process of weighing far more accurately than man can hope to do; and with extraordinary accuracy determine the weight of about 23 coins per minute. Peculiarly admirable as are these machines, their perfection has been greatly increased by improvements suggested by Mr. Richard Pilcher, who has immediate charge of those in the Royal Mint. Mr. Pilcher, whose inventive genius is only equalled by his desire to give to the public the benefit of his inventions, has rendered these automaton balances serviceable to the Mint; whereas, when they left the hand of Mr. William Cotton, they were of great service to the Bank of England alone, for there only two determinations, or in fact one determination is necessary. In that institution it is required to show that the coins issued by it are not below the legal weight for circulation, whereas the Mint must guarantee that coins leave its works neither above nor below the limits fixed by law; hence the necessity for the incorporation of Mr. Pilcher's improvements with Mr. Cotton's beautiful invention.

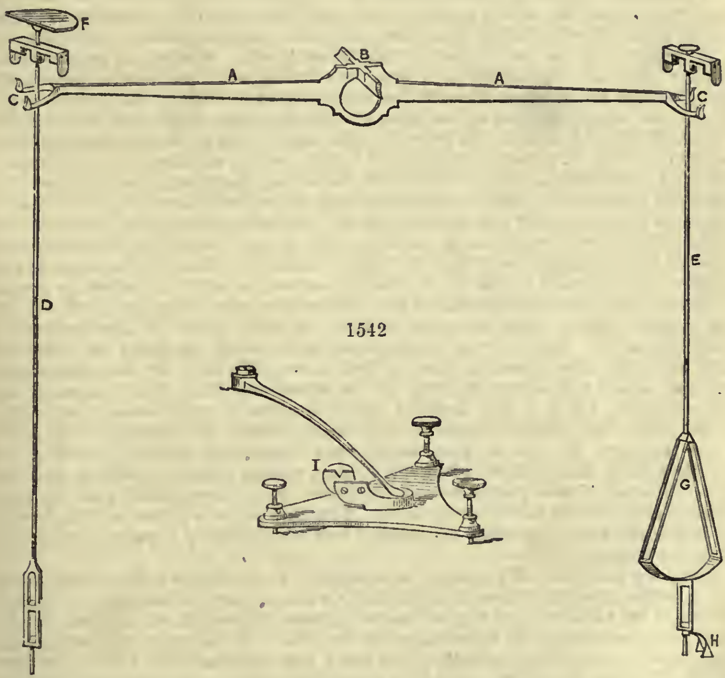
Fig. 1540 exhibits a view of a model of Cotton's automaton machine, for the purpose of illustration; and it should be mentioned that Messrs. D. Napier and Sons are the makers of the machines actually in use.

1540



The whole theory of this balance rests on the fact that the centre of gravity and the centre of action are in one line: either being disturbed, the balance is no longer equal. The machine gains its motion from a shaft fixed to the ceiling of the room. Steam contained in a boiler exists under an ever-varying pressure, arising from the amount of work which it may be necessary for the engine to perform, or from the irregular combustion of the fuel as well as from other causes. Since it is of the utmost importance that the automaton balance should be made to maintain a uniform pace, Messrs. Napier and Sons found it necessary to drive the shaft which gives it motion by a small atmospheric engine, which is placed in the weighing-room. It has been found that a chamber may be kept equably exhausted of air, if the atmosphere be admitted to it by a uniformly-weighted valve. Such a chamber is used in the Mint for other purposes, and Messrs. Napier conducted from this a pipe, by the agency of which the atmospheric engine is worked with a far more even and steady motion than could be obtained by steam; in fact, the exhausted chamber becomes a regulated spring, which softens down the variations in the motion of the steam-engine. The shaft supported by the ceiling conveys its motion to the weighing-machine by a line which, passing over friction-wheels, circulates round a stepped-wheel, which runs loose on the shaft communicating with J. The line is maintained with sufficient rigidity by a weight which is suspended at the end of the lever carrying friction-wheels. The weight is just sufficient to insure the continuous working of the machine, but it is so light as to permit the line to slip in the event of anything going wrong in the works of the balance. When the machine is to be set in motion, a kind of cheek is made—by screwing—to touch the face of the stepped-wheel, and thus, by friction, gives motion to the wheel J. This is an elegant mode of meeting a chance of accident, for in the event of the weight proving to be too heavy, any extra force simply disconnects this cheek from the face, and so stops the machine. The machine having been set in motion, the small wheel J (by communication with the larger wheels, J, all of which are driven by it), causes the cam K *a* to push forward the lever L, which pushes forward the flattened continuation of Y indicated by dotted lines, until it moves a coin placed in the collar at the bottom of the hopper M, on to the scale-pan F, which, for the sake of clearness, is isolated, and will be seen in *fig.* 1541. So soon as the coin has been placed on the scale-pan F, the cam P lowers a lever, *p*, the office of which is to permit the opening of the forceps Q, and thus to release the rod D, dependent from F upon the knife-edge C. The forceps are closed by the cam P, which raises *p*, and by it compresses an attached spring. The forceps are intended to hold *this* rod, D, while the coin is placed on F, because the friction caused by the placing of the coin would have a tendency to push F from the knife-edge on which

1541



1542

it is suspended, and thus blunt its delicate edge. While the forceps are opened the cam O, by its partial revolution, lifts the rod N, which is steadied in its motion by a pin rising from it and entering the inverted arch; its lower extremity working into a socket on the table on which the whole frame of the machine stands.

Towards its lower extremity the rod N will be seen to branch out right and left, until each end passes through a kind of step in the rods D, E, indicated more distinctly in *fig.* 1541. The office of this rod is to bring the beam, from which the rods D, E, are dependent, to a dead level, as well as to release both ends of the beam by one action. At the moment that the forceps Q have released the rod D, the cam O, by N, releases both the rods D, E, by rising from the steps, thus permitting the beam to determine the weight of the blank placed on F. A close inspection of the illustration will show that the rods A are suspended from and rest upon the knife-edges, C, of the beam, A, which has a centre knife-edge, T, by which the whole mass is supported and poised. The knife-edges are made to find their own planes or resting-places upon curved or hollow pieces of steel, thus securing the smallest point of contact with a certainty of the smallest amount of friction. In ordinary balances the substance to be weighed is placed in a pan, which is on the same level as the pan which contains the counterpoise; but in Mr. Cotton's balance this condition is of no consequence, so that the counterpoise rests ultimately upon a point which is at the same distance from the centre of action as the point upon which the matter to be weighed rests. The counterpoise, G, is placed in a kind of cage, and any variation from this standard is at once indicated, even if it reach only to the thousandth part of a grain. By law, the weight of a coin may vary to a certain extent from a standard weight; the variation or latitude allowed is called *remedy*, from the Latin *ad remedium*; and in weighing, this remedy is taken advantage of by a contrivance much simplified by Mr. Pilcher. The weight of a sovereign is 123·274 grains, but it may by law be either 123·474 grains, or it may fall to 123·074 grains. Mr. Pilcher therefore reduced the counterpoise to the minimum allowed, thus avoiding the placing of a remedy-wire for the light side; and he then made the remedy-wire *q* (shown in the first enlarged portion on the left-hand side of the illustration), which is placed on the stand I, upon a peculiarly-formed point indicated in *fig.* 1542, so heavy that any blank which would not raise it and the counterpoise, must be within the remedy on the *heavy* side. In accordance with this arrangement, the continuation of the rod E is terminated by a cage, so that if a coin be so *light* as to be unable to raise the counterpoise until the stirrup comes in contact with the remedy, it is too light to make a legal coin. This fact being determined, the motion of the machine causes the cam K to bring back the rod L, that it may be ready when required to push forward another coin, and the forceps Q to grasp the rod D, while the cam R permits the falling of the rod S, which is nearly counterpoised by the ball *m* (the precise length of the rod being regulated by the screw *j*), until its finger rests upon the indicator. The depth to which S shall fall is fixed by the step (shown in the enlarged portion of *fig.* 1541). This is, of course, determined by the forceps, securing D at the position indicated by the weight of the blank. The indicating-finger having come to rest, the continued motion of the machine causes the cam, W, to permit the shoot, U, to fall until one of its steps, V, comes into contact with the indicating-finger, when the lower part of the shoot must be exactly over, and form part of, one of the tubes which terminate in boxes labelled respectively 'heavy,' 'light,' 'medium.' The shoot having taken its position, the continued motion of the machine causes the cam K to induce the placing of another coin on the scale-pan F, and this coin, by advancing, pushes off the one just weighed, which, falling into and through the shoot, passes to the compartment reserved for it. Suppose the newly-placed coin to be too heavy for forming a legal coin, the same operation goes on, but it now lifts not only the counterpoise, but also causes the stirrup at H to lift the remedy-weight. This is a most delicate operation, for if a blow, however slight, be given, it would cause unsteadiness in the beam. Mr. Pilcher therefore determined to make the carriage, W, *fig.* 1542, which supports the remedy-wire, stand upon micrometer screws, by which the remedy-wire is made just to touch the stirrup, without pressure, while it also rests upon the most minute points, formed by cutting away every part of I which is not actually required—in fact, shelving it out. The scale-pan F is protected from draught by a lantern, while the coins are directed into the collar by a guard, as they slide down the hopper.

Some new machines have recently been supplied to the Mint by Mr. James Napier, but it is not certain that these are cheaper than the old ones. That they are lower in price may be admitted, and they are certainly more convenient in use, from the fact that the wheels shown at F are placed at the back. It is, however, to be regretted that Mr. Napier did not introduce into these new machines the recent inventions of Mr. William Bradshaw, which are supremely simple; and, now that they are effected, one cannot but wonder that so many minds having been engaged on these machines, improvements such as these have not earlier seen the light. To Mr. Bradshaw, particularly, great credit is due, for he was obliged to overcome, not only innate difficulties, but difficulties of position, and these latter were of no mean kind. It is to the credit of the Mint authorities that they finally adopted these improvements, and ordered the necessary alterations to be made in *all* the machines.

Mr. Bradshaw's improvements enable the automaton balances to weigh 30 per cent. more coins in the same time; yet they permit each coin to occupy a longer space of time in being weighed. This would appear to be a mechanical contradiction; but if reference be made to *fig.* 1540, it will be seen that the cam K pushes forward the lever L, which ultimately, by the slide, pushes the blanks on to the scale-pan F. By altering the shape of the cam K, Mr. Bradshaw causes it to do its work more rapidly, and thus leaves the piece on F longer than before; but that this time may not be lost, he alters also the shapes of the cam P, and of the cam O, so that the forceps Q are opened, and the beam is released more rapidly: thus the balance would be longer in action; but to utilise the time ready to be saved, he alters also the driving-pulley J, causing the machine to make 30 per cent. more determinations per minute, and that this may be effected with greater certainty he reduced the depth of the step, shown at V, to just one-half, so that the beam has to travel only half the distance it formerly travelled to determine the position of the light, heavy, or medium piece. He next proceeded to alter the rod N, because he observed that it received a tilting motion, arising from its being lifted by a shoulder, as shown in the woodcut. To overcome this defect he made the rod straight up to a certain point, where he divided it into a kind of loop which passed over the cam O, which, as it revolves, lifts this rod perpendicularly. He still found that the cam, O, had a tendency to push this rod against its bearings, so he placed a spring of brass between the top of its loop and the cam O, and by this contrivance made the cam to lift the brass, and that in its turn to raise the rod N. There was yet another difficulty, caused by an occasional stoppage of the action of the spring which softens the descent of the bearing of the rod, N, into its lower socket; this he removed by cutting a hole in the side of the socket, so that it can be seen at once if the spring be in action.

Great inconvenience arose from the collection of dust, spangles of bullion, and other foreign matter on parts of the balance. This Mr. Bradshaw overcame by two simple contrivances: first, he pierced the bottom of the grooved trays, so that these substances might in a great measure fall through while the blanks were being arranged in rouleaux, thus separating the largest pieces, which, falling down the shoot, would stop its action; and, secondly, he placed a glass shelf midway between the table and the beam, that is, beneath the hopper M, where it terminates, and above the beam A, where it is seen near the forceps Q, thus protecting the beam and forceps. These may appear to be trifling alterations: they are, nevertheless, to Cotton's balance what the compound metal balance-wheel is to a watch. Mr. Pilcher was granted an honorarium of 40*l.* for his invention of the file (to be described), but it is hoped that he and Mr. Bradshaw will be rewarded more generously for their improvements in Cotton's balance; for if, by judicious liberality, encouragements are offered to those in the Civil Service to give to the country the benefit of their inventions, we may hope that Government institutions will bear comparison with ordinary commercial manufactories as regards the developement of inventive genius. Nor is this a small matter, for all the working improvements in the Cotton balance have been made by those whose duty it is to attend to their working; yet no acknowledgment, either direct or indirect, has been made to the officers concerned. It is said that their salaries cover all their time and energy. This may be true, but such a policy is not calculated to result in great steps towards perfecting either machines or processes.

It is well to state that the beam in Mr. Cotton's balance is 8·90 inches in length, and that its weight is 288·41 troy grains.

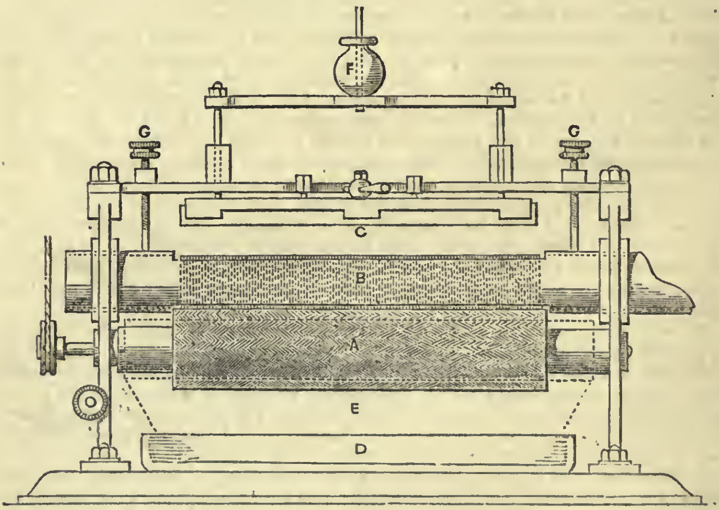
After overlooking, the coins are rung as blanks used to be, and then weighed separately, *all* the rejected going to the melting-pot, by which a waste of 50 per cent. is incurred at the extreme end of an elaborate process; but this unwise course, it is to be hoped, will soon be abandoned when its expensive and perfectly useless extravagance is considered. After the various operations of the weighing-room, the coin is collected and weighed into separate bags, each containing 701 sovereigns; the exact weight of the contents of each bag is noted; and the bags, having been placed in a truck, are taken to the Mint Office, where they undergo what is called *pyxing*, which is simply the selecting from each and every bag a pound weight, from which two coins are taken; each coin is weighed, and its weight recorded. Of these coins one is placed in the hands of the assayer, to determine its value as to per-centage of gold, and the other is sealed in a packet, which is placed in a *pyx* for the trial of THE PYX at Westminster—an ancient process now useless, because any skilled man can detect by assay a deterioration of the coin. These particulars having been taken, the coin is in due course delivered to the officers of the Bank of England, who conduct it in amounts of about 140,000*l.* to the Bank in a waggon.

It is to be regretted that the system so long adopted, and founded on the experience of years, has been altered, to the manifest disadvantage of the public; for it will be observed that under the circumstances which now obtain, there must be an enormous waste at the extreme end of a tedious and expensive process. For all coins which exceed the limits of the remedy, on either the light or the heavy side, are obliged to be remelted, because there is no practicable means by which the light pieces can be increased in weight, or the heavy pieces reduced, so as to bring them within the remedy. Thus, therefore, as much as 50 per cent. of finished coin is uselessly sacrificed. If this loss became one of money value alone it would be hard to bear, but it has, in addition, the effect of reducing the out-turn of the Mint, and has thus caused considerable dissatisfaction amongst the commercial world by producing a great scarcity of coin, for it has happened that so much as 70 per cent. of all the work done has required to be remelted. Now it can be understood if, say 50 per cent. of the work produced be lost, it amounts to a practical reduction of the powers of the Mint, and this reduction, wilfully incurred, has been used as an argument for the necessity of building new mint premises; instead of so expensive a plan being continued, the Mint authorities should return to the proper system of coining, by which the blanks were weighed before coining, and thus such pieces as were too heavy could be reduced by the file.

This file was invented by Mr. Pilcher, who, being the officer of this room, considers his duty to be neglected if there be any improvement capable of being made, but which is left undone: he never tires till the invention is complete, and the machine made. Mr. Albert Barre, the distinguished engraver to the Paris Mint, declares this file to have surmounted all the difficulties he has met with in this part of the process. In his own words, 'It leaves the face of the blank untouched, and free to develope the work of the engraver, which no other file does or can effect, because any metal which is *ploughed* out from the face of a blank leaves a hole which is not filled up in coining.'

Feeling that this much-desired re-introduction will take place, it is thought wise to give the following description of Pilcher's file, which, if not desired for the benefit of our own Mint, will be adopted by other coining countries:—*Fig.* 1543 is a representation of this compact machine. The blanks are placed in rouleaux in a tube, B, which is open at top and at bottom; through the opening at the bottom the blanks rest their *edges* on the file, A, which, as it revolves about 1,000 times per minute, files off metal from the edge of the blank. Each machine has two tubes, and when both have been filled the rod, C, which carries a triangular knife-edge, is released by a lever, and the knife-edge resting upon the upper edge of the blanks, B, with the intention of offering resistance to their rotary motion, enables the operator to remove *much or little* metal from their edges at pleasure by increasing the resistance which C offers by adding a weight, F, on to the gallery. D is a glass dish into which the dust, as it is removed from the edges of the blanks, falls, thus insuring a perfect *separation of the dust* from the blanks. The blanks in B are kept in their position by small blocks of ebony, which are secured by the thumb-screws, G. Motion is given by the wheel, J, which communicates with the driving pulley by a cord or catgut. The whole machine stands on a block of mahogany secured to a table of oak. A hopper of brass shown by dotted lines is provided, with a view to catch flying particles of the precious metals. Each file reduces 250 sovereign blanks per minute.

1543



The coined moneys are rung by boys to detect any which may be dumb or cracked, and which are rejected for melting. Dumb or cracked pieces arise when bubbles of air are enclosed in the bars at the time of pouring the fluid metal into the moulds in the melting-house.

Besides this source of dumb work, may be mentioned another of large occurrence in silver, and occasionally met with in gold, which results from an imperfect mixture of the alloy at the time of melting, and developes itself at the draw-bench, where whole fillets, of six feet long, may be seen to separate into two complete layers of metal, the inner surfaces being coated with a thin film of copper, frequently quite pure, but sometimes in the form of suboxide. It would thus appear that a globule of copper becomes enveloped in a volume of fluid gold or silver, and, in the act of pouring, this globule is drawn out into a kind of wire, perhaps extending some inches in length, enclosed in precious metal. When this is rolled it is all flattened together, but there is no adhesion between the surfaces, so that when the fillet passes through the draw-bench, the lateral motion given to the atoms of the metal causes the slip which finally separates the two surfaces of metal, and the eye at once detects the existence of the fault.

The law enacts that 20 lbs. weight troy of standard or crown gold shall be made into 934·50 sovereigns, and this proportion gives the means of determining the theoretical weight of one sovereign; for if the 20 lbs. troy weight produce 934·50 coins, it is only necessary to divide by that number the number of grains in 20 lbs. troy, and the quotient will represent the weight of a single sovereign, viz., 123·274478330658l059 troy grains; therefore the journey of 701 sovereigns should weigh 180·03210272873l942215 troy ounces, and a million 256821·829855377 troy ounces, equal to 7·8618927506797 tons avoirdupois; hence the War Indemnity of France weighed 1572·37855 tons.

The following measurements, taken from a set of proof coins of the present reign, will convey an idea of the probable size of any coin of the realm; but from the reason before stated, a man need not be disappointed should he find the diameters differ from any he may examine by an accurate gauge. While stating the diameters (which never vary beyond a few thousandths of an inch), it is thought proper to give the legal weight and legal tender of each denomination of coin current in Great Britain:—

	Denomination of Coin	Diameter	Weight in Troy		Legal Tender
		inches	grains	ounces	To the value of—
Gold	Sovereign	0·8680	123·2744	0·2568	The highest sum known.
Gold	Half-sovereign	0·7622	61·6372	0·1284	
Silver	Crown	1·5048	436·3636	0·9090	Forty shillings sterling.
Silver	Half-crown	1·2714	218·1818	0·4545	
Silver	Florin	1·1826	174·5454	0·3636	
Silver	Shilling	0·9296	87·2727	0·1818	
Silver	Sixpence	0·7648	43·6363	0·0909	
Silver	Fourpence	0·6456	29·0909	0·0606	
Silver	Threepence	0·6383	21·8181	0·4545	
Silver	*Maundy*				
Silver	Fourpence	0·6957	29·0909	0·0605	
Silver	Threepence	0·6383	21·8181	0·4545

Bronze	Halfpenny	1·0000	87·5000	0·1822	One shilling ,,
Bronze	Farthing	0·8000	43·7500	0·0911	One shilling ,,

It appears that the Royal Mint should sustain less loss than any other mint by the coining of gold and silver. If allowance be made for the sale of the sweep or dust which results from a coinage, the total loss, inclusive of every operation in coining, should be so small that it might be passed without notice; in fact, there ought to be a minute increase of weight from traces of oil which are left on the fillets to enable them to pass through the cylinders of the draw-bench. By melting there seems to be some loss of metal: this should reach about 100*l.* per million coined; such loss would be wholly explained by refining, through the removal of copper by oxidation; although this is minute, still it is enough to explain the loss which is thus indicated.

[1] Proclaimed illegal since 31st December 1869.

If the assays be closely watched there can be no loss, for the trial of the pyx invariably shows the gold coin to err on the side of purity. Therefore, if the Master of the Mint should determine to issue gold of exact standard, he may fairly cover every source of loss, and coin money without waste of metal. Each grain that is found in excess of the standard upon the pound weight of gold causes a loss of about 180*l*. upon each million coined. The moneyers formerly sustained a loss of about 700*l*. for each million coined, such loss being exclusive of melting. This has never been entirely satisfactory; and the loss by coining alone rarely reached so high an amount, although 373*l*. per million would seem to have been determined by some careful experiments as the necessary loss. This gold, it will be easily conceived, was lost by volatilisation, and by other small sources of water in so extensive an operation as that of coining. Although it is perhaps impossible to avoid all loss, it appears to be reduced to a minimum by the great attention that is now paid to every division of the process.—G. F. A.

MIRABILIS. A genus of plants belonging to the natural order *Nyctaginaceæ.* They are known to the French as *Belles de nuit.* The Peruvian species *Mirabilis jalapa*, or false jalap, has a purgative root, which was formerly mistaken for the true jalap. *M. dichotoma* is the well-known garden flower commonly called the 'Marvel of Peru,' or the *Fleur de quatres heures* of the French.

MIRBANE, ESSENCE OF. A fancy name under which M. C. Collas, of Paris, sold nitrobenzol.

MIRRORS. Under GLASS MANUFACTURE, the process of casting the large plates for mirrors has been described. We have therefore only to describe in this place the preparation of the plate glass and its silvering.

The smoothing of the plates is effected by the use of moist emery washed to successive degrees of fineness, for the various stages of the operation; and the polishing process is performed by rubbers of hat-felt and a thin paste of colcothar and water. The colcothar, called also crocus, is red oxide of iron prepared by the ignition of copperas, with grinding and elutriation of the residuum. See COLCOTHAR.

The last part, the polishing process, is performed by hand. This is managed by females, who slide one plate over another, while a little moistened putty of tin finely levigated is thrown between.

Large mirror-plates are now the indispensable ornaments of every large and sumptuous apartment; they diffuse lustre and gaiety around them, by reflecting the rays of light in a thousand lines, and by multiplying indefinitely the images of objects placed between opposite parallel planes.

The *silvering* of *plane* mirrors consists in applying a layer of tin-foil alloyed with mercury to their posterior surface. The workshop for executing this operation is provided with a great many smooth tables of fine freestone or marble, truly levelled, having round their contour a rising ledge, within which there is a gutter or groove which terminates by a slight slope in a spout at one of the corners. These tables rest upon an axis of wood or iron, which runs along the middle of their length; so that they may be inclined easily into an angle with the horizon of 12 or 13 degrees, by means of a hand-screw fixed below. They are also furnished with brushes, with glass rules, with rolls of woollen stuff, several pieces of flannel, and a great many weights of stone or cast-iron.

The glass-tinner, standing towards one angle of his table, sweeps and wipes its surface with the greatest care, along the whole surface to be occupied by the mirror-plate; then taking a sheet of tin-foil adapted to his purpose, he spreads it on the table, and applies it closely with a brush, which removes any folds or wrinkles. The table being horizontal, he pours over the tin a small quantity of quicksilver, and spreads it with a roll of woollen stuff; so that the tin-foil is penetrated and apparently dissolved by the mercury. Placing now two rules, to the right and to the left, on the borders of the sheet, he pours on the middle a quantity of mercury sufficient to form everywhere a layer about the thickness of a crown piece; then removing with a linen rag the oxide or other impurities, he applies to it the edge of a sheet of paper, and advances it about half an inch. Meanwhile another workman is occupied in drying very nicely the surface of the glass that is to be silvered, and then hands it to the master workman, who, laying it flat, places its anterior edge first on the table, and then on the slip of paper; now pushing the glass forwards, he takes care to slide it along so that neither air, nor any coat of oxide on the mercury can remain beneath the plate. When this has reached its position, he fixes it there by a weight applied on its side, and gives the table a gentle slope, to run off all the loose quicksilver by the gutter and spout. At the end of five minutes he covers the mirror with a piece of flannel, and loads it with a great many weights, which are left upon it for 24 hours, under a gradually-increased inclination of the table. By this time the plate is ready to be taken off the marble table, and laid on a wooden one sloped like a reading-desk, with its under edge resting on the ground, while the upper is raised successively to different elevations by means of a cord passing over a pulley in the ceiling of the room. Thus the mirror has its slope graduated from day to day, till it finally arrives at a vertical position. About a month is required for draining out the superfluous mercury from large mirrors; and from 18 to 20 days from those of moderate size. The sheets of tin-foil being always somewhat larger than the glass-plate, their edges must be pared smooth off, before the plate is lifted off the marble table.

Process for Silvering Concave Mirrors.—Having prepared some very fine Paris plaster by passing it through a silk sieve, and some a little coarser passed through hair-cloth, the first is to be made into a creamy liquor with water, and after smearing the concave surface of the glass with a film of olive-oil, the fine plaster is to be poured into it, and spread by turning about, till a layer of plaster be formed about $\frac{1}{10}$th of an inch thick. The second or coarse plaster, being now made into a thin paste, poured over the first, and moved about, readily incorporates with it, in its imperfectly-hardened state. Thus an exact mould is obtained of the concave surface of the glass, which lies about $\frac{3}{4}$ of an inch thick upon it, but is not allowed to rise above its outer edge.

The mould, being perfectly dried, must be marked with a point of coincidence on the glass, in order to permit of its being exactly replaced in the same position, after it has been lifted out. The mould is now removed, and a round sheet of tin-foil is applied to it, so large that an inch of its edge may project beyond the plaster all round; this border being necessary for fixing the tin to the contour of the mould by pellets of white wax, softened a little with some Venice turpentine. Before fixing the tin-foil, however, it must be properly spread over the mould, so as to remove every wrinkle; which the pliancy of the foil easily admits of, by uniform and well-directed pressure with the fingers.

The glass being placed in the hollow bed of a tight sack filled with fine sand, set in a well-jointed box capable of retaining quicksilver, its concave surface must be dusted with sifted wood-ashes, or Spanish-white contained in a small cotton bag, and then well wiped with clean linen rags to free it from all adhering impurity, and particularly the moisture of the breath. The concavity must be now filled with quicksilver to the very lip, and the mould being dipped a little way into it is withdrawn, and the adhering mercury is spread over the tin with a soft flannel roll, so as to amalgamate and brighten its whole surface, taking every precaution against breathing on it. Whenever this brightening seems complete, the mould is to be immersed, not vertically, but one edge first, and thus obliquely downwards till the centres coincide; the mercury, meanwhile, being slowly displaced, and the mark on the mould being brought finally into coincidence with the mark on the glass. The mould is now left to operate by its own weight in expelling the superfluous mercury, which runs out upon the sand-bag, and thence into a groove in the bottom of the box, whence it overflows by a spout into a leather bag of reception. After half an hour's repose the whole is cautiously inverted, to drain off the quicksilver more completely. For this purpose a box like the first is provided, with a central support rising an inch above its edges; the upper surface of the support being nearly equal in diameter to that of the mould. Two workmen are required to execute the following operation. Each steadies the mould with the one hand, and raises the box with the other, taking care not to let the mould be deranged, which they rest on the (convex) support of the second box. Before inverting the first apparatus, however, the reception-bag must be removed, for fear of spilling the mercury. The redundant quicksilver now drains off; and, if the weight of the sand-bag is not thought sufficient, supplementary weights are added at pleasure. The whole is left in this position for two or three days. Before separating the mirror from its mould the border of tin-foil, fixed to it with wax, must be pared off with a knife. Then the weight and sand-bag being removed, the glass is lifted up with its interior coating of tin-amalgam.

For Silvering a Convex Surface.—A concave plaster mould is made on the convex glass, and their points of coincidence are defined by marks. The mould is to be lined with tin-foil, with the precautions above described; and, the tin surface being first brightened with a little mercury, the mould is then filled with the liquid metal. The glass is to be well cleaned, and immersed in the quicksilver-bath, which will expel the greater part of the metal. A sand-bag is now to be laid on the glass, and the whole is to be inverted, as in the former case, on a support; when weights are to be applied to the mould, and the mercury is left to drain off for several days.

If the glass be of large dimensions, 30 or 40 inches for example, another method is adopted. A circular frame, or hollow ring of wood or iron, is prepared, of twice the diameter of the mirror, supported on three feet. A circular piece of new linen cloth of close texture is cut out, of equal diameter to the ring, which is hemmed stoutly at the border, and furnished round the edge with a row of small holes, for lacing the cloth to the ring, so as to leave no folds in it, but without bracing it so tightly as to deprive it of the elasticity necessary for making it into a mould. This apparatus, being set horizontally, a leaf of tin-foil is spread over it, of sufficient size to cover the surface of the glass; the tin is brightened with mercury, and then as much of the liquid metal is poured on as a plane mirror requires. The convex glass, well cleaned, is now set down on the cloth, and its own weight, joined to some additional weights, gradually presses down the cloth, and causes it to assume the form of the glass, which thus comes into close contact with the tin submersed under the quicksilver. The redundant quicksilver is afterwards drained off by inversion, as in common cases.

The following recipe has been given for silvering the inside of glass globes:—Melt in an iron ladle or a crucible equal parts of tin and lead, adding to the fused alloy one part of bruised bismuth. Stir the mixture well, and pour into it as it cools two parts of dry mercury; agitating anew, and skimming off the drossy film from the surface of the amalgam. The inside of the glass globe being freed from all adhering dust and humidity, is to be gently heated, while a little of the semi-fluid amalgam is introduced. The liquidity being increased by the slight degree of heat, the metallic coating is applied to all the points of the glass, by turning round the globe in every direction, but so slowly as to favour the adhesion of the alloy. The silvering is not so substantial as that of plane mirrors; but the form of the vessel, whether a globe, an ovoid, or a cylinder, conceals or palliates the defects by counter-reflection from the opposite surfaces.

Several processes have been introduced, and some of them patented, for precipitating silver on glass. These have not all been entirely successful, but the phenomena involved are of such an interesting character, that this article would be incomplete without some notice of them.

Mr. Drayton patented a process of the following character:—A solution of nitrate of silver, rendered neutral by the addition of a little ammonia, was floated over a plate of glass; or a vessel intended to be silvered was filled with this fluid; some spirits of wine was mixed with it, and then a small quantity of the oils of cloves and cassia added. By a complicated action, partly physical and partly chemical, metallic silver was separated from the salt in solution, and precipitated over the entire surface of the glass. The metallic film being of sufficient thickness, the solution was poured off, the coating well washed, dried, and protected from abrasion by a thick varnish or paint laid on the back. The defect in mirrors thus prepared was that small specks appeared in the silver, which became little centres of chemical action; the silver tarnishing, and circular spots extending from these points; so that the mirror, either for use or ornament, was ruined. The cause of this may be traced to the compound character of the solutions employed. Nitrate of silver, ammonia, spirits of wine, and essential oils, with water, form a very mechanical mixture, and as the silver fell, it no doubt entangled some of the organic matter, and this, however small, became the starting-point of those stains which eventually destroyed the mirror. Dr. Stenhouse showed that a large number of bodies possess the singular power of precipitating silver from its solution; amongst others, the following: gum-arabic, starch, salicine, gum-guaiacum, saccharic acid, aldehyde, oils of pimento, turpentine, or laurel, and especially grape-sugar.

Mr. Hale Thomson patented a silvering process which involved the use of grape-sugar. A certain portion of grape-sugar is put into a solution of nitrate of silver, rendered as neutral as possible, and a little heat is applied. By this means a beautiful film of very pure silver is spread over the glass. By a process analogous to this Foucault proposed to silver reflectors for lighthouses, and for telescopes. A process has also been patented involving the use of tartaric acid as the precipitating agent.

A method of coating glass with *platinum*, instead of silver, has been introduced in France, and carried out to some extent by Cresswell and Tavernier. A solution of bichloride of platinum is spread with a fine brush over the surface of the glass, and the metal is precipitated by means of oil of lavender.

MISPICKEL is arsenical pyrites. See Arsenic; Pyrites.

MITTLER'S GREEN. This colour has been made in France in limited quantities, for many years past, under the name of emerald green (*vert d'émeraude*), by MM. Pannetier and Binet, who kept their process secret. The great beauty of the product induced many to attempt its imitation. But its nature remained undiscovered; partly, no doubt, because the colour was observed to darken, and to emit steam when heated; circumstances which gave rise to an impression that it contained organic matter. When, at length, M. Guignet discovered the nature of the article, and the method of its production, he immediately patented his discovery, and, thus protected, was emboldened to enter upon its manufacture on a great scale, producing tons where the secret system had produced only pounds.

The preparation of Mittler's green is conducted in the following manner:—

A mixture of bichromate of potash and boracic acid, in the proportion of eight equivalents of crystallised boracic acid to one equivalent of the bichromate, or three parts crystallised boracic acid to one part of the bichromate, is calcined at a red heat. Oxygen and water are evolved, and a mass is obtained, which may be regarded as a double salt consisting of potassio-chromic borate. This is treated with water, which dissolves out boracic acid and borate of potash, leaving an insoluble chromic hydrate, which, when dried at a gentle heat and finely pulverised, constitutes the product in question.

The boracic acid is, of course, recovered from the wash of waters by the ordinary means for use in succeeding operations.

The mode of printing with this powder is similar to that adopted in printing with the ultramarines, albumen being generally employed as the fixing agent. Its use was at the outset attended with considerable practical difficulty, which, however, M. Kestner is stated to have now in a great measure overcome. The precise chemical constitution of this pigment is not yet fully elucidated, especially as to the question whether or not it retains any portion of boracic acid. On this subject, M. Guignet, after having described the process of its manufacture, observes that his product, like the hydrated binoxides of chromium, is converted by heat, first into the black binoxide, and subsequently (at a red heat) into the anhydrous sesquioxide. The loss of water during this transformation appears, from the mean of three analyses, to be 18·5 per cent.; corresponding to the formula, Cr^2O^3. 2HO (**Cr^2O^3. $2H^2O$**), for the hydrate. This would show a proportion of water less than that of the ordinary hydrate, of which it nevertheless presents the general character. On the other hand, M. Guignet conceives that it may possibly retain traces of boracic acid, the presence of which, however, he has found difficult to prove. Boracic acid, acting at a red heat upon bichromate of potash, may, he remarks, produce simultaneously chromic and potassic borate, or even a double compound of the two. Theoretically, this would yield to water soluble potassic borate, leaving behind only the insoluble hydrated oxide; but, in practice, a *complete* exhaustion of the mixed mass is hardly probable.

M. Salvetat, who has studied the *vert de Guignet*, assumes the formation to be a double compound of potassic borate and chromic borate.

Finding that the precise composition of this compound was thus, in fact, unknown, and that no complete analysis of it was extant, Dr. Hofmann was led to request Mr. Shipton, a young chemist working in his laboratory, to analyse the specimen exhibited in 1862 by M. Kestner, and placed by that gentleman at Dr. Hofmann's disposal.

The presence of boracic acid in this specimen was at once unmistakably indicated by the appearance of the characteristic green-edged flame, when a portion of it was exposed on a piece of platinum-foil, to the action of a strong red heat.

Dried at 100° Cent. the substance lost a small percentage of water (from 7·43 to 7·46 per cent.), which loss was increased by ignition. As, however, the determination of water by ignition would, in this case, have been attended with uncertainty, seeing that the partial transformation of the sesquioxide into the binoxide of chromium would have caused the percentage of water expelled to appear less than it really is, Mr. Shipton determined the water directly by strongly heating a portion, dried at 100° Cent. in a current of air, and collecting, in a chloride of calcium tube, the water thus evolved. The chromium was converted by fusion into chromic acid, and the latter determined in the form of chromate of lead. The boracic acid, lastly, was estimated by difference as loss.

Mr. Shipton arrived in this manner at the following percentages:—

Composition of Vert de Guignet after having been dried at 100° Cent.

	I.	II.	Mean.
Oxide of chromium	76·39	76·56	76·47
Boracic acid	11·89	12·30	12·10
Water	11·72	11·14	11·43
	100·00	100·00	100·00

MOCHA STONE. See AGATE.

MOHAIR is the hair of a goat which inhabits the mountains in the vicinity of Angora, in Asia Minor.

We are indebted for this account of mohair to the 'History of the Worsted Manufacture of England,' by James.

Very much akin to, and in Yorkshire rising into importance about the same time as that of alpaca, the mohair manufacture demands attention.

The goat is among the earliest animals domesticated by man, and undoubtedly, from the very earliest ages, the fabrication of stuffs from its hair was practised by the nations of antiquity. Throughout the middle ages the art of making beautiful stuffs from the covering of the goat prevailed.

After the Angora goats have completed their first year, they are clipped annually, in April and May, and yield progressively from 1 lb. to about 4 lbs. weight of hair. That of the female is considered better than the male's, but both are mixed together for the market, with the exception of the *two-year-old she-goat's fleece*, which is kept with the picked hair of other white goats (of which, perhaps, 5 lbs. may be chosen out of 1,000), for the native manufacture of the most delicate articles; none being ever exported in any unwrought state. Common hair is sold in the Angora bazaar for 9 piastres, or about 1*s.* 8½*d.* the oke (that is, 2¾ lbs.), whilst the finest picked wool of the same growth fetched 14 piastres the oke. When the fleeces are shorn, the women separate the clean hair from the dirty, and the latter only is washed, after which the whole is mixed together, and sent to the market. That which is not exported raw is bought by the women of the labouring families, who, after pulling portions loose with their fingers, pass them successively through a large and fine toothed comb, and spin it into skeins of yarn, of which six qualities are made. An oke of Nos. 1 and 3 fetched in the Angora bazaar from 24 to 25 piastres, and the like weight of Nos. 3 to 6 from 38 to 40 piastres. Threads of the first three Nos. had been usually sent to France, Holland, and Germany; those of the last three qualities to England. The women of Angora moisten the hair with much spittle before they draw it from the distaff, and they assert that the quality of the thread greatly depends upon this operation.

Formerly there was a prohibition against the export from Turkey of the Angora hair except when wrought, or in the form of homespun yarn; but about the time of the Greek revolution, this prohibition was removed. Up to that period, however, there had been little demand for the raw material in Europe, so that it sold in the year 1820 at only 10*d.* per pound in England. The reason of the raw material not being in request arose from the belief that, owing to the peculiarity of the fibre, it could not be spun by machinery. It soon, however, became apparent that mohair could be thus spun in England, and this was to be more desired, because the Angora spun-yarn had so many imperfections, from being thick and uneven, as to detract greatly from its value. This object, however, has been obtained, mainly by the perseverance of Mr. Southey, the eminent London wool-broker. Since then the use of the Angora wool has much extended, whilst the importation has much decreased, the English spun-yarn being preferred.

The demand for Angora hand-spun yarn has almost ceased, and its value in Turkey has fallen to one-half. Mohair is transmitted to England chiefly from the ports of Smyrna and Constantinople. In colour it is the whitest known in the trade, and is, consequently, peculiarly adapted for the fabrication of a certain class of goods. Besides Angora, quantities of an inferior sort of mohair are received from other parts of Asiatic Turkey; a very fine description of goat's hair is also sent from that country.

In England mohair is mostly spun, and to some extent manufactured, at Bradford, and also, in a less degree, spun at Norwich. Scotland is also engaged in working up mohair-yarn. At first great difficulty occurred in sorting and preparing the material for spinning, but by patient experiment this has been effectually surmounted, and a fine and even thread produced, fitted for the most delicate webs.

The price of Angora goat's hair has, since its importation into this country, fluctuated very much, partly from the variations in demand, and partly owing to the supply.

The *Importation* of goat's hair or wool—which will include mohair—in 1873 was as follows:—

	lbs.	Value
From Turkey	6,006,016	£752,621
,, British Possessions in South Africa .	348,266	23,850
,, Other countries	133,900	12,535
Total	6,488,182	£789,006

Numerous articles are manufactured from mohair. For instance, many kinds of camblets, which, when watered, exhibit a beauty and brilliancy of surface unapproached by fabrics made from English wools. It is also manufactured into plush, as well as for coach and decorative laces, and also extensively for buttons, braidings, and other trimmings for gentlemen's coats. Besides, it is made up into a light and fashionable cloth, suitable for paletots and such-like coats, combining elegance of texture with the advantages of repelling wet. A few years since, mohair striped and checked textures, for ladies' dresses, possessing unrivalled glossiness of appearance, were in request; but of late these have been superseded by alpaca. For many years the export of English mohair-yarn has been considerable to France.

The trade is enjoyed by Bradford and Norwich, but chiefly by the former place. This yarn is manufactured in France into a kind of lace, which, in a great measure, is substituted for the costly fabrics of Valenciennes and Chantilly. The Angora goat's-hair lace is as brilliant as that made from silk, and costing only about 1*s.* 2*d.* the piece, has come into very general wear among the middle classes. Mohair is also manufactured into fine shawls, selling from 4*l.* to 16*l.* each. Also large quantities of what is termed Utrecht velvet, suitable for hangings and furniture-linings for carriages, are made from it abroad. Recently, this kind of velvet has begun to be manufactured at Coventry, and it is fully anticipated that the English-made article will successfully compete with the foreign one in every essential quality.

MOIRE is the name given to the best watered silks. These silks are made in the same way as ordinary silks, but always much stouter, sometimes weighing, for equal surface, several times heavier than the best ordinary silks. They are always made of double width, and this is indispensable in obtaining the bold waterings, for these depend not only on the quality of the silk, but greatly on the way in which they are folded when subjected to the enormous pressure in watering. They should be folded in such a manner, that the air which is contained between the folds of it should not be able to escape easily; then when the pressure is applied the air, in trying to effect its escape, drives before it the little moisture which is used, and hence causes the watering. Care must also be taken so to fold it that every thread may be perfectly parallel, for if they ride one across the other, the watering will be spoiled. The pressure used is from 60 to 100 tons.

MOIRÉE MÉTALLIQUE, called in this country crystallised tin-plate, is a variegated primrose appearance, produced upon the surface of tin-plate, by applying to it in a heated state some dilute nitro-muriatic acid for a few seconds, then washing it with water, drying, and coating it with lacquer. The figures are more or less beautiful and diversified, according to the degree of heat, and relative dilution of the acid. This mode of ornamenting tin-plate is much less in vogue now than it was a few years ago.

MOLASSE is a sandstone belonging to the miocene strata, employed under that name by the Swiss for building.

MOLASSES is the brown viscid uncrystallisable liquor which drains from cane-sugar in the colonies. It is employed for the preparation of spirits of wine. See Sugar.

MOLYBDENUM (*Molybdène*, Fr.; *Molybdän*, Ger.) is a rare metal which occurs in nature sometimes as a sulphide, sometimes as molybdic acid, and at others as molybdate of lead. Its reduction from the acid state by charcoal requires a very high heat, and affords not very satisfactory results. When reduced by passing hydrogen over the ignited acid, it appears as an ash-grey powder, susceptible of acquiring metallic lustre by being rubbed with a steel burnisher; when reduced and fused with charcoal, it possesses a silver-white colour, is very brilliant, hard, brittle, of specific gravity 8·6; it melts in a powerful air-furnace, oxidises with heat and air, burns at an intense heat into molybdic acid, dissolves in neither dilute sulphuric, muriatic, nor fluoric acids, but in the concentrated sulphuric and nitric.

The protoxide consists of 85·69 of metal and 14·31 of oxygen; the binoxide consists of 75 of metal and 25 of oxygen; and the peroxide, or molybdic acid, of 66·6 of metal and 33·4 of oxygen. This metal is too rare at present to be used in any manufacture.

MOLYBDENUM BLUE. One of the preparations from the bisulphide of molybdenum.

MOMIE or **MUMMY.** A colour prepared from asphalte. It was supposed that the asphalte taken from the Egyptian mummies made the finest colour.

MOONSTONE, a transparent or translucent variety of felspar. It contains bluish-white spots, which, when held to the light, present a pearly or silvery play of colour, not unlike that of the moon. The moonstone is held in some estimation as an ornamental stone, but, in common with the other varieties of felspar, it is so soft that few lapidaries know how to work it to the greatest advantage.—H. W. B.

MORDANT, in dyeing and calico-printing, denotes a body which, having a twofold attraction for organic fibres and colouring particles, serves as a bond of union between them, and thus gives fixity to certain colouring substances, constituting them dyes. In order properly to appreciate the utility and the true functions of mordants, we must bear in mind that many colouring matters, even those forming dark-coloured solutions, have no affinity for the fibre to be dyed. When the goods are passed through such a coloured solution, they become stained only to the extent in which they retain the solution, and if they are afterwards put into water, the colour, being soluble, is all washed out. Suppose the coloured solution to be a decoction of logwood, and that the stuff is passed into it. It may be slightly coloured; but on being washed with water, all the colour is removed. But if, previous to being put through the logwood solution, the stuff be passed through a solution of protochloride of tin, a portion of the tin is retained by it, in virtue of an influence (a condition of capillarity) between the fibre and the salt. There will now be formed a beautiful wine-coloured compound, between the logwood and the tin upon the goods, when they are placed in the logwood-bath, which washing with water will not remove, the compound being insoluble. The tin in this case constitutes the mordant. It is not always essential that the mordant be put upon the fibre previous to being put into the coloured solution; they may be mixed together, and the goods placed in the mixture, when much of the coloured compound will combine with or adhere to the fibre; but, in general, this mode of applying the mordant is not so effective. If, as is usually said, the mordant enters into a real chemical union with the stuff to be dyed, the application of the mordant should obviously be made in such circumstances as are known to be most favourable to the combination taking place; and this is the principle of every day's practice in the dye-house.

Mordants are in general found among the metallic bases or oxides; whence they might be supposed to be very numerous, like the metals; but as they must unite the twofold condition of possessing a strong affinity for both the colouring-matter and the organic fibre, and as the insoluble bases are almost the only ones fit to form insoluble combinations, we may thus perceive that their number may be very limited. It is well known, that although lime and magnesia, for example, have a considerable affinity for colouring particles, and form insoluble compounds with them, yet they cannot be employed as mordants, because they possess no affinity for the textile fibres.

It will be observed from the above remarks, that the mordant serves a higher purpose than the mere bond of union between the colour and fibre; that it, in fact, constitutes a principal element in the colour. The colour forming the dye, in the case with the logwood and tin, is not that of hæmatoxylin, the colouring-matter of logwood; but of the compound formed between it and tin, and thus logwood, by different mordant bases, gives a variety of colours, from a grey to a black, and from a light lavender to a deep purple, &c. When an organic colouring-matter is imparted to any fibre without the intervention of a mordant, it can only produce one tint, which cannot be varied except in being light and dark.

Experience has proved, that of all the bases, those which succeed best as mordants are alumina, tin, and oxide of iron.

Blue-black dye.—The mordant much employed in some parts of Germany for this dye, with logwood, galls, sumach, &c., is *Iron-alum*, so called on account of its having the crystalline form of alum, though it contains no alumina. It is prepared by dissolving 78 pounds of red oxide of iron in 117 pounds of sulphuric acid, diluting this compound with water, adding to the mixture 87 pounds of sulphate of potash, evaporating the solution to the crystallising point. This potassa-sulphate of iron has a fine amethyst colour when recently prepared; and though it gets coated in the air with a yellowish crust, it is none the worse on this account. As a mordant, a solution of this salt, in from 6 to 60 parts of water, serves to communicate and fix a great variety of uniform ground colours, from light grey to brown, blue, or jet black, with quercitron, galls, logwood, sumach, &c., separate or combined. The above solution may be usefully modified by adding to every 10 pounds of the *iron-alum*, dissolved in 8 gallons (80 pounds) of warm water, 10 pounds of acetate (sugar) of lead, and leaving the mixture, after careful stirring, to settle. Sulphate of lead falls, and the oxide of iron remains combined with the acetic acid and the potash. After passing through the above mordant, the cotton goods should be quickly dried.

Colours of the above class are, however, mostly insoluble in water, and have to be dissolved or extracted by an alkaline solvent: and in this state have no affinity either for the fibre or a mordant. Safflower is an instance of this kind; the red colouring-matter of this vegetable is extracted by a weak alkaline lye, into which the goods to be dyed are afterwards put; and the alkali being neutralised by an acid, the colouring-matter is thus rendered insoluble in the liquor, in a state of minute division, and is gradually absorbed by the fibre, which becomes dyed of a red colour in depth according to the quantity of colour absorbed.

Indigo is another dye of this sort requiring an alkaline solvent, and not dyed with mordants. (See Dyeing.)

The following remarks will illustrate some of the necessary requirements of a mordant, which should be attended to by the dyer, in their application.

In order that a combination may result between two bodies, they must not only be in contact, but they must be reduced to their ultimate molecules. The mordants that are to be united with stuffs are, as we have seen, insoluble of themselves, for which reason their particles must be divided by solution in an appropriate vehicle. Now this solvent or menstruum will exert in its own favour an affinity for the mordant, which will prove, to that extent, an obstacle to its attraction for the stuff. Hence we must select such solvents as have a weaker affinity for the mordants than the mordants have for the stuffs. Of all the acids which can be employed to dissolve alumina, for example, vinegar is the one which will retain it with least energy, for which reason the acetate of alumina is now generally substituted for alum, because the acetic acid gives up the alumina with such readiness that mere elevation of temperature is sufficient to effect the separation of these two substances. Before this substitution of the acetate, alum alone was employed; but without knowing the true reason, all the French dyers preferred the alum of Rome, simply regarding it to be purest; and it is not many years since they have understood the real grounds of this preference. This alum has not, in fact, the same composition as the alums of France, England, and Germany, but it consists chiefly of cubic alum having a larger proportion of base. Now this extra portion of base is held by the sulphuric acid more feebly than the rest, and hence it is more readily detached in the form of a mordant. Nay, when a solution of cubic alum is heated, this redundant alumina falls down in the state of a subsulphate, long before it reaches the boiling point. This difference had not, however, been recognised, because Roman alum, being usually soiled with ochre on the surface, gives a turbid solution, whereby the precipitate of subsulphate of alumina escaped observation. When the liquid was filtered, and crystallised afresh, common octahedral alum alone was obtained; whence it was most erroneously concluded, that the preference given to Roman alum was unjustifiable, and that its only superiority was in being freer from iron. See ALUM.

Here a remarkable anecdote illustrates the necessity of extreme caution, before we venture to condemn from theory a practice found to be useful in the arts, or set about changing it. When the French were masters in Rome, one of their ablest chemists was sent thither to inspect the different manufactures, and to place them upon a level with the state of chemical knowledge. One of the fabrics, which seemed to him furthest behindhand, was precisely that of alum, and he was particularly hostile to the construction of the furnaces, in which vast boilers received heat merely at their bottoms, and could not be made to boil. He strenuously advised them to be modelled upon a plan of his own; but, notwithstanding his advice, which was no doubt very scientific, the old routine kept its ground, supported by utility and reputation, and very fortunately, too, for the manufacture; for had the higher heat been given to the boilers, no more genuine cubical alum would have been made, since it is decomposed at a temperature of about 120° F., and common octahedral alum would alone have been produced. The addition of a little alkali to common alum brings it into the same basic state as the alum of Rome.

The two principal conditions, namely, extreme tenuity of particles, and liberty of action, being found in a mordant, its operation is certain. But as the combination to be effected is merely the result of a play of affinity between the solvent and the stuff to be dyed, a sort of partition must take place, proportioned to the mass of the solvent, as well as to its attractive force. Hence the stuff will retain more of the mordant when its solution is more concentrated, that is, when the base diffused through it is not so much protected by a large mass of menstruum; a fact applied to very valuable uses by the practical man. On impregnating in calico-printing, for example, different spots of the same web with the same mordant in different degrees of concentration, there is obtained in the dye-bath a depth of colour upon these spots intense in proportion to the strength of their various mordants. Thus, with the solution of acetate of alumina in different grades of density, and with madder, every shade can be produced, from the fullest red to the lighest pink; and, with acetate of iron and madder, every shade from black to pale violet.

We hereby perceive that recourse must indispensably be had to mordants at different stages of concentration: a circumstance readily realised by varying the proportions of the watery vehicle. (See CALICO-PRINTING and MADDER.) When these mordants are to be topically applied, to produce partial dyes upon cloth, they must be thickened with starch or gum, to prevent their spreading, and to permit a sufficient body of them to become attached to the stuff. Starch answers best for the more neutral mordants, and gum for the acidulous; but so much of them should never be used as to impede the attraction of the mordant for the cloth. Nor should the thickened mordants be of too desiccative a nature, lest they become hard, and imprison the chemical agent before it has had an opportunity of combining with the cloth, during the slow evaporation of its water and acid. Hence the mordanted goods, in such a case, should be hung up to dry in a gradual manner, and when oxygen is necessary to the fixation of the base, they should be largely exposed to the atmosphere. The foreman of the factory ought, therefore, to be thoroughly conversant with all the minutiæ of chemical reaction. In cold and damp weather he must raise the temperature of his drying-house, in order to command a more decided evaporation; and when the atmosphere is unusually dry and warm, he should add deliquescent correctives to his thickening. But, supposing the application of the mordant and its desiccation to have been properly managed, the operation is by no means complete; nay, what remains to be done is not the least important to success, nor the least delicate of execution. Let us bear in mind that the mordant is intended to combine not only with the organic fibre, but afterwards also with the colouring-matter, and that, consequently, it must be laid entirely bare, or scraped clean, so to speak, that is, completely disengaged from all foreign substances which might invest it, and obstruct its intimate contact with the colouring-matters. This is the principle and the object of two operations, to which the names of *dunging* and *clearing* have been given. See CALICO-PRINTING.

If the mordant applied to the surface of the cloth were completely decomposed, and the whole of its base brought into chemical union with it, a mere rinsing or scouring in water would suffice for removing the viscid substances added to it but this never happens, whatsoever precautions may be taken; one portion of the mordant remains untouched, and besides, one part of the base of the portion decomposed does not enter into combination with the stuff, but continues loose and superfluous. All these particles, therefore, must be removed without causing any injury to the dyes. If in this predicament the stuff were merely immersed in water, the free portion of the mordant would dissolve, and would combine indiscriminately with all the parts of the cloth not mordanted, and which should be carefully protected from such combination, as well as the action of the dye. We must therefore add to the scouring-water some substance that is capable of seizing the mordant as soon as it is separated from the cloth, and of forming with it an insoluble compound; by which means we shall withdraw it from the sphere of action, and prevent its affecting the rest of the stuff, or interfering with the other dyes. This result is obtained by the addition of cow-dung to the scouring-bath: a substance which contains a sufficiently large proportion of soluble animal matters, and of colouring particles, for absorbing the aluminous and ferruginous salts. The heat given to the dung-bath accelerates this combination, and determines an insoluble and perfectly inert coagulum.

Thus the dung-bath produces at once the solution of the thickening paste; a more intimate nnion between the alumina or iron and the stuff, in proportion to its elevation of temperature, which promotes that union; an effectual subtraction of the undecomposed and superfluous part of the mordant, and perhaps a commencement of mechanical separation of the particles of alumina, which are merely dispersed among the fibres; a separation, however, which can be completed only by the proper scouring, which is done by the dash-wheel with such agitation and pressure (see BLEACHING) as vastly facilitate the expulsion of foreign particles.

Before concluding this article, we may say a word or two about astringents, and especially gall-nuts, which have been ranked by some writers among mordants. It is rather difficult to account for the part which they play. Of course we do not allude to their operation in the black dye, where they give the well-known purple-black colour with salts of iron; but to the circumstance of their employment for a variety of dyes, and also of dye-drugs, as sapan and Brazil-wood, madder, and logwood, and especially in the dye Adrianople or Turkey red. All that seems to be clearly established is, that the astringent principle or tannin, whose peculiar nature in this respect is unknown, combines like mordants with the stuffs, and fixes a greater quantity of the base upon it, and thus adds depth to the colour, as well as certain peculiarities of tint; but as this tannin has itself a brown tint, it will not suit for white grounds, though it answers quite well for pink grounds. When white spots are desired upon a cloth prepared with oil and galls, they are produced by an oxygenous discharge, effected either through chlorine or chromic acid. See CALICO-PRINTING, and the various MORDANTS there particularised under their respective heads.—J. N.

MOREEN. A stout woollen stuff, which is chiefly employed for curtains.

MORINDA CITRIFOLIA. This was first imported into Glasgow, from India, some years ago. It occurs in pieces of from 2 to 8 centimeters in length, and from 5 to 10 millimeters thick. Externally it is brown, internally yellow: the pigment, or colouring-matter, is exclusively concentrated in the bark; its colour is orange-yellow, and it has been named *morindin*.

The morindin is extracted from the root by exhausting with boiling alcohol; on cooling, the colouring-matter is deposited as an impure flocculent material, mixed with a red substance. This crude material is purified by repeated re-crystallisation, first from alcohol at 50 per cent., and finally from stronger alcohol acidulated with hydrochloric acid. Thus obtained, the substance forms satin-like, needle-shaped, yellow crystals. Morindin is sparingly soluble in cold water, more readily in boiling, but is deposited, on cooling, as a gelatinous mass. It is sparingly soluble in alcohol when cold, but readily when boiling, and best in a weaker spirit; it is insoluble in ether. The aqueous solutions are coloured orange by alkalis; lime- and baryta-water yield red precipitates; while acetate of lead forms a crimson precipitate; a mixture of a few drops of ammonia added to perchloride of iron, causes a brown precipitate in the aqueous solution; while ammoniated alum yields a reddish-yellow precipitate. Morindin dissolves in concentrated sulphuric acid with a deep purple-red colour; the solution, after having been kept for 24 hours, yields, on addition of water, a yellow precipitate, insoluble in water, which re-dissolves in ammonia with a violet colouration.

If submitted to the action of heat, morindin first fuses, and then enters into ebullition, emitting beautiful orange-vapours, which condense to beautiful red needle-shaped crystals, insoluble in water, but soluble in alkaline liquids. with a violet colour. This substance, which Dr. Anderson calls morindin, seems to be the same as that formed under the influence of sulphuric acid. The ammoniacal solution of morindin yields, with alum, a red lake, and gives, upon the addition of baryta-water, a blue precipitate. Morindin is dissolved by cold nitric acid, and decomposed by that liquid at boiling temperature. See Aal.

MORINE. This is the name given by Gerhardt to the principal colouring-matter of the *Morus tinctoria* or *old fustic*, a large tree which grows in many parts of the West Indies, and on the American Continent. It is used principally for dyeing woollens or silks, seldom or ever as a solitary colour, but as a ground-work for other colours, as in the dyeing of wools and silks black, in which process it greatly improves the black. It is used with indigo to form a green, and with salts of iron to yield an olive hue. The colouring-matter was first separated by Chevreul. It is extracted from the wood by boiling water, which, on cooling, when concentrated, deposits it as yellow crystalline powder, which must be purified by several crystallisations. It has the composition $C^{36}H^{16}O^{20}$ ($\mathbf{C^{18}H^{16}O^{10}}$). It possesses a sweetish and astringent taste; one part dissolves in 6·4 parts of cold water, and in 2·14 parts of boiling water. The solution is slightly acid, and precipitates salts of iron of a dark green colour; with salts of lead and protochloride of tin, it forms deep yellow precipitates. It is not precipitated by alum until after the addition of carbonate of potash, when a yellow lake is formed.

Concentrated sulphuric acid dissolves it in the cold, forming a yellow solution, from which it is again precipitated by diluting with water. It is readily soluble in alcohol and ether; insoluble in spirits of turpentine and the fatty oils. Alkalis deepen the colour of its solutions. See Fustic.

MORINGA. The seeds of the *Moringa pterygosperma* have been used for the oil they contain. These have been examined and reported on by Mr. Dugald Campbell, who says of the oil they yield:—'This oil is the very opposite to a dry oil, being extremely rich in fatty substances, and is of specific gravity 915·60 at 60° Fahr., water taken as 1·000. When it is kept cooled for a short time to 44° it becomes opaque, from crystals of the fatty substances forming throughout it, and it is now very viscid and thick. In this state it may be heated up to 65° before it assumes its original brightness. It is nearly tasteless, and almost without odour.' This oil is called *Oil of Ben*, and is much used by watchmakers. See Ben Oil.

MOROCCO. See Leather.

MORPHINE. *Syn.* Morphia. (*Morphine*, Fr.; *Morphin*, Ger.) $C^{34}H^{19}NO^{6} + 2$ aq. ($\mathbf{C^{17}H^{19}NO^{3} . H^{2}O}$). An organic base, contained (amongst others) in opium. As it is the substance upon which the sedative properties of opium depend, great attention has been paid to its extraction. Numerous processes have been devised for the purpose; but perhaps that of Gregory is, in facility and economy, as good as any. The aqueous infusion is precipitated by chloride of calcium to remove the meconic and sulphuric acids present. The filtered fluid is evaporated until the hydrochlorate of morphine crystallises out, so as to form a nearly solid mass, which is then strongly pressed: the liquid exuding contains the colouring-matters and several alkaloïds. The pressed mass is crystallised and squeezed repeatedly, and, if necessary, bleached with animal charcoal. The hydrochlorate, which contains a little codeine, is to be dissolved in water, and precipitated by ammonia; pure morphia precipitates, and the codeine remains in solution. The salts of morphia most employed in medicine are the hydrochlorate, the acetate, and the sulphate. A solution of five grains of morphia in one ounce of water is about the same strength as laudanum. *Apomorphia* is a remarkable base, obtained by Matthiessen and Wright by heating morphia for several hours in a closed tube with excess of hydrochloric acid. It may also be prepared, by a similar method, from codeine. Apomorphia differs from morphia in containing $H^{2}O^{2}$ ($\mathbf{H^{2}O}$) less; its formula is therefore $C^{34}H^{17}NO^{4}$ ($\mathbf{C^{17}H^{17}NO^{2}}$).

MORTAR. A mixture of lime with water and sand. The sand used in making mortar should be *sharp*—that is angular, not round—and *clean*—that is, free from all earthy matter, or other than siliceous particles. Hence *road-scrap-*

ings always, as being a mixture of sand and mud, and *pit-sand* generally, as being scarcely ever without a portion of clay, should be washed before they are used; which is seldom necessary with *river-sand*, this being cleaned by the flowing water.

'I have ascertained by repeated experiments that 1 cubic foot of well-burned chalk-lime fresh from the kiln, weighing 35 lbs., when well mixed with 3½ cubic feet of good river-sand, and about 1¼ cubic foot of water, produced above 3¼ cubic feet of as good mortar as this kind of lime is capable of forming. A smaller proportion of sand, such as two parts to one of lime, is, however, often used, which the workmen generally prefer; both because it requires less time and labour in mixing, which saves trouble to the labourers, and it also suits the convenience of the masons and bricklayers better, being what is termed *tougher*, that is, more easily worked, but it does not by any means make such good mortar. If, on the other hand, the sand be increased to more than the above proportion of 3½, it renders the mortar *too short*, that is, not plastic enough for use, and causes it also to be too friable, for excess of sand prevents mortar from setting into a compact adhesive mass. In short, there is a certain just proportion between these two ingredients which produces the best mortar, which I should say ought not to be less than 3, nor more than 3½, parts of sand to 1 of lime; that is when common chalk-lime, or other pure limes, are used, for different limes require different proportions. When the proportion of sand to lime is stated in the above manner, which is done by architects as a part of their specification or general directions for the execution of a building, it is always understood, when nothing is expressed to the contrary, that the parts are by fair level measure of the lime, and by stricken measure for the sand; and the lime is to be measured in lumps, in the same state in which it comes from the kiln, without slaking, or even breaking it into smaller pieces.'—*Pasley.*

MORTAR, HYDRAULIC, is the kind of mortar used for building piers or walls under or exposed to water, such as those of docks, &c. See HYDRAULIC CEMENT.

MOSAIC. (*Mosaïque*, Fr.; *Mosaisch*, Ger.) There are several kinds of mosaic, but all of them consist in imbedding fragments of differently-coloured substances, usually glass or stones, in a cement, so as to produce the effect of a picture. The beautiful chapel of Saint Lawrence in Florence, which contains the tombs of the Medici, has been greatly admired by artists on account of the vast multitude of precious marbles, jaspers, agates, aventurines, malachites, &c., applied in mosaic upon its walls. The detailed discussion of this subject belongs to a treatise upon the fine arts, but the progress of the invention is so curious that some brief notice of mosaic-work in general will not be out of place.

When, with his advancing intelligence, man began to construct ornamental articles to decorate his dwelling, or to adorn his person, we find him taking natural productions, chiefly from the mineral kingdom, and combining them in such a manner as will afford, by their contrasts of colour, the most pleasing effects. From this arose the art of mosaic, which appears, in the first instance, to have been applied only to the combination of dice-shaped stones (*tesseræ*) in patterns. This was the *opus musivum* of the Romans; improving upon which, we have the Italians introducing the more elaborate and artistic *pietra dura*, now commonly known as Florentine work. It is not our purpose to treat of any of the ancient forms of mosaic-work, further than it is necessary to illustrate the subject before us. The *opus tesselatum* consisted of small cubes of marble, worked by hand into simple geometrical figures. The *opus sectile* was formed of different crusts or slices of marble, of which figures and ornaments were made. The *opus vermiculatum* was of a far higher order than these: by the employment of differently-coloured marbles, and, where great brilliancy of tint was required, by the aid of gems, the artists produced imitations of figures, ornaments, and pictures, the whole object being portrayed in all its true colours and shades.

The advance from the *opus vermiculatum* to the fine mosaic-work, which had its origin in Rome, and is, therefore, especially termed Roman mosaic, was easy; and we find this delicate manufacture arising to a high degree of excellence in the city where it originated, and to which it has been almost entirely confined, Venice being the only city which has attempted to compete with Rome. To this art-manufacture we more especially direct attention, since a description of it will aid us in rendering intelligible the most interesting and peculiarly novel manufacture of mosaic rug-work, as practised by the Messrs. Crossleys. Roman, and also Venetian enamels, are made of small rods of glass, called indiscriminately *paste* and *smalt*. In the first place, cakes of glass are manufactured in every variety of colour and shade that are likely to be required. These cakes are drawn out into rods more or less attenuated, as they are intended to be used for finer or for coarser work, a great number being actually threads of glass. These rods and threads are kept in bundles, and arranged in sets corresponding to their colours, each division of a set presenting every desired shade. A piece of dark slate or marble is prepared, by being hollowed out like a box, and this is filled with plaster-of-Paris. Upon this plaster the pattern is drawn by the artist, and the *mosaicisti* proceeds with his work by removing small squares of the plaster, and filling in these with pieces cut from the rods of glass. Gradually, in this manner, all the plaster is removed, and a picture is formed by the *ends of the filaments of coloured glass*; these are carefully cemented together by a kind of mastic, and polished. In this way is formed, not only those exquisitely delicate mosaics which were, at one time, very fashionable for ladies' brooches, but tolerably large and often highly-artistic pictures. Many of our readers will remember the mosaic landscapes which rendered the Italian Court of the Great Exhibition so attractive; and in the Museum of Practical Geology will be found a portrait of the late Emperor of Russia, which is a remarkably good illustration of mosaic-work on a large scale. We may remark, in passing, that the whole process of glass-mosaic is well illustrated in this collection.

The next description of mosaic-work requiring a word is the manufacture of Tunbridge. The wood-mosaics of Tunbridge are formed of rods of wood, varying in colour, laid one upon the other, and cemented together, so that the pattern, as with the glass-mosaics, is produced by the ends of the rods.

MOSAIC GOLD. For the composition of this peculiar alloy of copper and zinc, called also *Or-molu*, Messrs. Parker and Hamilton obtained a patent in November 1825. Equal quantities of copper and zinc are to be 'melted at the lowest temperature that copper will fuse,' which, being stirred together so as to produce a perfect admixture of the metals, a further quantity of zinc is added in small portions, until the alloy in the melting-pot becomes of the colour required. If the temperature of the copper be too high, a portion of the zinc will fly off in vapour, and the result will be merely spelter or hard solder; but if the operations be carried on at as low a heat as possible, the alloy will assume first a brassy-yellow colour; then, by the introduction of small portions of zinc, it will take a purple or violet hue, and will ultimately become perfectly white, which is the appearance of the proper compound in its fused state. This alloy may be poured into ingots; but as it is difficult to preserve its character when re-melted, it should be cast directly into the figured moulds. The patentees claim exclusive right of compounding a metal consisting of from 52 to 55 parts of zinc, out of 100.

Mosaic gold, the *aurum musivum* of the old chemists, is a sulphuret of tin. See Alloys.

MOSAIC WOOL-WORK. There is no branch of manufacture which is of a more curious character than the mosaic wool-work of the Messrs. Crossleys of Halifax.

By referring to the article Mosaic there will be no difficulty in understanding how a block of wood, which has been constructed of hundreds of lengths of coloured specimens, will, if cut transversely, produce a great number of repetitions of the original design. Suppose, when we look at the transverse section presented by the end of a Tunbridge block, we see a very accurately-formed geometric pattern; this is rendered perfectly smooth, and a slab of wood is glued to it. When the adhesion is secure, as in a piece of veneering for ordinary cabinet-work, a very thin slice is cut off by means of a circular saw, and then we have the pattern presented to us in a state which admits of its being fashioned into any article which may be desired by the cabinet-maker. In this way, from one block, a very large number of slices can be cut off, every one of them presenting exactly the same design. If lengths of worsted are substituted for those of glass or of wood, it will be evident that the result will be in many respects similar. By a process of this kind the mosaic rugs—with very remarkable copies from the works of some of our best artists—are produced. In connection with this manufacture, a few words on the origin of this kind of work will not be out of place.

The tapestries of France have been long celebrated for the artistic excellence of the designs, and for the brilliancy and permanence of the colours. These originated in France, about the time of Henry IV., and the manufacture was much patronised by that monarch and his minister Sully. Louis XIV. and Colbert, however, were the great patrons of the beautiful productions of the loom. The minister of Louis bought from the brothers Gobelins their manufactory, and transformed it into a royal establishment, under the title of *Le Teinturier Parfait*. A work was published in 1746 in which it was seriously told that the dyes of the Gobelins had acquired such superiority that their contemporaries attributed the talent of these celebrated artists to a paction which one or the other of them had made with the devil.

In the Gobelins and Beauvais tapestry we have examples of the most artistic productions, executed with a *mechanical* skill of the highest order, when we consider the material in which the work is executed. The method of manufacture, involving artistic power on the part of the workman, great manipulatory skill, and the expenditure of much time, necessarily removes those productions from the reach of any but the wealthy. Various attempts have been made, from time to time, to produce a textile fabric which should equal those tapestries in beauty, and which should be sold to the public at much lower prices. None of these appear to have been successful, until the increasing applications of india-rubber pointed to a plan by which high artistic excellence might be combined with moderate cost. In Berlin, and subsequently in Paris, plans (in most respects similar to the plan we are about to describe) were tried, but in neither instance with complete success. Of course, there cannot now be many of our readers who have not been attracted by the many life-like representations of lions and dogs which have for the last few years been exhibited in the carpet-warehouses of the metropolis, and other large cities. While we admit the perfection of the manufacture, we are compelled to remark that the designs which have been chosen are not such as appear to us to be quite appropriate, when we consider the purposes for which a rug is intended. However, from their very attractive character and moderate cost, those rugs find a large number of purchasers, by whom they are doubtless greatly admired. It will, however, be obvious to our readers, that they are not consistent with the principles of design, and that there is a want of consistency in the idea of treading upon the 'monarch of the forest,' copied with that remarkable life-likeness which distinguishes the productions of Sir Edwin Landseer; or in placing one's feet in the midst of dogs or of poultry, when the resemblances are sufficiently striking to impress you with the idea that the dogs will bark and that the cock will crow. We believe that less picturesque subjects, in accordance with the law—which we conceive to be the true one—which gives true beauty only to that which is, in its applications, consistent and harmonious, would be yet greater favourites than those rugs now manufactured by the Messrs. Crossleys. And amidst the amount of good which these excellent men are doing to all who come within their influence, we are certain they might, with the means at their command, introduce an arrangement of colours which might delight by their harmonious blending, and a system of designs which, pure and consistent, should ever charm the eye, without attempting to deceive either it, or any of the senses. Every attempt to advance the taste of a people is worthy of all honour; and having the power, as the manufacturers of the mosaic rugs have, of producing works of the highest artistic excellence, we should be rejoiced to see them employing that power to cultivate amongst all classes a correct perception of the true and the beautiful.

With these remarks we proceed to a description of the manufacture.

Every lady who has devoted herself for a season, when it was the fashion to do so, to Berlin wool-work, will appreciate the importance of a careful arrangement of all the coloured worsteds which are to be used in the composition of her design. Here, where many hundreds of colours, combinations of colours, and shades are required, in great quantities and in long lengths, the utmost order is necessary; and the system adopted in this establishment is in this respect excellent. We have, for example, grouped under each of the primary colours, all the tints of each respective colour that the dyer can produce, and between each large division the mixtures of colour producing the neutral tones, and the interblending shades which may be required to copy the artist with fidelity. Skeins of worsted thus arranged are ever ready for the English *mosaicisti* in rug-work. Such is the material. Now to describe the manner of proceeding. In the first place an artist is employed to copy, of the exact size required for the rug, a work of Landseer's, or any other master, which may be selected for the purpose. Although the process of copying is in this case mechanical, considerable skill is required to produce the desired result. This will be familiar to all who have observed the peculiar characteristics of the Berlin wool-work patterns. The picture being completed, it is ruled over in squares, each of about twelve inches. These are again interruled with small squares, which correspond with the threads of which the finished work is to consist. This original being completed, it is copied upon lined paper by girls who are trained to the work, each girl having a square of about twelve inches to work on. These are the copies which go into the manufactory. A square is given to a young woman whose duty it is to match all the colours in wool. This is a task of great delicacy, requiring a very fine appreciation of colour. It becomes necessary in many cases to combine two threads of wool, especially to produce the neutral tints. It is very interesting to observe the care with which every variety of colour is matched. The skeins of worsted are taken, and a knot or knob being formed so as to increase the quantity of coloured surface, it is brought down on the coloured picture; and when the right shades have been selected, they are numbered, and a corresponding system of numbers are put on the pattern. In many of the rugs one hundred colours are employed. The selector of colours works under the guidance of a master, who was in this case a German gentleman, and to his obliging and painstaking kindness we are much indebted. Without his very exact description of every stage of the process, it would not have been easy to render this rare mosaic-work intelligible to our readers. When all the coloured wools have been selected, they are handed, with the patterns, to young women, who are termed the 'mistresses of a frame,' each one having under her charge three little girls.

The 'frame' consists of three iron stands, the two extreme ones being about 200 inches apart, and the other exactly in the middle. These stands are made of stout cast iron, and may be said to consist of two bowed legs, with two cross pieces of iron, one at the top of the legs, and the other about fifteen inches below, the space between them being that which is to be occupied by the threads of wool which are to form the required square block of wool. These frames are united together by means of cast-iron tubes, running from end to end. The observer is struck with the degree of strength which has been given to these frames. It appears that, for the purpose of merely holding together a few threads of wool, a much slighter frame might have been employed; and we certainly were surprised when we were informed that, at first, many frames were broken, and that they were compelled to have the stronger ones at present in use. The cause of this will be obvious, when we have proceeded a little further with our description. At one end of these frames sits the 'mistress,' with a stand before her, on which the pattern allotted to her is placed, and a vertical frame, over which the long coloured worsteds are arranged. By the side of this young woman sits a little girl, who receives each worsted from the mistress, and hands it to one of two children, who are on either side of the frame.

Commencing at one corner of the pattern, a thread is selected of the required colour, and handed to the first girl, who passes it to the second, whose duty it is to fasten it to a stiff, but slight bar of steel, about half an inch in width, which passes from the upper to the under bar of the frame. The third girl receives the thread, and carries it to the lower end of the frame, and fastens it to a similar bar of steel at that end. The length of each thread of worsted is rather more than 200 inches. It is well known that twisted wool does not lie quite straight without some force is applied to it; and of course the finished pattern would be incomplete, if all the threads did not observe the truest parallelism to each other. To effect this, a stretching force equal to four pounds is required to every thread. The child who carries the thread, therefore, pulls the worsted with this degree of force, and fastens it over the steel bar. Every block, forming a foot-square of rug-work, consists of fifty thousand threads; therefore, since every thread pulls upon the frame with a force equal to four pounds, there is a direct strain to the extent of 250,000 pounds upon the frame. When this is known, our surprise is no longer excited at the strength of the iron-work; indeed, the bars of hardened steel, set edgeways, were evidently bent by the force exerted.

Thread after thread, in this way, the work proceeds, every tenth thread being marked by having a piece of white thread tied to it. By this means, if the foreman, when he examines the work, finds that an error has been committed, he is enabled to have it corrected by removing only a few of the threads, instead of a great number, which would have been the case if the system of marking had not been adopted.

This work, requiring much care, does not proceed with much rapidity, and the constant repetition of all the same motions through a long period would become exceedingly monotonous, especially as talking cannot be allowed, because the attention would be withdrawn from the task in hand. Singing has therefore been encouraged, and it is exceedingly pleasing to see so many young, happy, and healthy faces performing a clean and easy task, in unison with some song, in which they all take a part. Harmonious arrangements of colour are produced, under the cheerful influence of harmonious sounds. Yorkshire has long been celebrated for its choristers, and some of the voices which we heard in the room devoted to the construction of the wool-mosaics bore evidence of this natural gift, and of a considerable degree of cultivation.

The 'block,' as it is called, is eventually completed. This, as we have already stated, is about a foot square, and it is 200 inches long. Being bound, so as to prevent the disturbance of any of the threads, the block is cut by means of a very sharp knife into ten parts, so that each division will have a depth of about 20 inches. Hearth-rugs are ordinarily about eight feet long, by about two feet wide, often, however, varying from these dimensions. Supposing, however, this to represent the usual size, twelve blocks, from as many different frames, are placed in a box, with the threads in a vertical position, so that, looking down upon the ends, we see the pattern. These threads are merely sustained in their vertical order by their juxtaposition. Each box, therefore, will contain 800,000 threads. The rug is now, so far as the construction of the pattern is required, completed; and the cost of producing the 'block,' of 200 inches in depth, eight feet in length, and two feet wide, including the cost of wool, and the payment for labour, is little short of 800*l*. When, however, it is known that these threads are subsequently cut into the length required to form the rug, and that these lengths are but the three-sixteenths of an inch in depth, it will be evident that the number of these beautiful carpets which can thus be obtained renders the manufacture fairly remunerative. The boxes into which the rugs are placed are fixed on wheels, and they have moveable bottoms, the object of which will be presently understood. From the upper part of the immense building devoted to carpet manufacture, in which this mosaic rug-work is carried on, we descend with our rug to the basement story. Here we find, in the first place, steam chests, in which india-rubber is dissolved in camphine. It may not be out of place to observe that camphine is actually spirits of turpentine, carefully rectified, and deprived of much of its smell, by being distilled from either potash or soda. Recently-prepared camphine has but little of the terebinthinous odour, but if it is kept long, and especially if it is exposed to the air, it again acquires, with the absorption of oxygen, its original smell. This is of course avoided in the manufacture of such an article as an hearth-rug as much as possible. The camphine is used as fresh as possible, and in it the india-rubber is dissolved, until we have a fluid about the consistence of, and in appearance like, carpenter's glue.

In an adjoining room were numerous boxes, each one containing the rug-work in some of the stages of manufacture. It must now be remembered that each box represents a completed rug—the upper ends of the thread being shaved off, to present as smooth a surface as possible. In every stage of the process now all damp must be avoided, as wool, like all other porous bodies, has a tendency to absorb and retain moisture from the atmosphere. The boxes, therefore, are placed in heated chambers. and they remain there until all moisture is dispelled; when this is effected, a layer of india-rubber solution is laid over the surface, care being taken in the application that every thread receives the proper quantity of the caoutchouc; this is dried in the warm chamber, and a second and a third coat is given to the fibres. While the last coat is being kept in the warm chamber, free from all dust, sufficiently long to dissipate some of the camphine, the surface on which the rug is to be placed receives similar treatment. In some cases ordinary carpet canvas only is employed; in others, a rug made by weaving in the ordinary manner is employed, so that either side of the rug can be turned up in the room in which it is placed. However this may be, both surfaces are properly covered with soft caoutchouc, and the 'backing' is carefully placed on the ends of worsted forming the rug in the box. By a scraping motion, the object of which is to remove all air-bubbles, the union is perfectly effected; it is then placed aside for some little time, to secure by rest that absolute union of parts between the two india-rubber surfaces which is necessary. The separation of the two parts is after this attended with the utmost difficulty; the worsted may be broken by a forcible pull, but it cannot be removed from the india-rubber. The next operation is that of cutting off the rug; for this purpose a very admirable, but a somewhat formidable machine is required. It is in principle, a circular knife, of twelve-feet diameter, mounted horizontally, which is driven by steam-power, at the rate of 170 revolutions in a minute.

The rug in its box is brought to the required distance above the edge of the box by screwing up the bottom. The box is then placed on a rail, and connected with a tolerably fine endless screw. The machine being in motion, the box is carried by the screw under the knife, and by the rapid circular motion, the knife having a razor-like edge, a very clean cut is effected. As soon as the rug is cut off to the extent of a few inches, it is fastened by hooks to strings which wind over cylinders, and thus raise the rug as regularly as it is cut. This goes on until the entire rug is cut off to the thickness of three-sixteenths of an inch. The other portion in the box is now ready to receive another coating, and the application of another surface, to form a second rug, and so on, until about one thousand rugs are cut from the block prepared as we have described.

MOSS AGATE, or **MOCHA STONE.** A variety of chalcedony enclosing dendritic or moss-like markings of an opaque brownish-yellow colour, which are produced by oxide of manganese or iron. It was the *dendrachates* of the ancients.

MOTHER-OF-PEARL (*Nacre de Perles*, Fr.; *Perlenmutter*, Ger.) is the hard, silvery, brilliant internal layer of several kinds of shells, particularly oysters, which is often variegated with changing purple and azure colours. The large oysters of the Indian seas alone secrete this coat of sufficient thickness to render their shells available to the purposes of manufactures. The genus of shell-fish called *Pentadinæ* furnishes the finest pearls, as well as mother-of-pearl; it is found in greatest perfection round the coasts of Ceylon, near Ormus in the Persian Gulf, at Cape Comorin, and among some of the Australian seas. The brilliant hues of mother-of-pearl do not depend upon the nature of the substance, but upon its structure. The microscopic wrinkles or furrows which run across the surface of every slice act upon the reflected light in such a way as to produce the chromatic effect; for Sir David Brewster has shown that if we take with very fine black wax, or with the fusible alloy of D'Arcet, an impression of mother-of-pearl, it will possess the iridescent appearance. Mother-of-pearl is very delicate to work, but it may be fashioned by saws, files, and drills, with the aid sometimes of a corrosive acid, such as the dilute sulphuric or muriatic; and it is polished by colcothar of vitriol.

MOTHER-WATER is the name of the liquid which remains after all the salts that will regularly crystallise have been extracted, by evaporation and cooling, from any saline solution.

MOULDS, ELASTIC. Being much engaged in taking casts from anatomical preparations, Mr. Douglas Fox, surgeon, Derby, found great difficulty, principally with hard bodies, which, when undercut, or having considerable overlaps, did not admit of the removal of moulds of the ordinary kind, except with injury. These difficulties suggested to him the use of elastic moulds, which, giving way as they were withdrawn from complicated parts would return to their proper shape; and he ultimately succeeded in making such moulds of glue, which not only relieved him from all his difficulties, but were attended with great advantages, in consequence of the small number of pieces into which it was necessary to divide the mould.

The body to be moulded, previously oiled, must be secured one inch above the surface of a board, and then surrounded by a wall of clay, about an inch distant from its sides. The clay must also extend rather higher than the contained body: into this warm melted glue, as thick as possible so that it will run, is to be poured so as to completely cover the body to be moulded: the glue is to remain till cold, when it will have set into an elastic mass, just such as is required.

Having removed the clay, the glue is to be cut into as many pieces as may be necessary for its removal, either by a sharp-pointed knife, or by having placed threads in the requisite situations of the body to be moulded, which may be drawn away when the glue is set, so as to cut it out in any direction.

The portions of the glue-mould having been removed from the original, are to be placed together and bound round by tape.

In some instances it is well to run small wooden pegs through the portions of glue, so as to keep them exactly in their proper positions. If the mould be of considerable size, it is better to let it be bound with moderate tightness upon a board to prevent it bending whilst in use; having done as above described, the plaster-of-Paris, as in common casting, is to be poured into the mould, and left to set.

In many instances wax may also be cast in glue, if it is not poured in whilst too hot; as the wax cools so rapidly when applied to the cold glue, that the sharpness of the impression is not injured.

Glue has been described as succeeding well where the elastic mould is alone applicable; but many modifications are admissible. When the moulds are not used soon after being made, treacle should be previously mixed with the glue (as employed by printers), to prevent it becoming hard.

The description thus given is with reference to moulding those bodies which cannot be so done by any other than an elastic mould; but glue moulds will be found greatly to facilitate casting in many departments, as a mould may be frequently taken by this method in two or three pieces, which would, on any other principle, require many.

MOUNTAIN BLUE. Blue copper ore. See Copper.

MOUNTAIN CORK. A form of asbestus. See Asbestus.

MOUNTAIN GREEN. Malachite, or green carbonate of copper. See Copper.

MOUNTAIN LEATHER. Asbestus is so called when it is so interlaced that the fibrous structure is not apparent. See Asbestus.

MOUNTAIN LIMESTONE. A term commonly applied to the carboniferous limestone, on account of its masses forming some of our finest mountain scenery. It may be regarded as the boundary rock of nearly all our coal-formations. See Carboniferous Limestone.

MOUNTAIN SOAP (*Savon de montagne*, Fr.; *Bergseife*, Ger.) is a tender mineral, soft to the touch, which assumes a greasy lustre when rubbed, and falls to pieces in water. It consists of silica 44, alumina 26·5, water 20·5, oxide of iron 8, lime 0·5. It occurs in beds, alternating with different sorts of clay, in the Isle of Skye, at Billin in Bohemia, &c. It has been often, but improperly, confounded with steatite.

MUCIC ACID (*Acid mucique*, Fr.; *Schleimsäure*, Ger.) is the same as the saclactic acid of Scheele, and may be obtained by digesting one part of gum arabic, sugar-of-milk, or pectic acid, with twice or thrice their weight of nitric acid. It forms white granular crystals, and has not been applied to any use in the arts.

MUCILAGE is a solution in water of gummy matter of any kind.

MUFFLE is the earthenware case or box, in the assay furnaces, for receiving the cupels, and protecting them from being disturbed by the fuel. See Assay.

MULBERRY OIL. A flavouring essence introduced by Mr. Condy, which consists chiefly of suberic ether. See Suberic Acid.

MULBERRY PAPER. The *Broussonetia papyrifera*; the inner bark of this species is used in China for the preparation of a kind of paper, and in Polynesia for the production of a peculiar cloth.

MULBERRY TREE. The *Morus nigra* is the common mulberry, and *M. alba* the white mulberry. The leaves of both species are used for feeding silkworms.

MULE. A machine for spinning cotton. See Cotton Spinning.

MULHOUSE BLUE. The name given to one of the aniline colours prepared by Gros, Renaud, and Schaeffer, of Mulhouse. It is formed by boiling the solution of rosaniline salt (nitrate is generally used) with a solution of gum-lac and carbonate of sodium. See Aniline.

MUM. A malt liquor made in Brunswick with wheat meal and oat and bean meal.

MUNDIC is the name of iron or arsenical pyrites among Cornish miners.

MUNGO (sometimes also termed *Shoddy*) is the artificial wool formed by tearing to pieces, and completely disintegrating old woollen cloths or garments, or even pieces of new cloth, such as tailor's clippings.

MUNJEET or East Indian madder, the *Rubia Munjista*. See Madder.

MUNJISTINE. An orange colouring-matter contained together with purpurine in munjeet. This colouring-matter has been so thoroughly investigated by Dr. Stenhouse, that it cannot be better described than in his own words. His paper in the 'Proceedings of the Royal Society of London,' vol. xii. p. 633, is entitled 'Preliminary Notice of an Examination of *Rubia Munjista*, the East Indian Madder, or Munjeet of commerce:'

'It is rather remarkable that while few vegetable substances have been so frequently and carefully examined by some of the most eminent chemists as the root of the *Rubia tinctorum* or ordinary madder, the *Rubia Munjista* or munjeet, which is so extensively cultivated in India, and employed as a dye-stuff, has been, comparatively speaking, very much overlooked, never having been subjected, apparently, to anything but a very cursory examination.

'From some incidental notices of munjeet in Persoz and similar writers, and a few experiments which I made some years ago, I was led to suspect that the colouring-matters in munjeet, though similar, are by no means identical with those of ordinary madder, and that probably the alizarine or purpurine of madder would be found to be replaced by some corresponding colouring principle. This hypothesis I have found to be essentially correct, for the colouring-matter of munjeet, instead of consisting of a mixture of alizarine and purpurine, contains no alizarine at all, but purpurine and a beautiful orange colouring-matter, crystallising in golden scales, to which I purpose giving the name of *munjistine*. Munjistine exists in munjeet in considerable quantity, and can therefore be easily obtained.

'The colouring-matter of munjeet may be extracted in various ways: that which I have found most suitable is as follows: each pound of munjeet in fine powder is boiled for four or five hours with 2 pounds of sulphate of alumina and about 16 pounds of water. The whole of the colouring-matter is not extracted by a single treatment with sulphate of alumina; the operation must be repeated, therefore, two or three times. The red liquid thus obtained is strained through cloth filters while still very hot, and the clear liquid acidulated with hydrochloric acid. It soon begins to deposit a bright red precipitate, the quantity of which increases on standing, which it should be allowed to do for about twelve hours. This precipitate is collected on cloth filters and washed with cold water till the greater portion of the acid is removed. It is then dried, reduced to a fine powder, and digested in a suitable extracting apparatus with boiling bisulphide of carbon, which dissolves out the crystallisable colouring principles of the munjeet, and leaves a considerable quantity of dark-coloured resinous matter. The excess of the bisulphide of carbon having been removed by distillation, the bright red extract, consisting chiefly of a mixture of munjistine and purpurine, is treated repeatedly with moderate quantities of boiling water and filtered. The munjistine dissolves, forming a clear yellow liquid, while almost the whole of the purpurine remains on the filter. When the solution is acidulated with hydrochloric or sulphuric acid, the munjistine precipitates in large yellow flocks. These are collected on a filter and washed slightly with cold water. The precipitate is then dried by pressure and dissolved in boiling spirits of wine, slightly acidulated with hydrochloric acid to remove any adhering alumina. As the munjistine does not subside from cold alcoholic solutions, even when they are largely diluted with water, about three-fourths of the spirit are drawn off by distillation, when the munjistine is deposited in large yellow scales. By two or three crystallisations out of spirit in the way just described, the munjustine is rendered perfectly pure.

'I have likewise succeeded in extracting munjistine directly from munjeet by boiling it with water, filtering the solution, which has a dark brownish colour, and then acidulating with hydrochloric acid. The precipitate which falls is collected on a filter, washed, dried, and treated with boiling spirits of wine, which leaves a large quantity of pectine undissolved.

'The munjistine which dissolves in the alcohol is obtained in a pure state by repeated crystallisations in the way already indicated. The first process which I have described is, however, by far the best. The colouring-matter of munjeet can likewise be extracted with boiling solutions of alum; but I find sulphate of alumina greatly preferable, as the alum by its tendency to crystallise very much impedes the filtration of the liquids. I likewise attempted to employ Professor C. Hopp's process with sulphurous acid, which gives such excellent results with ordinary madder, but I found it wholly inapplicable to munjeet.

'Munjistine, prepared by the processes described, when crystallised out of alcohol, forms golden-yellow plates of great brilliancy. It is but moderately soluble in cold, but dissolves pretty readily in boiling water, forming a bright yellow solution, from which it is deposited in flocks when the liquid cools. Saturated solutions almost gelatinise. It dissolves to some extent in cold, but more readily in boiling, spirit of wine, and is not precipitated by the addition of water. It dissolves in carbonate of soda with a bright red colour. In ammonia it forms a red solution with a slight tinge of brown caustic soda, producing with it a rich crimson colour. Both its aqueous and alcoholic solutions, when boiled with alumina, form beautiful flakes of a bright orange colour, almost the whole of the munjistine being withdrawn from solution. The flakes are soluble in a large excess of caustic soda, with a fine crimson colour. Munjistine dyes cloth mordanted with alumina a bright orange. With iron mordant it yields a brownish-purple colour, and with Turkey-red mordant a pleasing deep orange. These colours are moderately permanent, and bear the application of bran and soap tolerably well. The munjistine sensibly modifies the colours produced by munjeet, giving the reds a shade of scarlet, as has been long observed.

'Commercial nitric acid dissolves munjistine with a yellow colour, but does not appear to decompose it even on boiling. Fuming nitric acid (1·5) dissolves munjistine in the cold, and on application of heat decomposes it, no oxalic acid being produced. It readily dissolved in cold sulphuric acid with a bright orange colour; and the solution may be heated nearly to boiling without blackening or giving off sulphuric acid; it is reprecipitated by water in yellow flocks apparently unaltered. When bromine water is added to a strong aqueous solution of munjistine, a pale-coloured flocculent precipitate is immediately produced; this, when collected on a filter, washed and dissolved in hot spirit, furnishes minute tufts of crystals, evidently a substitution-product. I may remark in passing, that when alizarine is treated with bromine water in a similar way, it also forms a substitution-product, crystallising in needles.

'Munjistine, in some of its properties, bears considerable resemblance to Runge's madder orange, the *rubiacine* of Dr. Schunck; it is, however, essentially different from rubiacine in several of its properties, such as its solubility in water and alcohol, &c., and in the amount of its carbon—rubiacine, according to Dr. Schunck's analysis, containing 67·01 per cent. of that element, while munjistine contains only 64. The spectra afforded by solution of the two substances, as may be seen from the following extract from a letter received from Professor Stokes, are decidedly different:—

'"The two substances are perfectly distinguished by the very different colour of their solution in carbonate of soda, when a small quantity only of substance is used. The solution of munjistine is red, inclining to pinkish orange, that of rubiacine a claret-red. The tints are totally different, and indicate a different mode of absorption. Both present a single minimum in the spectrum, but while that of rubiacine extends from about D to F, that of munjistine extends from a good way beyond D to some good way beyond F. The beginning and end of the band in each case are not very definite, and vary of course with the strength of the solution; there can be no doubt of the radical difference in the position of the band of absorption. In this way it is easy to convince oneself that the difference of the colour is not to be explained by the possible admixture of some small impurity present in one or other of the specimens. With caustic potash, munjistine gives as nearly as possible the same colour as rubiacine, agreeing with the colour of rubiacine in carbonate of soda. There appears to be a slight difference in the spectrum of the munjistine and rubiacine solutions, but not enough to rely on; so that the substances are not to be distinguished by their solutions in *caustic* alkalis.

'A second perfectly valid distinction is, however, afforded by the different colour of the fluorescent light of the ethereal solutions. The solid substances themselves and their ethereal solutions are fluorescent to a considerable degree; but the tint of the fluorescent light of the ethereal solution of rubiacine is orange-yellow, while that of the ethereal solution of munjistine is yellow inclined to green. The examination in a pure spectrum shows that the difference is not due to the admixture of a small impurity, itself yielding a fluorescent solution; but the tints may be readily contrasted by daylight, almost without apparatus, by the method I have described in a paper, "On the Existence of a Second Crystallisable fluorescent Substance in the Bark of the Horse-chestnut" ("Quart. Journal Chem. Soc. vol. ii., p. 20). I consider either of the two points of difference I have mentioned sufficient by itself to establish the non-identity of munjistine and rubiacine."

'The purpurine which I succeeded in extracting from munjeet and in purifying from munjistine in the way already described, formed beautiful dark crimson needles having all the usual properties of that substance. When examined by Professor Stokes, they gave the very characteristic spectra of purpurine.

'*Tinctorial Power of Munjistine and Munjeet.*—Professor Runge stated in 1835 that munjeet contained twice as much available colouring-matter as the best Avignon madder. This result was so unexpected, that the Prussian Society for the Encouragement of Manufactures, to whom Professor Runge's memoir was originally addressed, referred the matter to three eminent German dyers, Messrs. Dannenberger, Böhn, and Nobiling. These gentlemen reported, as the result of numerous and carefully conducted experiments, that so far from munjeet being richer in colouring-matter than ordinary madder, it contained considerably less. This conclusion has been confirmed by the experience of my friend Mr. John Thorn, of Birkacre near Chorley, one of the most skilful of the Lancashire printers.

'From a numerous series of experiments I have just completed, I find that the garancine from munjeet has about half the tinctoral power of the garancine made from the best madder, viz. Naples roots. These, however, yield only about 30 to 33 per cent. of garancine, while munjeet, according to my friend Mr. Higgin of Manchester, yields from 52 to 55 per cent. Taking the present prices, therefore, of madder at 36 shillings per cwt. and munjeet at 30 shillings, it will be found that there will be scarcely any pecuniary advantage in using munjeet for ordinary madder-dyeing. The colours from munjeet are certainly brighter, but not so durable as those from madder, owing to the substitution of purpurine for alizarine. There is, however, great reason to believe that some of the Turkey-red dyers are employing garancine from munjeet to a considerable extent. When this is the case they evidently sacrifice fastness to brilliancy of colour. By treating such a garancine with boiling water, and precipitating by an acid in the way already described, its sophistication with munjeet may very readily be detected. The actual amount of colouring-matter in munjeet and the best madder is very nearly the same; but the inferiority of munjeet as a dye-stuff results from its containing only the comparatively feeble colouring-matters, purpurine and munjistine, a small portion of the latter being useful, whilst the presence of munjistine in large quantities appears to be positively injurious. So much is this the case that when the greater part of the munjistine is removed from munjeet-garancine by boiling water, it yields much richer shades with alumina mordants than before.'

MUNTZ'S METAL. A brass composed generally of 40 parts of zinc to 60 of copper. These proportions may be somewhat varied, but the above are commonly regarded as the most favourable for rolling into sheets. The metal being properly melted is cast into ingots, heated to a red heat, and rolled into sheathing, and worked into ship's bolts at that heat. It will not work well at a lower heat. This metal was originally patented by the late G. F. Muntz, of Birmingham, in 1832. It has to a large extent superseded the use of copper sheathing, as being cheaper, and at the same time keeping the ships' bottoms cleaner.

MUREX. This genus, belonging to the Mollusca, contains many beautiful shells, from which the Tyrian purple of the ancients was probably obtained.

MUREXANE. The purpuric acid of Prout.

MUREXIDE. Syn. *Purpurate of Ammonia.* $C^{16}H^{8}N^{6}O^{12}$ (**$C^{8}H^{8}N^{6}O^{6}$**). Murexide is one of those substances which, although investigated by many chemists of great reputation, has long been regarded as of uncertain constitution. This is the more remarkable from the fact that, owing to its extreme beauty it has always attracted a large amount of attention. It is invariably formed when the product of the action of moderately strong nitric acid on uric acid is treated with ammonia. This process, however, is rather valuable as a test of the presence of uric acid than as a method of procuring murexide. Dr. Gregory who has given much attention to the best methods of preparing the substance in question, has published the following formula for working on the small scale:—'Four grains of alloxantine and seven grains of hydrated alloxan are dissolved together in half an ounce by measure of water by boiling, and the hot solution is added to one-sixth of an ounce by measure of a saturated or nearly saturated solution of carbonate of ammonia, the latter being cold. This mixture has exactly the proper temperature for the formation of murexide; and it does not, owing to its small bulk, remain too long hot. It instantly becomes intensely purple, while carbonic acid is expelled; and as soon as it begins to cool the beautiful green and metallic-looking crystals of murexide begin to appear. As soon as the liquid is cold, these may be collected, washed with a little cold water, and dried on filtering-paper.'

The analyses of murexide are rather discordant, the carbon in all of them being in excess. This arises from the very large amount of nitrogen present, a certain portion becoming acidified passes into the potash apparatus, causing an undue increase in its weight. The following are the principal analyses:—

	Liebig and Wöhler	Liebig	Fritzsche	Beilstein	Calculation
Carbon . .	34·08	34·40	34·93	34·18	C^{16} 33·80
Nitrogen . .	32·90	31·80	30·80	30·35	N^{6} 29·58
Hydrogen . .	3·00	3·00	2·83	3·11	H^{6} 2·82
Oxygen . .	30·02	30·80	31·44	32·36	O^{12} 33·80

There appears no doubt whatever that the formula $C^{16}N^{6}H^{6}O^{12}$ represents its true composition. Murexide is formed when uramile, murexane, or dialuramide, as it is sometimes called, is boiled with peroxide of mercury. Dr. Gregory regarded murexane as a separate substance, and as identical with purpuric acid; he also considered $C^{6}N^{2}H^{4}O^{5}$ as its probable formula. This appears from more recent researches to be incorrect, as murexane is doubtless the same substance as uramile, while purpuric acid, which is bibasic, is represented by the formula $C^{16}H^{5}N^{5}O^{12}$. The formulæ above given for murexide and uramile renders the reaction of peroxide of mercury with the latter easily intelligible; it is, in fact, a very simple case of oxidation, thus:—

$$\underbrace{2C^{8}N^{3}H^{5}O^{6}}_{\text{Uramile.}} + 2O = \underbrace{C^{16}N^{6}H^{6}O^{12}}_{\text{Murexide.}} + 2HO \quad (\mathbf{C^{8}N^{6}H^{10}O^{6} + O = C^{8}N^{6}H^{8}O^{6} + H^{2}O}).$$

The limits of this work preclude any further notice of the scientific relations of murexide, but it is necessary that we should consider it in its character as a dye-stuff. It has been found that murexide forms a series of beautiful compounds with certain metallic oxides, more especially lead and mercury, and these compounds have been employed to a very large extent in the dyeing, and more especially printing, of cotton goods. It is plain that if uric acid were only obtainable from the urine of serpents or the sediments from the urine of mammalia, it could never be made use of in the arts. It happens, however, that the solid urine of birds contains it in large quantity, and since we have become acquainted with the vast deposits of guano existing in various parts of the globe, the manufacture of murexide has been carried out on a scale which would, a few years ago, have appeared impossible. We must, in order to be clear, divide the process into two parts: one being the preparation of uric acid from guano, the other the conversion of the acid into murexide.

Preparation of Uric Acid from Guano.—In order to get rid, as much as possible, of the impurities contained in the guano, it is in the first place to be treated with muriatic acid, which will remove carbonate and oxalate of ammonia, carbonate and phosphate of lime, and ammonio-magnesian phosphate. The uric acid will also be liberated from the substances with which it may be in combination. The operation may be performed in a leaden vessel, heated with a leaden coil, through which steam passes. It is essential to success that the guano be added slowly, otherwise the violent effervescence, which is caused by the decomposition of the carbonates by the acid, would cause the liquid to escape from the vessel. The mixture of guano and muriatic acid is then to be heated for an hour, after which it may be run off into tubs to be washed with water by decantation. The first washings contain a large quantity of ammonia in the state of sal-ammoniac; it should be worked up in some way, in order to prevent the loss of so valuable a salt. As soon as the residue of the guano is sufficiently washed it may be transferred to cloth filters and allowed to drain. The residue from the action of muriatic acid upon 200 lbs. of guano can now be treated by Braun's process for the extraction of the uric acid, It is to be placed in a copper boiler of sufficient capacity, and boiled for an hour with 8 lbs. of caustic soda and 120 gallons of water. It must be constantly stirred. Two or three pounds of quicklime are now to be slaked, enough water is then to be added to make the whole into a thin paste, which is to be poured into the mixture of caustic soda and guano residue. After a quarter of an hour's boiling the fire is to be removed, and the whole allowed to repose until clear. The bright liquid having been syphoned off from the residue, the latter is to be treated with 120 gallons more water and 6 lbs. of soda; 2 lbs. of slaked lime are also to be added in the same manner as in the first operation. The lime is for the purpose of removing extractive matter, and it has been found that it does not do to use it in any other manner than that described. If the soda and lime be allowed to react upon the guano residue at the same time, urate of lime is formed, which, owing to its comparative insolubility, causes much trouble in the subsequent operations.

The two alkaline fluids containing the urate of soda are to be precipitated while warm by a moderate excess of hydrochloric acid. The precipitated uric acid is then to be washed with water and dried.

Conversion of Uric Acid into Murexide by Braun's Process.—In the first place a very large bath of cold water must be provided, having a number of earthenware basins floating upon it. Into each of these basins $2\frac{1}{8}$th lbs. of nitric acid are to be poured, the strength of the acid being 36° Beaumé. One pound and three quarters of the uric acid, prepared as above, is now to be added by very small quantities at a time. If the temperature rises above 90° F. the whole is to be allowed to cool before adding any more uric acid. If the water in the bath be so cold that the temperature falls so low as to stop the reaction, it may be set up again by adding warm water to the bath, or, more conveniently, by sending some steam into it for a short time. At first the uric acid need only be added to the nitric acid by sprinkling it on the surface; towards the end of the operation, when the nitric acid has become enfeebled, it is necessary to stir it in. The quantity of mixture contained in two basins is now to be placed in an enamelled iron pot on a sand-bath. As the heat increases the fluid will boil up in the pot, and to prevent loss the vessel must be removed from the fire for a short time. The heating is to be repeated in this manner until the temperature rises to 248° F., and, after removing the pot to the coolest part of the sand-bath, half a pound of liquid ammonia is to be stirred in quickly. In a few minutes the whole is converted into what is called in commerce by the name of *Murexide en pâte.* To convert this into the purer product known as *Murexide en poudre*, it is to be repeatedly stirred up with water and filtered, to remove the saline and extractive matters.

In dyeing cotton by means of murexide, it is necessary to use lead and mercury as mordants. Lauth's process consists in fixing oxide of lead upon the fibre by first immersing it in a bath of acetate of lead, and then in ammonia, or by a bath of oxide of lead and lime. The dye is then mixed with pernitrate or perchloride of mercury and a little acetate of soda, and the cotton goods are worked in it for a sufficient time.

For printing, the murexide is mixed with thickened nitrate of lead, and the cloth after printing is dried and subsequently passed through a bath, containing 100 litres of water, 1 kilogramme of corrosive sublimate, and 1 kilogramme of acetate of soda.

In Sagar and Schultz's patent process they pad the cotton goods in a solution of murexide with 6 pounds of nitrate of lead in 8 gallons of water, to which when cold 6 ounces of corrosive sublimate, dissolved in 2 gallons of water, are added. The goods are dried after dyeing in the above solution, and the colour is fixed by again padding in a solution of wheaten starch, gum, gum-substitute, or any similar substance.

Silk may easily be dyed in a bath of murexide mixed with corrosive sublimate. Wool, after being well washed and rinsed, is to be dyed in a strong bath of murexide, and then dried. It is after this to be treated, at a temperature of 104° to 122° F., with a bath containing 60 grammes of corrosive sublimate, 75 grammes of acetate of soda, and 10 litres of water.—C. G. W.

Murexide has now so completely established its place in the arts, that the following notice of it by Dr. Hofmann in his Report on the Chemical Section of the Exhibition of 1862, forms a very appropriate addendum to Mr. Greville Williams' notice.

Historical Notice.—Since the year 1851 there has appeared on the chemical horizon a rare and beautiful substance, formerly looked upon as a laboratory curiosity, a product to be admired for its brilliant metallic lustre, and for the elegance of its delicate crystals, but not otherwise important. In consequence, however, of the application it found in the dyeing and printing of fabrics, it suddenly sprang into great request, and was prepared in extremely large quantities. This substance is *murexide*, first noticed by Prout, but obtained in the state of purity, analysed, and described by MM. Liebig and Wöhler, in the admirable paper on Uric Acid and its derivatives. It was destined, however, to have but a brief celebrity. After having shone for some time with great lustre, it was suddenly eclipsed by even more resplendent rivals—the gorgeous crimsons, purples, and violets derived from aniline and its homologues. Nevertheless, murexide deserves, for more than one reason, our serious attention; indeed, it would be difficult to mention a substance whose history is more instructive. Certainly the resources of modern chemistry were never more admirably illustrated than in the promptness with which the sudden demand for murexide was met; and an operation, delicate and complex, even as a laboratory process, made available on an industrial scale. Those who had only seen murexide adorning as a rarity the shelves of a museum, might well be astonished when they found it by hundredweights in the market, nearly equalling in purity the laboratory product itself, and sold at a price almost incredibly low.

The reporter had the good fortune to be a student in Professor Liebig's laboratory at the time, when, together with Professor Wöhler, he carried on those researches upon uric acid which became celebrated for the brilliant light they threw upon the nature and composition of murexide. He has thus had many opportunities of witnessing the difficulties which arose in the preparation of the substance; and he can record, as he shared, the triumph which the whole laboratory felt when a few grammes of it were first obtained in a state of purity.

Murexide has the formula $C^8H^8N^6O^6$, and has been considered by some as purpurate of ammonium. The acid of this salt cannot, however, be isolated. As soon as it is set free by means of a stronger acid, it is immediately decomposed into other products, murexan, alloxan, &c.

Preparation of Murexide.—The preparation of murexide involves two distinct operations, viz.:—1. The extraction and purification of uric acid. 2. The transformation of uric acid into murexide.

Sources of Uric Acid.—Uric acid is found in the excrements of serpents and birds, and in guano, as urate of ammonium. The excrements of serpents contain almost pure uric acid, partly combined with ammonium, partly free. The supply of these materials is, however, too limited to serve for any other than laboratory experiments.

Almost all the uric acid used in the arts is derived from guano. According to the process patented by Mr. Brooman, the guano is extracted by means of hot dilute hydrochloric acid, which dissolves out the carbonates, oxalates, and phosphates of ammonium, calcium, magnesium, &c. The insoluble residue consists of uric acid, mixed with sand, clay, sulphate of calcium, albumen, mucus, &c. It is treated with fresh quantities of hot hydrochloric acid, washed, drained, and dried. It may then be employed directly for the preparation of murexide.

But if a purer uric acid be required, it may be obtained by dissolving the crude acid in a boiling solution of dilute caustic potash, and precipitating the clear solution with an acid. The uric acid is thus obtained almost pure, and may be filtered, washed, and dried.

The uric acid can also be dissolved in rather concentrated sulphuric acid, heated to 60° to 80° C., and then precipitated by the addition of water, filtered, washed, and dried. 100 parts of good guano yield from two and a half to three parts of uric acid.

Transformation of Uric Acid into Murexide.—For this purpose the uric acid is first dissolved in cold nitric acid, which is placed, for this purpose, in earthenware pots of from four to five litres capacity, and has the uric acid gradually added to it in small quantities; each portion being allowed to dissolve entirely before a fresh quantity is introduced.

This operation takes from ten to twelve hours, and yields a dark brown liquid, consisting chiefly of nitrate of urea, alloxan, and alloxantine. These last two substances frequently form a crystalline crust on the surface of the liquid, and their simultaneous presence forms one of the most favourable conditions for the abundant formation of murexide.

The liquid thus obtained is treated in one or other of the two following modes:—

1. When it is desired to obtain purpurate of sodium, it is simply diluted with water, mixed with carbonate of sodium, and heated.

2. When, on the other hand, purpurate of ammonium, or murexide is required, carbonate of ammonium is added.

The liquid thus obtained is evaporated in glazed vessels of considerable size, care being taken not to raise the temperature beyond 80° C., and not to operate upon too much liquid at one time. In proportion as the liquid becomes more concentrated and pasty, ammonia, set free by the decomposition of the nitrate of urea or urea alone, reacts in its nascent condition, upon the alloxan and alloxantine, and forms murexide, which appears on cooling as a brownish-red or violet substance, sometimes of a greenish tint. This constitutes the *purple carmine* of Mr. Brooman.

It is, however, better to employ ammonia, or its carbonate, added in small quantities at a time to the nitric solution, till the acid liquid is neutral or slightly alkaline, which reaction it should permanently retain. This liquid is then heated to about 60° to 77° C., and yields, on cooling, crystals of murexide. The mother-liquid is again heated with small quantities of ammonia and cooled; when a fresh crop of crystals of murexide is obtained.

Crystallised Murexide.—During the last few years the dyers and printers have gradually abandoned the use of pastes of murexide, in order to employ it solely in the form of crystals. The manufacture of the latter has been brought to such perfection that, crystallised in the shape of magnificent needles, exquisitely beautiful and pure, it has come into commerce at very reduced prices.

Statistics of the Manufacture.—We may form an idea of the extent of this manufacture, at a time when it had reached its culminating point, from a statement made by Messrs. Schunck, Angus Smith, and Roscoe, that the weekly yield of murexide of one factory only—that of Mr. Rumney of Manchester—amounted to no less than twelve cwts., a quantity in the production of which, it is asserted, about twelve tons of guano were consumed. The cost of murexide in paste was originally 30*s.* per lb., but it has gradually fallen to half that price.

Isopurpurate of Ammonium.—According to a private communication from M. E. Kopp, the isopurpurate of ammonium of M. Hlasiwetz, a product obtained by the reaction of cyanide of potassium upon picric acid, is not only isomeric but identical with the murexide obtained from uric acid. M. Kopp bases his opinion upon the fact that in dyeing wool and silk with murexide the same processes are requisite, and give the same results, whether the murexide employed be prepared from picric acid or from uric acid. The dyed stuffs thus produced exhibit no greater differences of hue than may be observed in fabrics dyed by means of aniline reds of different preparations. The manufacture of murexide by means of picric acid and cyanide of potassium is extremely simple. To a hot saturated solution of the cyanide is added a solution of picric acid (one part dissolved in seven or eight parts of boiling water), and the mixture allowed to boil for some time. On cooling it deposits a crystalline mass consisting chiefly of impure purpurate of potassium. By filtering and squeezing through linen, redissolving the crystalline mass in hot water, and adding carbonate of potassium to the filtrate, the salt is reprecipitated: purpurate of potassium is thus obtained, this salt being but slightly soluble in the alkaline liquid. This precipitate is filtered off, pressed and redissolved in hot water; sal-ammoniac is then added, and on cooling, beautiful crystals of murexide are obtained.

Murexide Dyeing and Printing.—The first conception of the industrial application of murexide appears to belong to Dr. Saac, formerly of Wesserling, Haut Rhin, now of Barcelona; the processes for dyeing wool and silk by murexide is due to M. Depouilly; the methods for printing with this material upon cotton were devised by M. Ch. Lauth, who employs as mordants chiefly the salts of mercury, lead, and zinc.

In order to dye silk purple, separate aqueous solutions of murexide and of corrosive sublimate are prepared, containing respectively about five per cent. of colouring matter and of salt. The solution of murexide is mixed in the cold with a certain quantity of the sublimate, and the mixture is acidulated with nitric acid. In this cold bath the silk is agitated until the desired shade of colour has been produced. Subsequent immersion in a sublimate bath containing three per cent. of the salt, imparts to the colour its characteristic freshness and brilliancy; qualities in which it remained without a rival until eclipsed by the still more brilliant and more easily-prepared aniline colours.

In order to dye silk of a brilliant yellow, a salt of zinc is substituted for the salt of mercury, the rest of the process remaining the same. When the fabrics of silk have been dyed, they are passed through water rendered very slightly alkaline by means of a little carbonate of sodium, after which they are washed.

Wool may be dyed with murexide in different ways, either by using the corrosive-sublimate bath first and then applying the murexide; or, by first immersing the fabric in the murexide bath, and afterwards fixing the colour, by passing the web through water and a hot bath of corrosive sublimate to which a little acetate of sodium has been added. Sometimes a certain quantity of nitrate of lead is added to the murexide bath, in order to facilitate the fixing of the colouring-matter.

In order to produce rose-coloured or purple tints by murexide upon cotton, nitrate of lead and murexide are dissolved together in water.

The printed cloth is first suspended in a damp room, then introduced into a room pervaded by a slight ammoniacal atmosphere, which assists in fixing the purpurate of lead; and lastly, passed through a corrosive-sublimate bath, containing one and a half per cent. of salt, to fix the colour firmly on the fabric. This process may be conducted in various ways, but must always be based upon the employment of nitrate of lead and corrosive sublimate.

The murexide colours are very fresh and brilliant, and may be exposed to the light without fading. They are, however, excessively sensitive to the action of sulphurous acid, which tarnishes and discolours them with extreme rapidity. This drawback becomes very serious in places where the use of gas has become general; since in the combustion of even well-purified coal-gas there is always enough sulphurous acid generated to act upon fabrics dyed with murexide.

Although the manufacture of murexide has dwindled to a mere shadow of what it was a few years since, its early career will always be remembered as one of the most interesting and instructive episodes in the chemical history of colouring-matters.

MURIATES were, till the great chemical era of Sir H. Davy's researches upon chlorine, considered to be compounds of an undecompounded acid, the muriatic, with the different bases; but he proved them to be in reality compounds of chlorine with the metals. They are all, however, still known in commerce by their former appellation. The only muriates much used in the manufactures are *muriate of ammonia*, or SAL-AMMONIAC; and *muriate of tin*, for which see CALICO-PRINTING and TIN.

MURIATIC ACID. See HYDROCHLORIC ACID.

MUSACEÆ. The Plantain family. See BANANA.

MUSCADEL WINE. A rich wine of Languedoc. See WINE.

MUSCOVADA. The unrefined brown sugar of commerce. See SUGAR.

MUSCOVITE GLASS. Mica is sometimes so called. See MICA.

MUSK (*Musc*, Fr.; *Moschus*, Ger.) is a peculiar aromatic substance found in a sac between the navel and the parts of generation of a small male quadruped of the deer kind, called by Linnæus *Moschus moschiferus*, which inhabits Tonquin and Thibet. The colour of musk is blackish-brown; it is lumpy or granular, somewhat like dried blood, with which substance, indeed, it is often adulterated. The intensity of its smell is almost the only criterion of its genuineness. When thoroughly dried it becomes nearly scentless; but it recovers its odour when slightly moistened with water of ammonia. The Tonquin musk is most esteemed. It comes to us in small bags covered with a reddish-brown hair; the bag of the Thibet musk is covered with a silver-grey hair.

The musk deer, from the male of which animal species the bag containing this valuable drug is obtained, is a native of the mountainous Kirgesian and Langorian steppes of the Altaï, on the river Irtish, extending eastwards as far as the river Yenesei and Lake Baikal; and generally of the mountains of Eastern Asia, between 30° and 60° of N. lat. There are three kinds of musk known in the London market, which is in truth the great centre of the musk trade. The *Cabardieu*, or *Russian musk*, which is rarely, if ever, adulterated; from its poor fragrance, however, it does not fetch more than 8*s*. an ounce in the pod. The *Assam musk* is next in quality; it is very strong, but has a rank smell; the pods are very large and irregular in shape, their average value is about 20*s*. an ounce. The *Tonquin* or *Chinese musk* yields the kind mostly prized by the perfumer; it is more adulterated than either of the former named, but nevertheless realises at public auction an average of 30*s*. an ounce in the pod.

MUSLIN is a fine cotton fabric, which is worn either white, dyed, or printed.

To render it and other fabrics non-inflammable. This very important inquiry was committed by Professor Graham, at the desire of Her Majesty, to the care of Dr. Oppenheim and Mr. Frederick Versmann, from whose report the following important conclusions have been abstracted. After naming many salts found to be useless or nearly so, they proceed:—'With regard to sulphate of ammonia, the cheapest salt of ammonia, a solution containing 7 per cent. of the crystals, or 6·2 per cent. of anhydrous salt, is a perfect anti-flammable. In 1839, the Bavarian Embassy at Paris caused M. Chevalier to make experiments before them with a mixture of borax and sulphate of ammonia, as recommended by Chevalier, in preference to the sulphate alone. He thought the sulphate would lose part of its ammonia, and thereby give rise to the action of sulphuric acid upon the fabric. The authors say that they now have kept for six months whole pieces of muslin prepared in various ways with this salt, some having been even ironed; but cannot find that the texture was in the least degree weakened. Chevalier's mixture, on the contrary, became injurious to the fabric, not only at temperatures above 212°, but even at summer heat; and this can easily be explained, because he did not actually apply sulphate of ammonia and borax, but biborate of ammonia and sulphate of soda.'

Another drawback of Chevalier's mixture is the roughness which it gives to the fabric, and which could only be overcome by calendering the pieces, while sulphate of ammonia by itself has not this effect. The use of this salt must therefore be strongly recommended. Of all the salts experimented upon, only four appear to be applicable for light fabrics. These salts are—1. Phosphate of ammonia. 2. The mixture of phosphate of ammonia and chloride of ammonium. 3. Sulphate of ammonia. 4. Tungstate of soda.

The sulphate of ammonia is by far the cheapest and the most efficacious salt, and it was therefore tried on a large scale. Whole pieces of muslin (eight to sixteen yards long) were finished, and then dipped into a solution containing 10 per cent. of the salt, and dried in the hydro-extractor. This was done with printed muslins, as well as with white ones, and none of the colour gave way, with the sole exception of madder purple, which became pale. But even this change might be avoided, if care be taken not to expose the piece while wet to a higher than ordinary temperature. Most of these experiments were made at the works of Mr. Crum and of Mr. Cochran. The pieces had a good finish, and some of them were afterwards submitted to Her Majesty for inspection, who was pleased to express her satisfaction.

Table showing the smallest percentage of Salts required in Solution, for rendering Muslin Non-Inflammable ; A, *of Crystallised ;* B, *of Anhydrous Salts. Twelve square inches of the Muslin employed weighed* 33·4 *grains.*

Name of Salts	A	B	Remarks
Caustic soda	8	6·2	
Carbonate of soda	27	10	Injurious to the fabrics.
Carbonate of potash	12·6	10	
Bicarbonate of soda	6	5·4	Not sufficiently efficacious; too volatile.
Borax	25	13·2	Destroys the fabrics above 212° Fahr.
Silicate of soda	...	15·5	Injures the appearance of the fabrics.
Phosphate of soda	80	32	Not sufficiently efficacious.
Sulphate of soda	...	...	A concentrated 72 p. c. solution is insufficient.
Bisulphate of soda	20	18·5	Destroys the fabrics.
Sulphite of soda	25	10·3	
Tungstate of soda	20	16	*Recommended on account of its being the only salt not interfering with the ironing of the fabrics.*
Stannate of soda	20	15·9	Injurious.
Chloride of sodium	...	...	Concentrated solutions are insufficient.
Chloride of potassium	...	...	
Cyanide of potassium	...	10	Poisonous.
Sesquicarbonate of ammonia	...	...	Not available.
Oxalate of ammonia	...	...	
Biborate of ammonia	5	3·6	Destroys the fabrics above 212°.
Phosphate of ammonia	...	10	Efficient but expensive.
Phosp. of ammonia and soda	15	9·8	Expensive and scarcely sufficiently efficacious.
Sulphate of ammonia	7	6·2	*Very efficient, and recommended on account of its low price.*
Sulphite of ammonia	10	9	Deliquescent.
Chloride of ammonium	...	25	Not sufficiently efficacious.
Iodide of ammonium	...	5	
Bromide of ammonium	...	5	Too expensive.
Urea	...	40	
Thouret's mixture	...	12	Efficient, but expensive.
Chloride of barium	...	50	Not sufficiently efficacious.
Chloride of calcium	19·7	10	Deliquescent.
Sulphate of magnesia	50	24·3	Not sufficiently efficacious.
Sulphate of alumina	15	7·7	Destroys the fabric.
Potash-alum	33	18	Not efficacious enough, and destroys the fabric.
Ammonia-alum	25	13	
Sulphate of iron	54	28·8	Not sufficiently efficacious.
Sulphate of copper	18	10	Poisonous.
Sulphate of zinc	20	11·2	
Chloride of zinc	8	5·8	Deliquescent.
Protochloride of tin	5	4·6	Deliquescent.
Protochloride of tin and ammonium	5	4·7	Becomes yellow when exposed to the air.
Pinksalt	...	7	Injures the fabric.

Mr. Crum, who prepared some dresses with phosphate and some with sulphate of ammonia, arrived at the result, that, with the phosphate, the finish is chalky, and not transparent enough, whereas the finish with the sulphate is successful.

During the space of six months none of the fabrics prepared with sulphate of ammonia changed either in colour or in texture; it may therefore be considered as an established fact that the sulphate of ammonia may be most advantageously applied in the finishing of muslins and similar highly inflammable fabrics.

The authors felt, however, the necessity of inquiring further into the effect which ironing would have upon fabrics thus prepared; for all the above-mentioned salts, being soluble in water, require to be renewed after the prepared fabrics have been washed.

Now, the sulphate of ammonia does not interfere with the ironing so much as other salts do, because a comparatively small portion is required: but still, the difficulty is unpleasant, and sometimes a prepared piece, after being ironed, showed brown spots like iron-moulds. On covering the iron with plates of zinc or brass, these spots did not appear; but the difficulty still existed, and a white precipitate covering the plate showed evidently that it is the volatile nature of the salt which interferes with the process. An attempt to counteract this action of the salt, by adding wax and similar substances to the starch, remained also without any result.

For all laundry purposes the tungstate of soda only can be recommended. This salt offers only one difficulty, viz., the formation of a bitungstate, of little solubility, which crystallises from the solution. To obtain a constant solution this inconvenience must be surmounted; and it was found that not only phosphoric acid, in very small proportion, keeps the solution in its original state, but that a small percentage of phosphate of soda has the same effect.

The best way of preparing a solution of minimum strength is as follows:—A concentrated neutral solution of tungstate of soda is diluted with water to 28° Twaddle, and then mixed with 3 per cent. of phosphate of soda. This solution was found to keep, and to answer well; it has been introduced into Her Majesty's laundry, where it is constantly being used.

The effects of the soluble salts having been thus compared, a few remarks are necessary respecting the means which may be adopted permanently to fix anti-flammable expedients, so that the substances prepared may be wetted without losing the property of being non-inflammable.

Relying upon the property of alumina as a mordant, we tried the combination of oxide of zinc and alumina, obtained by mixing solutions of oxide of zinc in ammonia and of alumina in caustic soda; but, although this precipitate protects the fibre, it does not adhere to it when washed.

The oxychloride of antimony, obtained by precipitation from an acid solution of chloride of antimony by water mixed only with a little ammonia, is a good anti-flammable, and it withstands the action of water, but not that of soap and soda. It was not found that the solution of this and other salts in muriatic acid injured the texture of the fabric as long as this was dried at an ordinary temperature.

The borate and phosphate of protoxide of tin act effectually, if precipitated in the fibre from concentrated solutions of these salts in muriatic acid by ammonia; they withstand the influence of washing, and give a yellow tinge to the fabrics.

The same remarks apply to arsenate of tin. The stannates of lime and zinc protect the fabric, but do not withstand the action of soap or soda.

The oxides of tin give a favourable result, inasmuch as they really can be permanently fixed; the yellow tinge, however, which they impart to the fabrics will always confine their application to coarse substances, such as canvas, sail-cloth, or ropes.

The canvas thus prepared must be dried and then washed, to remove the excess of precipitate. Salt-water does not remove the tin from the canvas.

A piece about 40 yards in length has been prepared by order of the Storekeeper-General of the Royal Navy; but it was found to have lost in strength, and increased in weight too much to allow of its application.

These experiments, however, being the first successful attempts permanently to fix some anti-flammable agents, may have some interest, although they leave but little hope that the result of fixing anti-flammable expedients will ever be obtained without injuring the fabrics.

By determining the comparative value, and ascertaining the difficulties which have prevented, till now, the general use of protecting agents, the authors were led to exclude a number of salts hitherto proposed, and to advocate the adoption of sulphate of ammonia, and of tungstate of soda, in manufactories of light fabrics, and in laundries.

They hope, therefore, that the general introduction of these salts will soon greatly reduce danger and loss of life through fire.

MUSSEL-BAND. Thin shelly bands occurring in the coal-measures are called by the miners mussel-band, or mussel-bind.

MUST is the sweet juice of the grape.

MUSTA PAAT. *Hibiscus cannabinus.* A vegetable fibre, much used in Asia. See FIBRES.

MUSTARD. (*Moutarde*, Fr.; *Senf*, Ger.) The *Sinapis nigra*, or common black mustard, is the plant which yields the well-known seed used as a condiment to food. Flour of mustard is prepared as follows:—The seeds of black and white mustard are first crushed between rollers and then pounded in mortars. The pounded seeds are then sifted. The residue in the sieves is called *dressings*, and what passes through is the *impure flour of mustard*, which by a second sifting yields the pure flour. Common mustard is adulterated with wheat-flour, and coloured with turmeric, being rendered hot by pod-pepper.

Mustard consists of:—

Myronic acid, an inodorous, non-volatile, bitter, non-crystallisable acid.

Myrosine, a substance in many respects analogous to vegetable-albumen.

Sinapisine, white, brilliant, micaceous, volatile crystals.

Oil of Mustard.—Volatile oil of mustard is colourless or pale yellow; it has a penetrating odour, and a most acrid burning taste. It is represented by the formula $C^8H^5NS^2$ (**C^4H^5NS**).

Fixed Oil of Mustard.—This constitutes 28 per cent. of the seeds. It has a faint odour of mustard, and a mild oily taste.

M. Lenormand gives the following prescription for preparing mustard for the table. This is usually termed *French mustard*:—

With 2 lbs. of very fine flour of mustard, mix ½ an ounce of each of the following fresh plants: parsley, chervil, celery, and taragon; along with a clove of garlic, and 12 salt anchovies, all well minced. The whole is to be triturated with the flour of mustard till the mixture becomes uniform. A little grape-must or sugar is to be added to give the requisite sweetness; then 1 ounce of salt, with sufficient water to form a thinnish paste by rubbing in a mortar. With this paste the mustard-pots being nearly filled, a red-hot poker is thrust down into the contents of each, which removes (it is said) some of the acrimony of the mustard, and evaporates a little water, so as to make room for pouring a little vinegar upon the surface of the paste. Such table-mustard not only keeps perfectly well, but improves with age.

MUSTARD OIL. See OILS.

MUTAGE is a process used in the south of France to arrest the progress of fermentation in the must of the grape. It consists either in diffusing sulphurous acid, from burning sulphur matches, in the cask containing the must, or in adding a little sulphide (not sulphate) of lime to it. The last is the best process. See FERMENTATION.

MUTTON SUET is much used in leather manufactories for tallowing hides, Its composition is: carbon 78·996, hydrogen 11·700, oxygen 9·304.

MYRICINE is a vegetable principle which constitutes from 20 to 30 per cent. of the weight of bees'-wax, being the residuum from the solvent action of alcohol upon that substance. It is a greyish-white solid, which may be vaporised almost without alteration.

MYRRH is a gum-resin, which occurs in tears of different sizes; they are reddish-brown, semi-transparent, brittle, of a shining fracture, appear as if greasy under the pestle; they have a very acrid and bitter taste, and a strong, not disagreeable, smell. Notwithstanding the early knowledge of, and acquaintance with the use of myrrh, we had no accurate account of the tree which yields it until the return of Ehrenberg from his travels with Heinfrich during 1820–25, in various parts of Africa and Asia. He brought with him a specimen of the tree, which had been described and figured by Neesvon Esenbeck under the name of *Balsamodendron myrrha*. The plant is first noticed by Alexander Humboldt in 1826.—*Pereira.*

Myrrh is of three qualities:—The first quality, *Turkey myrrh*, occurs in pieces of irregular form and of various sizes, consisting of tears, usually covered with a fine powder or dust. The second quality, *East India myrrh*, is imported from the East Indies in chests; it consists of distinct tears or grains, which are rounded or irregular, and vary in size from that of a pin's head to a pepper corn. The third quality is also *East India myrrh*, but it occurs in pieces of a dark colour, and whose average size is that of a walnut.

Myrrh flows from the incisions of a tree which grows at Gison, on the borders of Arabia Felix. The tree figured by Humboldt is considered by Lindley as identical with the *Amyris Kataf* of Forskål. It consists of resin and gum in proportions stated by Pelletier at 31 of the former and 66 of the latter; but by Braconnot, at 23 and 77. It is used only in medicine.

N

NACARAT is a term derived from the Spanish word *nacar*, which signifies mother-of-pearl; and is applied to a pale red colour, with an orange cast. The *Nacarat* of Portugal, or *Bezetta*, is a crape or fine linen fabric, dyed fugitively of the above tint, which ladies rub upon their countenances to give them a roseate hue. The Turks of Constantinople manufacture the brightest red crapes of this kind.

NACREOUS. (*Nacre*, Fr.) A term applied to shells and minerals which have a pearly or iridescent lustre.

NAGYAGITE. A native telluride of lead containing gold, silver, and copper.

NAILS, MANUFACTURE OF. (*Clou*, Fr.; *Nagel*, Ger.) The forging of nails was till of late years a handicraft operation, and therefore belonged to a book of trades rather than to a dictionary of arts. But several combinations of machinery have been recently employed, under the protection of patents, for making these useful implements, with little or no aid of the human hand; and these deserve to be noticed, on account both of their ingenuity and importance.

As nails are objects of prodigious consumption in building their block-houses, the citizens of the United States very early turned their mechanical genius to good account in the construction of various machines for making them. So long since as the year 1810, it appears the Americans possessed a machine which performed the cutting and heading at one operation, with such rapidity that it could turn out upwards of 100 nails per minute. 'Twenty years ago,' says the secretary of the State of Massachusetts, 'some men, then unknown, and then in obscurity, began by cutting slices out of old hoops, and, by a common vice griping these pieces, headed them with several strokes of the hammer. By progressive improvements slitting-mills were built, and the shears and the heading tools were perfected; yet much labour and expense were requisite to make nails. In a little time Jacob Perkins, Jonathan Ellis, and a few others, put into execution the thought of cutting and of heading nails by water-power; but, being more intent upon their machinery than upon their pecuniary affairs, they were unable to prosecute the business. At different times other men have spent fortunes in improvements, and it may be said with truth that more than one million of dollars has been expended; but at length these joint efforts are crowned with complete success, and we are now able to manufacture, at about one-third of the expense that wrought nails can be manufactured for, nails which are superior to them for at least three-fourths of the purposes to which nails are applied, and for most of those purposes they are full as good. The machines made use of by Ordiorne, those invented by Jonathan Ellis, and a few others, present very fine specimens of American genius.

'To northern carpenters it is well known that in almost all instances it is unnecessary to bore a hole before driving a cut nail; all that is requisite is, to place the cutting edge of the nail across the grain of the wood; it is also true that cut nails will hold better in the wood. These qualities are, in some rough building works, worth twenty per cent. of the value of the article, which is equal to the whole expense of manufacturing. For sheathing and drawing, cut nails are full as good as wrought nails; only in one respect are the best wrought nails a little superior to cut nails, and that is where it is necessary they should be clenched. The manufacture of cut nails was born in our country, and has advanced, within its bosom, through all the various stages of infancy to manhood; and no doubt we shall soon be able, by receiving proper encouragement, to render them superior to wrought nails in every particular.

'The principal business of rolling and slitting-mills is rolling nail plates; they also serve to make nail rods, hoops, tires, sheet iron and sheet copper. In this State we have not less than twelve.

'These mills could roll and slit 7,000 tons of iron a year; they now, it is presumed, roll and slit each year about 3,500 tons, 2,400 tons of which, probably, are cut up into nails and brads, of such a quality that they are good substitutes for hammered nails, and in fact, have the preference with most people, for the following reasons; viz. on account of the sharp corner and true taper with which cut nails are formed; they may be driven into harder wood without bending or breaking, or hazard of splitting the wood, by which the labour of boring is saved, the nail one way being of the same breadth or thickness from head to point.'

Since the year 1820, numerous patents have been taken out in this country for the manufacture of nails by machinery. A few only of these can be noticed.

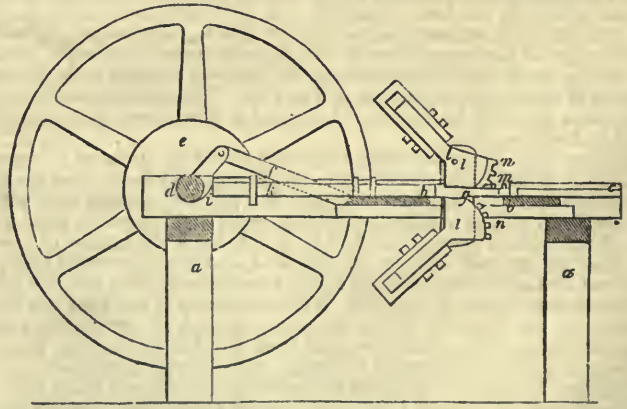
The first nail apparatus to which we shall advert is due to Dr. Church; it was patented by Mr. Thomas Tyndall, of Birmingham, in December 1827. It consists of two parts: the first is a mode of forming nails, and the shafts of screws, by pinching or pressing ignited rods of iron between indented rollers; the second produces the threads on the shafts of the screws previously pressed. The metallic rods, by being passed between a pair of rollers, are rudely shaped, and then cut asunder between a pair of shears; after which they are pointed and headed, or otherwise brought to their finished forms, by the agency of dies placed in a revolving cylinder. The several parts of the mechanism are worked by toothed wheels, cams, and levers. The second part of Dr. Church's invention consists of a mechanism for cutting the threads of screws to any degree of obliquity or form.

Mr. Edward Hancorne, of Skinner Street, London, nail-manufacturer, obtained a patent in October 1828, for a nail-making machine, of which a brief description may give a conception of this kind of manufacture. Its principles are similar to those of Dr. Church's more elaborate apparatus.

The rods or bars having been prepared in the usual way, either by rolling or hammering, or by cutting from sheets or plates of iron, called slitting, are then to be made red-hot, and in that state passed through the following machine, whereby they are at once cut into suitable lengths, pressed into wedge forms for pointing at the one end, and stamped at the other end to produce the head. A longitudinal view of the machine is shown in *fig.* 1544. A strong iron frame-work, of which one side is shown at *a a*, supports the whole of the mechanism. *b* is a table capable of sliding to and fro horizontally. Upon this table are the clamps, which lay hold of the sides of the rod as it advances; as also the shears which cut the rod into nail-lengths.

These clamps or holders consist of a fixed piece and a moveable piece; the latter being brought into action by a lever. The rod or bar of iron shown at *c*, having been made red-hot, is introduced into the machine by sliding it forward upon the table *b*, when the table is in its most advanced position; rotatory motion is then given to the crank-shaft *d*, by means of a band passing round the rigger pulley *e*, which causes the table *b* to be drawn back by the crank-rod *f*; and as the table recedes, the horizontal lever is acted upon, which closes the clamps. By these means the clamps take fast hold of the sides of the heated rod, and draw it forward, when the moveable chap of the shears, also acted upon by a lever, slides laterally, and cuts off the end of the rod held by the clamps: the piece thus separated is destined to form one nail.

1544



Suppose that the nail placed at *g*, having been thus brought into the machine and cut off, is held between clamps, which press it sideways (these clamps are not visible in this view); in this state it is ready to be headed and pointed.

The *header* is a steel die *h*, which is to be pressed up against the end of the nail by a cam, *i*, upon the crank-shaft; which cam at this period of the operation acts against the end of a rod *k*, forming a continuation of the die *h*, and forces up the die, thus compressing the metal into the shape of a nail-head.

The *pointing* is performed by two rolling snail-pieces or spirals *l*, *l*. These pieces are somewhat broader than the breadth of the nail; they turn upon axles in the side frames. As the table *b* advances, the racks *m*, on the edge of this table, take into the toothed segments *n*, *n*, upon the axles of the spirals, and cause them to turn round.

These spirals pinch the nail at first close under its head with very little force; but as they turn round, the longer radius of the spiral comes into operation upon the nail, so as to press its substance very strongly, and squeeze it into a wedge form. Thus the nail is completed, and is immediately discharged from the clamps or holders. The carriage is then moved again by the rotation of the crank-shaft, which brings another portion of the rod *c*, forward, cuts it off, and then forms it into a nail.

Dr. William Church, February 1832, obtained a patent for improvements in machinery for making nails. These consist, first, in apparatus for forming rods, bars, or plates of iron, or other metals; secondly, in apparatus for converting the rods, &c. into nails. The machinery consists of laminating rollers, and compressing dies.

The method of forming the rods from which nails are to be made is very advantageous. It consists in passing the bar or plate iron through pressing rollers, which have indentations upon the peripheries of one or both of them, so as to form the bar or plate into the required shape for the rods, which may be afterwards separated into rods of any desired breadth, by common slitting-rollers.

The principal object of rolling the rods into these wedge forms, is to measure out a quantity of metal duly proportioned to the required thickness or strength of the nail in its several parts; which quantity corresponds to the indentations of the rollers.

Thomas John Fuller patented an improved apparatus for making square-pointed, and also flat-pointed nails. His invention consisted of the application of vertical and horizontal hammers (mounted in his machine) combined for the purpose of tapering and forming the points of the nails; which, being made to act alternately, resemble hand-work, and are therefore not so apt to injure the fibrous texture of the iron, as the rolling machinery is. He finishes the points by rollers.

William Southwood Stocker introduced a machine apparently of American parentage, as it has the same set of features as the old American mechanisms of Perkins, at the Britannia Nail Works, Birmingham, and all the other American machines for pressing metal into the forms of nails, pins, screw-shafts, rivets, &c.; for example, it possesses pressers or hammers for squeezing the rods of metal and forming the shanks, which are all worked by a rotatory action; cutters, for separating the appropriate lengths, and dies for forming the heads by compression, also actuated by revolving cams or cranks.

Mr. Stocker intended, in fact, to effect the same sorts of operations by automatic mechanisms as are usually performed by the hands of a nail-maker with his hammer and anvil; viz. the shaping of a nail from a heated rod of iron, cutting it off at the proper length, and then compressing the end of the metal into the form of the head. His machine may be said to consist of two parts, connected in the same frame; the one for shaping the shank of the nail, the other for cutting it off and heading it. The frame consists of a strong table to bear the machinery. Two pairs of hammers, formed as levers, the one pair made to approach each other by horizontal movements, the other pair by vertical movements, are the implements by which a portion at the end of a red-hot rod of iron is beaten or pressed into the wedge-like shape of the shaft of a nail. This having been done, and the rod being still hot, is withdrawn from the beaters, and placed in the other part of the machine, consisting of a pair of jaws like those of a vice, which pinch the shank of the nail and hold it fast. A cutter upon the side of a wheel now comes round, and, by acting as the moving chap of a pair of shears, cuts the nail off from the rod. The nail shank being still firmly held in the jaws of the vice, with a portion of its end projecting outwards, the heading die is slidden laterally, until it comes opposite to the end of the nail; the dye is then projected forward with great force, for the purpose of what is termed upsetting the metal at the projecting end of the nail, and thereby blocking out the head.

A main shaft, driven by a band and rigger as usual, brings, as it revolves, a cam into operation upon a lever which carries a double inclined plane or wedge in its front or acting part. The wedge being by the rotatory cam projected forwards between the tails of one of the pairs of hammers, causes the faces of these hammers to approach each other, and to beat or press the red-hot iron introduced between them, so as to flatten it upon two opposite sides. The rotatory cam passing round, the wedge-lever is relieved, when springs instantly throw back the hammers; another cam and wedge-lever now bring the second pair of hammers to act upon the other two sides of the nail in a similar way. This is repeated several times, until the end of the red-hot iron rod, gradually advanced by the hands of the workmen, has assumed the desired form, that is, has received the bevel and point of the intended nail.

The rod is then withdrawn from between the hammers, and in its heated state is introduced between the jaws of the holders, for cutting off and finishing the nail. A bevel pinion upon the end of the main shaft takes into and drives a wheel upon a transverse-shaft, which carries a cam that works the lever of the holding-jaws. The end of the rod being so held in the jaws or vice, a cutter at the side of a wheel upon the transverse-shaft separates, as it revolves, the nail from the end of the rod, leaving the nail firmly held by the jaws. By means of a cam, the heading-die is now slidden laterally opposite to the end of the nail in the holding-jaws, and, by another cam upon the main-shaft, the die is forced forward, which compresses the end of the nail, and spreads out the nail into the form of a head. As the main-shaft continues to revolve, the cams pass away, and allow the spring to throw the jaws of the vice open, when the nails fall out; but, to guard against the chance of a nail sticking in the jaws, a picker is provided, which pushes the nail out as soon as it is finished.

In order to produce round shafts, as for screw blanks, bolts, or rivets, the faces of the hammers and the dies for heading must be made with suitable concavities.

NANKIN is a peculiarly coloured cotton cloth, originally manufactured in the above-named ancient capital of China from a native cotton of a brown-yellow hue. Nankin cloth has been long imitated in perfection by our own manufacturers; and is now exported in considerable quantities from England to Canton. The following is the process for dyeing calico a nankin colour:—

2. Take 300 lbs. of cotton-yarn in hanks, being the quantity which four workmen can dye in a day. The yarn for the warp may be about No. 27's, and that for the weft 23's or 24's.

2. For *aluming* the quantity, take 10 lbs. of saturated alum free from iron (see MORDANT); divide this into two portions; dissolve the first by itself in hot water, so as to form a solution of specific gravity 1° Beaumé. The second portion is to be reserved for the galling-bath.

3. *Galling* is given with about 80 lbs. of oak-bark finely ground. This bark may serve for two quantities, if it be applied a little longer a second time.

4. Take 30 lbs. of fresh slaked quicklime, and form with it a large bath of lime-water.

5. *Nitro-muriate of tin.*—For the last bath 10 or 12 lbs. of solution of tin are used, which is prepared as follows:—

Take 10 lbs. of strong nitric acid, and dilute with pure water till its specific gravity be 26° Beaumé. Dissolve in it 4,633 grains (10½ ounces avoird.) of sal-ammoniac and 3 ounces of nitre. Into this solvent, contained in a bottle set in cold water, introduce successively, in very small portions, 28 ounces of grain-tin granulated. This solution, when made, must be kept in a well-stoppered bottle.

Three coppers are required, one round, about 5 feet in diameter, and 32 inches deep, for scouring the cotton; two rectangular coppers, tinned inside, each 5 feet long and 20 inches deep. Two boxes or cisterns of white wood are to be provided, the one for the lime-water bath, and the other for the solution of tin, each about 7 feet long, 32 inches wide, and 14 inches deep; they are set upon a platform 28 inches high. In the middle, between these two chests, a plank is fixed, mounted with twenty-two pegs for wringing the hanks upon as they are taken out of the bath.

6. *Aluming.*—After the cotton-yarn has been scoured with water in the round copper, by being boiled in successive portions of 100 lbs., it must be winced in one of the square tinned coppers, containing 2 lbs. of alum dissolved in 96 gallons of water, at a temperature of 165° Fahr. It is to be then drained over the copper, exposed for some time upon the grass, rinsed in clear water, and wrung.

7. The *galling.*—Having filled four-fifths of the second square copper with water, 40 lbs. of ground oak-bark are to be introduced, tied up in a bag of open canvas, and boiled for two hours. The bag being withdrawn, the cotton-yarn is to be winced through the boiling tan-bath for a quarter of an hour. While the yarn is set to drain above the bath, 28 ounces of alum are to be dissolved in it, and the yarn being once more winced through it for a quarter of an hour, is then taken out, drained, wrung, and exposed to the air. It has now acquired a deep but rather dull yellowish colour, and is ready without washing for the next process. Bablah may be substituted for oak-bark with advantage.

8. The *liming.*—Into the cistern filled with fresh-made lime-water, the hanks of cotton-yarn suspended upon a series of wooden rods, are to be dipped freely three times in rapid succession; then each hank is to be separately moved by hand through the lime-bath, till the desired carmelite shade appear. A weak soda-lye may be used instead of lime-water.

9. The *brightening* is given by passing the above hanks after squeezing, rinsing, and airing them, through a dilute bath of solution of tin. The colour thus produced is said to resemble perfectly the nankin of China.

Another kind of nankin colour is given by oxide of iron, precipitated upon the fibre of the cloth from a solution of the sulphate by a solution of soda. See CALICO-PRINTING.

NAPHTHA. The term 'naphtha' originally included all inflammable fluids produced during the destructive distillation of organic substances, as well as the fluid hydrocarbons which issue from the earth in certain parts of the world. In this way mineral burning-oil, when first introduced, was called Boghead or Bathgate naphtha; but the term was objectionable, as it confounded the safe-burning oil with the explosive spirit which also is applied to different technical uses, and it is now completely in abeyance. The light spirit from shales and cannels are identical, being composed partly of the olefiant, partly of the paraffin series, while earth-naphtha appears to belong to the latter series. Coal, caoutchouc, bones, wood, and peat, during destructive distillation, first give off naphthas, which are distinguished by their lighter specific gravity when compared with the later products from the still. But this is comparative; for, while an ordinary shale-naphtha may have a density of about 0·750, coal-naphtha has commercially a specific gravity of 0·850.

A description of the new methods of refining shale-oils and naphtha is given further on. (See Shales and Mineral Oils.) But the following description by Greville Williams of his early investigations on Boghead-naphtha (as all the light distillates from Torbanehill mineral were at first designated) is classical.

On the Chemical Nature of the Fluid Hydrocarbons constituting Boghead-Naphtha.

If, when preparing paraffin-oil from coal, the crude oil is rectified with water, a clear transparent naphtha is obtained. This fluid, as found in commerce, is by no means of constant quality. By quality we mean the power of distilling between given limits of temperature. Some kinds are of about the same degree of volatility as commercial benzole, while others distil at nearly the same temperatures as common coal-naphtha. The hydrometer is not a safe guide in choosing this naphtha; this arises from the fact that photogens, of very different degrees of volatility, have almost the same densities. The safest plan is to put the fluid into a retort, having a thermometer in the tubulature, and distil the contents almost to dryness. The careful observation of the range of the mercurial column during the operation is the best mode of ascertaining the quality of the fluid.

The more volatile portions which distil over with water are free from solid bodies, and consist of a mixture of fluids belonging to three series of homologous hydrocarbons, namely, the benzole series; the olefiant gas, or C^nH^n series; and the radicals of the alcohols.

As no works on chemistry contain any directions for the proximate separation of complex mixtures of hydrocarbons, the following description of the method adopted by the author of this article for the separation of the substances contained in Boghead-naphtha may be useful.

It is necessary, in the first place, to determine whether each substance is to be obtained in a state of absolute purity, or whether it is merely desired to obtain the various series distinct from each other. In the process given, it will be supposed that the individual hydrocarbons are required in a state of purity, because it is easy for the operator to leave out any part of the method which may be unnecessary under the particular circumstances of the case. The first step is to obtain constant boiling-points, for it must be remembered that if, when any organic fluid is subjected to distillation with a thermometer in the tubulature of the retort or still, the mercury continues to rise as the fluid comes over, it is at once demonstrated that the substance distilling is not homogeneous. In order to obtain the fluids of constant boiling-point, it is essential to subject them to a complete series of fractional distillations. This is an operation involving great labour, so much so that, in investigating Boghead-naphtha, upwards of one thousand distillations were made before tolerably constant boiling-points were secured. In order to perform the operation successfully, two series of bottles are required, one for the series being *distilled*, and the other for the series *distilling*. As many bottles are necessary as there are 10-degree fractions to be obtained. Thus, supposing the fluid, when first distilled, came over between 100° and 200°, and it has been determined to obtain 10-degree fractions, the receiver is to be changed for every 10° that the mercury rises. Thus, 10 bottles will be required for the fractions distilling, and the same number for the fractions being distilled into. The operation will be commenced by putting the original fluid (dried carefully with chloride of calcium or sticks of potash) into a retort capable of holding at least half as much more fluid as the quantity inserted. Through the tubulature passes a pierced cork, supporting a thermometer, the lower end of which should not dip into the fluid. To the neck of the retort is adapted a good condensing arrangement, so placed that the bottles can be placed beneath the exit-pipe. All the bottles having blank-paper labels attached, the distillation is to be commenced. The first signs of distillation are to be watched for, but no fluid is to be separately received as an individual fraction until boiling has commenced. As soon as it is found that the mercury indicates 10° more than the temperature at which the distillation commenced, the bottle is to be changed, and so on at every 10°. When the whole fluid is distilled away, a smaller retort is to be taken, capable of well holding each 10°-fraction, without fear of anything boiling over. Suppose the first fraction of the first distillation came over between 100° and 110°, it is to be placed in the retort, and the distillation carried on as before. But it will, in almost every instance, be found that the boiling-point will have been reduced 30° or 40° by the removal of the fluids of higher boiling-point. Under any circumstances, however, the distillate is to be received in bottles, and labelled with the boiling-point and the number of the rectification. When all the first 10°-degree fraction has distilled away into the second series of bottles, the next is to be operated on, and so on. By this means only two series of bottles are ever being used at once, viz., the series being distilled, and the series being distilled *into*. Many fluids may be obtained of steady boiling-point by 15 or 16 rectifications, involving, in the case of 10 fractions in each series, at least 150 distillations. But most complex organic fluids, such as naphthas, have a much wider range of boiling-point than 100°. Boghead-naphtha, for example, commences at about 289° Fahr., and rises above 500°. But in the second distillation, the first fraction, instead of distilling at 289°, came over at 250°, the depression of boiling-point being nearly 40°. By proceeding in this manner six times, a fraction was obtained boiling at 210°. When a 10°-fraction no longer splits up during distillation, that is to say, when it comes over almost between the same points at which it last distilled, it will be proper to commence the separation of the various substances present in each fraction. Before doing this, it is often advisable to make a few preliminary experiments, with the view of ascertaining the nature of the fluids present. The more volatile portions may be tested for benzole by converting them into aniline in the method given in the article BENZOLE. The simplest way of detecting the C^nH^n series (homologous with olefiant gas; see HOMOLOGOUS) will be by ascertaining whether the naphtha is capable of decolourising weak bromine-water. Supposing the presence of these to have been demonstrated, the complete separation of the hydrocarbons may be effected as follows:—Four or five ounces of bromine are to be placed in a large flask, capable of being closed with a well-fitting stopper. About eight volumes of water are then added, and the naphtha of the most volatile fraction is to be poured in by very small portions, the contents of the flask being well shaken after each addition.

By this mode of proceeding, the dark colour of the bromine will gradually fade, and finally disappear. In order to insure a complete reaction, it is better at this stage to add a little more bromine, until the colour is permanent after shaking. A little mercury is now to be poured in, and agitated with the fluids in the flask, to remove all excess of bromine. The oily bromine-compound is now to be separated by means of a tap-funnel, from the mercury and water, and digested with chloride of calcium until every trace of water is removed. The dry brominated oil is now to be distilled, when the radical and benzole series of hydrocarbons will distil away, leaving the brominated oil, which may then be distilled into a vessel by itself. The next step will be to separate the radicals from the benzole series. For this purpose long-necked assay-flasks are necessary. Into one of these vessels, of 3 or 4 ounces capacity, 2 drachms of nitric acid should be poured; 1 drachm of the naphtha is then to be added by very small portions, the flask being kept cool by immersion in cold water. It is essential during the whole time to keep the flask in active motion, in order to bring the hydrocarbon and acid into close contact, and also to cool the contents. If this last precaution be neglected, a violent reaction will occur, and cause the loss of the greater portion of the fluid. When the whole of the drachm of acid has been added, and it is found that the temperature no longer rises on removing the flask from the cold water, the product is to be poured into a narrow and conical glass, and allowed to repose until the hydrocarbon, unacted on, rises to the surface in the form of a transparent brilliant green fluid. The fluid below is then to be removed by means of a pipette, furnished at the upper end with a hollow elastic ball of vulcanised caoutchouc. By this means suction with the lips becomes unnecessary, and the vapours of hyponitric acid are prevented from irritating the lungs. The indifferent hydrocarbon—that is, the fluid unacted on by the acid—is as yet by no means pure; it obstinately retains traces of the benzole and C^nH^n series. It is, therefore, to be transferred to a flask furnished with a well-fitting stopper, and treated with nitric acid (specific gravity 1·5) a considerable number of times. This second treatment may, without any danger of any explosive reaction, be made upon one or two ounces of the partially-purified hydrocarbon. When it is found that the separated nitric acid no longer produces milkiness on being thrown into water, it may be assumed that the benzole and C^nH^n class of hydrocarbons are entirely removed. When the treatment with acid has been repeated a sufficient number of times, the fluid is to be placed in a clean flask, and well agitated with a solution of caustic potash, which will remove the nitrous vapours which are the cause of the green colour. The purified hydrocarbon is then to be separated by a tap-funnel from the water, and dried by digestion with sticks of caustic potash. If it be desired to obtain the radical in a state of absolute purity, it must be distilled three or four times over metallic sodium.

The indifferent hydrocarbons obtained by the above process are colourless mobile fluids, having an odour somewhat resembling the flowers of the white thorn. They are very volatile, even at low temperatures, and have an average density of about 0·716. When the fractions with proper boiling-points have been selected, it will be found that they correspond in specific gravity, percentage composition, and vapour-density with the radicals of the alcohols, as will appear by the following Table, where the experimental results obtained by the author of this article in his examination of Boghead-naphtha are compared with the numbers found by other observers with the radicals obtained by treatment of the hydriodic ethers by sodium, and also by the electrolysis of the fatty acids.

Comparative Table of the Physical Properties of the Alcohol Radicals, as obtained from Boghead-Naphtha, with those procured from other sources.

Radicals	Formulæ		Boiling Points, Fahr.				
			Frankland	Kolbe	Wurtz	Brazier and Gosslett	C. G. Williams
Propyle	$C^{12}H^{14}$	C^6H^7	..	..	..	..	154·4°

Caproyle	$C^{24}H^{28}$	$C^{12}H^{28}$	..	..	0·7574	0·7568	..	..	5·983	5·83	5·87

It has been said that the above hydrocarbons distilled away from the bromine-compound in company with others which were removed by treatment with nitric acid. It was subsequently found that the products formed by the action of the acid were nitro-compounds belonging to the benzole series. The bromine compound contains the C^nH^n series of hydrocarbons, the individual members being determined by the boiling-point of the fraction selected for experiment. If we select that portion boiling steadily between 160° and 170°, we shall have a bromine-compound of the formula $C^{12}H^{12}Br^2$; but if the boiling-point of the naphtha lies between 180° and 190° the bromine-compound will be $C^{14}H^{14}Br^2$. It is exceedingly remarkable that if either of these substances be treated alternately with alcoholic potash and sodium, the original hydrocarbon is regenerated. By the mode of operating indicated above, it is possible, therefore, to obtain two out of the three series of hydrocarbons in a pure state. The third, namely, the benzole series, must be recognised by obtaining products of decomposition.

The acids and bases accompanying the hydrocarbons in Boghead-naphtha have not been fully investigated; it has, however, been ascertained that certain members of the phenole series of acids and pyridine class of bases are always present. The quantities present in the naphtha of commerce are small in consequence of the purification of the fluid by the agency of oil of vitriol, followed by a treatment with caustic soda.—C. G. W.

NAPHTHA, BONE. *Syn.* Bone Oil; Dippel's Animal Oil. This fluid is procured in large quantities during the operation of distilling bones for the preparation of animal charcoal. The hydrocarbons of bone oil have not as yet been examined, but it has been found that the benzole series are present, accompanied by large quantities of basic oils. The acid portions are also uninvestigated. The bases have been very fully studied by Dr. Anderson, who discovered in bone oil the presence of no less than ten bases, several of them being quite new.

The odour of bone oil is exceedingly offensive and difficult of removal. It does not arise entirely from the presence of the powerfully-smelling bases, for even after repeated treatment with concentrated acids it retains its repulsiveness. This is partly owing to the presence of some unknown neutral nitrogenous bodies. When a slip of deal wood is moistened with hydrochloric acid and held over a vessel of crude bone oil, it rapidly acquires a deep crimson tint. This is in consequence of the presence of the extraordinary basic substance pyrrol. The latter, when in a crude state, possesses a most disgusting smell, so much so, that the offensiveness of bone oil was at one time mainly attributed to its presence. It has, however, been discovered that pyrrol when perfectly pure has a most fragrant and delightful perfume, somewhat recalling that of chloroform, but still more pleasing.

The basic portion of bone oil may be extracted by shaking it up with moderately strong oil of vitriol. This must be done with precaution, as large quantities of gases are evolved, consisting of carbonic acid, hydrosulphuric and hydrocyanic acids. The fluid when permitted to repose separates into two layers, the upper being the purified oil, and the lower the acid solution of the bases. The latter being separated is to be distilled until about one-third has passed over. This distillate will contain the chief portion of the pyrrol. The head of the still is then to be removed and the fluid boiled for some time to remove the last trace. The acid solution, after filtration through charcoal, is to be supersaturated with lime and distilled. The distillate contains the whole of the bases. The apparatus should be so arranged that those bases which are excessively volatile, and consequently come over as gases, may be received in hydrochloric acid. The hydrochloric solution and the oily bases are to be examined separately. The former is to be evaporated carefully to the crystallising point, and then allowed to cool. By this means the ammonia may be removed by crystallisation as chloride of ammonium.

When no more sal-ammoniac can be obtained by crystallisation, the mother-liquid is to be treated with potash, in an apparatus so arranged that any gaseous products evolved may be collected in hydrochloric acid. The retort must have a thermometer in the tubulature to enable the temperature to be properly regulated. All the bases distilling below 212°, are to be received in hydrochloric acid, and their presence demonstrated by converting them into platinum salts, and fractionally crystallising. The bases distilling above 212°, are to be separated by fractional distillation. An examination of the hydrochloric solution will, according to Dr. Anderson, demonstrate the presence of methylamine, ethylamine, propylamine, butylamine, and amylamine. The following table contains the names and physical properties of the bases which are contained in that portion of the basic oil which distils above 212°. The amylamine, and even the propylamine, can be separated from the basic oils, by fractional distillation, instead of the fractional crystallisation of platinum salts, but the latter involves less labour.

Table of the Physical Properties of the Pyridine Series of Bases.

Base	Formulæ		Boiling Point	Density at 32°	Vapour-Density	
					Experiment	Calculation
Pyridine .	$C^{10}H^5N$	$\mathbf{C^5H^5N}$	242°	0·9858	2·916	2·734
Picoline .	$C^{12}H^7N$	$\mathbf{C^6H^7N}$	275°	0·9613	3·290	3·214
Lutidine .	$C^{14}H^7N$	$\mathbf{C^7H^7N}$	310°	0·9467	3·839	3·699
Collidine .	$C^{16}H^{11}N$	$\mathbf{C^8H^{11}N}$	356°	0·9439	...	4·137

Bone oil will not become very valuable as a naphtha for general purposes until some cheap method of removing its odour has been discovered. The *Oleum animale Dipellii* of the older chemists and pharmaceutists was prepared by distilling bones; it was very similar in properties to bone oil.—C. G. W.

NAPHTHA, CAOUTCHOUC. *Syn.* Caoutchoucine; Caoutchine. Caoutchouc, by destructive distillation, yields several hydrocarbons, the accounts of which are contradictory. By repeated rectifications they may be separated into fluids of steady boiling-points. The late Dr. Gregory succeeded in obtaining a fluid hydrocarbon from caoutchouc which distilled at 96°, but when treated with sulphuric acid, and the fluid separated by means of water, another hydrocarbon was obtained boiling at 428°. It is most probable, however, that the true composition of caoutchoucine has not yet been made out. This will appear by consulting the analyses yet made, many of them indicating too low a hydrogen for the C^nH^n series, and more nearly approximating to n (C^5H^4). It is quite plain, however, that caoutchine is, in every sense of the term, a naphtha. Caoutchine is one of the best solvents known for india-rubber.—C. G. W. See Caoutchouc.

NAPHTHA, COAL. Ordinary coal-naphtha is the first product in the distillation of coal-tar. The latter is placed in large iron stills, holding from 800 to 1,500 gallons, and distilled by direct steam. The first distillate is about 850° S. G. When 950° S. G. is made, all the naphtha or *light oil* is obtained. The distillate from 950° to 1000° S. G. is the *middle oil*; above that to about 106° S. G. is the *heavy oil.*

The residue obtained in the first distillation is run off into cisterns or tar ponds to allow of the removal of the water. This residue is called boiled tar. Pitch oil may be obtained from it by distillation by the naked fire, every 1,000 gallons will yield about 320 gallons of pitch oil. The residue of pitch in the still is run out while in a melted state. The rough coal-naphtha contains a great number of impurities of various kinds; the principal cause of the foul odour being the organic bases described in the article NAPHTHA, BONE. To remove these the naphtha is transferred to large cylindrical vessels lined with lead. These vessels contain a vertical axis passing down them, supporting blades of wood covered with lead, and pierced with holes. The axis or shaft has, at its upper end, a crank to enable it to be rotated. The naphtha having been run into the vessel, sulphuric acid is added, and the shaft with its blades made to revolve. By this means the naphtha and acid are brought into intimate contact. The whole is then allowed to settle, and the vitriol which has absorbed most of the impurities, and acquired, in consequence, a thick tarry consistence, is run off. This acid treacly matter is known in the works as 'sludge.' The naphtha floating above the sludge is then treated a second time with acid, if the naphtha be required of good quality. During the process, the naphtha acquires a sharp smell of sulphurous acid, and retains a certain amount of sulphuric acid in solution. The next process is to treat it with solution of caustic soda to remove these impurities. This may be effected in an apparatus similar to the first. The naphtha, after removal of the caustic liquor, is next run off into a still, and rectified; it then forms the coal-naphtha of commerce.

Coal tar of commerce is derived mainly from the rich cannels, or from the tars made from coal in the London gas-works, or from the gas-works of the English towns. The latter tar is richer in naphtha than the London; while the tar from the Scotch cannels yields from seven to thirteen per cent. of crude naphtha of a specific gravity of about ·930, which is blown from it by steam introduced into the still. A still containing 2,500 gallons of the other tars would yield on an average forty gallons.

The commercial value of naphtha has fluctuated since the extensive introduction of the coal-tar colour industries, according to their varied fortunes during the last twenty years.

The more or less volatile varieties were sought after just as the varied shades of aniline, the manufacture of which they suited, headed the market. By a series of fractional distillations, both with wet and dry steam, washings with sulphuric acid (specific gravity 1·845), a series of naphthas, more or less rich in benzole, and containing other valuable products are obtained. The naphtha which flows over at a temperature up to 204° Fahr. is called 90 per cent. benzole; that flowing between 204° and 210°, is designated 80 per cent. benzole, and is again fractionally distilled up to 204°; while the residue, on being treated with high-pressure steam, yields a quantity of 40 per cent. naphtha.

Subjecting a charge of 1,587 gallons of crude naphtha and light oil to the series of operations indicated, we obtain, first 897 gallons of once-run naphtha, and 56 gallons of the last runnings, the remaining 634 gallons being only fit to mix with dead oil. The 897 gallons of once-run naphtha yields, after purification by sulphuric acid, 301 gallons of 90 per cent. benzole, 195 gallons of 40 per cent., 237 gallons of solvent naphtha, 12 gallons of last runnings, and 152 gallons of residuum.

The 40 per cent. naphtha contains also toluol and xylol, and is most suitable for making aniline red; the 90 per cent. variety is best adapted for the manufacture of aniline blue or black.

In describing coal-naphtha, we shall take a cursory review of the nature and properties of most of the substances produced by the distillation of coal-tar. It will be unnecessary here to enter into a minute description of the acids existing in coal-tar, inasmuch as they have already been treated of in the article CARBOLIC ACID.

On the hydrocarbons of coal-naphtha.—The following are the principal constituents of those coal-naphthas the boiling-points of which range between 190° and 350°:—

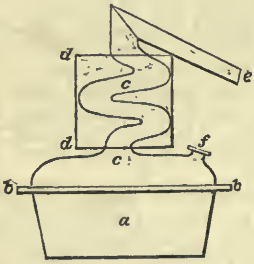
Base	Formulæ		Boiling Point	Specific Gravity
Benzole . . .	$C^{12}H^{6}$	$\mathbf{C^{6}H^{6}}$	177°	0·850 at 60°
Toluole . . .	$C^{10}H^{8}$	$\mathbf{C^{5}H^{8}}$	230°	0·870
Xylole . . .	$C^{16}H^{10}$	$\mathbf{C^{8}H^{10}}$	259°	
Cumole . . .	$C^{18}H^{12}$	$\mathbf{C^{9}H^{12}}$	304°	
Cymole . . .	$C^{20}H^{14}$	$\mathbf{C^{10}H^{14}}$	347°	0·861 at 57°

The fluid hydrocarbons boiling above this point have not been well studied. Ordinary coal-naphtha, in addition to the above hydrocarbons, contains traces of the homologues of olefiant gas, alluded to in the article NAPHTHA.

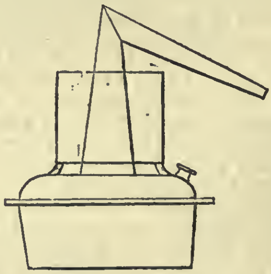
All the above-mentioned hydrocarbons may be separated from each other by careful and sufficiently numerous fractional distillations. It is proper before considering them as pure, to shake them up several times with oil of vitriol, and, after well washing first with water, and afterwards with an alkaline solution, to dry them very carefully with chloride of calcium or sticks of potash. It will be observed that in the above table the specific gravities of the hydrocarbons are not in harmony; this arises from the fluids upon which the experiments were made not having all been procured from the same source; for it has been found that the same bodies, as procured from different sources, often present small but appreciable differences in odour, density, boiling-point, and other physical properties.

The benzole of coal-naphtha may almost entirely be separated by distilling in an apparatus first devised for the purpose by Mr. C. B. Mansfield. The annexed figures from G. Williams's 'Handbook of Chemical Manipulation,' illustrate the vessels he employed for the purpose. *Fig.* 1545 consists of a copper or tinned iron still, *a*, holding about two gallons. The flange *b b*, is merely to support the apparatus in the ring of a gas or charcoal furnace, preferably the former. A wide worm, *c c*, passes through the top of the still into a water-tight cistern, *d d*. The worm ends in a discharge-pipe, *e*. The latter is to be attached to a common worm tub containing cold water. The crude benzole, or coal-naphtha, is to be placed by means of the opening *f* into the still, and all the joints of the apparatus being closed, and effectual condensation insured, the fire is to be lighted. The naphtha soon begins to boil, but nothing comes over, because the water in *d d* effects condensation. In a short time, however, the water in *d d* begins to get warm, and, as soon as 177° is reached, benzole begins to come over, and is perfectly condensed in a second worm, kept cold by means of water. It is plain that as the fluids of higher boiling-points begin to come over, the water in *d d* will boil, but distillation then ceases entirely. The reason of this is, that nothing can make the head *c c* hotter than 212°, because of its being surrounded with water. All hydrocarbons that are not volatile at 212° are consequently condensed there, and fall back into *a*. The benzole distilling over is

1545



1546

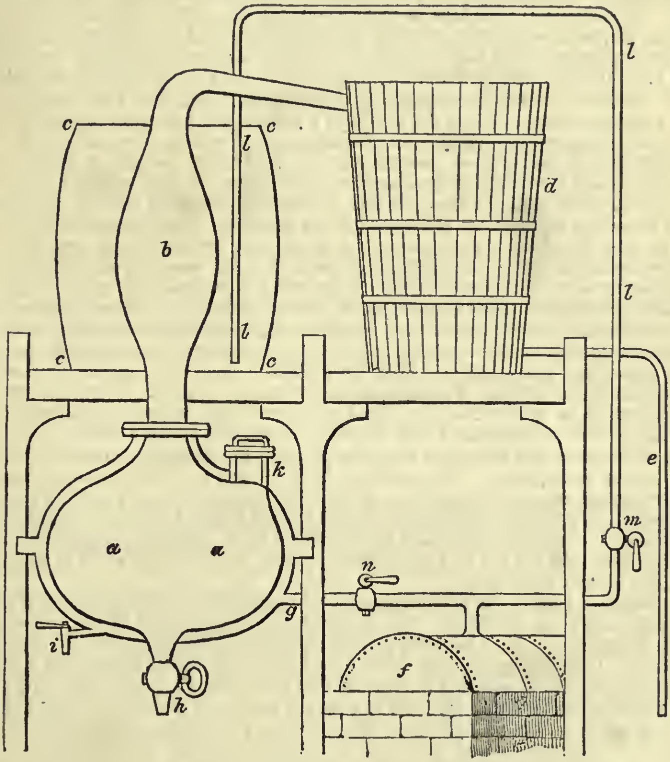


quite pure enough for all ordinary purposes. It may, if required very pure, be rectified a second time in the same apparatus, taking care that the head does not get hotter than 180° or 190°. If the benzole is wanted absolutely free from its accompanying hydrocarbons, it must be purified by freezing. For this purpose the rectified benzole is to be placed in a thin glass or metal vessel, and surrounded with snow or pounded ice mixed with salt. The whole apparatus is to be surrounded with sawdust and covered with woollen cloths to prevent access of heat. As soon as the benzole is frozen, it is to be placed in a funnel and allowed to drain. The solid mass when thawed is pure benzole. By this mode of proceeding, a considerable quantity of fluid is always accumulated, which refuses to freeze and yet boils at the proper temperature for benzole. G. Williams found it to contain a small quantity of the C^nH^n series of hydrocarbons (homologous with olefiant gas). Mr. Church states it to contain benzole in a peculiar condition; he calls it parabenzole. The presence of the C^nH^n series may always be proved by the readiness with which the fluid decolourises bromine-water.

A similar form of apparatus for rectifying benzole, and one that answers almost as well, is that represented in *fig.* 1546. It will be seen that the worm *c c* of *fig.* 1545 is replaced by a straight tube. The mode of use is precisely the same.

Where the benzole is to be extracted from coal-naphtha on the large scale, the following apparatus will be found convenient:—The boiler *a a*, *fig.* 1547, surrounded by a steam-jacket, is connected at its upper extremity with a head, *b*, answering to the worm *c* in *fig.* 1545. The head plays into the worm-tub *d*; the benzole being conveyed by the exit-pipe, *e*, to the reservoir, or close tank, in which it is to be stored. The tub, *c c c c*, contains water to condense the hydrocarbons which are to be removed from the benzole. In order to save time, it is convenient at the commencement of the operation to heat the water in *c c c c* to about 170°; this is effected by means of the steam-pipe *l l l*, which is connected with the boiler *f*. The steam is admitted to the jacket of the still by means of the pipe *g*. The steam can be regulated or stopped altogether by means of the stopcock *n*. The cock *m*, is to regulate the admission of steam to the vessel *c c c c*. The man-hole is represented at *k*. A small cock to allow the condensed water in the jacket to be run off, is seen at *i*. Unless the naphtha is

1547



of the best quality the benzole will be difficult to extract by the heat of the jacket alone. It will then be necessary to send direct steam into *a a*. When no more benzole comes over, the remaining naphtha is to be run out of the still by the stopcock *h*. Although the boiler *f* is, for the sake of space, represented in the figure as if placed beneath the support of the condenser or worm-tub, it should in practice be removed to a considerable distance for fear of the vapour of the hydrocarbon reaching the stoke-hole and causing an explosion. The condenser *b* may be arranged in the form of a worm like *c* in *fig.* 1545, but the precaution is scarcely necessary if the chamber at *b*, *fig.* 1547, be made sufficiently capacious. The benzole obtained in the above apparatus is, of course, contaminated with toluole; if, however, the rectification be repeated, the water in the chamber *c c c c* not being permitted to become hotter than 180° Fahr., the resulting benzole will be almost pure. One distillation is amply sufficient for the preparation of the commercial article.

A rectifying column somewhat like Coffey's still may also be employed for preparing benzole.

The less volatile naphtha remaining in the still is by no means valueless; it is adapted for almost all the purposes for which ordinary coal-naphtha is applicable. By removing the fluid by the tap *h*, and distilling it in an ordinary still, a very good coal-naphtha of a density of about 0·870 will be obtained.

It is extremely curious that naphthas which contain large quantities of naphthaline will often distil without the latter crystallising out. It is volatilised in the vapour of the naphtha, and therefore escapes observation. But if a little chlorine be poured into the fluid, or if a little chloride of lime be added, followed by an acid, and the fluid be then distilled, the naphthaline will come over in the solid state, so that it can be removed by mechanical methods. It does not appear to be due to the formation of Laurent's chloride of naphthaline, for the product contains only traces of chlorine.

Benzole has been much used of late to remove greasy and fatty matters from cotton, wool, silk, and mixed fabrics. It is by no means essential that the benzole should be absolutely pure for this purpose. By this it is meant that the presence of naphthas, boiling somewhat above 177°, does not materially affect the usefulness of the fluid. If, however, the naphtha is to be employed for removing greasy stains from dresses, gloves, or other articles to be worn, the purer and more volatile the hydrocarbon, the more readily and completely the odour will be removed by evaporation. Mr. F. C. Calvert patented the application of benzole to some purposes of this kind. He first purified the naphtha by means of sulphuric acid and caustic alkalis in the usual manner, and then rectified it at a temperature not exceeding 212°.

For this purpose the apparatus described in *fig.* 1547 will be found well suited. The inventor applies the rectified coal-naphtha, or nearly pure benzole, to the following purposes:—1st, for removing spots and stains of grease, *i.e.* fatty or oily matters, tar, paint, wax, or resin, from cotton, woollen, silk, and other fabrics, when, in consequence of its volatility, no mark or permanent odour remains. 2nd, for removing fatty or oily matters from hair, furs, feathers, and wools, and for cleaning gloves and other articles made of leather, hair, fur, and wool. 3rd, for removing the fatty matters which exist naturally in wool. 4th, for removing from wool, tar, paint, oil, grease, and similar substances used by farmers for marking, salving, and smearing their sheep. 5th, for cleansing or removing the oily or fatty matters which are contained in cotton-waste that has been used for cleansing or wiping machinery or other articles to which oil or grease has been applied. In order to remove the above matters by means of coal-naphtha, the articles, if small, are merely rubbed with it. On the large scale the matters to be operated on are placed in suitable vessels, and the naphtha is run in. After contact for some hours the fluid is run off, and the fabrics are passed through squeezers and submitted to strong pressure to remove the greater portion of the benzole or naphtha. The naphthas which run out are distilled off, so that the greasy matters may be preserved and used for lubricating machinery or other purposes.

Furniture paste may also be made from light coal naphtha or benzole by the following process:—One part of wax and one of resin is to be dissolved in two parts of the hydrocarbon, with the aid of heat. When entirely dissolved, the whole is allowed to cool, and is then fit for use.

Naphthaline is used for the preparation of lamp-black, but the quantity employed for that purpose is but small. The quantity annually produced by the various gas-works is enormous. Its odour and volatility prevent its being applied to lubricating purposes. It often happens that much valuable time is lost by unscientific operators in endeavouring to remove the smell from such substances as naphthaline; they forget that the odour of a body of this class is a part of itself, and cannot be removed without its destruction. It is possible that the compounds of naphthaline may one day be applied to useful purposes. By treating naphthaline with excess of chlorine, and removing fluid substances with ether, a crystalline paste is obtained. This paste, dissolved in boiling benzole and allowed to repose, deposits beautiful rhombohedral crystals, often of large size. They have exactly the form of Iceland spar, and, like that substance, possess the power of double refraction. When nitronaphthaline is treated with acetic acid and iron filings in the same manner as that employed by M. Béchamp for the production of aniline, a base is obtained of the formula $C^{20}H^{9}N$; it is called Naphthalamine. It is, therefore, isomeric with cryptidine, but has no other point of resemblance.

If treated with nitric acid, naphthaline yields phthalic acid, and this by elimination of carbonic acid may be either converted into benzole or into benzoic acid. Benzoic acid is now derived commercially from naphthaline.

The relation which appears to exist between naphthaline and alizarine is also very interesting. Alizarine is now prepared artificially from anthracene or paranaphthaline, by processes described under the articles ALIZARINE and ANTHRACENE.

Naphthalamine, which is the base corresponding to aniline, is now manufactured in the same way as that body is from benzole. It yields beautiful commercial dyes, viz.: Martius yellow, Magdala red, Naphthaline violet, and Naphthaline blue.

It is said that naphthaline has been employed with advantage in the treatment of psoriasis. M. Emery states that it succeeded in twelve out of fourteen cases. In the two where it failed the one patient was a woman thirty years of age, who had been afflicted for eight years with *psoriasis gyrata*; the other patient was a young man who had suffered for several years with *lepra vulgaris.* In the latter case, two months' treatment having effected no good, pitch ointment was substituted, which effected a cure in two months. The naphthaline was employed in the form of ointment in the strength of ½ or 1 drachm of lard. The application is sometimes, however, attended with severe inflammation of the skin, which must be relieved with poultices.

The dead oils, as the less volatile parts of coal-tar are called, contain several substances, the nature of which is very imperfectly known. Among them may be mentioned pyrene and chrysene. The former has been examined by Laurent, who gives the formula $C^{30}H^{12}$ for it. They are found in the very last portions that pass in the distillation of coal-tar. They are also said to be produced during the distillation of fatty or resinous substances. The portions which distil last are in the form of a reddish or yellowish paste, which rapidly darkens in colour on exposure to light. Ether separates it into two portions, one soluble, containing the pyrene, the other insoluble, containing the chrysene. The pyrene may be obtained by exposing the etherial solution to a very low temperature, which will cause it to crystallise out. The composition of pyrene is, according to Laurent,—

	Experiment.	Calculation.	
Carbon	93·18	C^{30}	93·7
Hydrogen	6·11	H^{12}	6·3
	99·29		100·0

The portion insoluble in ether consists of chrysene in a tolerably pure state. G. Williams found that it crystallises on cooling from a solution in Boghead naphtha, in magnificent yellow plates, with a superb lustre resembling crystallised iodide of lead. The following are the results of its analysis. His combustion was made upon chrysene crystallised as above:—

	Laurent.		C. G. W.	Calculation		
Carbon	94·83	94·25	94·63	94·74	C^{18}	108
Hydrogen	5·44	5·30	5·37	5·26	H^{6}	6
	100·27	99·55	100·00	100·00		114

See CHRYSENE.

No commercial use has been yet devised for these interesting bodies; which are also bye-products in paraffin refineries. But the brilliant discoveries of Graebe and Lieberman have raised anthracene from the category of waste materials. In 1868 they obtained anthracene from alizarine, and in the following year they were able to disclose a process for the manufacture of the valuable dye from the unsavoury coal-tar product. A large extension of the coal-tar colour manufacture has ensued. Anthracene is obtained from the heavier coal oils, which when exposed to the action of a powerful freezing mixture, often deposit a mass of crystals only partly soluble in alcohol. The soluble portion consists of naphthaline; the other portion is anthracene, or paranaphthaline. It appears, from the analyses which have been made, to be isomeric with naphthaline. It fuses at 356°, and boils at about 580°. The density of its vapour, determined at 848°, was 6·741°, agreeing very well with the formula $C^{30}H^{12}$, which requires 6·643. This formula is one and a half times naphthaline, thus: $C^{20}H^{8} + C^{10}H^{4} = C^{30}H^{12}$. For a description of the methods by which anthracene is now prepared from coal-tar, and alizarene from anthracene, the reader is referred to these articles respectively, and to the Supplement to Watts's 'Dictionary of Chemistry.'

Metanaphthaline is a peculiar substance which appears to be closely related to the above products. It is formed during the manufacture of resin gas. It is a fatty substance fusing at 158°, and distilling at about 617°; it is at present but little known.

The following Table, taken from *Traité des Dérivés de la Houille*, by Gerard and De Laire, epitomises the operations of French tar-distillers:—

FIRST DISTILLATION OF COAL IN THE RETORTS.

Gas. Tar. Coke.

SECOND DISTILLATION OF THE TAR.

1. Light oils (boiling 30° to 150° Cent.). 2. Medium or creasote oils (boiling 140° to 200° Cent.). 3. Anthracene oils, or heavy oils, containing naphthaline and anthracene (boiling 200° to 350° Cent.).

THIRD DISTILLATION.

Light Oils.

Into 2 fractionals.

No. 1. That which passes over, up to 140° Cent., constituting naphtha.

No. 2. That which passes over, above 140° Cent., is mixed with No. 2 fractional distillation of the middle oils.

Middle Oils.

Into 3 fractionals.

No. 1. That which passes over, up to 130° Cent., is remixed with the naphtha.

No. 2. That which passes betwixt 130° and 200° = rectified creasote oil.

No. 3. That which passes over, above 200° Cent., is counted anthracene oil.

TREATMENTS BY WASHING.

Rectified Light Oils or Naphthas.

(39° to 140° Cent.). Subjected to

1 washing with pure water.
2 washings with sulphuric acid.
2 washings with water.
1 washing with soda.
2 washings with water.

Middle Rectified Oils.

(140° to 200° Cent.) Subjected to

1 washing with pure water.
2 washes with sulphuric acid.
2 washes with pure water.
1 washing with soda.
2 washes with pure water.

Crude Heavy Anthracene Oils.

(200° to 350° Cent.) Subjected to

1 wash with pure water.
2 washes with hydrochloric acid.
1 wash with pure water.
1 wash with soda.
2 washes with water.

FOURTH DISTILLATION.

Naphtha.

Into 4 fractionals.

No. 1.	That which passes betwixt	39°— 80° Cent.
No. 2.	„ „	80°—115° Cent. benzole.
No. 3.	„ „	115°—150° Cent.
No. 4.	„	a little over 150° Cent.

Middle Rectified Oils.

Into 2 fractionals.

No. 1. That which passes 140° to 190° Cent.

No. 2. That which passes over 190° Cent. is mixed with the heavy oils.

Pure Heavy Oils.

Into 3 fractionals.

No. 1. That which passes from 215° to 230° Cent.

No. 2. That which passes from 230° to 290° Cent.

No. 3. That which passes from 300° to 340° Cent.

The *Light Oils* or *Naphthas* contain the following bodies:—

	Boiling-point. Cent.
Ammonia and ammoniacal salts	...
Amylene	39°
Traces of propylene, butylene dissolved in their homologous liquids	...
Caproylene or hexylene	55° to 70°
Hydruret of hexyle	68°
Petinine	80°
Benzine	82° to 83°—0·850
Œnanthylene or heptylene	94°
Toluene	105° to 108°
Parabenzine	97° to 98°
Hydruret of octyle	116° to 118°

	Boiling-point. Cent.
Xylene	127° to 128°
Picoline	133°—0·955
Cumene	151°
Hydruret of decyle	158°
Pyridine	150°
Cymene	175°
Traces of phenic acid	...

The various treatments specified in the Table are to remove several of these bodies, which give the crude naphtha its offensive odour, and hinder its retaining a permanent white colour. In the various acid and alkaline treatments 5 per cent. of ordinary sulphuric acid is used, which is counteracted by 2 to 3 per cent. of caustic soda of a density 1·305.

The *Middle Oils*, after their first rectification, and their augmentation with the fractional distillation of the heavier naphthas, contain the following bodies:—

	Boiling-point		Boiling-point
Picoline	133°	Aniline	182°
Pyridine	150°	Phenic acid	187°
Cumene	145° to 151°	Parvoline	188°
Lutidine	154°	Toluidine	198°
Eupion	169°	Cresylic acid	203°
Cymene	179°	Coridine	211°
Collidine	175°	Naphthaline	from 79°, from 218°

Just 5 per cent. of sulphuric acid is given at each of the two treatments of the middle oil; and the amount of soda used depends on the quantity of cresylic or phenic acids—a very variable amount—the individual oil may contain. To estimate the quantity of phenic acid, agitate 4 or 5 kilogrammes of the middle oil with an excess of caustic soda of specific gravity 1·305, for an hour or two; allow it to repose; then decant the soda-liquor; wash it with hot water; then filter; treat the clear filtrate with hydrochloric acid, and the phenic acid will separate. As the equivalent of phenic acid ($C^6H^6O = 94$) is about $1\frac{1}{2}$ that of soda ($Na^2O = 62$), 1 part of soda should fix 2 parts of the acid. Part of those middle oils is also used in dissolving caoutchouc.

The *Heavy Oils*, until recent discoveries of the utilisation of the waste bodies anthracene and naphtha, were not usually distilled. Their distillate betwixt 215° and 230° is almost all naphthaline; that betwixt 290° and 320° is principally anthracene.

The *Heavy Oils* contain:—

	Boiling-point
Aniline	182°
Phenic acid	187°
Parvoline	188°
Cresylic acid	203°
Phlorylic acid	203°
Coridine	211°
Naphthaline	217° to 218°
Rubidine	230°
Quinoleine or leucoline	235° to 237°
Viridine	251°
Lepidine	260°
Anthracene and paranaphthaline	310° to 359°
Chrysene	...
Pyrene	...

The proportions of acid and alkali in this treatment are 6 per cent. of soda and 10 per cent. of hydrochloric or sulphuric acid. In order to expiscate the odour, this oil, after distillation, is treated with 4 per cent. of sulphate of iron.

The rectified oil may be used for greases, for creasoting railway-sleepers, as an antiseptic, or for fuel or gas-making.

NAPHTHA, NATIVE. In a great number of places in various parts of the world, a more or less fluid inflammable matter exudes. It is known as Persian naphtha, Petroleum, Rock-oil, Rangoon tar, Burmese naphtha, &c.

The American petroleum consists in its more volatile portions of amyl, hydrogen, hydride of amyl, C^5H^{12} boiling at 68°, and hydride of caproyl C^6H^{14} boiling at 92°;

the portion capable of being safely used in lamps is represented by the hydrocarbons C^7H^{16} and $C^{12}H^{26}$. The higher series of the marsh-gas group, which are composed according to the formulæ $C^{20}H^{42}$ and $C^{27}H^{56}$, exhibit a butter-like consistency and belong to the paraffins met with in petroleums. Rangoon oil assumes at ordinary temperatures the consistency of butter.

Messrs. Warren De La Rue and Hugo Müller find the fluid to consist of two principal series of hydrocarbons, namely, the benzole class and another, unacted upon by acids, and apparently consisting of the radicals of the alcohol. In addition to the fluid hydrocarbons, Burmese naphtha contains a considerable quantity of paraffin.

Burmese naphtha or Rangoon tar is obtained by sinking wells about 60 feet deep in the soil; the fluid gradually oozes in from the soil, and is removed as soon as the quantity accumulated is sufficient. The crude substance is soft, about the consistence of goose grease, with a greenish brown colour, and a peculiar but by no means disagreeable odour. It contains only 4 per cent. of fixed matters. In the distillations De La Rue and Müller employed superheated steam for the higher, and ordinary steam for the lower temperatures. At a temperature of 212°, 11 per cent. of fluid hydrocarbons distil over; they are entirely free from paraffin. Between 230° and 293° Fahr., 10 per cent. more fluid distils, containing, however, a very small quantity of paraffin. Between the last-named temperature and 320° Fahr., the distillate is very small in quantity, but from that to the fusing point of lead, 20 per cent. more is obtained. The latter, although containing an appreciable amount of paraffin, remains fluid at 32° Fahr. At this epoch of the distillation, the products begin to solidify on cooling, and 31 per cent. of substance is obtained of sufficient consistency to be submitted to pressure. On raising the heat considerably, 21 per cent. of fluids and paraffin distil over. In the last stage of the operation, 3 per cent. of pitch-like matters are obtained. The residue in the still consisting of coke containing a little earthy matter, amounts to 4 per cent. We thus have as the products in this very carefully-conducted and instructive distillation:—

Below 212°	Free from paraffin	11·0
230° to 293°	A little paraffin	10·0
293° to 320°		
320° to fusing point of lead	Containing paraffin, but still fluid at 320°	20·0
At about the fusing point of lead	Sufficiently solid to be submitted to pressure	31·0
Beyond fusing point of lead	Quantity of paraffin diminishes	21·0
Last distilled	Pitchy matters	3·0
Residue in still	Coke containing a little earthy impurity	4·0
		100·0

All the above distillates are lighter than water. Almost all the paraffin may be extracted from the distillates by exposing them to a freezing mixture. In this manner no less than between 10 and 11 per cent. of this valuable solid hydrocarbon may be obtained from Burmese naphtha.

Naphtha appearing closely to resemble the above is found at Alfreton, Amiano (Duchy of Parma), Baku (borders of the Caspian), Barbadoes, Clermont (France), Gobian, near Bezières (France), Galicia, Neufchâtel (Switzerland), Tegernsee (Bavaria), Trinidad, United States, Val di Noto in Sicily, Wallachia, Zante, St. Zibio (Modena), Sehndee near Hanover, near Hamburg, Kleinschöppenstadt, Brunswick, in the Pyrenees and other portions of Spain and France. Petroleum, well salt, and combustible gases are associated together in the Bavarian Alps, in Tuscany, Modena, Parma, the Carpathian Mountains, in America, and other localities. As marsh-gas is given off from beds of rock-salt some chemists have suggested that CH^4 might yield by condensation the homologous hydrocarbons C^6H^{14} and C^7H^{16} forming the bulk of the volatile portions of petroleum and paraffin. Naphtha was one of the ingredients said, by some old authors, to enter into the composition of the Greek fire.—C. G. W.

Naphtha was originally a mineralogical term; but much confusion has arisen in its application, or in that of its mineralogical synonym Petroleum, to articles of commerce or manufacture. The first distillate of coal-tar resembled in appearance and in some properties the fluid described as oozing in many places from the earth; hence the apparent propriety of adapting an old name for the new manufactured product. But both articles have now become important foundations for two very different industries, and it has been found that the earth-oil cannot give benzole, the coal-tar colour producer. So it has been tacitly agreed by technologists to give the name *Naphtha* to the distillate from coal-tar, whilst *Petroleum* is assigned to the natural products; for though specimens of these may be chemically different, they serve the same manufacturing purposes and are commercially looked upon as one body. But as the similarity in the processes of manufacture of both bodies must strike an intelligent workman, we need not feel surprised when he calls alike the products of shale petroleum, or coal-tars from the still naphthas. The distinction, moreover, is convenient; as the products of the first two bodies serve different technical purposes from the subsequent ones. They have also become the subject of legislative provision on account of the lamentable accidents which they have sometimes occasioned; though the confusion in terminology is well illustrated in a recent enactment which designates as petroleum all bodies from rock-oil, schists, or peat inflaming below 100° Fahr. It has been generally thought that the application of the term *spirit* would be a convenient substitute for shale or petroleum naphtha.

According to Wiederhold, crude or native naphtha gives by fractional distillation:—

Petroleum spirit	48·6 per cent. of	0·70	spec. grav.	boiling at	100° Cent.
	45·7 ,,	0·73	,,	,,	200° ,,
Refined petroleum	5·7 ,,	0·80	,,	above	200° ,,

The lightest distillates of American petroleum, Sherwood oil, or shale have been much investigated in regard to use as anæsthetics or as carburetters. Names have thus been given to the varied fractional distillates. Kleinschmidt of St. Louis specifies the following:—

			Beaumé.	
Oils distilling over below	37°·7	specific gravity	·0° — ·60° = 90°–97°	= Rhigolin
,, ,, at	76·6	,,	0·63 – 0·61 = 80–90	= Gasolin
,, ,, ,,	137·0	,,	0·67 – 0·63 = 70–80	= Naphtha
,, ,, ,,	148·0	,,	0·73 – 0·67 = 60–70	= Benzine
,, ,, ,,	183–219	,,	0·78 – 0·82 = 40–60	= Kerosen.

The late Sir James Simpson took great interest in the anæsthetic powers of the first series; on account of them petroleum gained its healing repute amongst the American Indians; applied externally they soothe neuralgic complaints.

Gasolin is mainly relied on as the carburetting agent by several new patent gas companies who thus purpose to enrich common coal-gas, water-gas, or atmospheric air. Spirit of specific gravity of about 0·650 and with a boiling-point of 58° Cent. is preferred for this purpose, and as this spirit, which the preceding analysis shows constitutes so large an item in crude petroleum, is too dangerous to burn in common lamps, it is sold at the price of a waste product. It is believed that one gallon of spirit will carburet 500 cubic feet of gas, raising it in luminosity to 30 or 33 candle-power of flame. The opposing elements of odour and danger may stand in the way; but the same process may be adapted in using this spirit for heating or smelting operations. Mr. Wills, F. C. S. gives the following calculations founded on Dalton's law for ascertaining the vapour-tension of liquids. ('Journ. Soc. of Arts, No. 1070, vol. xxi.)

Table of percentage of vapour of petroleum spirit of a specific gravity ·650 *present in air or other medium at different temperatures.*

Temperature.		Percentage.	Temperature.		Percentage.
–10° Cent.	(14° Fahr.) .	5·7	–15° Cent.	(60° Fahr) .	22·0
0 ,,	(32 ,,) .	10·7	20 ,,	(68 ,,) .	27·0
10 ,,	(50 ,,) .	17·5	40 ,,	(104 ,,) .	39·0

This diffusibility through air in the state of vapour of petroleum has occasioned many lamentable accidents, to prevent which various legislative measures have been passed. When a light is applied to a common paraffin-oil lamp, in which the oil is at once converted into vapour, ignition will occur. Explosion will also supervene on shipboard or in a room, in which a mixture of common air and hydrocarbon-vapour, whether from low specific gravity, or from the construction of the reservoir-cell, have been allowed to accumulate in the proportions which cause coal-mine or domestic gas mixed with air to explode. Petroleum and the paraffin oils alike consist of a series of oils bound together by links and very similar in composition. But the first members of the series are very easily detached from the others, and their vapours come off at ordinary temperatures. Mere specific gravity does not, as was once thought, determine the safety of an oil. The specific gravity of mineral oil ranges from 814° to 830°, the extreme point at which it easily ascends a wick without charring it. But petroleums of 800° have been shown perfectly safe by the tests of flash-point and firing-point; whilst others standing at higher numbers on the hydrometer have not stood them. In America the original way of testing the firing-point of oils is by placing a light in the open vessel containing them, which is being also heated, and noting the exact degree on a thermometer whose bulb is also immersed in the fluid, when flame appears on its surface. In this country, again, legislation is based on the fact that light vapours arise many inches from the surface of the oil, and can be ignited there long before the body of the oil takes fire. In the open test which was first prescribed by Act of Parliament, the vessel holding the oil was inclosed in a water-bath heated by a spirit lamp, a thermometer again inserted, the whole protected by a screen extending half round the surface of the vessel, and a match, in, say the form of a piece of string, applied a full inch at least above the surface of the oil. In the close test the surface of the oil-holding vessel is covered; openings only being left for the firing-string and the thermometer. There is a difference of 15° to 25° in the firing-point of the two tests; the tests reduce the degrees in the inverse order to that in which they have been given. An American cargo with a firing-test certified at port of transit, will have it diminished about 10° by the open test, and 20° by the close test. The law now stands for Britain prohibiting the sale of petroleum under 100°. It varies in different countries. At Antwerp, which regulates the petroleum importation of Germany, there is no prohibitory enactment. The State of Maine, U. S., specifies 115° igniting test, whilst Massachusetts and Vermont agree on 110° Fahr. (See 'Report of Select Committee of the House of Lords on the Petroleum Bill, 1872.')

Petroleum and paraffin spirits or naphtha have also acquired the synonym of 'turpentine-substitute,' because of their application in varnishes and other house paints; but, as the name implies, cheapness mainly regulates this use.

Hirzel (Spec. A. D. 1863, No. 2987) proposes to extract essences and perfumes, by petroleum spirit, as a substitute for bisulphide of carbon. Others have patented this substance as an extractor of vegetable and animal oils. G. Ville, the French agricultural chemist, shows that were this method applied to the culture of the ordinary oleaginous plants much good would result. If 35 hect. of the colza were treated ordinarily by hydraulic press, 808 kil. of oil would be given; but by the aid of petroleum spirits the produce is increased to 1,039 kil. (See *Les Engrais Chimiques*, par M. G. Ville, tom. ii. p. 176, &c. Paris, 1872).

Ville is inclined to think that from 6 to 8 per cent. of oil is left in seeds after the action of the hydraulic press. Of course where oleaginous plants are mainly grown for their oil and fibre, as in the Western States of America, or where the cake is returned as a manure into the soil, as recommended by G. Ville, this process is commercially available.

Sponge lamps have been suggested to use mineral spirits either as portable gas for illuminants or a quick and ready heating-power. The chandlers last winter exhibited at least two ingenious French contrivances for this purpose. With proper precautions, no danger can supervene. Any other hydrocarbon incautiously managed will cause peril. Turpentine emits a volatile vapour a little above 110° F.; and a can of it kept in a storehouse a little above the boiler is said to have caused an explosion resulting in the famous burning of the steamer 'Amazon.' Other like calamities have been traced to this source. Such volatile oils expand at the rate of 1 in 30 in a temperature of 60° F., that is to say, between 40° F. and blood-heat; other oils of the series expand at correspondingly higher temperatures. The oil which gave its sad pre-eminence to the Abergele accident was a Welsh-made oil of 130 spec. grav., and a high firing-point. When such vapours mix with atmospheric air in the proportion of 1 in 7 or thereabouts, an explosion occurs on the proximity of a light.

On first igniting a paraffin lamp, the heat from the burning wick causes the lighter oils to ascend in vapour. Should the whole contents of the reservoir be too suddenly raised into vapour, manifestly 'there's death in the pot.' A dangerous oil will assume this state at 80° or 90° F., but only a very small portion of a safe oil will vaporise at these temperatures. Dr. Lyon Playfair gave the following evidence before a recent Parliamentary Committee:—'I would burn no oil in my own house, nor would I advise a friend of mine to burn any in his house, under 120° F. as the very minimum, but I should prefer 130°, that is to say, 120° for the vapour, and 130° for the permanent ignition. Oil with a high firing-point gives out more light than the other kind. It burns quite as long and gives out more illumination. A gallon of oil at 130° of permanent ignition, produces 25 per cent. more light than a gallon at 100°. The light from the low-igniting oil is not more at the time it is burning, but those who are accustomed to burn light petroleum, sometimes like it better than heavier and safer oils, as they find that they can manage the wick more easily.'

At an expense of about 2*d*. per gallon, petroleum can be refined so as to be perfectly safe.

The following remarks on the formation of naphthaline from practical gas manufacturers are of considerable interest. Mr. Hyde, at a meeting of the Gas-light Association of the United States held at Cleveland, after generally describing this substance, proceeded to say:—It had a peculiar faintly aromatic odour, not unlike narcissus; it was heavier than water, and was readily dissolved by naphtha. During the fifteen years of his experience as engineer of the Cleveland Gas-light and Coke Company, in the manipulation of the gas varied results had been observed. In the process of condensing and washing the gas, their usual method had been to condense first and then to wash. At one time it was thought advisable to erect a spray-washer between the hydraulic main and the condensers, as was the method in many gas works. Soon after there was observed a rapid accumulation of naphthaline in the drain leading to the tar-well, in the purifiers and pipes about the works, and also in the distributing mains in the streets. At a subsequent period these spray-washers were removed and placed between the condensers and purifiers, used in connection with the purifiers, and very much less naphthaline was crystallised. During the periods mentioned the heats of the benches were what was termed 'high.' During the past cold season there was used with the common bituminous coal from four to eight per cent. of cannel coal. The heats were not high, the gas was kept hot while passing from the retort-house to the condensers—about 150 feet—by encasing the pipe; the condensation was very gradual, by the use of an open-air condenser, and but a small amount of water used in the scrubber and no spray-washer. During this period they had no crystallised naphthaline. It had always been observed that wherever high heats were carried more naphthaline was crystallised than with medium heats; and that when a bench was lightly charged, after being cleaned of carbon and while hotter than usual, naphthaline appeared more abundantly than under ordinary circumstances. His deductions from his experience at the Cleveland works were as follow:—The crystallising of naphthaline was caused first by 'high heats,' and the amount increased by rapid cooling of the gas by contact with cold water, cold pipes, and other rapid cooling; and that naphthaline was more likely to be developed in gas made from slack coal than from lump coal. The remedy he would suggest for the annoyance was the use of a small percentage of cannel coal, in connection with the common bituminous coals, moderate heats, long exposure of the gas to hot pipes or other condensing operations before reaching the cooling condenser; slow cooling of the gas, and scrubbing with a small amount of fresh or ammoniacal water of moderate temperature; and, also, when found necessary, the introduction of a small continuous supply of naphtha into any horizontal pipes about the work after condensation, or into the drips of the inlet and outlet pipes to the gas-holder. The evaporation of the naphtha would dissolve the naphthaline crystals.

Another gas-engineer remarked that high heats had been so constantly upbraided as the parent of naphthaline, and so thoughtlessly and unjustly, that he must try to rescue them from blame. He admitted that high heats undoubtedly place them in a position to be annoyed with the crystal, but so did the use of steam put them in jeopardy from railway accidents. Of late years they had been putting brain-work into their retort-houses faster than into the other apparatus, and the result was the unfortunate crystal under dissection. High heats, low seals, rapid evolution of the gases, hasty removal from the retort, and sudden plunging at a high temperature into the showers of spray-washers, or through yards of chilling condensers, soon gave birth to the lusty and troublesome crystal nuisance that sheds its unthankful favours upon gas managers. The agency of heats in producing naphthaline lies simply in converting into a gas, at a high heat, olefiant qualities, that at low heats pass over as oils. In order to retain this (at that point) easily-condensed volatile oil in a gaseous form, three methods were open to them: they might mix free hydrogen with their coal-gas at a high temperature; they might introduce into their coal-gas, gas made from naphtha; or adopt the plan of having a long connecting main, protected from atmospheric changes, between the hydraulic main and condensing apparatus, so retaining the crude gas as long as possible in contact with its own condensable vapours, and subjecting it to a gradual lowering of temperature. He had made the practice of introducing the water into his condensers at the 'outlet' end, and taking the overflow from the 'inlet' end, so causing the gas to come first in contact with pipes somewhat higher tempered than he could otherwise do, and so continuing his scheme of gradual cooling. He used but little water in actual contact with the gas, believing more in the efficacy of the dry scrubbing it got in passing the divisions of the washer than in water as a cooling agent in that stage. Following these general views, he had succeeded in escaping any further trouble from naphthaline, save an occasional warning presence in his purifiers, when he accepted the hint and looked for something wrong at the back of them. When gentlemen came to understand the chemical laws governing the deposit of naphthaline, the great step to its prevention would have been taken, and it would pass out of the category of nuisances and be blessed for its useful qualities.

For the gas-engineer it seems most important to prevent the crystallisation of naphthaline, and this it appears can be done by keeping the gas containing naphthaline in contact with the light volatile oils; though all the chemical properties of naphthaline are not yet discovered, it is a well-known fact that naphthaline shows a great affinity for light hydrocarbons. In gas generated at a low temperature, many of the volatile substances are lost in an undistilled condition, with the tar in the hydraulic main and connecting pipes, in their liquid form, and combine with, or rather, take up, the naphthaline. Under an increased heat the greater part of these oils would form fixed gas, and consequently increase the volume of the gas manufactured. Though it is a great advantage to make use of as great a quantity of these lighter oils as possible in distilling the same to gas, we all know that all the lighter oils cannot be used up entirely in the distillation of cold, and thus it seems the duty of an enlightened gas-engineer not to waste the same, but to make a judicious use of it in keeping the gas as long as possible in contact with the gaseous vapours, and thus preventing the crystallisation of the naphthaline which is contained in the gas. The lighter oils, as long as they are united, will, whenever they settle down in a condensed state, carry away a great deal of naphthaline in a liquid form, and the naphthaline will, in a pipe placed in proper descent, be carried on to the drips. The lighter-oil vapours will separate from the gas at low temperature; in condensing, therefore, it is thought by many best that the take-off pipes from the hydraulic main should be nearly on a level with the same, and should be of sufficient length. Clegg gives as a rule, that for every inch of diameter, the take-off pipe should have a length of ten feet, the working pressure being two inches; for instance, the take-off pipe being ten inches in diameter, the proper length would be one hundred feet. By increased working pressure they will of course require increased length in the ratio of their square roots; but even at this rate a great deal of the lighter oils will be lost in condensation.

It had been found by experience that those oils, if collected in a little tank and re-vapourised, will greatly diminish the tendency of the naphthaline to crystallise, and at the same time improve the quality of the gas. The form of such an apparatus should be a small iron tank, closed at the top, and placed below the level of inlet pipe of the condenser, to which all drip water, and with it the lighter oils, must be conducted; the lighter oils will, from the nature of their specific gravity, float on the top of the tank. By passing a coil of steam-pipes through the tank the lighter oils will be vapourised, and the naphthaline will settle at the bottom, and from there can, from time to time, be let off. If there be an insufficient amount of these lighter oils, some benzine, benzole, or naphtha can be added with advantage, particularly if coal be used containing only a small proportion of these lighter oils. Hydrocarbon-vapours will surely liquefy naphthaline in any pipe or vessel.

A further tendency of naphthaline to crystallise will be created if gas containing naphthaline is passed in from a hot to a cold place; say, for instance, if the gas be stored in the holder, and the same, without a building, is exposed to the heat of a high temperature; when let into pipes in the ground, which are located in a lower temperature, naphthaline will surely crystallise, and in course of time will stop up the pipes more or less; or if the street mains are, in certain locations, laid too near the surface of the ground, and afterwards the gas be passed into pipes located in lower ground, by which a variation of temperature is created, naphthaline will have a tendency to crystallise.

Recently the derivatives of naphthaline, which are almost innumerable, have been receiving much attention; and many colouring-matters are produced by its reactions. These have not, however, as yet found a place, to any considerable extent, in commerce.

Naphthylin, *Diamine Violet*, *Naphthalin Yellow* (known also as Manchester Yellow and Jaune d'Or) are described in Crookes's 'Practical Handbook of Colours,' and Watts's 'Dictionary of Chemistry.' See also NAPHTHALINE DYES.

NAPHTHALIDINE. See NAPHTHYLAMINE.

NAPHTHALINE. $C^{20}H^{8}$ ($\mathbf{C^{10}H^{8}}$). A solid, crystalline hydrocarbon contained in coal-tar. It is especially interesting in consequence of its being the substance so long and perseveringly studied by Laurent. Its combinations and derivatives are immensely numerous, and, in a theoretical point of view, of the greatest importance, the well-established theory of substitutions being, to a great extent, founded upon the results obtained by treating naphthaline with nitric acid and the halogens.

NAPHTHALINE DYES. Within the last few years a number of colouring-matters, some of which are employed commercially, have been obtained from naphthylamine, itself a derivative from naphthaline. In preparing *naphthaline red*, or as it is often called, *Magdala red*, the naphthylamine is first converted into azodinaphthyldiamine, by the action of nitrous acid; and this, when treated with naphthylamine, yields a peculiar base, which forms naphthaline red. *Naphthaline blue* and *naphthaline violet* are obtained by acting on the red base with iodide of methyl, or iodide of ethyl, or by treating it with pernitrate of mercury, chloride of copper, chlorate of potash, etc. *Naphthaline yellow*, known also as *Manchester yellow*, *Martius yellow*, and *Jaune d'or*, is prepared by adding nitrite of soda to a solution of hydrochlorate of naphthylamine, when diazonaphthol is formed. On heating this with nitric acid, binitronaphthylic acid is produced, and the lime or soda compound, of this acid forms naphthaline yellow. This pigment is used for dyeing wool and silk, without the aid of a mordant, and for modifying the tint of magenta. The naphthaline dyes are fully described in Crookes's 'Practical Handbook of Colours,' and in Watts's 'Dictionary of Chemistry.'

NAPHTHYLAMINE. $C^{20}H^{9}N$ (**$C^{10}H^{9}N$**). An organic base, isomeric with cryptidine, produced from nitronaphthaline by the action of reducing-agents, such as sulphide of ammonium, or protacetate of iron.

NAPLES YELLOW. (*Jaune minéral*, Fr.; *Neapelgelb*, Ger.) This is a fine yellow pigment prepared from antimony. It is said to be prepared by calcining about 12 parts of metallic antimony with 8 parts of red lead and 4 parts of oxide of zinc in a reverberatory furnace. The mixed oxides are to be well rubbed together and fused; after this, the fused mass is to be reduced to a very fine powder. This colour is principally prepared in Italy; but the chrome yellows have almost entirely superseded it. See YELLOW COLOURS.

NARCOTINE. $C^{44}H^{23}NO^{14}$ (**$C^{22}H^{23}NO^{7}$**). An alkaloid contained in opium. It may be obtained in large quantities from the coloured and uncrystallisable mother-liquors obtained in the preparation of morphine by Gregory's process.

NATIVE ALLOY. A name sometimes given to OSMIUM-IRIDIUM, which see.

NATIVE METALS. See the respective metals, as COPPER, &c.

NATROLITE, from the Latin *natron*, soda. This mineral occurs reniform, botryoïdal, and massive; it has a splintery fracture; is, on the edges, translucent, and of a pearly lustre. It consists of soda, alumina, silica, and water; it is found in Scotland, Switzerland, Saxony, and Nova Scotia. Natrolite receives a high polish, and it has, therefore, been used for rings and other ornaments.

NATRON is the name of the native sesquicarbonate of soda, which occurs as a deposit on the sides of several lakes to the west of the Delta of Egypt; also as thin crusts on the surface of the earth, rarely an inch in thickness, at the bottom of a rocky mountain, in the province of Sukena, near Tripoli, and two days' journey from Fezzan, and is called by the Africans *Trona*. The walls of Cassar (Qasrr), a fort now in ruins, are said to have been built of it. At the bottom of a lake at Lagunillas, near Merida in Venezuela, is found a substance called by the Indians *Urao*, which is tolerably pure sesquicarbonate of soda. It is collected every two years by the natives, who, aided by a pole, plunge into the lake, separate the bed of earth which covers the mineral, break the urao, and rise with it to the surface of the water; it is then removed to the magazine, and dried in the sun. Natron is also found near Smyrna, in Tartary, Siberia, Hungary, Hindostan, and Mexico; in the last country there are several natron lakes, a little to the north of Zacatecas, as well as in many other provinces.

These deposits are never pure sesquicarbonate of soda, but contain generally some sulphate of soda, chloride of sodium, and earthy matters.

NATURE-PRINTING. (*Naturselbstdruck*, Ger.) The following description of this very beautiful process is an abstract of a lecture delivered by Mr. Henry Bradbury at the Royal Institution:—

Nature-printing is the name given to a technical process for obtaining printed reproductions of plants and other objects upon paper, in a manner so truthful, that only a close inspection reveals the fact of their being copies; and so distinctly sensible to even touch are the impressions, that it is difficult to persuade those unacquainted with the manipulation that they are an emanation of the printing-press.

The distinguishing feature of the process consists: first, in impressing natural objects—such as plants, mosses, seaweeds, and feathers—into plates of metal, causing, as it were, the objects to engrave themselves by pressure; secondly, in being able to take such casts or copies of the impressed plates as can be printed from at the ordinary copper-plate press.

This secures, in the case of a plant, on the one hand, a perfect representation of its characteristic outline, of some of the other external marks by which it is known, and even in some measure of its structure, as in the venation of ferns and the ribs of the leaves of flowering plants; and, on the other, affords the means of multiplying copies in a quick and easy manner, at a trifling expense compared with the result—and to an unlimited extent.

The great defect of all pictorial representations of botanical figures has consisted in the inability of art to represent faithfully those minute peculiarities by which natural objects are often best distinguished. Nature-printing has therefore come to the aid of this branch of science in particular, whilst its future development promises facilities for copying other objects of nature, the reproduction of which is not within the province of the human hand to execute; and, even if it were possible, it would involve an amount of labour scarcely commensurate with the result.

Possessing the advantages of rapid and economic production, the means of unlimited multiplication, and, above all, unsurpassable resemblance to the original, nature-printing is calculated to assist much in facilitating not only the *first-sight* recognition of many objects in natural history, but in supplying the detailed evidences of identification—which must prove of essential value to botanical science in particular.

Experiments to print direct from nature were made as far back as about 250 years; it is certain, therefore, that the present success of the art is mainly attributable to the general advance of science, and the perfection to which it has been brought in particular instances.

On account of the great expense attending the production of woodcuts of plants in early times, many naturalists suggested the possibility of making direct use of Nature herself as a copyist. In the 'Book of Art,' of Alexis Pedemontanus (printed in the year 1572), and translated into German by Wecker, may be found the *first* recorded hint as to taking impressions of plants.

At a later period, in the *Journal des Voyages*, by M. de Moncoys, in 1650, it is mentioned that one Welkenstein, a Dane, gave instruction in making impressions of plants.

The process adopted to produce such results at this period consisted in laying out flat and drying the plants. By holding them over the smoke of a candle, or an oil-lamp, they became blackened in an equal manner all over; and, by being placed between two soft leaves of paper, and being rubbed down with a smoothing-bone, the soot was imparted to the paper, and the impression of the veins and fibres was so transferred. But though the plants were dried in every case, it was by no means absolutely necessary; as the author has proved by the simple experiment of applying lamp-black or printer's ink to a fresh leaf, and producing a successful impression.

Linnæus, in his *Philosophia Botanica*, relates that in America, in 1707, impressions of plants were made by Hessel; and later (1728—1757), Professor Kniphof, at Erfurt (who refers to the experiments of Hessel), in conjunction with the bookseller Fünke, established a printing-office for the purpose. He produced a work entitled *Herbarium Vivum*. The range and extent of his work, 12 folio volumes, containing 1,200 plates, corroborates the curious fact of a printing-office being required. These impressions were obtained by the substitution of printer's ink for lamp-black, and flat pressure for the smoothing-bone; but a new feature at this time was introduced—that of colouring the impressions by hand according to nature—a proceeding which, though certainly contributing to the beauty and fidelity of the effect, yet had the disadvantage of frequently rendering indistinct, and even of sometimes totally obliterating, the tender structure and finer veins and fibres. Many persons at the time objected to the indistinctness of such representations and the absence of parts of the fructification; but it was the decided opinion of Linnæus that to obtain a representation of the difference of species was sufficient.

In 1748 Seligmann, an engraver at Nuremberg, published in folio-plates figures of several leaves he had reduced to skeletons. As he thought it impossible to make drawings sufficiently correct, he took impressions from the leaves in red ink, but no mention is made of the means he adopted. Of the greater part he gave two figures, one of the upper and another of the lower side.

In the year 1763 the process is again referred to in the *Gazette Salutaire*, in a short article upon a *Recette pour copier toutes sortes de Plantes sur Papier.*

About 25 or 30 years later, Hoppe edited his *Ectypa Plantarum Ratisbonensium*, and also his *Ectypa Plantarum Selectarum*, the illustrations in which were produced in a manner similar to that employed by Kniphof. These impressions were found also to be durable, but still were defective.

In the year 1809 mention is made in Pritzell's *Thesaurus* of a 'New Method of taking Natural Impressions of Plants'; and lastly, in reference to the early history of the subject, the attention of scientific men was called to an article, in a work published by Grazer, in 1814, on a 'New Impression of Plants.'

Twenty years afterwards the subject had undergone remarkable change, not only in the results produced, but also in the mode of operation to be pursued, which consisted in fixing an impression of the prepared plant in a plate of metal by pressure. It also appears, on the authority of Professor Thiele, that Peter Kyhl, a Danish goldsmith and engraver, established at Copenhagen, applied himself for a length of time to the ornamentation of articles in silver ware, and the means he adopted were, taking copies of flat objects of nature and art in plates of metal by means of two steel rollers. Here may be remarked the first real steps of the process from a simple contrivance to an art. The subsequent development which science has given to these means, and the amplifications which experience has added, have realised what can now be produced; but it should not be assumed that adaptation and amplification are invention.

Various productions in silver of Kyhl's process were exposed in the Exhibition of Industry held at Charlottenburg in May 1833. In a manuscript written by this Danish goldsmith, entitled 'The Description (with forty-six plates) of the Method to copy Flat Objects of Nature and Art,' dated May 1, 1833, is suggested the idea of applying this invention to the advancement of science in general. The plates accompanying this description represented printed copies of leaves, of linen and woven stuffs, of laces, of feathers of birds, scales of fishes, and even of serpent-skins.

It would appear that Peter Kyhl was no novice at the process. He distinctly points out what he conceives to be its value by the subjects that he tried to copy, and he enters into detail as to the precautions to be observed in the operation of impressing metal plates so as to insure successful impressions. His manuscript explains that he had experimented with plates of copper, zinc, tin, and lead. Still there existed obstacles which prevented him from making any application of his invention. In the case of zinc, tin, and copper plates, the plant, from the extreme hardness of the metals, was too much distorted and crushed; while in lead, though the impression was as perfect as could be, there were no means of printing many copies, as it was not possible, after the application of printer's ink, to retain the polished surface that had been imparted to the leaden plate, or to cleanse it so thoroughly as to allow the printer to take impressions free from dirty stains. This was a serious obstacle, which was not compensated for even by the peculiarly rich surface of the parts that were impressed, attributable to the lead being more granular than copper, the effect of which is so favourable to adding density or body of colour, without obliterating the veins and fibres.

Peter Kyhl died in the same year that he made known his invention. At his death his manuscripts and drawings were deposited in the archives of the Imperial Academy of Copenhagen.

To proceed to more modern efforts. Dr. Branson of Sheffield in 1847 commenced a series of experiments, an interesting paper upon which was read before the Society of Arts in 1851; and therein, for the first time, was suggested the application of that second and most important element in Nature-printing, which is now its essential feature—the Electrotype.

It then occurred to Dr. Branson that an electrotype copy would obviate the difficulty. He afterwards stated that he abandoned the process of electrotyping, in consequence of his finding it tedious, troublesome, and costly to produce large plates. Having occasion, however, to get an article cast in brass, he was astonished at the beautiful manner in which the form of the model was reproduced in the metal. He determined, therefore, to have a cast taken in brass from a gutta-percha mould of ferns, and was much gratified to see the impression rendered almost as minutely as by the electrotype process; the mode of operation is to place a frond of fern, algæ, or similar flat vegetable form, on a thick piece of glass or polished marble; by softening a piece of gutta-percha of proper size, and placing it on the leaf and pressing it carefully down, it will receive a sharp and accurate impression from the plant. The gutta-percha, allowed to harden by cooling, is then handed to a brass-cutter, who reproduces it in metal from its moulding-base.

In 1851 Professor Leydolt of the Imperial Polytechnic Institute at Vienna, availing himself of the resources of the Imperial Printing-Office, carried into execution a new method he had conceived of representing agates and other quartzose minerals in a manner true to nature. Professor Leydolt had occupied himself for a considerable period in examining the origin and composition of these interesting objects in geology. In the course of his experiments and investigations he had occasion to expose them to the action of fluoric acid, when he found, in the case of an agate, that many of the concentric rings were totally unchanged, while others, to a great extent decomposed by the acid, appeared as hollows between the unaltered bands. It then occurred to Professor Leydolt that the surfaces of bodies thus corroded might be printed from, and copies multiplied with the greatest facility.

The simplest mode for obtaining printed copies is to take an impression direct from the stone itself. The surface, after having been treated with fluoric acid, is washed with dilute hydrochloric acid and dried; then carefully blackened with printer's ink. By placing a leaf of paper upon it, and by pressing it down upon every portion of the etched or corroded surface with a burnisher, an impression is obtained, representing the crystallised rhombohedral quartz, *black*, and the weaker parts that have been decomposed by the action of the acid, *white*. It requires but a small quantity of ink, and particular care must be exercised in the rubbing down of the impression. This mode is good as far as it goes, but it is slow and uncertain, and incurs a certain amount of risk, owing to the brittle nature of the object; and the effect produced is not altogether correct, since it represents those portions black that should be white and those white that should be black.

The stone not being sufficiently strong to be subjected to the action of a printing-press, an exact *facsimile* cast, therefore, of it must be obtained, and in such a form as can be printed from. To effect this, the surface of any such stone (previously treated with fluoric acid), must be extended by embedding it in any plastic composition that will yield a flat and polished surface, so that the composition surrounding the corroded stone will be level with its surface; all that is necessary now is to prepare the whole surface for the electrotype apparatus, by which a perfect *facsimile* is produced, representing the agate impressed, as it were, into a polished plate of copper. This forms the printing-plate. The ink in this case, as opposed to the mode before referred to, is not applied upon the surface, but in the depressions caused by the action of the acid on the weaker parts; the paper is forced into these depressions in the operation of printing, which results in producing an impression in relief.

Mr. R. F. Sturges of Birmingham states that, in August 1851, he was engaged in making certain experiments with steel rollers and metal plates for ornamenting metallic surfaces, for which he obtained a patent sealed in January 1852. He produced plates in lead, tin, brass, and steel from various fabrics, such as wire-lace, thread-lace, perforated paper, and even from steel engravings, particularly a medallion of the Queen, from which impressions were printed, and which were distributed among his friends; but, that which he did led to no such result as we are at present considering, and nothing more was heard of the subject until the publication of nature-printing in its present state. He, however, also considers himself the undoubted *inventor* of nature-printing, notwithstanding what had been done by the experiment of Kyhl in 1833.

Mr. Aitken too, about this period was occupied in making experiments for the ornamentation of Britannia metal, and also claims the invention, having introduced the use of natural objects, and, as he says, expressly for printing purposes. But Sturges and Aitken only followed Kyhl in their operations, as the one experimented with steel rollers for the purpose of ornamenting metallic surfaces, while the other applied the same to printing purposes, both of which experiments were carried out by Kyhl.

In the Imperial Printing-Office at Vienna, the first application of taking impressions of lace on plates of metal, by means of rollers, took place in the month of May 1852: according to Councillor Auer's statement in his pamphlet, it originated in the Minister of the Interior, Ritter von Baumgartner, having received specimens from London, which so much attracted the attention of the Chief Director, that he determined to produce others like them. This led to the use of gutta-percha after the manner that Dr. Branson had used it; but finding this material did not possess altogether the necessary properties, the experience of Andrew Worring induced him to substitute lead, which was attended with remarkable success. This was, however, only following in the steps of Kyhl. Professor Haidinger, on seeing specimens of these laces, and learning the means by which they had been obtained, proposed the application of the process to plants.

The substitution of lead for gutta-percha was a great step in the process, but would have been insufficient had not the requisite means already existed for producing faithful copies of those delicate fibrous details that were furnished in the examples of the impressions of botanical and other figures in metal. These means consisted mainly in the great perfection to which the precipitation of metals upon moulds or matrices by electro-galvanic agency has been brought, the application of which—more generally known by the name of the Electrotype process—was suggested and executed by Dr. Branson in 1851; still he met with no signal success, which may be attributed to his experiments having been conducted on a limited scale.

The *first* practical application of nature-printing for illustrating a botanical work, and which has been attended with considerable success, is to be found in Chevalier Von Heufler's work on the mosses collected from the valley of Arpasch, in Transylvania; the *second* (*first in this country*), is a work on the 'Ferns of Great Britain and Ireland,' by Thomas Moore, published under the editorship of the late Dr. Lindley. Ferns, by their peculiar structure and general flatness, are especially adapted to develop the capabilities of the process, and there is no race of plants where minute accuracy in delineation is of more vital importance than in that of the ferns; in the distinction of which, the form of indentations, general outline, the exact manner in which repeated subdivision is effected, and especially the distribution of veins scarcely visible to the naked eye, play the most important part. To express such facts with the necessary accuracy, the art of photography would have been insufficient, until nature-printing was brought to its present state of perfection.

The beautiful productions which have been given to the public by Mr. Henry Bradbury sufficiently prove the applicability of the processes which we have described. The colouring of the plates has been greatly improved by practice; and by the deposition of nickel on the surface of the electrotype plate the printer has been enabled to print off thousands of impressions without any evidence of deterioration.

NEALING. See ANNEALING.

NEB-NEB is the East Indian name of Bablah. See BABLAH.

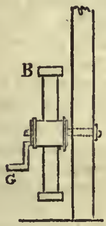
NEEDLE MANUFACTURE. When we consider the simplicity, smallness, and moderate price of a needle, we should be naturally led to suppose that this little instrument requires neither much labour nor complicated manipulations in its construction; but when we learn that every sewing needle, however inconsiderable its size, passes through the hands of 120 different operatives before it is ready for sale, we cannot fail to be surprised.

The best steel, reduced by a wire-drawing machine to the suitable diameter, is the material of which needles are formed. It is brought in bundles to the needle factory, and carefully examined. For this purpose, the ends of a few wires in each bundle are cut off, ignited, and hardened by plunging them into cold water. They are now snapped between the fingers, in order to judge of their quality; the bundles belonging to the most brittle wires are put aside, to be employed in making a peculiar kind of needle.

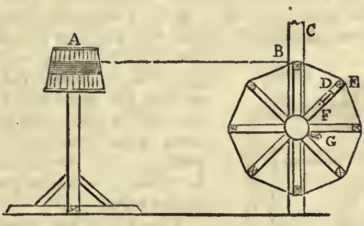
After the quality of the steel wire has been properly ascertained, it is calibred by means of a gauge, to see if it be equally thick and round throughout, for which purpose merely some of the coils of the bundle of wires are tried. Those that are too thick are returned to the wire-drawer, or set apart for another size of needles.

The first operation, properly speaking, of the needle factory, is unwinding the bundles of wires. With this view the operative places the coil upon a somewhat conical reel, *fig.* 1548, whereon he may fix it at a height proportioned to its diameter. The wire is wound off upon a wheel B, formed of eight equal arms, placed at equal distances round a nave, which is supported by a polished round axle of iron, made fast to a strong upright C, fixed to the floor of the workshop. Each of the arms is 54 inches long; and one of them D, consists of two parts: of an upper part, which bears the cross bar E, to which the wire is applied; and of an under part, connected with the nave. The part E slides in a slot in the fixed part F, and is made fast to it by a peg at a proper height for placing the ends of all the spokes in the circumference of a

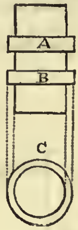
1549



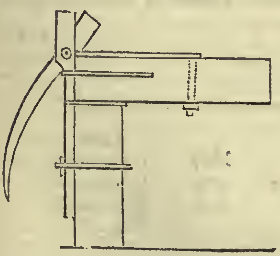
1548



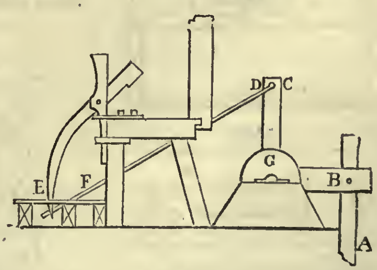
1552



1550



1551



circle. This arrangement is necessary, to permit the wire to be readily taken off the reel, after being wound tight round its eight branches. The peg is then removed, the branch pushed down, and the coil of wire released. *Fig.* 1549 shows the wheel in profile. It is driven by the winch-handle G.

The new-made coil is cut in two points diametrically opposite, either by hand shears, of which one of the branches is fixed in a block by a bolt and a nut, as shown in *fig.* 1550, or by means of the mechanical shears, represented in *fig.* 1551. The crank A is moved by a hydraulic wheel, or by steam-power, and rises and falls alternately. The extremity of this crank enters into a mortise cut in the arm B, of a bent lever B G C, and is made fast to it by a bolt. An iron rod D F, hinged at one of its extremities to the end of the arm C, and at the other to the tail of the shears or chisel E, forces it to open and shut alternately. The operative, placed upon the floor under F, presents the coil to the action of the shears, which cut it into two bundles, composed each of 90 or 100 wires, upwards of 8 feet long. The chisel strikes 21 blows in the minute.

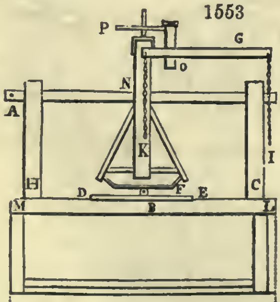
These bundles are afterwards cut with the same shears into the desired needle lengths, these being regulated by the diameter. For this purpose the wires are put into a semi-cylinder of the proper length, with their ends at the bottom of it and are all cut across by this gauge. The wires thus cut are deposited in a box placed alongside of the workman.

Two successive incisions are required to cut 100 wires, the third is lost; hence the shears, striking 21 blows in a minute, cut in 10 hours fully 400,000 ends of steel wire, which produce more than 800,000 needles. The wires thus cut are more or less bent, and require to be straightened. This operation is executed with great promptitude, by means of an appropriate instrument. In two strong iron rings A B, *fig.* 1552, of which one is shown in front view at C, 5,000 or 6,000 wires, closely packed together, are put; and the bundle is placed upon a flat, smooth bench L M, *fig.* 1553, covered with a cast-iron plate D E, in which there are two grooves of sufficient depth for receiving the two ring bundles of wire, or two openings like the rule F, *fig.* 1553, upon which is placed the open iron rule F, shown in front in *fig.* 1555 upon a greater scale. The two rings must be carefully set in the intervals of the rule. By making this rule come and go five or six times with such pressure upon the bundles of wires as causes it to turn upon its axis, all the wires are straightened almost instantaneously.

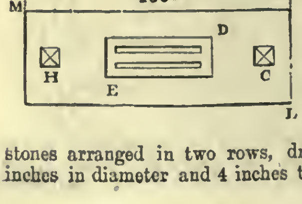
The construction of the machine, represented in *fig.* 1553, may require explanation. It consists of a frame in the form of a table, of which L M is the top; the cast-iron plate, D E, is inserted solidly into it. Above the table—seen in *fig.* 1554 in plan—there are two uprights, C H, to support the cross-bar, A A, which is held in forks cut out in the top of each of the two uprights. This cross-bar, A A, enters tightly into a mortise cut in the swing piece, N, at the point, N, where it is fixed by a strong pin, so that the horizontal traverse communicated to the cross-bar, A A, affects at the same time the swing-piece, N. At the bottom of this piece is fixed, as shown in the figure, the open rule, F, seen upon a larger scale in *fig.* 1555.

When the workman wishes to introduce the bundle, B, he raises, by means of two chains, I, K, *fig.* 1553, and the lever, G O, the swing-piece and the cross-bar. For this purpose he draws down the chain, I; and when he has placed the bundle properly, so that the two rings enter into the groove, E D, *fig.* 1553, he allows the swing-piece to fall back, so that the same rings enter the open clefts of the rule, F; he then seizes one of the projecting arms of the cross-bar, A, alternately pulling and pushing it in the horizontal direction, whereby he effects, as already stated, the straightening of the wires.

1553



1554



The wires are now taken to the pointing-tools, which usually consist of about 30 grind-

1555

1556

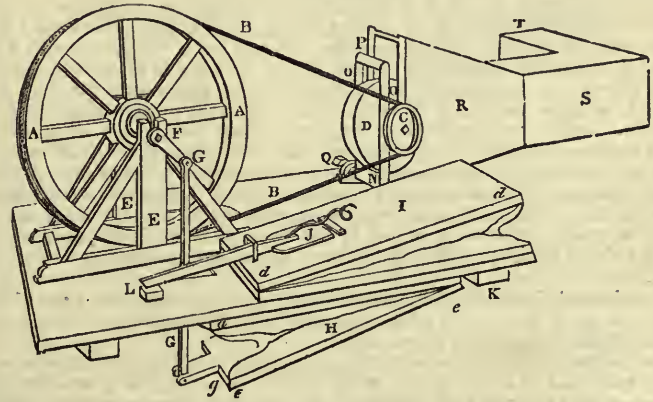
1557

1558

stones arranged in two rows, driven by a water-wheel. Each stone is about 18 inches in diameter and 4 inches thick. As they revolve with great velocity and are liable to fly in pieces, they are partially encased by iron plates, having a proper slit in them to admit of the application of the wires. The workman seated in front of the grindstone seizes 50 or 60 wires between the thumb and forefinger of his right hand, and directs one end of the bundle to the stone. By means of a bit of stout leather called a thumb-piece, of which A, *fig.* 1558, represents the profile, and B the plan, the workman presses the wires, and turns them about with his forefinger, giving them such a rotatory motion as to make their points conical. This operation, which is called *roughing down*, is dry grinding; because, if water were made use of, the points of the needles would be rapidly rusted. It has been observed long ago that the siliceous and steel dust thrown off by the stones is injurious to the eyes and lungs of the grinders, and many methods have been proposed for preventing its bad effects. The machine invented for this purpose by Mr. Prior is one of the most effective.

A A, *fig.* 1559, is the fly-wheel of an ordinary lathe, round which the endless cord B B passes, and embraces the pulley, C, mounted upon the axle of the grindstone, D. The fly-wheel is supported by a strong frame, E E, and may be turned by a winch-handle, as usual, or by mechanical power. In the needle factories, the pointing-shops are in general very large, and contain several grindstones running on the same long horizontal shaft, placed near the floor of the apartment, and driven by water or steam-power. One of the extremities of the shaft of the wheel, A, has a kneed or bent winch, F, which by means of an intermediate crank, G G, sets in action a double bellows, H I, with a continuous blast, consisting of the air-feeder, H, below, and the air-regulator, I, above. The first is composed of two flaps, one of them, *a a*, being fast and attached to the floor, and the other, *e e*, moving with a hinge-joint; both being joined by strong leather nailed to their edges. This flap has a tail, *g*, of which the end is forked to receive the end of the crank, G. Both flaps are perforated with openings furnished with valves for the admission of the air, which is thence driven into a horizontal pipe,

1559



K, placed beneath the floor of the workshop, and may be afterwards directed in an uninterrupted blast upon the grindstone, by means of the tin tubes, N O O, which embrace it, and have longitudinal slits in them. A brass socket is supposed to be fixed upon the ground; it communicates with the pipe, K, by means of a small copper tube, into which one of the extremities of the pipe, N, is fitted; the other is supported by the point of a screw, Q, and moves round it as a pivot, so as to allow the two upright branches, O O, to be placed at the same distance from the grindstone. These branches are soldered to the horizontal pipe, N, and connected at their top by the tube, P.

The wind which escapes through the slits of these pipes blows upon the grindstone, and carries off its dust into a conduit, R, *fig.* 1559, which may be extended to S, beyond the wall of the building, or bent at right angles, as at T, to receive the conduits of the other grindstones of the factory.

A safety valve, J, placed in an orifice formed in the regulator flap, I, is kept shut by a spiral spring of strong iron wire. It opens to allow the superfluous air to escape, when by the rising of the bellows, the tail, L, presses upon a small piece of wood, and thereby prevents their being injured.

The wires thus pointed at both ends are transferred to the first workshop, and cut in two, to form two needles, so that all of one quality may be of equal length. For each sort a small instrument, *fig.* 1557, is employed, being a copper-plate nearly square.

having a turned-up edge only upon two of its sides: the one of which is intended to receive all the points, and the other to resist the pressure of the shears. In this small tool a certain number of wires are put with their points in contact with the border, and they are cut together flush with the plate by means of the shears, *fig.* 1550, which are moved by the knee of the workman. The remainder of the wires are then laid upon the same copper or brass tool, and are also cut even; there being a trifling waste in this operation. The pieces of wire out of which two needles are formed are always left a little too long, as the pointer can never hit exact uniformity in his work.

These pointed wires are laid parallel to each other in little wooden boxes, and transferred to the head-flattener. This workman, seated at a table with a block of steel before him, about 3 inches cube, seizes in his left hand 20 or 25 needles, between his finger and thumb, spreading them out like a fan, with the points under the thumb, and the heads projecting; he lays these heads upon the steel block, and with a small flat-faced hammer strikes successive blows upon all the heads, so as to flatten each in an instant. He then arranges them in a box with the points turned the same way.

The flatted heads have become hardened by the blow of the hammer; when annealed, by heating and slow cooling, they are handed to the *piercer*. This is commonly a child, who laying the head upon a block of steel, and applying the point of a small punch to it, pierces the eye with a smart tap of a hammer, applied first upon one side, and then exactly opposite upon the other.

Another child trims the eyes, which he does by laying the needle upon a lump of lead, and driving a proper punch through its eye; then laying it sidewise upon a flat piece of steel, with the punch sticking in it, he gives it a tap on each side with his hammer, and causes the eye to take the shape of the punch. The operation of piercing and trimming the eyes is performed by clever children with astounding rapidity, who become so dexterous as to pierce with their punch a human hair and thread it with another, for the amusement of visitors.

The next operative makes the groove at the eye, and rounds the head. He fixes the needle in pincers, *fig.* 1556, so that the eye corresponds to their flat side: he then rests the head of the needle in an angular groove, cut in a piece of hard wood fixed in a vice, with the eye in an upright position. He now forms the groove with a single stroke of a small file, dexterously applied, first to the one side of the needle, and then to the other. He next rounds and smooths the head with a small flat file. Having finished, he opens the pincers, throws the needle upon the bench, and puts another in its place. A still more expeditious method of making the grooves and finishing the heads has been long used in most English factories. A small ram is so mounted as to be made to rise and fall by a pedal lever, so that the child works the tool with his foot, in the same way that the heads of pins are fixed. A small die of tempered steel bears the form of the one channel or groove, another similar die that of the other, both being in relief; these being worked by the lever pedal, finish the grooving of the eye at a single blow, by striking against each other with the head of the needle between them.

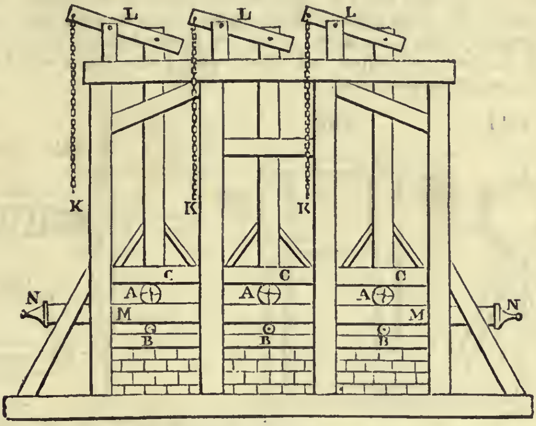
The whole of the needles thus prepared are thrown pell-mell into a sort of drawer or box, in which they are by a few dexterous jerks of the workman's hands made to arrange themselves parallel to each other.

The needles are now ready for the tempering; for which purpose they are weighed out in quantities of above 30 lbs., which contain from 250,000 to 500,000 needles, and are carried in boxes to the *temperer*. He arranges these upon sheet-iron plates, about 10 inches long and 5 inches broad, having borders only upon the two longer sides. These plates are heated in a proper furnace to bright redness for the larger needles, and to a less intense degree for the smaller; they are taken out and inverted smartly over a cistern of water, so that all the needles may be immersed at the same moment, yet distinct from another. The water being run off from the cistern, the needles are removed, and arranged by agitation in a box, as above described. Instead of heating the needles in a furnace, some manufacturers heat them by means of a bath of melted lead.

After being suddenly plunged in the cold water, they are very hard and excessively brittle. The following mode of tempering them is practised at Neustadt. The needles are thrown into a sort of frying-pan along with a quantity of grease. The pan being placed on the fire, the fatty matter soon inflames, and is allowed to burn out; the needles are now found to be sufficiently well tempered. They must, however, be re-adjusted upon the steel anvil, because many of them get twisted in the hardening and tempering.

Polishing is the longest, and not the least expensive, process in the needle manufacture. This is done upon bundles containing 500,000 needles; and the same machine, under the guidance of one man, polishes from 20 to 30 bundles at a time; either by water- or steam-power. The needles are rolled up in canvas along with some quartzose sand interstratified between the layers, and this mixture is besmeared with rape-seed oil. *Fig.* 1565 represents one of the rolls or packets of needles 12 inches long, strongly bound with cords. These packets are exposed to the to-and-fro pressure of wooden tables, by which they are rolled about with the effect of causing every needle in the bundle to rub against its fellow, and against the siliceous matter, or emery, enclosed in the bag. *Fig.* 1560 represents an improved table for polishing the needles by attrition-bags. The lower table, M M, is moveable, whereas in the old construction it was fixed; the table C has merely a vertical motion, of pressure upon the bundles, whereas formerly it had both a vertical and horizontal motion. Several bundles may obviously be polished at once in the present machine. The table M M, may be of any length that is required, and from 24 to 27 inches broad; resting upon the wooden rollers, B, B, B, placed at suitable distances, it receives a horizontal motion, either by hand or other convenient power; the packets of needles A, A, A, are laid upon it, and

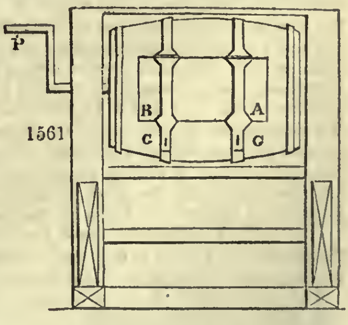
1560



over them the tables C, C, C, which are lifted by means of the chains K, K, K, and the levers, L, L, L, in order to allow the needles to be introduced or removed. The see-saw motion forces the *rouleaux* to turn upon their own axes, and thereby creates such attrition among their contents as to polish them. The workman has merely to distribute these rolls upon the table M, in a direction perpendicular to that in which the table moves; and whenever one of them gets displaced, he sets it right, lifting by the help of the chain the loaded table. The table makes about 20 horizontal double vibrations in the minute; whereby each bundle, running over 24 inches each time, passes through 40 feet per minute, or 800 yards in the hour.

Scouring by the cask.—After being worked during 18 or 20 hours under the tables, the needles are taken out of the packets and put into wooden bowls, where they are mixed with sawdust to absorb the black grease upon their surfaces. They are next introduced into a cask, *fig.* 1561, and a workman seizing the winch P, turns it round a little; he now puts in some more sawdust at the door, A, B, which is then shut by the clasps G, G, and continues the rotation till the needles are quite clean and clear in their eyes; which he ascertains by taking out a sample of them from time to time.

1561

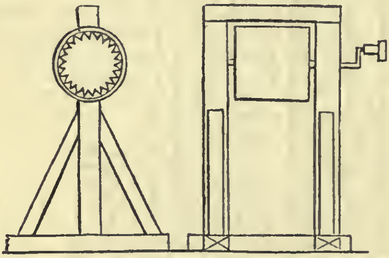


Winnowing is the next process, by means of a mechanical ventilator similar to that by which corn is winnowed. The sawdust is blown away, and the grinding powder is separated from the needles, which remain apart clean and bright.

The needles are in the next place arranged in order, by being shaken as above described, in a small, somewhat concave, iron tray. After being thus laid parallel to each other, they are shaken up against the end of the tray, and accumulated in a nearly upright position, so that they can be seized in a heap and removed in a body upon a pallet-knife, with the help of the forefinger.

The preceping five operations, of making up the *rouleaux*, rolling them under the tables, scouring the needles in the cask, winnowing, and arranging them, are repeated ten times in succession, in manufacturing the best articles; the only variation being in the first process. Originally the bundles of needles are formed with alternate layers of siliceous schist and needles; but after the seventh time, bran freed from flour by sifting is substituted for the schist. The subsequent four processes, are, however, repeated as described. It has been found in England, that emery-powder mixed with quartz and mica or pounded granite, is preferable to everything else for polishing needles at first by attrition in the bags; at the second and following operations, emery mixed with olive oil is used, up to the eighth and ninth, for which putty or oxide of tin with oil is substituted for the emery; at the tenth the putty is used with very little oil; and, lastly, bran is employed to give a finish. In this mode of operating, the needles are *scoured* in the copper cask shown in elevation in *fig.* 1563, and in section in *fig.* 1562. The inner surface of this cask is studded with points to increase the friction among the needles; and a quantity of hot soap-suds is repeatedly introduced to wash them clean. The cask must be slowly turned upon its axis, for fear of injuring the mass of needles which it contains. They are finally dried in the wooden cask by attrition with sawdust; then wiped individually with a linen rag or soft leather; when the damaged ones are thrown aside.

1563 1562



1564

1565

1566

Sorting of the needles.—This operation is performed in a dry upper chamber, kept free from damp by proper stoves. Here all the points are first laid the same way; and the needles are then picked out from each other in the order of their polish. The sorting is effected with surprising facility. The workman places 2,000 or 3,000 needles in an iron ring, *fig.* 1566, 2 inches in diameter, and sets all their heads in one plane; then on looking carefully at their points, he easily recognises the broken one; and by means of a small hook fixed in a wooden handle, *fig.* 1564, he lays hold of the broken needle, and turns it out. These defective needles pass into the hands of another workman, who points them anew upon a grindstone, and they form articles of inferior value. The needles which have got bent in the polishing must now be straightened. The whole are finally arranged exactly according to their lengths by the tact of the sorter with his finger and thumb.

The needles are divided into quantities for packing in blue papers, by putting into a small balance the equivalent weight of 100 needles, and so measuring them out without the trouble of counting them individually.

The *bluer* receives these packets, and taking 25 of the needles at a time between the forefinger and thumb, he presses their points against a very small hone-stone of compact micaceous schist, mounted in a little lathe, he turns them briskly round, giving the points a bluish cast, while he polishes and improves them. This partial polish is in the direction of the axis; that of the rest of the needles is transverse, which distinguishes the boundaries of the two. The little hone-stone is not cylindrical, but quadrangular, so that it strikes successive blows with its corners upon the needles as it revolves, producing the effect of filing lengthwise. Whenever these angles seem to be blunted, they are set again by the *bluer.*

It is easy to distinguish good English needles from spurious imitations; because the former have their axes coincident with their points, which is readily observed by turning them round between the finger and thumb.

The construction of a needle requires numerous operations; but they are rapidly and uninterruptedly successive, so that a child can *trim* the eyes of 4,000 needles per hour.

NEEDLE ORE, or *Aciculite.* A native sulphide of bismuth, copper, and lead, in acicular crystals, found in Siberia. See AIKENITE.

NEPHRITE. See JADE.

NERO ANTICO. The name given by the Italians to the black marble used by the Egyptian and other ancient statuaries. See MARBLE.

NEROLI is the name given by perfumers to the essential oil of orange-flowers. It is procured by distillation with water, in the same way as most other volatile oils. Since, in distilling water from neroli, an aroma is obtained different from that of the orange-flower, it has been concluded that the distilled water of orange-flowers owes its scent to some principle different from an essential oil. See PERFUMERY.

NET (*Filet, réseau*, Fr.; *Netz*, Ger.) is a textile fabric of knotted meshes, for catching fish, and other purposes. Each mesh should be so secured as to be incapable of enlargement or diminution. The French Government offered in 1802 a prize of 10,000 francs to the person who should invent a machine for making nets upon automatic principles, and adjudged it to M. Buron, who presented his mechanical invention to the *Conservatoire des Arts et Métiers*. All the nets now used by our fishermen are made by machinery; the largest number being woven in Scotland.

NETTLE TREE. The *Celtis Australis*. The wood of the nettle-tree is nearly as compact as box, and takes a very high polish; it is sometimes used in the manufacture of flutes.

NEUTRALISATION is the state produced when acid and alkaline matters are combined in such proportions that neither predominates, as evinced by the colour of tincture of litmus and cabbage remaining unaffected by the compound.

NEUTRAL TINT. A factitious grey pigment, composed of blue, red, and yellow, in various proportions, used by water-colour painters.

NEW JERSEY TEA. The dried leaves of the *Ceanothus Americanus*.

NEW RED SANDSTONE. See SANDSTONE.

NEW ZEALAND FLAX. See PHORMIUM.

NICARAGUA WOOD. The tree yielding this wood has not been ascertained; it is supposed to be a species of *Hæmatoxylon*. This wood, and a variety called Peach wood, are sent to this country for the use of the dyers. They are similar in colour to Brazil wood; but they are not sufficiently sound for any use in manufacture.

NICKEL. The ores of nickel, found in these islands, are the following:—

Annabergite. Arsenate of nickel, found at Huel Chance and Pengelly mines in Cornwall.

Emerald nickel. Said to have been found by Dr. Heddle on chromate of iron from Swinaness, in Unst, one of the Shetland Islands.

Millerite. Sulphide of nickel. This mineral has been found in septaria, at Ebbw Vale in Monmouthshire; at Combo Martin, and at Huel Chance and Pengelly, in Cornwall.

Eisennickelkies. Sulphide of iron and nickel. On the property of the Duke of Argyll, near Inverary, this ore has been found in considerable quantities. Greg and Lettsom give the following analysis of 'a specimen of the rough ore taken and reduced to powder':—Iron, 43·76; nickel, 14·22; sulphur, 34·46; silica, 5·90; lime, 1·45: total, 99·79.

Kupfernickel. Copper nickel. Two or three mines in Cornwall have produced this ore in some quantities. It has been worked at Huel Chance and at Pengelly, and at the Fowey Consols mine. Mr. Aitkin, of Falkirk, in 1872, re-opened the so-called silver mine at Bathgate, and discovered a peculiar ore of nickel in a fissure or vein between a whinsill and the limestone; about three tons were obtained, and the work was discontinued.

Rammelsberg has given us the following analysis of a foreign kupfernickel, which corresponds very nearly with some of our English products:—Arsenic, 48·80; nickel, 39·94; cobalt, 0·16; antimony, 8·00; silica, 2·00.

For the less important and foreign ores of nickel, the reader is referred to *Dana*, or to *Brooke and Miller's Mineralogy*.

Nickel is usually associated with cobalt ores, and much chemical ingenuity has been employed to effect the perfect separation of these metals,—both of which are now very valuable in the arts. Extensive nickel refineries, in which the separation is skilfully carried out, but in all with some considerable secresy, now exist in this country. The art of working the ores of nickel and cobalt seems unknown in Great Britain, if we may judge by the fact that, though found in sufficient abundance, they are nowhere in this country converted into zaffre and speiss, the two primary marketable products elsewhere obtained from these ores. Although, therefore, no nation in the world consumes in its manufactures more cobalt and nickel than Great Britain, yet for these metals it is almost entirely dependent upon Norway, Northern Germany, and the Netherlands; from whence we import large quantities annually. The foreign ores not unfrequently yield 12 or 15 per cent. In the German ore the quantity of metallic ingredients are of a fusible character; consequently, when simply subjected to heat in a reverberatory furnace, the earthy and metallic elements separate of themselves by the mere disparity of their specific weights; and the siliceous gangue, with a portion of oxide of iron, rises to the top; leaving a metallic compound of arsenic, cobalt, nickel, copper, and perhaps iron beneath. This latter, when carefully roasted in an oxidising furnace, in contact with sand or ground flint, affords at once an impure silicate of cobalt and arsenide of nickel,—two marketable products.

Since the manufacture of German silver, or *Argentine plate*, became an object of commercial importance, the extraction of nickel has been undertaken upon a considerable scale. The cobalt ores are its most fruitful sources, and they are now generally treated by the method of Wöhler, to effect the separation of the two metals. The arsenic is expelled by roasting the powdered *speiss*, first by itself, next with the addition of charcoal-powder, till the garlic smell be no longer perceived. The residuum is to be mixed with three parts of sulphur and one of potash, melted in a crucible with a gentle heat, and the product being edulcorated with water, leaves a powder of metallic lustre, which is a sulphide of nickel free from arsenic; while the arsenic associated with the sulphur, and combining with the resulting sulphide of potassium, remains dissolved. Should any arsenic still be found in the sulphide, as may happen if the first roasting-heat was too great, the above process must be repeated. The sulphide must be finally washed, dissolved in concentrated sulphuric acid, with the addition of a little nitric; the metal is to be precipitated by a carbonated alkali, and the carbonate reduced with charcoal.

In operating upon kupfernickel, or speiss, in which nickel predominates, after the arsenic, iron, and copper, have been separated, ammonia is to be digested upon the mixed oxides of cobalt and nickel, which will dissolve them into a blue liquor. This being diluted with distilled water deprived of its air by boiling, is to be decomposed by caustic potash, till the blue colour disappears, when the whole is to be put into a bottle tightly stoppered, and set aside to settle. The green precipitate of oxide of nickel, which slowly forms, being freed by decantation from the supernatant red solution of oxide of cobalt, is to be edulcorated and reduced to the metallic state in a crucible containing crown-glass.

The reduction of the oxide of nickel with charcoal requires the heat of a powerful air-furnace or smith's-forge.

Nickel possesses a fine silver-white colour and lustre; it is hard, but malleable, both hot and cold; may be drawn into a wire $\frac{1}{50}$th of an inch, and rolled into plates $\frac{1}{500}$th of an inch thick. A small quantity of arsenic destroys its ductility. When fused it has a specific gravity of 8·279, and, when hammered, of 8·66 or 8·82; it is susceptible of magnetism, in a somewhat inferior degree to iron, but superior to cobalt. Its melting-point is nearly as high as that of manganese. It is not oxidised by contact of air, but may be burned in oxygen gas.

There is one oxide and a sesquioxide of nickel. The oxide is of an ash-grey colour, and is obtained by precipitation with an alkali from the solution of the chlo ide or nitrate. The sesquioxide is black, and may be procured by exposing the nitrate to a heat under redness. The hydrated oxide has a dirty pale-green colour.

Analysis of Nickel.

Nickel may be detected by cyanide of potassium in an acid solution of it and cobalt; the cyanide being added until the precipitate first formed is redissolved: dilute sulphuric acid is then added, and the mixture warmed and allowed to stand. A precipitate appearing shows the presence of nickel, whether it be cobalt-cyanide or simple cyanide of nickel.

Nickel and cobalt are almost always associated together, and are very difficult to separate.

Upon the fact that in a solution of oxide of cobalt containing free hydrochloric acid the whole of the metal is converted into the super-oxide, by means of chlorine, while the chloride of nickel remains unaltered in the acid solution, H. Rose based a successful method for the separation of the metals. His method is as follows:—

Both metals are dissolved in hydrochloric acid; the solution must contain a sufficient excess of free acid; it is then diluted with much water; if 1 or 2 grammes of the oxides are operated on, about 2 lbs. of water are added to the solution. As cobalt possesses a much greater colouring-power than nickel, not only in fluxes, but also in solutions, the diluted solution is of a rose colour, even when the quantity of nickel present greatly exceeds that of the cobalt. A current of chlorine gas is then passed through the solution for several hours: the fluid must be thoroughly saturated with it, and the upper part of the flask above the liquid must remain filled with the gas after the current has ceased. Carbonate of baryta in excess is then added, and the whole allowed to stand for 12 or 18 hours, and frequently agitated. The precipitated superoxide of cobalt, and the excess of carbonate of baryta, are well washed with cold water, and dissolved in hot hydrochloric acid; after the separation of the baryta by sulphuric acid, the cobalt is precipitated by hydrate of potash, and, after being washed and dried, is reduced in a platinum or porcelain crucible by hydrogen gas. The fluid filtered from the superoxide of cobalt is of a pure green colour. It is free from any trace of cobalt. After the removal of the baryta by means of sulphuric acid, the oxide of nickel is precipitated by caustic potash. Even this method did not give exact results on the first trial. 0·318 gr. metallic nickel and 0·603 gr. metallic cobalt were employed, and 0·430 gr. oxide of nickel and 0·580 gr. cobalt were obtained:

	Employed	Obtained
Nickel	34·53	36·75
Cobalt	65·47	62·98
	100·00	99·73

The cause of these incorrect results is, that the solution was filtered an hour or two after the precipitation of the superoxide of cobalt by the carbonate of baryta. It is necessary, however, to wait a considerable time, at least 12 hours, or even 18 is better, and allow the excess of carbonate of baryta to remain in contact with the solution, as the superoxide of cobalt is precipitated very slowly: this explains the diminution of the cobalt and increase of the nickel in the above experiment.

It will be readily perceived that not only cobalt, but also other metals, as iron and manganese, may be separated from nickel by this method. On the other hand, oxide of cobalt may be separated from the oxide of zinc, and other strongly basic oxides, which are not converted into superoxides. Nickel and cobalt can, moreover, be separated from metals to which they bear a close analogy in various ways.

From nickel, manganese may be best separated in the same manner as cobalt. Manganese may be separated from both of them, however, by a method which, in its essential parts, was proposed by Wackenroder. It is based upon the fact that, although nickel and cobalt are not precipitated from their solutions by sulphuretted hydrogen, especially when they are slightly acid, still the sulphides precipitated by hydrosulphate of ammonia are not dissolved by very dilute hydrochloric acid. When the oxides are contained in an acid solution (which should not contain nitric acid, however), it is made ammoniacal, and they are precipitated as sulphurets by hydrosulphate of ammonia. Very dilute hydrochloric acid is then added to the solution, until it has a very slight acid reaction; the sulphides of nickel and cobalt remain undissolved; they are washed with water containing a little sulphuretted hydrogen and a trace of hydrochloric acid. The sulphide of manganese is dissolved with facility, but, although the fluid filtered from the sulphides of nickel and cobalt gives only a rather dirty flesh-coloured precipitate on the addition of ammonia and hydrosulphate of ammonia, still the sulphide of manganese contains small portions of sulphide of cobalt or nickel; and when, therefore, it is treated anew with very dilute hydrochloric acid, minute quantities of the black sulphides remain behind. By this repeated treatment a very nearly correct separation may be obtained; but the results are more satisfactory in the separation of cobalt from manganese than of nickel from the latter metal, evidently because nickel is not very perfectly precipitated by hydrosulphate of ammonia: 0·303 gr. of metallic cobalt and 0·385 gr. of binoxide of manganese gave—after the sulphide had been converted by *aqua regia* into oxide, and this precipitated by hydrate of potash, and after the chloride of manganese dissolved was free from sulphuretted hydrogen and precipitated by carbonate of soda—0·302 metallic cobalt and 0·392 oxide of manganese.

0·251 gr. of oxide of nickel and 0·296 gr. oxide of manganese, treated in the same manner, gave 0·214 oxide of nickel and 0·324 oxide of manganese.

Iron also may be separated from nickel, and better still from cobalt, in the same manner as manganese, since sulphide of iron, like sulphide of manganese, is easily soluble in very dilute hydrochloric acid; but in this case the resolution of the sulphide of iron is likewise necessary: 0·425 gr. metallic cobalt and 0·170 gr. sesquioxide of iron, when treated in this manner, gave 0·414 gr. metallic cobalt and 0·172 gr. sesquioxide of iron.

For the details of processes which have been found useful in the separation of nickel from other bodies, the reader is referred to Watts's 'Dictionary of Chemistry.'

Alloys of Nickel.—Various alloys of nickel have been formed under different names; the following are a few of them:—

Argentane, or *German Silver*, consists of 8 parts of copper, 2 parts of nickel, and 3 parts of zinc. This composition has often a yellow tinge, and it is consequently employed for inferior articles only. Another formula gives copper 50·000, zinc 25·0, and nickel 25·0.

White Argentane, or *Argentine Plate*, is usually copper 8 parts, nickel 3 parts, zinc 3 parts. This is a very fine alloy, and passes under different names, according to the caprice of the manufacturer. A manufacturer's receipt which we have seen is: copper 60·0, zinc 17·0, nickel 23·5.

Electrum, copper 8 parts, nickel 4 parts, and zinc 3 parts. This composition has many advantages, especially in its fine colour, and its resistance of oxidation.

Copper 8 parts, nickel 6 parts, and zinc 3 parts, is a very hard and fine compound-metal; but from its hardness there is some difficulty in working it.

Tutenague of China—*Packfong* of the East Indies—is copper 8 parts, nickel 3 parts, and zinc 3½ parts.

A solder for German silver is prepared by fusing together 4 parts of the ordinary argentine and 5 parts of zinc.

Nickel may, it appears, be alloyed with iron. Stromeyer describes a native compound of this kind; and Berthier states that, by heating the arsenide of nickel with iron in any proportions, double arsenides are obtained, which are hard and brittle, with a cast-iron colour.

The process of nickel-plating, now extensively practised, is described under Electro-Metallurgy.

NICOTIANA TABACUM. The tobacco plant; so called in honour of John Nicot of Nismes, ambassador from the King of France to Portugal, who procured the first seeds from a Dutchman, who obtained them from Florida. See Tobacco.

NICOTIANINE. This is a concrete volatile oil, obtained by distilling tobacco-leaves with water; a turbid liquid comes over, and, after standing some time, this oil forms on the surface; only a very small quantity is produced, 6 lbs. of the leaves yield only 11 grains. This oil is solid, has the odour of tobacco, and a bitter taste. It is volatile, insoluble in water and the dilute acids, and in alcohol and ether, but soluble in caustic potash. It has a resemblance to camphor, and was called by Gmelin 'Tobacco Camphor.'

NICOTINE. This alkaloïd is the active principle of the tobacco-plant; it was first obtained, in an impure state, by Vauquelin in 1809. It is contained in the different species of tobacco, probably in the state of malate or citrate. It was obtained pure by Possel and Reimann from the leaves of the *Nicotiana tabacum*, *Macrophylla rustica*, and *M. glutinosa*. Nicotine and its salts have been examined and analysed by MM. Ortigasa, Barral, Melsens, and Schlösing.

The following is the process employed by M. Schlösing for extracting the nicotine from the tobacco:—

The tobacco-leaves are exhausted by boiling-water; the extract is then evaporated till solid, or to a syrupy consistence, and shaken with twice its volume of alcohol. Two layers are formed; the under layer is black and almost solid, and contains some malate of lime, the upper layer containing all the nicotine. This latter is concentrated by distillation, and again treated with alcohol to precipitate certain substances. This solution is concentrated, and treated with a concentrated solution of potash; it is allowed to cool, and is then agitated with ether, which dissolves all the nicotine. To the ethereal solution is added powdered oxalic acid, when oxalate of nicotine is precipitated as a syrupy mass. This is washed with ether, treated with potash, taken up with water, and distilled in a salt-bath, when the nicotine comes over, and may be rendered pure and colourless by redistilling in a current of hydrogen.

M. Melsens has observed the presence of nicotine in the condensed products of tobacco-smoke. The oil which is formed in pipes after smoking tobacco in them, and which gives the colour to the pipe, contains nicotine. The question may then perhaps be asked, 'If tobacco-smoke contains such a deadly poison, why are there not more ill effects from smoking?' It may perhaps be answered in this way: tobacco when smoked only yields about $\frac{1}{150}$th or less of its weight of nicotine, and then very little of that is condensed in the mouth. And, again, the system may become accustomed to it, as is the case with opium-eaters, and *then* it requires much more to take an effect; it can scarcely be doubted, though, that the continual habit of smoking large quantities of tobacco is injurious.

Nicotine when pure is a colourless, transparent, oily liquid, possessing an acrid odour and an acrid burning taste. Its density is 1·024, and that of its vapour 5·607. It restores the blue colour of reddened litmus, and renders turmeric brown. It becomes yellowish by age, and when exposed to the air becomes brown and thick, absorbing oxygen. It is very soluble in water, alcohol, and the oils (fixed and volatile); also in ether, which has the power of extracting it completely from its aqueous solution.

It is very hygrometrical; exposed to a moist atmosphere it rapidly absorbs water, but loses it again in an atmosphere dried by potash. When thus hydrated it becomes a solid crystalline mass if exposed to the cold of a mixture of ice and salt. When anhydrous it does not become solid at 14° Fahr. It boils at 482° Fahr. and is at the same time slightly decomposed; but notwithstanding its high boiling-point, it may be easily distilled with the vapour of water without decomposition.

The vapour of nicotine is so irritating, that we should experience a difficulty of breathing in a room where a drop of that alkaloïd had been volatilised. Its vapour burns with a white smoky flame, depositing charcoal, like an essential oil. Nicotine turns the plane of polarisation strongly to the left. From the volume of its vapour, and from the quantity of sulphuric acid required to form with it a neutral salt, the formula of nicotine would appear to be $C^{20}H^{14}N^{2}$ ($\mathbf{C^{10}H^{14}N^{2}}$); but from some of its combinations it would appear to be half of this, viz. $C^{10}H^{7}N$.

By the aid of heat nicotine dissolves sulphur, but not phosphorus. Nicotine unites with acids, forming salts, which are very deliquescent, difficultly crystallisable, insoluble in ether, except the acetate, and when pure possess no smell, but an acrid tobacco taste. The double salts which nicotine forms crystallise much more easily.

The aqueous solution of nicotine is colourless, transparent, and strongly alkaline; it forms a white precipitate in a solution of corrosive sublimate, also in a solution of acetate of lead, and with both chlorides of tin. The precipitate which it forms with solutions of the salts of zinc is soluble in an excess of nicotine. Salts of copper give with it, at first, blue precipitates, but these dissolve in excess of nicotine, forming a deep blue solution, as they do when supersaturated with ammonia. Bichloride of platinum yields with it a yellow granular precipitate. A solution of permanganate of potash is immediately decolourised by a solution of nicotine.

NIELLO (Ital.). *Nigellum.* An art to which we owe the origin of engraving. It consisted in drawing a design with a style upon gold and silver, and then cutting it with a burin; a black composition made by heating together copper, silver, lead, and sulphur, which when cold was pounded, was then laid upon an engraved plate, a little borax sprinkled over it, and placed over a charcoal fire, when the composition dissolved and flowed into the lines of the design. When cold, the metal was scraped and burnished, and the niello presented the effect of a drawing in black upon gold or silver. The art was known to the ancients and practised during the middle ages; specimens, though rare are to be met with in museums. In the fifteenth century these designs were frequently engraved with great delicacy, and the shadows *hatched* with lines, precisely like a copper-plate engraving. The origin of taking paper impressions from metal plates is ascribed to the practice of Maso Finiguerra, a Florentine goldsmith, who, in the middle of the fifteenth century, was in the habit of taking impressions of his incised work on cups and plaques in a viscid water-ink on paper, for the purpose of testing the state of his work. Such impressions of the early fathers of copper-plate printing still exist, and are known also as *niellos*. See SULPHURS.

NIOBIUM. A metal discovered in 1801 by Hatchett in a mineral called *columbite*, and hence it was named *columbium*. Rose rediscovered this metal in 1846, and gave it the name it now bears. Niobium is a black powder; specific gravity 6·27. See Watts's 'Dictionary of Chemistry.'

NITRATES OF AMMONIA, LEAD, POTASH, SILVER, SODA, STRONTIA. The salts of nitric acid which are employed in the arts are described under the heads of the metallic or earth constituent.

NITRE. The common name for Nitrate of Potash. See POTASH, NITRATE OF.

NITRE, CUBIC. Nitrate of soda. See CUBIC NITRE and SODA, NITRATE OF. Our *Imports* of cubic nitre have been as follow:—

	1872 Tons	1872 Value	1873 Tons	1873 Value
From Peru	1,365,195	£1,045,383	2,176,239	£1,604,040
Bolivia	156,870	120,475	145,371	105,492
Chili	55,966	42,451	85,260	57,173
Other countries	16,166	12,122	537	426
Total	1,594,197	£1,220,411	2,407,407	£1,767,131

NITRIC ACID, *Aquafortis* (*Acide nitrique*, Fr.; *Salpetersäure*, Ger.), exists, in combination with the bases, potash, soda, lime, and magnesia, in both the mineral and vegetable kingdoms. This acid is never found insulated. It was distilled from saltpetre so long ago as the thirteenth century, by igniting that salt mixed with copperas or clay, in a retort. Nitric acid is generated when a mixture of oxygen and nitrogen gases, confined over water or an alkaline solution, has a series of electrical explosions passed through it. In this way the salubrious atmosphere may be converted into corrosive aquafortis. When a little hydrogen is introduced into the mixed gases, standing over water, the chemical agency of the electricity becomes more intense, and the acid is more rapidly formed from its elements, with the production of some nitrate of ammonia. The formula of the hydrated acid is HO,NO^5 (**HNO^3**); its equivalent being 54.

Nitric acid is usually made on the small scale by distilling, with the heat of a sand-bath, a mixture of 3 parts of pure nitre, and 2 parts of strong sulphuric acid, in a large glass retort, connected by a long glass tube with a globular receiver surrounded by cold water. By a well-regulated distillation, a pure acid, of specific gravity 1·500 may be thus obtained, amounting in weight to about two-thirds of the nitre employed. To obtain the whole nitric acid equal weights of nitre and concentrated sulphuric acid may be taken; in which case but a moderate heat need be applied to the retort. The residuum will be bisulphate of potash. When only the single equivalent proportion of sulphuric acid is used, namely 48 parts for 100 of nitre, a much higher heat is required to complete the distillation, whereby more or less of the nitric acid is decomposed, while a compact neutral sulphate of potash is left in the retort, very difficult to remove by solution in water, and therefore apt to destroy the vessel.

Aquafortis is manufactured upon the great scale in iron pots or cylinders of the same construction as are described under Hydrochloric Acid. The more concentrated the sulphuric acid is, the less corrosively will it act upon the metal: and it is commonly used in the proportion of one part by weight to two of nitre.

Commercial aquafortis is very generally contaminated with sulphuric and muriatic acids, as also with alkaline sulphates and muriates. The quantity of these salts may be readily ascertained by evaporating in a glass capsule a given weight of the aquafortis; while that of the muriatic acid may be determined by nitrate of silver; and of sulphuric acid, by nitrate of baryta. Aquafortis may be purified, in a great measure, by redistillation at a gentle heat; rejecting the first liquid which comes over, as it contains the chlorine impregnation; receiving the middle portion as genuine nitric acid; and leaving a residuum in the retort, as being contaminated with sulphuric acid.

Since nitrate of soda has been so abundantly imported into Europe from Peru, it has been employed by many manufacturers in preference to nitre for the extraction of nitric acid, because it is cheaper, and because the residuum of the distillation, being sulphate

A Table of Nitric Acid, by Dr. Ure.

of soda, is more readily removed by solution from glass retorts, when a range of these set in a gallery furnace is the apparatus employed. Nitric acid of specific gravity 1·47 may be obtained colourless; but by further concentration a portion of it is decomposed, whereby some nitrous acid is produced, which gives it a straw-yellow tinge. At this strength it exhales white or orange fumes, which have a peculiar, though not very disagreeable smell; and even when largely diluted with water it tastes extremely sour. The greatest density at which it can be obtained is 1·51 or perhaps 1·52, at 60° Fahr., in which state, or even when much weaker, it powerfully corrodes all animal, vegetable, and most metallic bodies. When slightly diluted, it is applied, with many precautions, to silk and woollen stuffs, to stain them of a bright yellow hue.

In the anhydrous state, this body consists of 26·15 parts by weight of nitrogen, and 73·85 of oxygen; or of 2 volumes of the first gas and 5 volumes of the second.

When of specific gravity 1·5, the acid boils at about 210° Fahr.; of 1·45, it boils at about 240°; of 1·42, it boils at 253°; and of 1·40, at 246° F. If an acid stronger than 1·420 be distilled in a retort, it gradually becomes weaker; and if weaker than 1·42, it gradually becomes stronger, till it assumes that standard density. Acid of specific gravity 1·485 has no more action upon tin than water has, though when either stronger or weaker it oxidises it rapidly, and evolves fumes of nitrous gas with explosive violence. In two papers upon nitric acid, published by Dr. Ure in the fourth and sixth volumes of the 'Journal of Science' (1818 and 1819), he investigated the chemical relations of these phenomena. Acid of 1·420 consists of 1 atom of dry acid and 4 of water; acid of 1·485, of 1 atom of dry acid and 2 of water; the latter compound possesses a stable equilibrium as to chemical agency; the former as to calorific. Acid of specific gravity 1·334, consisting of 7 atoms of water and 1 of dry acid, resists the decomposing agency of light. Nitric acid acts with great energy upon most combustible substances, simple or compound, giving up oxygen to them, and resolving itself into nitrous gas, or even nitrogen. Such is the result of its action upon hydrogen, phosphorus, sulphur, charcoal, sugar, gum, starch, silver, mercury, copper, iron, tin, and most other metals.

Nitric acid is never obtained as the waste product of any chemical operation. Its manufacture is invariably the primary object of the process by which it is procured.

It has been proposed to decompose nitrate of soda by the action of boracic acid, so as to produce biborate of soda, or borax, and thus render the nitric acid a secondary product. The success of this process depends, however, upon a circumstance of a somewhat curious kind. Strong nitric acid is much more volatile than weak acid; and hence it is more easily expelled from its combination with soda in a concentrated than in a diluted form. Now, boracic acid has 3 atoms of water in its crystallised condition; therefore, if we take 2 atoms of this acid, we have 6 atoms of water to unite with the 1 atom of nitric acid capable of being disengaged from nitrate of soda; whereas this quantity of nitric acid needs at most but 2 atoms. The secret, therefore, is to dry the boracic acid in the first instance, so as to get rid of the surplus water; and this is easily done at a temperature of 212° Fahr., at which two-thirds of the water readily leave the boracic acid, and thus afford a mono-hydrated compound, 2 atoms of which contain precisely the amount of water needed for 1 atom of nitric acid, and also of the boracic acid requisite for the production of the biborate of soda. There are some peculiarities connected with the application of the necessary temperature, but they are of less importance. The biborate of soda is afterwards dissolved in hot water, and crystallised.

Anhydrous nitric acid, known to modern chemists as *nitric anhydride, nitric oxide*, or *nitrogen pentoxide*, was discovered in 1849 by M. Deville, who isolated it by the action of dry chlorine gas on nitrate of silver, heated at first to about 200° Fahr., and then reduced in temperature to about 150°. The anhydride, or radical of the acid, is expelled, and condenses in transparent, brilliant, colourless crystals, which are extremely unstable, and readily dissolve in water, with production of ordinary nitric acid.

NITRITES. Salts formed by the combination of nitrous acid with the metals, earths, or alkalis. See Watts's 'Dictionary of Chemistry.'

NITROBENZOL. *Azobenzol.* $C^{12}H^{5}(NO^{4})$ [$\mathbf{C^{6}H^{5}(NO^{2})}$]. It is important in the arts, both as a source of aniline for the manufacture of dye-colours, and on account of its use for flavouring, as a substitute for oil of bitter almonds, which it closely resembles in flavour when pure, and over which it has the advantage of not being poisonous.

It is prepared from benzol (which see) by adding it, drop by drop, into hot, fuming nitric acid; the nitrobenzol separates on dilution with water in the form of a yellowish oil, which may be purified by washing with water alone, or a solution of carbonate of soda. It has a density of 1·209 at 60° Fahr. (15·5 Cent.), and just above the freezing-point of water is converted into a crystalline solid. It is nearly insoluble in water; but alcohol and ether dissolve it in all proportions. Its conversion into aniline under the influence of reducing-agents has been before mentioned. See ANILINE.

Nitrobenzol may be viewed as having been derived from benzol, $C^{12}H^6$ (**C^6H^6**), by the substitution of one equivalent of hydrogen by the tetroxide of nitrogen.

NITROGEN. *Symbol*, N; *equivalent*, 14; *combining-measure*, two volumes; *specific gravity*, 0·9713; *Syn.* Azote. (*Nitrogène*, *Azote*, Fr.; *Stickstoff*, *Salpeterstoff*, Ger.) This gas, which serves so important a purpose in diluting the atmospheric oxygen to the point necessary for healthy respiration, has been known, in a more or less impure state, since 1772, when Dr. Rutherford showed that the vitiated air from the lungs contained a principle incapable of supporting life, but differing from carbonic acid.

Preparation.—Nitrogen is usually prepared from atmospheric air by removing its oxygen. This may be done in a variety of ways:—1. By burning some substance in a confined portion of air, and removing the oxide by a solvent. Thus, alcohol burnt in air yields nitrogen, water, and carbonic acid, The water condenses, and the carbonic acid may be absorbed by agitation with lime-water. The oxygen may also be taken away by the combustion of phosphorus. The phosphoric acid produced, being soluble in water, is easily removed. 2. The most elegant mode of obtaining the nitrogen, and one which, properly performed, is susceptible of the highest quantitative accuracy, is to pass air over red-hot copper, which absorbs the oxygen, forming oxide of copper, pure nitrogen remaining. 3. The oxygen of atmospheric air may also be removed by certain solvents. A solution of pyrogallate of potash, or, rather a solution of pyrogallic acid in an excess of potash, takes the oxygen from air with great rapidity and great precision. Upon this fact Liebig founded his process for estimating the percentage of oxygen in certain gaseous mixtures. A very pure nitrogen may be obtained, according to Corenwinder, by heating a solution of nitrate of potash with chloride of ammonium. Nitrogen may be obtained from ammonia by the action of chlorine, which combines with the hydrogen. Flesh gently heated with diluted nitric acid yields the gas, contaminated with its binoxide. The latter may conveniently be got rid of by passing the gases liberated through two Liebig's potash-bulbs filled with a moderately-concentrated solution of protosulphate of iron.

Properties.—Nitrogen has, especially until lately, been regarded as one of the most inert of the elements, as a body with but slight tendency to enter into combination, and, when combined, being easily removed by even the least energetic reaction. This opinion has been founded on too limited a study of its properties. It is true that with some elements it unites but feebly, and such combinations are, in a few cases, decomposed by the slightest causes; and, in the case of the so-called iodide and chloride, by mere friction or percussion. But the energies of nitrogen are not to be estimated from these compounds alone. There are bodies with which it exhibits an intense desire for union; among these may be mentioned carbon, titanium, and boron. Hydrogen and certain organic groups also unite readily with nitrogen, forming stable and highly characteristic classes of compounds.

Determination of the Purity of Nitrogen Gas.—The simplest and most accurate process is that of M. Bunsen. The first thing is to determine whether a combustible gas containing oxygen be present. For this purpose it is merely necessary to pass an electric spark through the gas contained in a eudiometer. If the bulk remains unaltered the absence of any considerable amount of combustible gas mixing with oxygen is proved. But they may be present in such small quantity, as compared with the noncombustible gas, that no explosion can ensue on passing the spark. It is then necessary to add some battery-gas in order to render the mixture inflammable. [By 'battery-gas' is understood the gas obtained by the electrolysis of water.] For the purpose of the experiment, we may add to every 100 volumes of the gas under examination 40 volumes of battery-gas. If the volume after explosion be unaltered, the total absence of oxygen and combustible gases is demonstrated. It is still possible that the nitrogen may be contaminated with oxygen, although inflammable gases are absent. To determine this fact we must add both hydrogen and battery-gas in such proportions that the volume of the original gas plus hydrogen is to that of the battery gas as 100 : 40. If no oxygen be present the volume after explosion will be that of the original gas and the hydrogen; the reason being that if oxygen had been present some of the hydrogen would have disappeared in order to form water. The nitrogen gas may still be contaminated by a trace of a combustible gas. To determine this point as much common air is to be added to the last mixture containing hydrogen as will form a detonating mixture with that hydrogen. This detonating mixture so produced should form from 26 to 64 per cent. of the incombustible gases. If, on making the explosion, it is found that two-thirds of the condensation is equal to the volume of the hydrogen added, it will show that no combustible gas was present, and that, therefore, the original gas consisted of pure nitrogen.

Compounds of Nitrogen with Oxygen.—The following table contains the composition and principal physical properties of the oxides of nitrogen:—

Table of the Composition and Physical Properties of the Oxides of Nitrogen.

Name	Formulæ		Specific gravity of gas	Combining vol.	Atomic weight	Weight of 100 c. inches of gas or vapour
Protoxide of nitrogen, *syn.* nitrous oxide or laughing gas . .	NO	**N^2O**	1·527	Two volumes	22·	46·3 grains
Binoxide of nitrogen, *syn.* nitric oxide .	NO^2	**N^2O^2**	1·039	„	30·	32·2 „
Nitrous acid, *syn.* hyponitrous acid .	NO^3	**N^2O^3**	2·630	„	38·	81·5 „
Peroxide of nitrogen, *syn.* hyponitric acid	NO^4	**N^2O^4**	1·720	„	46·	53·3 „
Nitric acid . .	$NO^5.HO$ or NO^6H	**NO^3H**	...	...	63·	...

In the above table the densities of the vapours of nitrous and nitric acids are given as obtained by calculation on the hypothesis that they could exist at 60° and 30 inches without condensation; that is to say, as the numbers would come out in a determination of the vapour-density by the method by M. Dumas.

Special Affinities of Nitrogen.—In the same manner that ordinary metallic substances absorb oxygen with avidity from the atmosphere, especially at more or less elevated temperatures, so other elementary bodies combine with nitrogen to form the nitrides. Messrs. Wöhler and Sainte-Claire Deville have carefully investigated this subject, and with great success. When a mixture of titanic acid and charcoal is heated in a charcoal tray (contained in a charcoal tube) to a temperature sufficient to fuse platinum, and a current of dry nitrogen is sent over the mixture, the gas is absorbed with such rapidity that, no matter how rapid the current, none escapes from the tube.

Boron also possesses great tendency to combine with nitrogen at high temperatures. Amorphous boron heated in a current of ammonia becomes incandescent; the nitrogen is absorbed, and the hydrogen escapes, and may be inflamed at the exit of the apparatus. A mixture of boracic acid and charcoal, if ignited in a current of nitrogen, yields the white infusible nitride of boron, first described by Mr. Balmain under the name of Æthogen, but subsequently more accurately investigated by M. Wöhler.

Silicon also combines with nitrogen under favourable circumstances. These facts, coupled with the old experiment made by the French chemists on the nitride of potassium, and the action of ammonia at a red heat upon iron, show that nitrogen is far from being the inert substance generally supposed.—C. G. W.

NITROGEN, BINOXIDE OF; *Nitrogen dioxide*, or *Nitric oxide* (*Deutoxide d'azote*, Fr.; *Stickstoffoxyd*, Ger.), NO^2 (**N^2O^2**), is a gaseous body which may be obtained by pouring upon copper or mercury, in a retort, nitric acid of moderate strength. The nitrous gas comes over in abundance without the aid of heat, and may be received over water freed from air, or over mercury, in the pneumatic trough. It is elastic and colourless; what taste and smell it possesses are unknown, because the moment it is exposed to the mouth or nostrils, it absorbs atmospherical oxygen, and becomes nitrous or nitric acid. Its specific gravity is 1·0393, or 1·04; whence 100 cubic inches weigh 36·66 gr. Water condenses not more than $\frac{1}{20}$th of its volume of this gas. It extinguishes animal life, and the flame of many combustibles; but of phosphorus, well kindled, it brightens the flame in a remarkable degree. A mixture of nitric acid and bisulphide of carbon burns with a flame of high actinic power, and may be used in photography. Nitric oxide consists of 47 parts of nitrogen gas, and 53 of oxygen gas, by weight; and of equal parts in bulk, without any condensation. The constitution of this gas, and the play of affinities which it exercises in the formation of sulphuric acid, are deeply interesting to the chemical manufacturer.

The *Hyponitrous Acid* (*Salpetrigesäure*, Ger.), like the preceding compound, deserves notice here, on account of the part it plays in the conversion of sulphurous into sulphuric acid, by the agency of nitre. It is formed by mingling four volumes of binoxide of nitrogen with one volume of oxygen; and appears as a dark-orange vapour, which is condensable into a liquid at a temperature of 4° below zero, Fahr. When distilled, this liquid leaves a dark yellow fluid. The pure hyponitrous acid consists of 37·12 nitrogen and 62·88 oxygen; or of two volumes of the first, and three of the second. Water converts it into nitric acid and binoxide of nitrogen; the latter of which escapes with effervescence. This acid oxidises most combustible bodies with peculiar energy; and though its vapour does not operate upon dry sulphurous acid, yet, through the agency of steam, it converts it into sulphuric acid, itself being simultaneously transformed into binoxide of nitrogen; ready to become hyponitrous acid again, and to perform a circulating series of important metamorphoses. See SULPHURIC ACID.

NITROGEN, PROTOXIDE OF, or *Nitrous Oxide* (*Protoxide d'azote*, Fr.; *Stickstoffoxydul*, Ger.), NO (**N^2O**), is a gas which displays remarkable powers on the system when inhaled, causing in many persons unrestrainable feelings of exhilaration, whence it has been called the laughing or intoxicating gas; but the effects often vary. When pure this gas does not seem to be injurious; but the bad effects which sometimes follow its use are most probably due to the use of the gas when not quite pure. It is now used by dentists and surgeons as an anæsthetic.

It was first discovered by Dr. Priestley in 1776, and was afterwards studied by Sir H. Davy, who called it nitrous oxide; it was Davy also who first observed its stimulating effects when taken into the lungs.

It is prepared by heating solid nitrate of ammonia in a flask, provided with a bent tube to carry away the gas; care must be taken in applying the heat, to avoid the tumultuous disengagement of the gas; the nitrate melts and enters into gentle ebullition, and the gas is steadily evolved. If too much heat be applied, the flask becomes filled with white fumes, which have an irritating odour, and the gas which comes over is little else than nitrogen. Protoxide of nitrogen should always be collected over warm water, as cold water dissolves nearly its own volume of this gas. The following equation expresses the decomposition of the nitrate of ammonia:—

$$NH^4NO^6 = 2NO + 4HO \quad (\mathbf{NH^4NO^3 = N^2O + 2H^2O})$$

the only products being water and protoxide of nitrogen. Protoxide of nitrogen, at ordinary temperatures, is a colourless, transparent, and almost inodorous gas, of distinctly sweet taste. Its specific gravity is 1·525; 100 cubic inches weigh 47·29 grains; it is therefore much heavier than atmospheric air. It supports the combustion of a taper or a piece of phosphorus with almost as much energy as pure oxygen; it is easily distinguished, however, from that gas by its solubility in cold water, and by not forming red fumes when mixed with binoxide of nitrogen. It has been liquefied, although with difficulty; it requiring at 45° Fahr. a pressure of fifty atmospheres; the liquid when exposed under the bell-glass of an air-pump is rapidly converted into a snow-like solid.

When mixed with an equal volume of hydrogen, and fired by the electric spark in the eudiometer, it explodes with violence, and liberates its own measure of nitrogen; every two volumes of the gas contain therefore two volumes of nitrogen, and one volume of oxygen condensed into two volumes. By weight it contains 14 parts of nitrogen to 8 of oxygen. See LAUGHING GAS.

NITRO-GLUCOSE. When we act on finely-powdered cane-sugar with nitrosulphuric acid, a pasty mass is first formed; if this be stirred for a few minutes, lumps separate from the liquid. When these lumps are kneaded in water, until every trace of acidity is removed, they acquire a white and silky lustre; these are the above-named substance.

NITRO-GLYCERINE. A compound produced by the action of strong nitric and sulphuric acid on glycerine at a low temperature. The following modes of preparation are from Watts's 'Dictionary of Chemistry':—

1. A hundred grammes of syrupy glycerine of specific gravity 1·262 are gradually added to 200 c.c. of nitric acid of specific gravity 1·52, immersed in a freezing mixture, the liquid being continually stirred, the temperature allowed to fall to −10° Cent. before each fresh addition, and never to rise above 0°. A homogeneous mixture having been thus obtained, 200 c. c. of strong sulphuric acid are gradually added, the mixture being still kept below 0°. The oily nitro-glycerine (200 grms.) which then floats on the surface is separated by a tap-funnel from the acid liquid (which yields 20 grms. more of nitro-glycerine on being diluted with water), and dissolved in the smallest possible quantity of ether; the solution is repeatedly shaken with water till the water no longer reddens litmus; the ether evaporated, and the remaining nitroglycerine heated over the water-bath until its weight remains constant. The product

amounts to 184 grms. of pure nitro-glycerine. According to Railton, nitro-glycerine is decomposed by evaporation even *in vacuo* over sulphuric acid at ordinary temperatures.

2. Half an ounce of dehydrated glycerine is poured, with constant stirring, into a mixture of 2 ozs. of oil of vitriol and 1 oz. fuming nitric acid of specific gravity 1·52, the temperature of the mixture being kept below 25° Cent. by external cooling with ice; and as soon as oily drops begin to form on the surface, the mixture is poured, with constant stirring into 50 ozs. of cold water. Nitro-glycerine then separates, and may be purified by washing and drying, in small portions, in a vapour-bath.

According to Gladstone, nitro-glycerine exhibits different properties according to the manner in which it is prepared. Ordinary hydrated glycerine, added to a mixture of 3 pts. sulphuric and 1 pt. fuming nitric acid, is converted into a liquid which detonated violently under the hammer; but anhydrous glycerine treated in like manner, yields a non-explosive body which burns without noise. Both kinds of nitro-glycerine when exposed to a mixture of solid carbonic acid and alcohol become gummy, and assume the appearance of fatty acids; and both decompose spontaneously with evolution of red vapours. A sample of nitro-glycerine, which decomposed in this manner on exposure to summer sunshine, yielded crystals of oxalic acid, together with two liquids, the upper of which contained nitric acid, ammonia, oxalic acid, hydrocyanic acid, and other compounds not examined. Mills found that nitro-glycerine kept a fortnight, no longer exploded when struck, but showed no signs of decomposition or chemical alteration.

Nitro-glycerine is well adapted for blasting, its destructive action being estimated at about ten times that of an equal weight of gunpowder. The first attempts to apply it as a mining agent were by A. Nobel, a Swedish engineer, in 1864. Some experiments were first made with gunpowder saturated with nitro-glycerine. This powder burnt much as usual in the open air, but when confined in shells or blast-holes it produced greater destructive effects than ordinary gunpowder. Nitro-glycerine cannot be employed as a blasting agent in the ordinary way, as the application of a flame from a cannon-fuse would not cause it to explode; but when it is introduced in a suitable case into a blast-hole, and a fuse having a small charge of gunpowder attached to its extremity is fixed immediately above it, the concussion produced by the exploding gunpowder effects the explosion of nitro-glycerine. The use of nitro-glycerine is, however, attended with very great danger, on account of its great liability to explode by concussion or by friction during transport. Moreover, it solidifies at a temperature probably as high as 8° C. (56° Fahr.), and the friction of the frozen particles is very apt to give rise to explosion. Nobel has, however, found that the danger of accidental explosion of nitro-glycerine may be obviated by mixing it with wood-spirit, which renders it non-explosive by percussion or by heat. When required for use, it may be recovered by adding water to the mixture, which precipitates the nitro-glycerine. See Explosive Compounds.

NITRO-MURIATIC ACID, or *Aqua regia* (*Acide nitro-muriatique*, Fr.; *Salpetersalzsäure*, *Königswasser*, Ger.), is the compound menstruum invented by the alchemists for dissolving gold. If strong nitric acid, orange-coloured by saturation with nitrous or hyponitric acid, be mixed with the strongest liquid hydrochloric acid, no other effect is produced than might be expected from the action of nitrous acid of the same strength upon an equal quantity of water; nor has the mixed acid so formed any power of acting upon gold or platinum. But if colourless concentrated nitric acid and ordinary hydrochloric acid be mixed together, the mixture immediately becomes yellow, and acquires the power of dissolving these two noble metals. Mr. E. Davy seems first to have obtained a gaseous compound of chlorine and binoxide of nitrogen in 1830, and a combination of these two constituents was distilled from *aqua regia*, and liquefied by M. Baudrimont in 1843. But it was not until M. Gay-Lussac investigated the subject (*Annales de Chimie*, 3me sér. xxiii. 203; or *Chemical Gazette*, 1848, p. 269) that the true nature of the mutual action of nitric and hydrochloric acids was fully explained. When these two acids are mixed in a concentrated state, a reaction soon commences, the liquid becomes red, and effervescence takes place, from the escape of chlorine and a chloro-nitric vapour. On passing this gaseous mixture through a U-tube, the bent part of which is immersed in a freezing mixture of ice and salt, the chloro-nitric compound is condensed as a dark-coloured liquid, and is thus separated from the chlorine which accompanied it.

Chloro-nitric acid, NO^2Cl^2 (**$NOCl^2$**), may be represented as a peroxide of nitrogen, in which two equivalents of oxygen are replaced by two equivalents of chlorine. This chloro-nitric acid does not take any part in the dissolving of gold and platinum, which is effected by the chlorine alone. Chloro-nitric acid may also be formed by mixing the two gases, binoxide of nitrogen and chlorine, in equal volumes, which assume a brilliant orange colour, and suffer a condensation of exactly one-third of their original volume. Another compound of chlorine and binoxide of nitrogen always appears simultaneously with this in variable proportions. Its composition is NO^2Cl (**NOCl**), and may be represented as nitrous acid, NO^3, in which one atom of oxygen has been replaced by its equivalent of chlorine. It is a vaporous liquid, possessing similar properties to the other, but having a much greater vapour-density.

The theoretical vapour-density of the chloro-nitric acid is 1·74, and that of the chloro-nitrous acid 2·259.

The vapours of both these compounds are decomposed, when conducted into water, into hydrochloric acid and hyponitric acid or nitrous acid. They are also decomposed by mercury; the chlorine combining with the metal, leaving pure binoxide of nitrogen.

Various proportions of nitric and hydrochloric acids are used in making *aqua regia;* sometimes two or three parts, and sometimes six parts of hydrochloric acid to one part of nitric acid; and occasionally chloride of ammonium, instead of hydrochloric acid, is added to nitric acid for particular purposes, as for making a solution of tin for the dyers. An *aqua regia* may also be prepared by dissolving nitre in hydrochloric acid.

NITROUS ACID (NO^3 [$\mathbf{N^2O^3}$]; equivalent, 38), is obtained by mixing four measures of binoxide of nitrogen with one measure of oxygen; they unite and form an orange-red vapour, which, when exposed to a temperature of 0° Fahr., condenses to a thin mobile green liquid. It is decomposed by water, and is converted into nitric acid and binoxide of nitrogen.

$$3NO^3 + HO = HNO^6 + 2NO^2 \quad (\mathbf{3N^2O^3 + H^2O = 2HNO^3 + 2N^2O^2}).$$

On this account it cannot be made to unite directly with metallic oxides; the salts of this acid are therefore obtained by an indirect process. Nitrate of potash, when exposed to a high temperature, is decomposed, losing oxygen and becoming nitrate of potash; some caustic potash is also formed at the same time. To obtain it pure, this is dissolved in water, and while boiling we had nitrate of silver, when we obtain first of all a dark precipitate of oxide of silver, caused by the caustic potash; which is separated by a filter, and on cooling the liquid the nitrate of silver crystallises in white needles, which may be purified by recrystallisation. From this salt the pure nitrites may be obtained; for instance, by adding to a solution of nitrite of silver chloride of potassium we obtain the potash salt.

Hyponitric Acid (NO^4 [$\mathbf{N^2O^4}$]; equivalent, 46), is best procured by distilling, in a coated glass retort, perfectly dry nitrate of lead. Hyponitric acid and oxygen pass over into a receiver, surrounded with a freezing mixture; the former condenses into a liquid, while the oxygen passes off by the safety tube, and only oxide of lead remains in the retort. This hyponitric acid or *peroxide of nitrogen* is a liquid, colourless at −4° Fahr., but is at higher temperatures yellow and orange. It boils at 82° Fahr., gives off a dark red vapour, which becomes almost black when further heated. A beautiful lead-salt of this acid has been discovered by M. Péligot. It is formed by digesting a dilute solution of nitrate of lead with finely-divided metallic lead at a temperature between 150° and 170° Fahr. See Watts's 'Dictionary of Chemistry.'

NOBLE METALS. This was a division formerly adopted: it included those metals which can be separated from oxygen by heat alone; these are mercury, silver, gold, platinum, palladium, rhodium, iridium, and osmium.

NOILS is the term used in the worsted trade for the short wool taken from the long staple by the process of combing, and is used to give apparent solidity or thickness in the handling of cloth.

NON-INFLAMMABLE FABRICS. See Muslin, *non-inflammable.*

NOPAL is the Mexican name of the plant *Cactus opuntia,* upon which the cochineal insect breeds.

NORDHAUSEN ACID. Brown fuming sulphuric acid, used as a solvent of indigo. See Sulphuric Acid.

NORIUM. The name of a metal which was thought to be always associated with zirconium. It is, however, doubtful if it has any existence.

NOTATION. In 1815, Berzelius, the chemist, proposed a system of notation in which the use of initial letters was adopted to signify the elementary bodies. This idea has been continued and improved upon by modern chemists. The modern system of notation endeavours to express by initial letters, figures, and a few simple signs, not merely the elements, but their combinations. The modern system of notation will be best studied in Watts's 'Dictionary of Chemistry.' See Formulæ, Chemical.

NOYAU. A liquor flavoured with the kernels of peach-stones. An inferior kind is flavoured with the essential oil of bitter almonds.

NUGGET, or *Pepita.* A lump of gold as found in nature. Usually those masses are found in hollow spaces, beneath the deposits which have been made by ancient torrents. They are, of course, always derived from the quartz-lode in which the gold has been originally deposited. These lodes have been worn down by the long-continued action of water, and by the same agent the more friable quartz has been removed, the gold being left eventually nearly pure. See Gold.

The following are the weights of a few of the largest nuggets which have been found:—

	lbs.	oz.
'Welcome Nugget,' Ballarat, Victoria	168	3
A mass found in the Ural Mountains	79	0
The Dascombe nugget, found at Bendigo	27	8
Another from the same locality	28	0
Ditto Ditto	45	0
From Forest Creek, Mount Alexander, Victoria	27	6

NUT-GALLS. See Gall-Nuts.

NUT-OIL. An oil professedly obtained from walnuts, which is thought to be superior to the best linseed-oil for delicate pigments; when deprived of its mucilage it is pale, transparent, and limpid. See Oils.

NUTMEG (*Muscade*, Fr.; *Muskatennuss*, Ger.) is the fruit of the *Myristica moschata*, of Thunberg, *M. officinalis* of Linnæus, a very beautiful tree of the family of the *Laurineæ* of Jussieu.

The nutmeg grows in the Molucca Islands; it is cultivated in Java, Singapore, Sumatra, and many islands of the Indian Ocean, and also in some parts of the West Indies. The Dutch, it is said, endeavoured to confine the growth of the nutmeg to three of the Banda Isles; but their attempts were frustrated by a pigeon, called the nutmeg-bird, which, extracting the nutmeg from its pulpy pericarp, digests the mace, but voids the nutmeg in its shell, which, falling in a suitable situation, readily germinates. Young plants thus obtained are used for transplanting into nutmeg-parks. In the Banda Isles there are three harvests annually; the ripe fruit is gathered by means of a barb attached to a long stick, the mace separated from the nut, and both separately cured.

Mace is prepared for the market by drying it for some days in the sun: some flatten it by the hands in single layers; others cut off the heels, and dry the mace in double blades.

Nutmegs require more care in curing, on account of their liability to the effects of an insect (the nutmeg-insect). They are well and carefully dried in their shells by being placed on hurdles, or gratings, and smoke-dried for about two months by a slow wood fire, at a heat not exceeding 140° Fahr.

Dr. Pereira informs us that, 'In the London market, the following are the sorts of round nutmegs distinguished by the dealers:—

'1. *Penang nutmegs.*—These are unlimed or brown nutmegs. They are sometimes limed here for exportation, as on the Continent the limed sort is preferred. According to Newbold the average amount annually raised at Penang is 400 piculs (of 133½ lbs. each).

'2. *Dutch*, or *Batavian nutmegs.*—These are limed nutmegs. In London they scarcely fetch so high a price as the Penang sort.

'3. *Singapore nutmegs.*—These are a rougher, unlimed, narrow sort, of somewhat less value than the Dutch kind. According to Mr. Oxley, 4,085,361 nutmegs were produced in Singapore in 1848, or about 252 piculs (of 133½ lbs. each), but the greater number of trees had not come into full bearing; and it was estimated that the amount would in 1849 be 500 piculs.'

The *long* or *wild-nutmeg* is also met with in commerce.

Mace of two kinds is found in the market—the *true* and *false*.

Of the true maces there are the following varieties:—

1. *Penang mace.*—This fetches the highest price. It is flaky and spread. The annual quantity produced in Penang is about 130 piculs (of 133½ lbs. each).

2. The *Dutch* or *Batavian mace* is a fleshy sort; it is not considered equal to the Penang mace, and rarely fetches so high a price.

3. The *Singapore mace* is regarded as very inferior to the other sorts. It is, however, often of fine flavour and good colour, and, when selected, is sold with the better sorts.

The *wild* or *false* mace is devoid of aromatic flavour.

The uses of nutmegs and mace in dietetics are well known. An essential oil of nutmegs (*Oleum myristicæ*) is obtained by submitting water and nutmegs to distillation. By distillation they yield from 9 to 10 lbs. of essential oil for every cwt.

This volatile oil is largely imported into this country, and is used for scenting soap, and in perfumery.

NUTMEG, BUTTER OF. See OILS.

NUTRITION, or that process by which a living being is nourished and its growth maintained, has so important a bearing upon the practical question of health, that a brief exposition of the subject, especially with reference to the food of man, may fairly find a place in this work.

Every living animal organism needs a constant supply of matter from without, partly to furnish materials for those chemical changes by which the forces of the organism are developed, and partly to compensate for the wear and tear which the structure suffers in the performance of its various functions. The quantity of matter thus required in the shape of food varies in different organisms, and in the same organism under different conditions; indeed, the more work an animal performs the greater its waste, and consequently the greater the amount of food which it requires. It has been calculated that a full-grown man of average weight, in ordinary activity, loses daily about 4,600 grains of carbon and about 300 grains of nitrogen. It is clear that if the body is to remain in equilibrium, neither losing nor gaining in weight, these quantities of carbon and nitrogen must be supplied from without, and presented in a form available for nutrition.

All kinds of food have been divided into two groups: those containing nitrogen, and those destitute of this element. To the *nitrogenous* group belong all proteinaceous compounds, consisting mainly of carbon, hydrogen, oxygen, and nitrogen, with more or less sulphur and phosphorus. This group includes *albumen*, or white-of-egg; *syntonin*, which forms the chief constituent of muscular tissue or lean meat; *fibrin*, one of the derivatives of blood; *casein*, obtained from cheese; *gluten*, from flour; and *legumin*, from peas and beans. To the *non-nitrogenous* group belong all amylaceous compounds, such as starches, sugars, and gums: these contain only carbon, hydrogen, and oxygen; and, as the hydrogen and oxygen exist in exactly the proper proportion to form water, they may be appropriately called *carbo-hydrates*, consisting as they do of carbon and the elements of water. The non-nitrogenous food-stuffs also include all animal and vegetable fats and oils; these consist, likewise, of carbon, hydrogen, and oxygen, but the hydrogen is in excess of that necessary to form water with the oxygen. Liebig termed the nitrogenous foods *elements of nutrition* or *flesh-formers*, since he believed that they only were capable of conversion into blood, and therefore of building up the body; whilst he characterised the non-nitrogenous principles as *elements of respiration* or *heat-givers*, since he maintained that they served merely to sustain the temperature of the body by the slow combustion of their carbon and hydrogen by means of the atmospheric oxygen taken into the system through the lungs. It is now known, however, that this sharp limitation of functions to each class of foods is not strictly correct. It is true that nitrogenous compounds are absolutely necessary to replace the nitrogen which is carried out of the system in the shape of urea; yet they may also contribute to the production of heat by oxidation of part of their carbon and hydrogen. But although proteinaceous compounds are thus absolutely necessary to the support of life, and may even be used alone, there are strong physiological and economical reasons in favour of their due admixture with the non-nitrogenous kinds of food. It should not be forgotten that it is necessary to introduce into the diet certain mineral substances, such as common salt and the various saline matters present in most animal and vegetable substances. In such a typical food as milk we find the proteinaceous, saccharine, oleaginous, and mineral matters so nicely balanced, that all the nutritive functions in infancy are well sustained by this single article of diet. Bread and meat may also be cited as a representative mixed diet; the gluten of the bread and the lean of the meat representing the nitrogenous principles, and the starch of the bread and the fat of the meat being non-nitrogenous, whilst mineral matters are found in both. The amount of carbon and nitrogen which was previously stated to be daily excreted by a man of ordinary activity may be replaced by a diet made up of about 2 lbs. of bread and ¾ lb. of meat per day.

For further information on this subject, see Watts's 'Dictionary of Chemistry.'

The following remarks on the law regulating the balance of the food are retained from the longer article by the late Robert Dundas Thomson which appeared in the last edition, since they place the question in a very clear light.

During the present century a large amount of experiment has clearly demonstrated that animals cannot subsist on starch, sugar, or other foods destitute of nitrogen; and therefore, the inference was fairly deduced that the animal system possessed no power of assimilating nitrogen from the air (*Magendie*). Further consideration led to the conclusion that milk constitutes the type of what nutriment should be, since it is supplied for animal support by nature at the earliest period of human existence

(*Prout*), and contains nitrogenous matter, oil, and sugar. Afterwards, experiments were made to determine the amount of nitrogen in food, and the relative value of nutriment was tabularly stated, in dependence on the ratio of nitrogen present in each species (*Boussingault*, *Ann. de Chim.* lxiii. 225, 1836), a method which has been superseded. It was subsequently inferred that nitrogenous matter supplied the waste of the muscular tissue, while the non-nitrogenous constituents of the food served for respiratory purposes, or the production of animal heat by obviating the too rapid transformation of the muscular elements of the body (*Liebig*, *Organische Chemie*, 1842). This was the true key to the solution of the problem as to the function of the nitrogenous and non-nitrogenous food, and it laid open a wide field for enquiry in reference to the applications of rational systems of dieting to the animal system. For example, it was found in a series of experiments conducted for the British Government in 1845, that in a stall-fed cow in one day, taken from an average of several months, the amount of food conveyed into the circulation of the blood of the animal, was 14·56 lbs. weight; and when the nature of this mass of nutriment was subjected to chemical inquiry, it appeared that 1·56 lb. consisted of nitrogenous matter, and 13 lbs. of non-nitrogenous food. When the relation between these two quantities is calculated, it results that the nitrogenous is to the non-nitrogenous food as 1 to 8·33, in the case of an animal at rest. This observation led to researches into the relative constitution of food as employed by different nations; and the deduction was made, that it is a law of nature that animals under the different conditions of rest and exertion, require food in which the relation of the nutrient or nitrogenous food is different in reference to the non-nitrogenous or heat-producing (calorifiant) constituent:—that the animal system may be viewed, as in an analogous condition to a field, from which different crops extract different amounts of matter, which must be ascertained by experiment;—an animal at rest consuming more calorifiant food, in relation to the nutritive constituents, than an animal in full exercise. From the analyses then instituted the following table was constructed:—

Approximate relation of nutritive or nitrogenous to calorifiant matter.

		Relation of Nutritive to Calorifiant Matter.
Milk food for a growing animal		1 to 2
Beans		1 „ 2½
Peas, Linseed		1 „ 3
Scottish oatmeal		1 „ 5
Wheat flour, Semolina, Indian corn, Barley	Food for an animal at rest	1 „ 7 to 1 „ 8
Potatoes		1 „ 9
East Indian rice		1 „ 10
Dry Swedish turnips		1 „ 11
Arrowroot, Tapioca, Sago		1 „ 26
Starch		1 „ 40

These proportions will consequently vary considerably according to the richness of the grain or crop, and hence similar tables which have been subsequently published by others will be found to differ in some of the details from the preceding data; but the facts now stated—given as approximate—are probably as good averages as could be selected.—R. D. Thomson, 'Medico-Chirurgical Trans.,' xxix., and 'Experim. Researches on the Food of Animals,' 1846, p. 162.

The Table on the following page is an illustration of the law of the equilibrium of the food.

The table is read thus:—an English soldier consumes weekly 11,703 grammes (a gramme equal to 15·44 grains) of food. In this food 1,119 grammes are nitrogenous or flesh-forming matter; 3,937 non-nitrogenous or heat-producing material; 152 mineral substance; the organic matter containing 2,219 grammes carbon. The relation of the nitrogenous to the non-nitrogenous matter is as 1 to 3·50. From this table the results have been deduced that soldiers and sailors consuming 35 ounces of nitrogenous or flesh-forming food weekly, and 70 to 74 ounces of carbon, the proportion of the carbon in the flesh-forming, to that in the respiratory or heat-forming food, is as one to three. Older persons require only 25 to 30 flesh-forming matter weekly, and from 72 to 78 respiratory food; the relation of the carbon in these is as 1 to 5. Boys of from ten

to twelve years of age require 17 ounces of flesh-forming matter, the relation of the carbon in the flesh-forming to the heat-producing aliment being as 1 to 5½. In workhouses and jails, less heat-producing matter is consumed, in consequence of the shelter and heat supplied artificially to the inmates. In prisons, where hard labour is in force, the consumption of flesh-forming or nitrogenous nutriment increases. It has been estimated that in a man weighing 140 lbs., the weight of the flesh-forming matter of the blood is 4 lbs., that of the muscular tissue 27½lbs., and in the bones 5lbs., making a total of 36½ lbs.; and that in the course of 18 weeks these 36½ lbs. are introduced into the system. (Playfair, 'New Edin. Phil. Journal,' 1854, 56,262).

NUX VOMICA; *Strychnos nux vomica*, Linn. The seeds of a tree growing in

Coromandel and other parts of India and Ceylon. From these strychnine is obtained. See STRYCHNINE.

Nux vomica bark was at one time confounded with Angustura or Cusparia bark, and serious consequences might have ensued but that the error was discovered in time. It is now rarely seen.

O

OAK. (*Chêne*, Fr.; *Eich*, Ger.) This well-known European tree is so familiar that it scarcely requires any description. The varieties generally known in England are the following:—*Quercus pedunculata*, Common Oak, which is a native of Britain, and is largely employed in building ships. *Quercus ilex*, Evergreen Oak: this tree is not a native, but has been cultivated in Britain from the most remote period. *Quercus cerris*, Turkey Oak: introduced into this country more than a century since. *Quercus coccinea*, Scarlet Oak: the leaves changing with the first frosts to a brilliant scarlet. *Quercus sessiliflora*, Common short-stalked Oak: this is said to excel for building purposes any other oak.

Oak, Bog. Oak trees which have been buried for a long period in peat bogs, become intensely black; and this 'bog oak' is employed in the manufacture of furniture and articles of ornament.

OAK-BARK. The oak tree is generally barked from the beginning of May to the middle of July. The barkers make a longitudinal incision with a mallet furnished with a sharp edge, and a peculiar incision by means of a barking-bill. The bark is then removed by peeling-irons, the separation being promoted, when necessary, by beating the bark. It is collected and stacked in pieces about 2 feet long. Oak-bark contains, according to Braconnot, tannic acid, tannates of the earths, gallic acid, pectin, and lignin. Davy, in his 'Agricultural Chemistry,' gave the following as the relative quantities of tannin contained in oak-bark:—

480 lbs. of entire bark of a middle-sized oak cut in spring .	29 lbs.
„ coppice oak	32 „
„ oaks cut in autumn	21 „
White interior cortical layers	72 „

See LEATHER; TAN; TANNING.

OAK, DYER'S. See GALL-NUTS.

OAK-GALLS. See GALL-NUTS.

OAST. *Hop Oast.* A kiln for drying hops, heated by a stove with flues.

OATS. (*Avoine*, Fr.; *Hafer*, Ger.) The oat is extensively cultivated in these islands, especially in Scotland. In fact, Scotland is the country admittedly the best fitted for the growth of oats. The estimated number of acres of cultivated land in Scotland is 2,400,000; of which 220,000 are under wheat, 280,000 under barley, and 1,270,000 under oats.

Oats returned as sold in various Market Towns in England and Wales.

These returns of the sale of oats were obtained from 290 towns previous to Jan. 1, 1865, and from 150 towns since. They represent, therefore, but very imperfectly the quantity of oats produced in these Islands. Our agricultural statistics are, unfortunately, in a very unsatisfactory state.

OBSIDIAN. A glassy mineral; so called, it is stated, from *Obsidius*, a Roman, who brought it from Africa. It is a true volcanic glass, and occurs in streams, or in detached masses near many volcanic mountains. It was largely employed by the ancient Mexicans as a material for knives and other cutting-instruments.

OCCLUSION. A term applied by the late Professor Graham to the absorption of gases by metals, and the shutting up of the same. Hydrogen in the nascent state is absorbed in large quantities by palladium, and to some extent by other metals. This gas is held by the metal until exposed to heat or other conditions, by which it is liberated. *Occlude* is an old word in our language signifying *to shut up.* See Latham's 'Dictionary of the English Language.'

OCHRE. (*Ocre*, Fr.; *Ocker*, Ger.) Ochre is, truly, a peroxide of iron and water; but a native earthy mixture of silica and alumina, with oxide of iron in various proportions, and sometimes calcareous matter and magnesia, is usually regarded as ochre. The term is applied, indeed, without any great degree of exactness, to any combinations of the earths with iron, which can be employed for pigments and the like. According as the colour varies, we have *yellow*, *brown*, and *red* ochres.

In Cornwall considerable quantities of ochres are obtained by carefully washing the ferruginous mud, which is separated from poor tin and copper ores after they have been submitted to the action of the stamps and the ordinary processes of washing and roasting.

The iron paints formerly prepared by Mr. Wolston of Brixham must be regarded as ochres. They are found in connection with iron lodes which exist in the rocks around the coast. These paints have been employed for several years in the Royal Naval Arsenals and other government establishments. The wood and iron huts of our camps have been painted with them. They have also been employed for coating the boilers of steam-engines.

A large supply of ochre is obtained from the island of Anglesea, but the ochres of Anglesea are not natural; they are artificial productions, formed in the lakes, into which scrap-iron is thrown to precipitate the copper contained in the water, and forms very large accumulations of the oxide of iron, which is sold as ochre. There is now a large demand for these iron-ochres, as they are extensively employed for the purification of gas.

In the more recent formations ochre occurs in beds some feet thick, which lie generally above the Oolite, are covered by sandstone and quartzose sands, more or less ferruginous, and are accompanied by grey plastic clays, of a yellowish or reddish colour. The ochry earths are prepared by grinding and washing; in some cases they are also exposed to the action of the fire, to increase the oxidation of the iron, and deepen the colour.

The following is a section of the ochre-pits at Shotover Hill, near Oxford, where the Oxford ochre is obtained:—

Beds of highly ferruginous grit, forming the summit of the hill	6 feet.
Grey sand	3 "
Ferruginous concretions	1 "
Yellow sand	6 "
Cream-coloured loam	4 "
Ochre	6 inches.

Beneath this there is a second bed of ochre, separated by a thin bed of clay.

Reddle, employed for marking sheep in Devonshire, and a variety found near Rotterdam (which is much used for grinding spectacle-glasses at Sheffield), may be said to belong to this class. See OXIDES OF IRON, *for polishing.*

Bole, *Armenian Bole*, or *Lemnian Earth*, may be ranked with the ochres. See BOLE, and TIERRA DI SENNA.

The *Ochre of Bitry* and *Italian Rouge* are ochres which are found principally near Vierzon and St. Amand (Nièvre). The ochres from Holland are also much esteemed.

It will thus be apparent that ochre occurs in all formations, from the earliest known rocks—where it is probably due to the decomposition of the sulphides of iron—up to the alluvial deposits of yesterday; in many of which ochreous formations may be watched in the progress.

Ochre in mineralogy is a term applied to many products of decomposition, as, *cobalt-ochre*, *bismuth-ochre*, *chrome-ochre*, *antimony-ochre*, &c.

OCUBA WAX. A vegetable wax, collected on the shores of the Amazon from the fruit of the *Myristica Ocuba*. This wax is easily bleached; and in Brazil it is used extensively for candles.

ODOMETER. An instrument which can be attached to the wheel of a carriage, which, moving regularly with the wheel, indicates the distance passed over in any journey.

ODONTOGRAPH. An instrument, invented by Professor Willis, to enable the millwright to draw and design, with great uniformity and precision, the teeth of wheels.

ŒNANTHIC ETHER is used for flavouring wines. Lichtenberger of Bavaria exhibited it so largely in 1862 that Dr. Hofman remarks: 'To judge from the quantities exhibited, this article would seem to be manufactured in a systematic manner, and upon a very large scale. The substance is a solid, and, according to all appearance, a pure definite compound, the chemical investigation of which would present considerable interest.'

OIL-CAKE, or **OIL-SEED CAKE.** After the expression of the oil, especially from linseed, the mass remaining is so called. It is much used for feeding cattle. Our *Importations* of oil-seed cake have been as follow:—

	Tons		Tons
1867 . . .	121,838	1870 . . .	158,453
1868 . . .	162,339	1871 . . .	162,804
1869 . . .	159,295	1872 . . .	134,300

OIL OF VITRIOL is the old name of concentrated SULPHURIC ACID.

OILS (*Huiles*, Fr.; *Oele*, Ger.) form a class of valuable and interesting substances, and are divided into two great classes, viz. fixed or fatty oils, and volatile or essential oils. The members of one class differ greatly, in nearly every respect, from those of the other class. The former are usually bland and mild to the taste; the latter hot and pungent. The term *distilled*, applied especially to the last class, is not quite correct, since some of them are obtained by expression, as the whole of the first class may be, and commonly are. All the known fatty substances found in organic bodies, without reference to their vegetable or animal origin, are, according to their consistence, arranged under the chemical heads of oils, butters, and tallows. They all possess the same ultimate constituents—carbon, hydrogen, and generally oxygen, and some few of the essential oils, sulphur also; but, as a class, they are noted for containing a large proportion of carbon, which renders them valuable as food, and as sources of light.

Oils have been known and used from the remotest ages. The olive-tree is frequently mentioned by Moses; and it appears to have been introduced into Europe at an early period, probably by the Greeks.

Mineral and coal oils are noticed under the respective heads of NAPHTHA; PETROLEUM; SHALE, and MINERAL OILS, &c.

For the present we shall only take notice of the fixed or fatty oils. These are widely distributed through the organs of vegetable and animal nature. They are found in the seeds of many plants, associated with mucilage, especially in those of the dicotyledonous class, occasionally in the fleshy pulp surrounding some seeds, as the olive; also in the kernels of many fruits, as of the nut and almond tree; and, finally, in the roots, barks, and other parts of plants. In animal bodies, the oily matter occurs enclosed in thin membranous cells, between the skin and the flesh, between the muscular fibres, between the abdominal cavity in the omentum, upon the intestines, and round the kidneys, and in a bony receptacle of the skull of the spermaceti whale; sometimes in special organs, as, of the beaver in the gall-bladder, or mixed in a liquid state with other animal matters, as in the milk.

Braconnot, but particularly Raspail, has shown that animal fats consist of small microscopic, partly polygonal, and partly reniform particles, associated by means of their containing sacs. These may be separated from each other by tearing the recent fat asunder, rinsing it with water, and passing it through a sieve. The membranes being thus retained, the granular particles are observed to float in the water, and afterwards to separate, like the globules of starch, in a white, pulverulent, semicrystalline form. The particles consist of a strong membranous skin, enclosing *stearine* and *elaine*, or solid and liquid fat, which may be extracted by trituration and pressure. These are lighter than water, but sink readily in spirit of wine. When boiled in strong alcohol, the oily principle dissolves, but the fatty membrane remains. These granules have different sizes and shapes in different animals: in the calf, the ox, the sheep, they are polygonal, and from $\frac{1}{70}$th to $\frac{1}{450}$th of an inch in diameter; in the hog they are kidney-shaped, and from $\frac{1}{70}$th to $\frac{1}{140}$th of an inch; in man they are polygonal, and from $\frac{1}{70}$th to $\frac{1}{900}$th of an inch; in insects they are usually spherical, and not more than $\frac{1}{600}$th of an inch.

The fat oils are contained in that part of the seed which gives birth to the cotyledons; they are not found in the plumula and radicle. Of all the families of plants the *Cruciferæ* are the richest in oleiferous seeds; and next to these are the *Drupaceæ*, *Amentaceæ*, and *Solaneæ*. The seeds of the *Gramineæ* and *Leguminosæ* contain rarely more than a trace of fat oil. One root alone, that of the *Cyperus* *esculenta*, contains a fat oil. The quantity of oil furnished by seeds varies not only with the species, but, in the same seed, with culture and climate. Nuts contain about half their weight of oil; the seeds of the *Brassica oleracea* and *B. campestris*, one-third; the variety called colza in France, two-fifths; hemp-seed, one-fourth; and linseed from one-fourth to one-fifth. Unverdorben states that a last, of 10 quarters, of linseed, yields 40 ahms = 120 gallons English, of oil; which is about 1 cwt. of oil per quarter.

The fat oils, when first expressed without much heat, taste merely unctuous on the tongue, and exhale the odour of their respective plants. They appear quite neutral by litmus-paper. Their fluidity is very various, some being solid at ordinary temperatures, and others remaining fluid at the freezing-point of water. Linseed-oil, indeed, does not congeal till cooled from 4° to 18° below 0° Fahr. The same kind of seed usually affords oils of different degrees of fusibility; so that in the progress of refrigeration one portion concretes before another. Chevreul considered all the oils to be composed of two, and sometimes three, different species, viz. *stearine*, *margarine*, and *oleine*; the consistence of the oil or fat varying as either of these predominates. These bodies are all compounds of *glycerine*, with a fatty acid. At all ordinary temperatures oleine is liquid; margarine is solid, and melts at 116° Fahr.; stearine is still more solid, and melts at about 130° Fahr. The two latter may be prepared from pure mutton fat, by melting it in a glass flask, and then shaking it with several times its weight of ether; when allowed to cool, the stearine crystallises out, leaving the margarine and oleine in solution. The soft mass of stearine may be strongly pressed in a cloth, and further purified by re-crystallisation from ether. It forms a white friable mass, insoluble in water, and nearly so in cold alcohol; but boiling spirit takes up a small quantity. It is freely soluble in boiling ether; but, as it cools, nearly all crystallises out.

Margarine may be prepared from the ethereal mother-liquor, from which the stearine has separated, by evaporating it to dryness; the soft mixture of margarine and oleine is then pressed between folds of blotting-paper; the residue again dissolved in ether, from which the margarine may now be obtained tolerably pure. It very much resembles stearine, but, as above mentioned, has a lower melting-point.

It is rather doubtful if oleine has ever been prepared in a perfectly pure state, the separation of the last particles of margarine being very difficult. It may be obtained by subjecting olive-oil to a freezing mixture, when the margarine will nearly all separate, and the supernatant fluid oil may be taken as oleine.

Oleine may also be procured by digesting the oils with a quantity of caustic soda, equal to one half of what is requisite to saponify the whole; the stearine and margarine are first transformed into soap, then a portion of the oleine undergoes the same change, but a great part of it remains in a nearly pure state. This process succeeds only with recently-expressed or very fresh oils.

The fat oils are completely insoluble in water. When agitated with it, the mixture becomes turbid, but if it be allowed to settle the oil collects by itself upon the surface. This method of washing is often employed to purify oils. Oils are little soluble in alcohol, except at high temperatures. Castor oil is the only one which dissolves in cold alcohol. Ether, however, is an excellent solvent of oils, and is therefore employed to extract them from other bodies in analysis; after which it is withdrawn by distillation.

Fat oils may be exposed to a high temperature without undergoing much alteration; but when they are raised to nearly their boiling-point, they begin to be decomposed. The vapours that then rise are not the oil itself, but certain products generated in it by heat. These changes begin somewhere under 600° of Fahr., and require for their continuance temperatures always increasing.

If, instead of raising the heat generally, we submit the fats or oils directly to a red heat, as by passing them through a red-hot tube, they are decomposed completely, and are almost entirely transformed into gaseous carburetted hydrogens, the mixture of which serves for illuminating purposes, and yields a far better light than ordinary coal-gas. In places where the seed and fish oils can be procured at a low price, these substances might be employed with great advantage for this purpose.

Action of Alkalis on the Oils.—When the fat or oils are boiled with potash or soda, they are decomposed into glycerine and the fatty acids, with assimilation of water by both the glycerine and the fatty acids. Thus oleine yields glycerine and oleic acid; margarine, glycerine and margaric acid; and stearine, glycerine and stearic acid. The glycerine dissolves in the water and the fatty acids unite with the alkalis, forming soaps (see SOAPS). The action of ammonia on the oils is much less energetic; it, however, readily mixes with them, forming a milky emulsion, called volatile liniment, used as a rubefacient in medicine. Upon mixing water with this, or by neutralising the ammonia by an acid, or even by mere exposure to the air, the ammonia is removed, and the oil again collects. By the prolonged action of ammonia, however, on the oils, true ammoniacal soaps are formed, and at the same time a peculiar body is formed, called by its discoverer (Boullay) *margaramid.*

It is obtained by boiling the ammoniacal soap with water, when the margaramid swims on the top, and when allowed to cool solidifies. It is purified by solution in boiling alcohol, which deposits it again on cooling in the crystalline state. It is a white, perfectly neutral solid, unalterable in the air, insoluble in water, very soluble in alcohol and ether, especially by the aid of heat. It fuses at about 140° Fahr., and burns with a smoky flame. It is decomposed when boiled with potash or soda, forming true soaps, with the liberation of ammonia, and also by acids of a certain degree of concentration.

The alkaline earths and some metallic oxides unite with the fatty acids, forming insoluble soaps, which in the case of lead is called a plaister.

After glycerine and the fatty acids have once been separated, they do not readily again unite; but Berthelot has succeeded in effecting this, by enclosing them for a considerable time in a sealed tube, and subjecting them to a more or less elevated temperature, when the true oils are again produced.

Action of Acids upon the Oils.—Sulphuric acid (concentrated), when added to the oils, unites with them energetically; the mixture becomes heated, and, unless cooled, chars with the liberation of sulphurous acid. When the mixture is cooled the fats and oils undergo a similar change to that which the alkalis effect. There is formed some sulpho-glyceric acid, as well as combinations of margaric and oleic acids with sulphuric acid; these latter are again decomposed when mixed with water, liberating the fatty acids.

Nitric Acid (concentrated) attacks the fatty bodies very rapidly, sometimes causing ignition. Dilute nitric acid acts less powerfully, forming the same compounds which we obtain by acting on the several constituents of the oils separately.

Hyponitric acid, or *nitrous acid*, converts the oleine of the non-drying oils into a solid fat, *elaidine.*

Chlorine and *bromine* act on the fatty oils, producing hydrochloric and hydrobromic acids, and some substitution-compounds containing chlorine or bromine.

When moist chlorine gas is passed into the oils, the temperature rises, but it does not cause explosion. Bromine, on the contrary, acts with violence. The chlorine and bromine products thus obtained are generally of a yellow colour, without taste or smell. They are heavier than water, and possess a greater consistence than the pure oils. Exposed to the air when slightly heated, they become considerably harder.

Iodine also attacks the oils forming substitution-compounds.

The fatty oils are divided into two classes, drying and non-drying oils, which are characterised by their different deportments when exposed to the atmosphere. In close vessels, oils may be preserved unaltered for a very long time, but with contact of the atmosphere they undergo progressive changes. Certain oils thicken and eventually dry into a transparent, yellowish, flexible substance, which forms a skin upon the surface of the oil and retards its further alteration. Such oils are said to be *drying*, or *siccative*, and are on this account used in the preparation of varnishes and painters' colours. Other oils do not dry up, though they become thick, less combustible, and assume an offensive smell. These are the *non-drying oils.* In this state they are called *rancid*, and exhibit an acid reaction, and irritate the fauces when swallowed, in consequence of the presence of a peculiar acid, which may be removed in a great measure by boiling the oil along with water and a little common magnesia for a quarter of an hour, or till it has lost the property of reddening litmus. While oils undergo the above changes, they absorb a quantity of oxygen equal to several times their volume. Saussure found that a layer of nut-oil, one quarter of an inch thick, enclosed along with oxygen gas over the surface of quicksilver in the shade, absorbed only three times its bulk of that gas in the course of eight months; but when exposed to the sun in August, it absorbed 60 volumes additional in the course of ten days. This absorption of oxygen diminished progressively, and stopped altogether at the end of three months, when it had amounted to 145 times the bulk of the oil. No water was generated, but 21·9 volumes of carbonic acid were disengaged, while the oil was transformed in an anomalous manner into a gelatinous mass, which did not stain paper. To a like absorption we may ascribe the elevation of temperature which happens when wool or hemp besmeared with olive or rapeseed oil, is left in a heap: circumstances under which it has frequently taken fire, and caused the destruction of cloth-mills and other buildings and ships.

Although most of the fixed oils and fats are mixtures of two or more of the substances, *oleine*, *margarine*, and *stearine*, yet there appear to be different modifications of these substances in drying and non-drying oils; for instance, it is only the oleine of the non-drying oils that solidifies when treated with nitrous acid or nitrate of mercury;

and again the difference is shown in the fact of some oils drying completely, while others only thicken and become rancid.

The following is a list of the *Non-drying* Oils and their specific gravity :—

No.	Plants	Oils	Specific gravity
1	Olea Europæa	Olive oil	0·9176
2	Amygdalus communis	Almond oil	0·9180
3	Sesamum orientale	Oil of sesamum	
4	Guilandina mohringa	Oil of behen or ben	
5	Fagus sylvatica	Beech oil	0·9225
6	Sinapis nigra et arvensis	Oil of mustard	0·9160
7	Brassica napus et campestris	Rapeseed oil	0·9136
8	Prunus domestica	Plum-kernel oil	0·9127
9	Theobroma cacao	Butter of cacao	0·8920
10	Cocos nucifera	Cocoa-nut oil	
11	Cocos butyracea vel avoira elais	Palm oil	0·9680
12	Laurus nobilis	Laurel oil	
13	Arachis hypogæa	Ground-nut oil	
14	Valeria Indica	Piney tallow	0·9260
15	Brassica campestris oleifera	Colza oil	0·9136
16	Brassica præcox	Summer rapeseed oil	0·9139
17	Raphanus sativus oleifera	Oil of radish seed	0·9187
18	Prunus cerasus	Cherry-stone oil	0·9239
19	Pyrus malus	Apple-seed oil	
20	Euonymus Europæus	Spindle-tree oil	0·9380
21	Cornus sanguinea	Cornilberry-tree oil	
22	Cyperus esculenta	Oil of the roots of Cyprus grass	0·9180
23	Hyoscyamus niger	Henbane-seed oil	0·9130
24	Æsculus hippocastanum	Horse-chestnut oil	0·9270

The non-drying oils are used as food, for illuminating purposes, and for the greasing of machinery, &c.

The following is a list of the *Drying* Oils :—

No.	Plants	Oils	Specific gravity
1	Linum usitatissimum et perenne	Linseed oil	0·9347
2	Corylus avellana	Nut oil	0·9260
3	Juglans regia		
4	Papaver somniferum	Poppy oil	0·9243
5	Cannabis sativa	Hemp oil	0·9276
6	Cucurbita pepo, et melapepo	Cucumber oil	0·9231
7	Helianthus annuus et perennis	Oil of sunflower	0·9262
8	Ricinus communis	Castor oil	0·9611
9	Nicotiana tabacum et rustica	Tobacco-seed oil	0·9232
10	Vitis vinifera	Grape-seed oil	0·9202
11	Hesperis matronalis	Oil of Julienne	0·9281
12	Myagrum sativa	Oil of camelina	0·9252
13	Reseda luteola	Oil of weld-seed	0·9358
14	Lepidium sativum	Oil of garden cresses	0·9240
15	Atropa belladonna	Oil of deadly nightshade	0·9250
16	Gossypium Barbadense	Cotton-seed oil	
17	Pinus abies	Pinetop oil	0·9285

The drying oils are used principally for varnishes and for painters' colours. As the quicker they dry the more valuable they are for these purposes, it is desirable still to increase their natural siccative properties as much as possible, and this is generally effected by boiling the oils with litharge (oxide of lead), by which a certain portion of the litharge is dissolved by the oil; but in what way this process tends to increase the siccative properties of the oil is not understood. Chevreul stated that it is not necessary to boil the oils, that a much lower heat acts quite as well. Liebig imagined that the boiling with litharge effects the separation of the mucilaginous and other foreign matters, which tend to protect the oils from the action of the oxygen of the atmosphere, and has proposed a process for their separation without the aid of heat. It consists in shaking the oil, previously triturated with litharge, with a solution of the basic acetate of lead for some time, and afterwards allowing the whole to remain still, when the oil separates, and will then dry in twenty-four hours. The solution of acetate of lead which remains may be again used by converting it into the subacetate. A portion of oxide of lead is dissolved by the oil, and when its presence would be prejudicial, it may be removed by shaking the oil with dilute sulphuric acid. In boiling the oils with acetate of lead and litharge, some painters add about an eighth part of resin, which in that proportion greatly improves the appearance of the paints when dry.

Before describing these oils separately, it is necessary to show the means used for obtaining them from the seeds, &c.

Fat Oil Manufacture.

Olive Oil.—It is the practice of almost all the proprietors in the neighbourhood of Aix, in Provence, to preserve the olives for fifteen days in barns or cellars, till they have undergone a species of fermentation, in order to facilitate the extraction of their oil. If this practice were really prejudicial to the product, as some theorists have said, would not the high reputation and price of the oil of Aix have long ago suffered, and have induced them to change their system of working? In fact, all depends upon the degree of fermentation excited. They must not be allowed to mould in damp places, to lie in heaps, to soften so as to stick to each other, and discharge a reddish liquor, or to become so hot as to raise a thermometer plunged into the mass up to 96° Fahr. In such a case they would afford an acrid nauseous oil, fit only for the woollen or soap manufactories. A slight fermentative action, however, is useful towards separating the oil from mucilage. The olives are then crushed under the stones of an edge-mill, and next put into a screw-press, being enclosed in bulrush-mat bags (*cabas*), laid over each other to the number of eighteen. The oil is run off from the channels of the ground-sill into casks, or into stone cisterns called *pizes*, two-thirds filled with water. The pressure applied to the *cabas* should be slowly graduated.

What comes over first, without heat, is called the virgin oil. The *cabas* being now removed from the press, their contents are shovelled out, mixed with some boiling water, again put in the bags, and pressed anew. The hot water helps to carry off the oil, which is received in other casks or *pizes*. The oil ere long accumulates at the surface, and is skimmed off with large flat ladles; a process which is called *lever l'huile*. When used fresh, this is a very good article, and quite fit for table use, but is apt to get rancid when kept. The subjacent water retains a good deal of oil by the intervention of the mucilage; but by long repose in a large general cistern, called *l'enfer*, it parts with it, and the water is then drawn off from the bottom by a plug-hole: the oil which remains after this is of an inferior quality, and can be used only for factory purposes.

The marc being crushed in a mill, boiled with water, and expressed, yields a still coarser article.

All the oil must be *fined* by keeping in clean tuns, in an apartment, heated to 60° Fahr. at least, for twenty days; after which it is run off into strong casks, which are cooled in a cellar, and then sent into the market.

In Spain the olives are pressed by conical iron rollers elevated above the stage or floor, round which they move on two little margins to prevent the kernel being injured, the oil from which is said to have an unpleasant flavour. Spanish olive-oil, however, is inferior to other kinds, from the circumstance of the time which elapses between the gathering and the grinding of the olives. This is unavoidable on account of the small number of mills, which are not in proportion to the quantity of fruit to be pressed. The olives are therefore allowed to lay in heaps to wait their turn, and consequently often undergo decomposition.

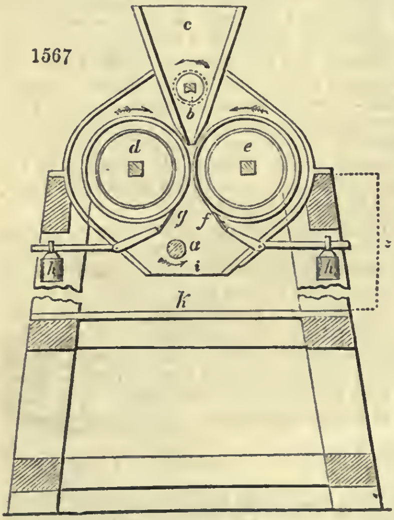
The machinery employed by the Neapolitan peasants in the preparation of the Gallipoli oil is of the rudest kind. The olives are allowed to drop from the trees when ripe, when they are picked up chiefly by women and children, and carried to the mill. The oil, when expressed, is sent in sheep- or goat-skins, carried on mules, to Gallipoli, where it is allowed to clarify in cisterns cut in the rock on which the town is built. From these it is conveyed in skins, to basins near the sea-shore, and from these basins the casks are filled.

According to Sieuve, 100 lbs. of olives yield about 32 lbs. of oil: 21 of which come from the pericarp, 4 from the seed, and 7 from the woody matter of the nut. That obtained from the pericarp is the finest.

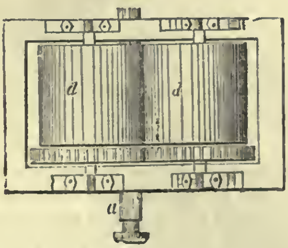
Oil of Almonds is manufactured by agitating the kernels in bags, so as to separate their brown skins, grinding them in a mill, then enclosing them in bags, and squeezing them strongly between a series of cast-iron plates, in a hydraulic press; without heat at first, and then between heated plates. The first oil is the purest, and least apt to become rancid. It should be refined by filtering through porous paper. Next to olive-oil, this species is the most easy to saponify. Bitter almonds being cheaper than the sweet are used in preference for obtaining this oil, and they afford an article equally bland, wholesome, and inodorous. But a strongly-scented oil may be procured, according to M. Planché, by maccrating the almonds in hot water, so as to blanch them, then drying them in a stove, and afterwards subjecting them to pressure. The volatile oil of almonds is obtained by distilling the marc or bitter-almond cake along with water.

Linseed, Rapeseed, and Poppyseed Oils.—The seeds of these, and other oleiferous seeds, were formerly treated for the extraction of their oil, by pounding in hard wooden mortars with pestles shod with iron, set in motion by cams driven by a shaft turned with horse- or water-power; then the triturated seed was put into woollen bags which were wrapped up in hair-cloths, and squeezed between upright wedges in press-boxes by the impulsion of vertical rams driven also by a cam mechanism. In the best mills upon the old construction, the cakes obtained by this first wedge pressure, were thrown upon the bed of an edge-mill, ground anew, and subjected to a second pressure, aided by heat now, as in the first case. These mortars and press-boxes constitute what are called Dutch mills. They are still in use both in this country and on the Continent, and are by some persons thought preferable to the hydraulic presses.

1567



1568



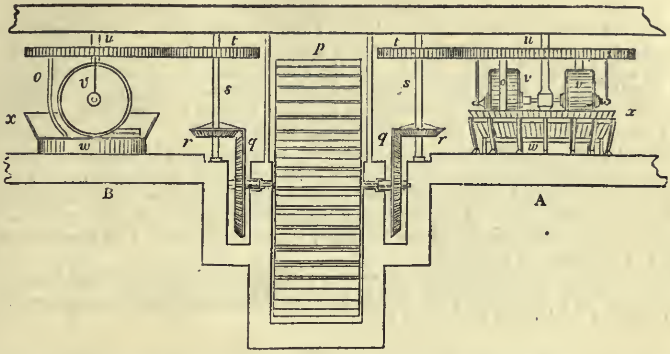
The roller-mill for merely bruising the linseed, &c., previous to grinding it under edge-stones and to heating and crushing it in a Dutch or a hydraulic oil-mill, is represented in *figs.* 1567 and 1568. The iron shaft, *a*, has a winch at each end, with a heavy fly-wheel upon the one of them, when the machine is to be worked by hand. Upon the opposite end is a pulley, with an endless cord which passes round a pulley on the end of the fluted roller, *b*, and thereby drives it. This fluted roller, *b*, lies across the hopper, *c*, and by its agitation causes the seeds to descend equally through the hopper, between the crushing rollers, *d*, *e*. Upon the shaft, *a*, there is also a pinion which works into two toothed wheels on the shafts of the crushing cylinders, *d* and *e*, thus communicating to these cylinders motion in opposite directions. *f*, *g*, are two scraper-blades, which by means of the two weights, *h*, *h*, hanging upon levers, are pressed against the surfaces of the cylinders, and remove any seed-cake from them. The bruised seeds fall through the slit, *i*, of the case, and are received into a chest which stands upon the board, *k*.

Machines of this kind are now usually driven by steam-power. Hydraulic presses have been of late years introduced into many seed-oil mills in this country; but it is still a matter of dispute whether they or the old Dutch oil-mill, with bags of seed compressed between wedges, driven by cam-stamps, be the preferable; that is, afford the largest product of oil with the same expenditure of capital and power.

This bruising of the seed is merely a preparation for its proper grinding, under a pair of heavy edge-stones, of granite, from 5 to 7 feet in diameter; because unbruised seed is apt to slide away before the vertical rolling-wheel, and thus escape trituration.

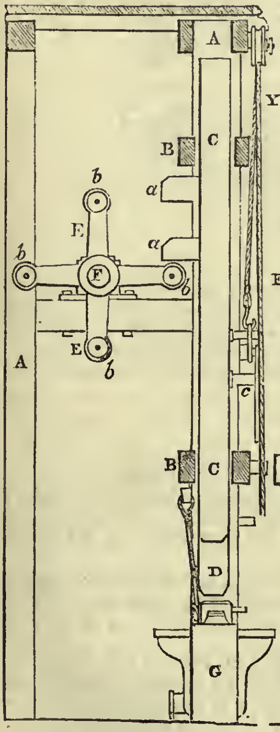
The edge-mill, for grinding seeds, is represented in *fig.* 1569. *p* is the water-wheel, which may drive several pairs of horizontal bevel-wheels working in *q*, *q*, and turning

1569

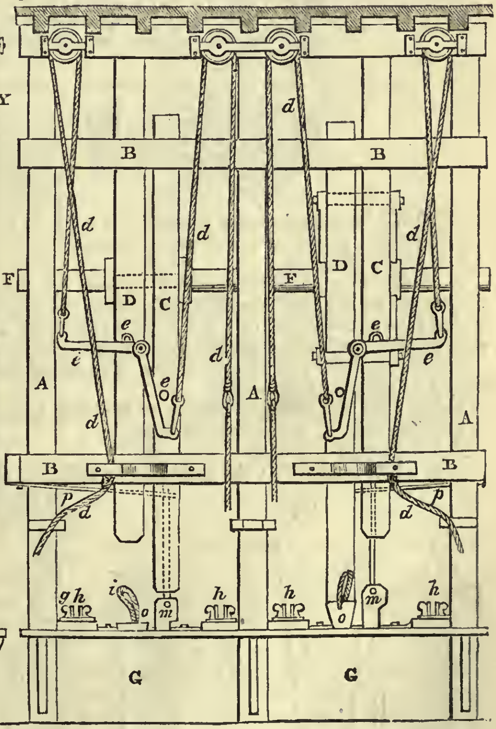


the shafts, *s*, *s*; *t*, *t*, two horizontal spur-wheels fixed to the upper part of the vertical shafts, and driving the large wheels, *u*, *u*. To the shafts of these latter wheels are

1571



1570



fixed the runners, *v*, *v*, which traverse upon the bed-stone, *w*, *w*; *x*, *x*, are the curbs surrounding the bed-stone, to prevent the seeds from falling off; *o*, is the scraper. Mill A represents a view, and mill B, a section of the bed-stone and curb. Some hoop the stones with an iron rim, but others prefer the rough surface of granite, and dress it from time to time with hammers, as it becomes irregular. These stones make from 30 to 36 revolutions upon their horizontal bed of masonry or iron in a minute. The centre of the bed, where it is perforated for the passage of the strong vertical shaft which turns the stones, is enclosed by a circular box of cast iron, firmly bolted to the bed-stone, and furnished with a cover. This box serves to prevent any seeds or powder getting into the step or socket, and obstructing the movement. The circumference of the mill-bed is formed of an upright rim of oak-plank, bound with iron. There is a rectangular notch left in the edge of the bed and corresponding part of the rim, which is usually closed with a slide-plate, and is opened only at the end of the operation, to let the pasty seed-cake be turned out by the oblique arm of the bottom scraper. The two parallel stones, which are set near each other, and travel round their circular path upon the bed, grind the seeds not merely by their weight, of three tons each, but also by a rubbing motion, or attrition; because their periphery being not conical, but cylindrical, by its rolling upon a plane surface, must at every instant turn round with friction upon their resting-points. Strong cast-iron boxes are bolted upon the centre of the stones, which by means of screw clamps seize firmly the horizontal shafts that traverse and drive them, by passing into a slit-groove the vertical turning-shaft. This groove is lined with strong plates of steel, which wear rapidly by the friction, and need to be frequently renewed.

The following are drawings of the wedge or Dutch seed-crushing machines.

Fig. 1570, front elevation of the wedge seed-crushing machine, or wedge-press. *Fig.* 1571, section in the line X X of *fig.* 1572.

1572

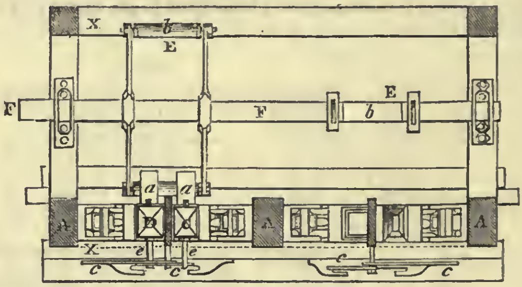


Fig. 1572, horizontal section in the line Y Y, of *fig.* 1571.

A, A, upright guides, or framework of wood.

B, B, side guide-rails.

D, driving stamper of wood, which presses out the oil; C, spring stamper, or relieving wedge, to permit the bag to be taken out when sufficiently pressed. E is the lifting shaft, having rollers, *b, b, b, b, fig.* 1571, which lift the stampers by the cams, *a a, fig.* 1571. F is the shaft from the power-engine, on which the lifters are fixed.

G is the cast-iron press-box, in which the bags of seed are placed for pressure laterally by the force of the wedge.

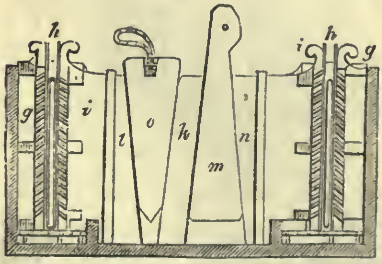
o, figs. 1569 and 1573; the spring, or relieving wedge.

e, lighter rail; *d*, lifting-rope to ditto.

f, f, f, flooring overhead.

g, figs. 1570, and 1573; the back iron, or end-plate minutely perforated.

1573



h, the horse-hair bags (called hairs), containing the flannel bag, charged with seed; *i*, the dam-block; *m*, the spring wedge.

Fig. 1572, A, upright guides; C and D, spring and driving stampers; E, lifting roller; F, lifting-shaft; *a, a*, cams of stampers.

Fig. 1573, a view of one set of the wedge-boxes, or presses, supposing the front of them to be removed: *o*, driving wedge; *g*, back iron; *h*, hairs; *i*, dam-block; *k*, speering or oblique block, between the two stampers; *l*, ditto; *n*, ditto; *m*, spring wedge.

The first pressure requires only a dozen blows of the stamper, after which the pouches are left alone for a few minutes till the oil has had time to flow out; in which interval the workmen prepare fresh bags. The former are then unlocked, by making the stamper fall upon the loosening wedge or key, *m*.

The weight of the stampers is usually from 500 to 600 lbs.; and the height from which they fall upon the wedges is from 16 to 21 inches.

Such a mill as that now described can produce a pressure of from 50 to 75 tons upon each cake of the following dimensions:—8 inches in the broader base, 7 inches in the narrower, 18 inches in the height; altogether nearly 140 square inches in surface, and about $\frac{3}{4}$ of an inch thick.

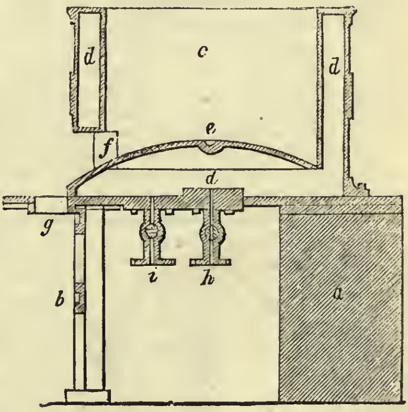
The seeds which have been burst between the rolls, or in the mortars of the Dutch mills, are to be spread as equally as possible, by a shovel, upon the circular path of the edge-stones, and in about half an hour the charge will be sufficiently ground into a paste. This should be put directly into the press, when fine cold-drawn oil is wanted. But in general the paste is heated before being subjected to the pressure. The pressed cake is again thrown under the edge-stones, and, after being ground the second time, should be exposed to a heat of 212° Fahr., in a proper pan, called a steam-kettle, before being subjected to the second and final pressure in the woollen bags and hair-cloths.

Fig. 1574 is a vertical section of the steam-kettle of Hallette, and *fig.* 1575 is a view of the seed-stirrer. *a*, is the wall of masonry, upon which, and the iron pillar *b*, the pan is supported. It is enclosed in a jacket, for admitting steam into the intermediate space *d*, *d*, *d*, at its sides and bottom; *c*, is the middle of the pan in which the shaft of the stirrer is planted upright, resting by its lower end in the step *e*; *f*, is an opening, by which the contents of the pan may be emptied; *g*, is an orifice into which the mouth of the hair or worsted bag is inserted, in order to receive the heated seed, when it is turned out by the rotation of the stirrer and the withdrawal of the plug *f* from the discharge aperture; *h*, is the steam induction pipe; and *i*, the eduction-pipe, which serves also to run off the condensed water.

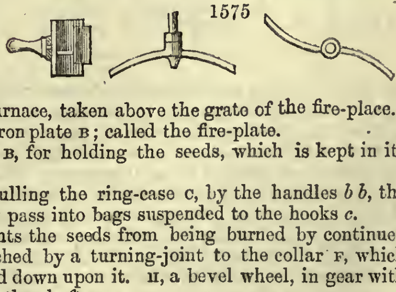
When, in the course of a few minutes, the bruised seeds are sufficiently heated in the pans, the double door *f* is withdrawn, and they are received in the bags below the aperture *g*. These bags are made of strong twilled woollen cloth, woven on purpose. They are then wrapped in a hair-cloth, lined with leather.

The hydraulic oil-press is generally double: that is, it has two vertical rams placed parallel to each other, so that while one side is under pressure, the other side is being discharged. The bags of heated seed-paste or meal are put into cast-iron cases, which are piled over each other to the number of 6 or 8, upon the press-sill, and subjected to a force of 300 or 400 tons, by pumps worked with a steam-engine. The first pump has usually 2 or $2\frac{1}{2}$ inches diameter for a ram of 10 inches, and the second pump 1 inch. Each side of the press, in a well-going establishment, should work 38 lbs. of seed-flour every 5 minutes. Such a press will do 70 quarters of linseed in the days' work of one week, with the labour of one man at 20*s.* and three boys at 5*s* each; and will require a 12-horse power to work it well, along with the rolls and the edge-stones.

1574



1575



The apparatus for heating the seeds by naked fire, as used in Maudsley and Field's excellent seed-crushing mills, on the wedge or Dutch plan, is represented in the *figs.* 1576, 1577, 1578, and 1579.

Fig. 1576 is an elevation or side view of the fire-place of a naked heater; *fig.* 1577 is a plan, in the line U U of *fig.* 1576. *Fig.* 1578 is an elevation and section parallel to the line V V of *fig.* 1577. *Fig.* 1579 is a plan of the furnace, taken above the grate of the fire-place.

A, fire-place shut at top by the cast-iron plate B; called the fire-plate.

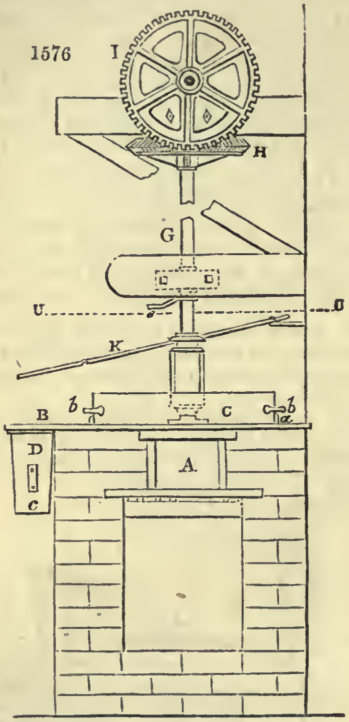
C, iron ring-pan, resting on the plate B, for holding the seeds, which is kept in its place by the pins or bolts *a*.

D, funnels, *Britchen*, into which by pulling the ring-case C, by the handles *b b*, the seeds are made to fall, from which they pass into bags suspended to the hooks *c*.

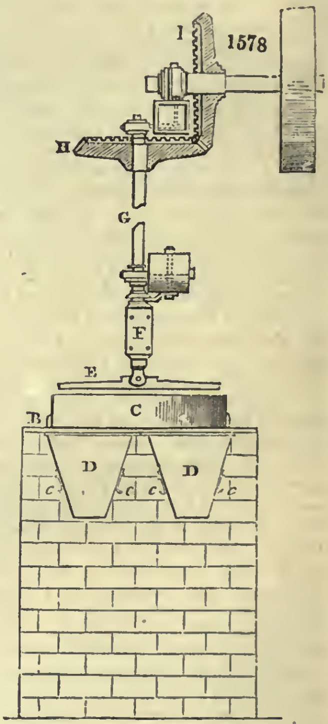
E, *fig.* 1578, the stirrer, which prevents the seeds from being burned by continued contact with the hot plate. It is attached by a turning-joint to the collar F, which turns with the shaft G, and slides up and down upon it. H, a bevel wheel, in gear with the bevel wheel I, and giving motion to the shaft G.

K (*fig.* 1576), a lever for lifting up the agitator or stirrer E. *c*, a catch for holding up the lever K, when it has been raised to a proper height.

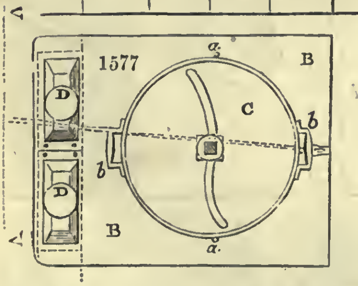
A patent was taken out in May 1849, by Messrs. Bessemer and Heywood for a machine to be used for expressing oils from seeds. *Fig.* 1580 is a drawing of it. The bed-plate of framing, *a*, which should be cast in one piece, forms, at a^1, a cistern for the reception of the oily matters which fall therein as they are expressed. At the opposite end of the bed-plate there are formed projections a^2, in which brasses, *b*, are fitted, and with the caps, *c*, form bearings for the crank-shaft, *d*, to turn in. There



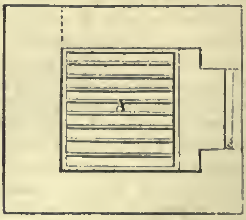
1576



1578

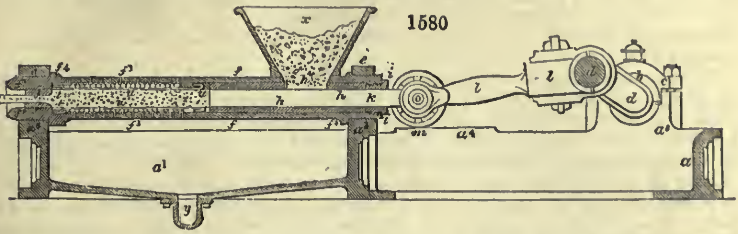


1577



1579

are also two other projections, a^3, a^3, cast on to the bed-plate, and are provided with caps, *e*, in a similar manner to the caps of plummer-blocks. These caps are for the purpose of retaining firmly in its place the pressing-cylinder, *f*, which should be made of tough gun-metal, and of such thickness as to be capable of withstanding a considerable amount of internal pressure. Within the cylinder, *f*, is fitted a *lining*, which consists of a gun-metal tube, *n*, having a spiral groove, *r*, cut on the outside of it, and presenting the appearance of an ordinary square-threaded screw. At very short intervals all along the spiral groove there are conical holes, *s*, drilled through the tube *n*, and communicating with the interior of it. At n^1 the inside of the tube is enlarged, and is provided with a steel collar, *t*. The opposite end of the tube at n^1 is reduced in diameter, and is provided externally with a steel collar, *u*. A plain cylindrical bag, with open ends, formed of fustian, hair-cloth, or similarly pervious material, is made of such a diameter as will fit closely to the inside of the tube n;



and within this bag is placed a cylinder, of wire gauze or finely-perforated metal. The steel collar t is forced into the end of the wire gauze, by which it becomes driven into the recess formed at n^1, and is securely held there by the pressure of the collar t. The bag and wire gauze are then tightly stretched over the end, n^2, of the tube, and the collar u driven tightly on, by which means the bag and wire gauze are securely held in their places. The lining-tube, n, is then put into the pressing-cylinder as far as the shoulder, g. A tubular-piece, h, is next put in, and brought into contact with the collar u, and then the gland, i, is screwed home, whereby the lining n is firmly retained within the pressing-cylinder. The end of the pressing-cylinder is contracted at f^1, and forms a shoulder for the abutment of the collar j, the diameter of the aperture in which regulates the pressure to which the matters under operation are subjected. Within the tube n there is fitted a solid plunger, h, which receives motion from the crank d by means of the connecting-rod l, the parallel motion .being obtained by the wheels, m, on the cross-head, traversing on the side of the bed-plate at a^4. x is a hopper bolted to a flange, f^2, on the pressing-cylinder, and communicating therewith. There is also an opening in the tube n at n^1, corresponding with the opening into the hopper, so that any materials placed in the hopper may fall into the tube n, when the plunger k is withdrawn from beneath the opening. At that part of the pressing-cylinder which is occupied by the 'lining,' there are drilled numerous small holes, f^3, which communicate at various points with the spiral groove in the tube n. On the outside of the pressing-cylinder there are formed two collars, f^4, f^4, which abut against the projecting pieces, a^3, and caps, e, and cause the pressing-cylinder to be retained firmly in its place. When steam-power is to be employed to give motion to the oil-press, it is preferable to have the crank which is actuated by the steam-piston formed on the end d^1, on the crank-shaft of the oil-press, and placed at such an angle to the crank d, that when the crank d is pushing the plunger k to the end of its stroke, the steam-piston will be at the half-stroke, whereby the motive-power applied will be the greatest at the time that the press offers the most resistance; and the steam-piston also, when passing its dead points, will have to overcome the friction of the machinery only, as the plunger, k, will be in the middle of its back-stroke. When any other motive-power is applied to turn the crank d, it will be necessary to put a fly-wheel on the shaft d^1, as also such cog-wheels as will be necessary to connect it with the first mover. When this apparatus is to be employed in expressing linseed-oil, the seed, after having been ground and treated in the way now commonly practised, is put into the hopper, and, motion being transmitted to the crank in the manner before described, the plunger k will commence a reciprocating movement in the tube n of the pressing-cylinder. Each time that it recedes in the direction of the crank it will move from under the opening in the hopper, and allow a portion of the seed to fall into the tube, while the reverse motion of the plunger will drive it towards the open end of the cylinder, its passage being much retarded by the friction against the sides of the tube-lining, but chiefly by the contraction of the escape-aperture through the collar j, which will produce a considerable amount of resistance, and consequently the plunger will have to exert an amount of pressure upon the seed in proportion as the escape-aperture is made larger or smaller. The collar, j, is made moveable, and, by withdrawing the plunger entirely from the tube, it can be exchanged at any time for another having a larger or smaller opening. The lining may at any time be removed from the cylinder, and the worn parts removed when found requisite. The action of the plunger is somewhat like that of the plunger of an hydraulic press-pump, the seeds being pumped in at one end of the pressing-cylinder, and allowed to escape at the other, while the whole of the interior of the pressing-cylinder that contains seed is lined with hair-cloth or other suitable pervious material, and, that it may be protected from injury, is covered with wire gauze or finely-perforated metal. The bag is thus completely defended from within, while it is supported at every part by the tube *n*, on the outside, and is thus subjected to very little wear, and to no risk of bursting. The expressed oil, passing through the wire gauze and bag, finds its way through a perforation into the spiral channel *r*, and from thence it finds ready egress by the perforations f^3 in the pressing-cylinder, and, as it falls, is received by the cistern a^1, from which it can be drawn by the pipe *y*.

Two or more presses may be used side by side, actuated either by one crank-throw or by separate throws upon one shaft, placed with reference to each other in such manner as greatly to equalise the amount of resistance throughout the revolution of the crank-shaft. Although the one here described is a cylindrical pressing-plunger, an angular section may be given to the pressing vessel and plunger, and may of course be used to express oils from any seeds containing them. In the drawing no method is shown for heating the seed-cake to be subjected to pressure therein; but, as it is known to be desirable to heat some matters from which oil is to be expressed, the following method is described:—

When heat is to be applied during the process of pressing, it is desirable to make the pressing-cylinder of somewhat larger diameter, and of greater length, and to divide the cistern a^1 into two separate compartments, over both of which the pressing-cylinder is to extend; a strong wrought-iron tube is to enter the open end of the pressing-cylinder, and to extend about half-way to the hopper, where it terminates in a solid pointed end; this tube is to occupy the centre of the pressing-cylinder, and will consequently leave an annular space around it, which will be occupied by the seed, meal, or other matters under operation. Steam is let into this iron tube, and its temperature thereby raised to any desired point. The end of the tube which extends beyond the pressing-cylinder is to be securely attached to a bracket projecting from the bed-plate, so that it may be firmly held in its position, notwithstanding the force exerted against the pointed end of it. The effect of this arrangement will be that, as the seed, meal, &c., fall into the pressing-cylinder, and are pushed forward by the plunger, they will give out a portion of their oil in that state known as *cold-drawn*, which will fall into the first compartment of the cistern a^1. The further progress of the meal along the pressing-cylinder will bring it in contact with the pointed end of the heating-tube; here it will have to divide itself, and pass along the annular space between the heating-tube and the lining, and, being thus spread into a thin cylindrical layer around the tube, it will readily absorb heat therefrom, when a second portion of oil will be given out, and received by the second compartment of the cistern; and thus will the operations of cold- and hot-pressing be carried on simultaneously.
